maternal BMI, unmarried status, and racial minority status. As originally described by Selye, deviation of an organism from its homeostatic set point (i.e., stress) initiates a highly conserved endocrine and sympathetic nervous response to promote adaptation and return to homeostasis.[565,566] The primary endocrine response centers on the synthesis and secretion of glucocorticoids, cortisol in humans and corticosterone in rodents, from the adrenal. Glucocorticoids exert a panoply of effects on metabolism, immune function, and cognition that promote adaptation acutely, but compromise well-being when present chronically.[567,568] Glucocorticoids independently play a critical role in fetal maturation and the timing for parturition in many species. In humans, the rise in glucocorticoids late in typical term pregnancy is thought to promote fetal lung, and other organ, maturation in preparation for delivery, and accelerate the labor process by inducing PG synthesis by the fetal membranes.[186–188,569,570] Prematurely, chronically elevated glucocorticoids associated with stress during pregnancy are hypothesized to induce PGs prior to term, and cause vascular, cervical, and myometrial responses that promote preterm delivery. Consistent with this notion, in otherwise uncomplicated pregnancies, high psychosocial stress was associated with significantly increased biomarkers of inflammation, such as C-reactive protein and a shorter cervix late in gestation.[571] Additionally, women with higher indices of anxiety according to the Spielberger questionnaire demonstrated increased mean uterine artery resistance index,[572] a parameter associated with a higher rate of preterm birth.[573]

Progestin Therapy to Prevent Preterm Birth

The idea of progesterone therapy to control parturition, and especially to prevent preterm labor, was proposed in the 1940s, but it was not until the late 1950s that sufficient amounts of progesterone became available for clinical studies. Small trials in the 1950s and 1960s suggested that administration of large amounts of progesterone could be used repress the contractions of labor.[297,298] However, more thorough studies in the 1970s and 1980s produced mixed and conflicting results, and consequently the approach was abandoned because its effectiveness was questionable. In addition to the conflicting clinical data, the approach was, and to date still is, burdened by the biological conundrum of how further progestin supplementation of already high endogenous progesterone levels could have effects. Nonetheless, several meta-analyses of early studies rekindled interest by showing that prophylactic progestin therapy (rather than therapy at the time of labor) may reduce the incidence of preterm birth.[574–576] Studies were therefore conducted to assess the effectiveness of prophylactic treatment with natural progesterone administered vaginally or a caproate ester of 17α-hydroxyprogesterone (17HPC) given as long-acting intramuscular injections beginning at around midgestation.[577,578] Taken together, those trials showed that prophylactic progestin therapy decreases the incidence of preterm birth and improves neonatal outcome, but only in women with an increased risk for preterm birth (based on a prior preterm birth). Subsequent studies showed that the therapy was also effective in women with a short cervix detected by ultrasound at midgestation, which is a strong predictor for preterm birth.[95,579] Interestingly, da Fonseca[577] reported that progesterone via vaginal suppositories did not change the incidence of women presenting with preterm labor but increased the effectiveness of tocolytic treatment with beta-mimetics to prevent preterm birth compared with women in the placebo group. This effect is consistent with nongenomic actions of progesterone reported in myometrial strips,[303] wherein progesterone decreases contractility and augments the capacity for beta-mimetics to block OT-induced contractions. Prophylactic vaginal administration of progesterone, however, failed to alter preterm birth rates in the general population, and administration of 17HPC to women with twin pregnancies (who generally deliver preterm) did not decrease the incidence of preterm birth.[580,581] The reason why progestin therapy is effective in only a small subset of at-risk pregnancies is unclear, and the value of prophylactic progestin therapy to prevent preterm birth in the general population is yet to be established.[582]

Animal models of preterm birth

Defining causal mechanisms for preterm birth has necessitated the establishment of informative animal models, as experimental manipulation and analysis of human pregnancy are not possible with existing technologies. As with using nonprimate models for the elucidation of term pregnancy, divergence in endocrine control mechanisms for the maintenance and termination of pregnancy provides similar challenges to extrapolating model organism findings to human pregnancy.[6,7] This limitation once again revolves around the overt progesterone withdrawal associated with labor, preterm or term, in ruminants and rodents, but missing in human term and preterm labor. Nonetheless, important observations from the animal studies will facilitate developing new mechanistic hypotheses for humans. Several species and experimental paradigms have been developed to understand mechanisms for preterm birth. Here, we will summarize key findings from three species: sheep, mice, and nonhuman primates.

Sheep: Elegant physiological studies in sheep have established premature activation of the fetal hypothalamic–pituitary–adrenal axis, or exposure to exogenous glucocorticoids, as drivers of parturition at

term or preterm.[3–5] Pioneering studies by Liggins and colleagues demonstrated that fetal infusion with ACTH or cortisol initiated a shift from progesterone to estradiol synthesis by the ovine placenta, and initiated preterm birth.[4] This exogenous exposure, resulting in fetal adrenal activation or directly providing the product of fetal adrenal activation, cortisol, mimics the normal-term parturition pathway in sheep. Glucocorticoid administration to pregnant women, as routinely occurs in those with threatened preterm labor, to accelerate lung maturation of the fetus does not result in preterm labor. This finding demonstrates that glucocorticoids, while accelerating human fetal organ maturation, do not exert the same effects for parturition initiation in humans and sheep. In rodents, glucocorticoid administration tends to delay the onset of parturition.[583]

Beyond the role of glucocorticoids in precipitating parturition in sheep, ovine pregnancy has provided an important model for understanding the effects of nutrition on preterm birth risk. An important study by Bloomfield and colleagues[584] investigated the role of periconceptual undernutrition by comparing the timing of birth in well-fed ewes to those that had undergone moderate undernutrition from 60 days before conception through 30 days following conception (15% maternal weight loss). This limited period of undernutrition resulted in a significantly lower mean gestational age at birth in the restricted-feeding group (139 days) in comparison to the typically fed animals (146 days; $p < 0.05$). The ramifications for human pregnancy, particularly related to low maternal BMI, are intriguing. The mechanism for the early labor in the sheep was premature activation of the HPA axis.[585,586] This mechanism is unlikely to be responsible for early birth in human undernourished pregnancies, but precocious activation of the normal human pathway for labor may similarly result.

Mice: With the advent of transgenic and gene knockout technologies, mice provide a tractable system for investigating the mechanisms by which developmental pathways and environmental exposures determine gestation length. The caveats that the mouse provides for investigating term partition mechanisms—luteal progesterone production, multifetal pregnancy, and overt progesterone withdrawal at parturition—similarly confound the extrapolation of these mechanisms for preterm birth in this species to human pregnancy. Recently, however, models of preterm birth in mice without overt progesterone withdrawal have been reported.

Gene ablation studies in mice have most often generated lines that fail to initiate parturition at term. More recently, however, several interesting gene-targeting studies have produced strains that undergo spontaneous preterm birth. Because of human data demonstrating the downregulation of HPDG in the chorion of women experiencing preterm labor and delivery, Roizen and colleagues generated mice with a hypomorphic allele of HPGD, as complete inactivation of HPGD in female mice results in infertility (Roizen and Muglia, unpublished data). Matings of HPGD hypomorphic males and females resulted in pregnancies that delivered approximately 1 day preterm on average.[406] Matings of wild-type males with HPGD hypomorphic females resulted in pregnancies that did not significantly differ from pregnancies in wild-type females mated to wild-type males. This finding suggests an important role for fetal HPGD in regulating the timing for birth in mice, in the same compartment of the fetal–maternal interface as has been implicated in humans. Furthermore, the preterm birth in HPGD pregnancies was not associated with progesterone withdrawal, indicating that one genetic manipulation can shift the pattern of endocrine regulation of labor from a progesterone-withdrawal to a nonprogesterone-withdrawal phenotype.[406] The pregnancy characteristics of the HPDG hypomorphic line also demonstrated a relative predominance of PGE_2, as compared with $PGF_{2\alpha}$, in accord with human pregnancy. Dey and colleagues reported the generation of mice with uterine-specific disruption of the tumor suppressor p53.[587,588] These mice demonstrate accelerated uterine decidual senescence, activation of the target of rapamycin complex 1 (mTORC1) signaling, and preterm birth. This uterine p53 deletion model provides a new paradigm for antecedents of preterm birth that are established early in pregnancy and incur later consequences for birth timing. Mice with deletion of the cannabinoid receptor type 1 also manifest preterm labor (approximately one-half day early), but this appears to be due to accelerated luteolysis.[589] Most recently, uterine deletion of the transforming growth factor beta superfamily member, Nodal, resulted in mice with pregnancy termination predominantly at day 17.5 of gestation (term 19.5 days) that resulted from aberrant placentation and a diminished decidua basalis.[590] Maternal serum progesterone concentration was reduced at day 16.5 compared to controls, but remained at a level above that usually associated with luteolysis-mediated term delivery in mice. Whether the Nodal model reflects progesterone withdrawal or not remains to be determined.

Several infection and inflammation models have been developed in rodents, and they have been systematically reviewed in Elovitz and Mrinlani.[591] Initially, investigations in mice explored the ability of the TLR4 ligand lipopolysaccharide (LPS), which was administered systemically, to cause preterm labor. Given at day 14.5–15.5 of gestation, LPS typically results in preterm labor within 24 h in gravid female mice.[419,592,593] The LPS exposure is associated with induction of uterine PTGS2 expression, enhanced generation of $PGF_{2\alpha}$, and overt progesterone withdrawal.[594] In contrast, the use of

heat-killed *Escherichia coli* (HKE) administered by intrauterine injection caused preterm labor without progesterone withdrawal.[460] It is likely that the differing routes of administration, with more restricted local effects with intrauterine administration, yield these differences for progesterone regulation. Given the ability to explore individual components of the signaling cascade induced by bacterial exposure, several studies have dissected the role for individual cytokines and receptors in this process. While, as expected, maternal TLR4 is required for preterm birth due to HKE exposure,[595] loss of individual cytokines in genetically ablated mice, such as IL1β, the IL1 receptor, and IL6, did not protect from preterm birth.[596–598] Loss of both IL1R1 and TNF receptor superfamily member 1A in mice did demonstrate some protection from preterm birth with HKE, suggesting redundancy in cytokine signaling pathways.[599]

To investigate the signals potentially coordinating fetal maturation with the timing for birth, Mendelson and colleagues explored the role of the pulmonary surfactant protein A (SPA).[600] SPA not only serves to promote pulmonary function but also may signal to activate macrophages to initiate a proinflammatory response. Intraamniotic injection of SPA during mouse pregnancy prior to its normal induction during fetal lung development caused preterm labor within 6–24 h of administration.[600] Conversely, injection of an antibody to SPA in normal pregnancies delayed the time to the onset of labor.[600] The intraamniotic injection of SPA was associated with migration of fetal macrophages into the myometrium and activation of IL1β and NFκB. These actions are anticipated to generate downstream signals directly leading to uterine contractions. Mice deficient in SPA or SPA and SPD have normal onset of parturition in their first pregnancy, but exhibit an approximately 12 h delay in later pregnancies.[601] Mice deficient in TLR2, which is believed to be activated by SPA, also manifest a mild delay in the onset of parturition.[601] Whether similar actions occur in human pregnancy is uncertain. In laboring women, macrophages of fetal origin have not been detected in the myometrium, and fetal SPA levels are robustly elevated several weeks prior to the onset of term labor in humans.[602,603]

Nonhuman primates: Nonhuman primates, particularly rhesus macaques, have been important models for preterm birth based upon their similar physiology to human pregnancy. Perhaps the most informative studies related to preterm birth in these nonhuman primates evaluate inflammatory and infectious contributions to preterm birth. For example, Novy and colleagues developed a very useful chronically catheterized model system in rhesus monkeys that allows serial sampling of maternal and fetal compartments for hormone and cytokine changes associated with preterm birth.[408,459] They demonstrated that acute administration of IL1β or TNFα in the amniotic fluid during rhesus pregnancy at 80% of gestation (130 days) initiated a sustained cytokine cascade, with endogenous production of TNFα and IL1β, and preterm contractions and delivery.[459] Intraamniotic administration of *Ureaplasma* at a similar time during gestation likewise initiated a fetal and maternal cytokine response, and preterm delivery.[604] Curiously, the sheep does not initiate preterm labor and delivery with intraamniotic *Ureaplasma* administration.[605] Thus, the rhesus provides a necessary system for mechanistic insights, including the identification of biomarkers that may more accurately predict the likelihood of human preterm birth associated with *Ureaplasma* colonization.

Decidual Hemorrhage

Vaginal bleeding during early pregnancy is an important risk factor for preterm birth. Bleeding in the first trimester is associated with a twofold increase in rate of preterm birth (95% confidence interval (CI): 1.6–2.5), while if bleeding is present in more than one trimester, the odds ratio for PPROM increases to 7.4 (95% CI: 2.2–25.6).[606,607] The most likely sites of bleeding arise between the decidua parietalis and the chorion, or the basal plate of the placenta and the decidua (abruption placenta). Vascular lesions in the decidual vessels adjacent to the placenta have been reported in one-third of women with preterm labor and intact membranes or PPROM, but only one-eighth of women delivering at term.[608–610] The biochemical mechanisms leading to preterm labor and membrane rupture with decidual hemorrhage include augmented thrombin generation.[611,612] The decidua is an abundant source of tissue factor, a strong initiator of the coagulation cascade. Hemorrhage involving the decidua would then generate large quantities of thrombin. Thrombin has been found to stimulate uterine contractions in a dose-dependent manner, and it also stimulates the production of MMP1, urokinase-type plasminogen activator, and tissue-type plasminogen activator by decidualized endometrial stromal cells in culture, and MMP3 in the decidua, which degrades local ECM components and further serves to induce MMP1 and MMP9 in the fetal membranes.[613–615] Thrombin additionally activates cytokine production, such as IL8 by decidual cells, a potent neutrophil chemoattractant, and IL11, an inducer of PGE_2.[611,616]

Postterm Birth and Failure to Progress

Postterm birth is defined as delivery after 42 weeks of completed gestation. The rate of postterm birth ranges from 3% to 14%, depending upon the population studied.[617–619] Like preterm birth, postterm birth is associated with significant adverse sequelae for both the mother and the infant, including Cesarean

delivery, postpartum hemorrhage, shoulder dystocia, fetal hypoxic–ischemic injury, and meconium aspiration. Prolonged pregnancy (i.e., lasting more than 41 weeks of completed gestation) is associated with increased risk for the same detrimental outcomes.[620,621] Several maternal risk factors have been associated with postterm pregnancy. These include nulliparity, obesity or high (>35 kg/m^2) BMI, and previous postterm birth.[618,621,622] Black race is associated with a decreased frequency of postterm birth.[618] The recurrence of postterm birth in the same mother suggests a potential role for genetic contributors, as has been suggested by several studies. In addition, the association of placental sulfatase deficiency to prolonged pregnancy risk, by limiting late gestation rises in estrogen production, further supports the involvement of genetic factors to postterm delivery.[623] The mechanisms by which maternal BMI and nulliparity increase the risk for postterm birth remain unclear. Alterations in the endocrine and metabolic milieux of pregnancy resulting from both of these influences have been postulated, but direct evidence has not yet been obtained.

Animal models of postterm birth have arisen through both naturally occurring variations and targeted genetic manipulations. In general, small litter size in typically multifetal rodent gestations is associated with prolonged gestation prior to delivery.[624] Often, the consequence of this is excessive fetal size resulting in failure of delivery of the pup after placental detachment.[625] This pregnancy outcome, which can result in death of the dam and pups, would be strongly selected against during evolution. As a reflection of this evolutionary pressure, small numbers of implanted embryos early in gestation are often inadequate to sustain pregnancy. Several mouse genetic models are associated with postterm pregnancy or complete inability to initiate parturition. The largest functional category of mutations yielding this outcome in mice is that associated with PG, specifically $PGF_{2\alpha}$, action in late gestation. Mutations in cPLA2 and PTGS1 result in impaired $PGF_{2\alpha}$ synthesis, and mutations in the FP receptor result in defective $PGF_{2\alpha}$ signaling and lead to delayed or absent partition.[403,405,626,627] The target for control of parturition in these situations is on the maternal ovarian CL to cause luteolysis. Direct uterotonic actions of $PGF_{2\alpha}$ appear dispensable, as ovariectomy rescues the normal onset and progression of labor in FP knockout mice.[403] The redundant actions of other PGs and OT likely compensate for loss of FP action in the myometrium. Mutations in 20-α hydroxysteroid dehydrogenase can similarly result in prolonged gestation by limiting the conversion of progesterone to biologically inactive metabolites.[628] Genetic ablation of steroid 5-α reductase type I (SRD5α1) also leads to late parturition in mice.[282,629] In this circumstance, luteolysis occurs at the normal time. However, prolonged actions of progesterone on the cervix, due to impaired local metabolism by SRD5α1, lead to a failure of cervical ripening and pup delivery.[282,629] Recently, mutations in the transcription factor Kruppel-like factor 9 have been associated with prolonged gestation in mice.[630] The mechanism for this abnormal parturition may stem from dysregulated PR isoform switching late in gestation. To date, the involvement of none of these mechanisms has been associated with postterm human gestation.

Uterine Atony

During late pregnancy, the placental bed receives approximately 800 ml/min of blood flow.[631,632] With detachment and delivery of the placenta, cessation of this high rate of blood flow must occur to prevent postpartum hemorrhage. The mechanism by which hemorrhage is prevented is compression of the uterine vasculature by contraction and retraction of myometrial fibers. Failure to achieve this uterine contraction, uterine atony, results in significant morbidity and mortality in many parts of the world where access to uterine contractile agents is not available.[633] Risk factors for uterine atony include uterine overdistention due to multifetal pregnancy, polyhydramnios and fetal macrosomia, exposure to uterine relaxants such as magnesium sulfate, prolonged labor, induction or augmentation of labor, manual removal of the placenta, obesity, advanced maternal age, and previous postpartum hemorrhage.[634,635] To prevent or treat uterine atony, uterine massage and injection of OT are first-line therapies.[633] The administration of ergometrine or methylergonovine also has proven efficacious. These agents cause prolonged tonic uterine contraction by activating smooth muscle α-adrenergic receptors. Atony that is refractory to OT and ergot alkaloids necessitates further intervention by PG administration, typically 15-methyl $PGF_{2\alpha}$ or misoprostol, and derivatives of prostaglandin E1.[633] Hemostatic agents such as activated factor VII or tranexamic acid, or interventions such as uterine tamponade, are additional adjunctive therapies that can be applied.[636–638]

CLINICAL CONTROL OF PARTURITION: TOCOLYTICS AND INDUCTION OF LABOR

Women who develop preterm labor may be candidates for tocolytic therapy. The foundation for tocolytic agents centers on their ability to block the physiological pathways described for myometrial activation during parturition. Tocolytic agents are typically administered after the onset of preterm parturition is clinically apparent. The goal of therapy is to inhibit uterine contractility

and ultimately achieve uterine quiescence in an effort to prolong gestation. There are a number of tocolytic agents that are currently used in the management of preterm labor in contemporary practice, although none is clearly superior to the others. There is no single agent currently considered to be the first-line tocolytic medication.[639] All currently available tocolytic agents have relatively limited efficacy, with the ability to delay delivery for only a short period of time (ranging from a few days to a week), likely due to redundant uterine contraction activation mechanisms.

Women who present with preterm labor between the gestational ages of 24 and 34 weeks may be considered candidates for tocolytic therapy. Tocolytic therapy is recommended only within this gestational age window because this is when antenatal corticosteroid therapy has proven efficacious to reduce neonatal morbidity.[640,641] There are some uncommon circumstances in which some practitioners may feel that inhibition of contractions at previable gestational ages may prevent serious pregnancy complications, or that it may be of use for women who develop late-preterm labor (34–36 weeks) in an effort to stabilize the pregnancy long enough to transport the patient to a tertiary care facility before delivery.

The most commonly used tocolytic agents inhibit uterine contractions through decreasing the availability of calcium or inhibiting its transfer into myometrial cells (magnesium sulfate, beta-mimetics, and calcium channel blockers). Others attempt to inhibit uterine myometrial contractions through blocking uterotonins such as PGs or oxytocin receptor (oxytocin receptor antagonists).

Calcium Channel Blockers

Calcium channel blockers are nonspecific smooth muscle relaxants. They act on L-type calcium channels, which are widely expressed in cardiac and smooth muscle cells, by inhibiting the slow influx of extracellular calcium into the muscle.[642] They were originally, and remain most commonly, used for their vasodilatory effect in the treatment of hypertension. Calcium channel blockers have a much more potent relaxant effect on smooth muscle as compared to their direct effect on myocardium, with only minimal negative inotropism.[643] Their antagonistic effect on slow calcium current into the muscle results in low intracellular calcium and smooth muscle relaxation. Their potent smooth muscle relaxant effect on the uterus has more recently led to their use as a tocolytic agent in an effort to inhibit myometrial contractility in cases of preterm labor. The most commonly used calcium channel blocker for tocolysis of preterm labor is nifedipine, which is widely used and often considered the preferred first-line agent. Although it is a nonspecific smooth muscle relaxant, it has demonstrated a potent myometrial relaxant effect, which is superior to other tocolytic agents studied on human myometrial cells in vitro.[644]

Magnesium Sulfate

Magnesium sulfate was until recently the most frequently used tocolytic agent for treatment of preterm labor.[645] Following harsh criticism in the obstetric literature regarding its lack of proven efficacy and concerns regarding its high risk of adverse side effects, many obstetric practitioners have begun to use calcium channel blockers rather than magnesium sulfate for first-line treatment of preterm labor.[646] The mechanism of action of magnesium sulfate is not as well described as that of calcium channel blockers, but it appears to function in a similar manner by competitively blocking intracellular calcium channels, decreasing calcium availability and thus inhibiting smooth muscle contractility.[647] It also competes with calcium at the motor end plate, where it reduces excitation by inhibiting acetyl choline release.[648] Magnesium sulfate has poor patient tolerance when administered in adequate doses for tocolysis. Due to limited evidence of benefit, maternal risk of toxicity, and poor patient tolerance, the use of magnesium for the treatment of preterm labor is decreasing in recent years in favor of other tocolytic agents.

Prostaglandin Synthase Inhibitors

PG synthesis inhibitors, or more specifically COX inhibitors, block the conversion of arachidonic acid to mature PGs. Indomethacin is the most widely used COX inhibitor used for tocolysis of preterm labor. It is a nonselective COX inhibitor, acting on both PTGS1 and PTGS2 (i.e., COX1 and COX2). Other more selective PTGS2 inhibitors, such as celecoxib and rofecoxib, also have been used for inhibition of preterm labor.

Indomethacin tocolysis is generally well tolerated by the mother with few side effects following a short course of treatment. Indomethacin does cross the placenta and has been associated with a variety of adverse effects in the fetus. Constriction of the ductus arteriosus occurs in up to 50% of fetuses exposed to indomethacin after several days of therapy by inhibiting the formation of prostacyclin and PGE_2, which are necessary to maintain ductal vasodilation.[649] Other fetal and neonatal complications have been reported with use of indomethacin such as oligohydramnios, primary pulmonary hypertension, and necrotizing enterocolitis.[409,650,651] Although a causal link with most severe neonatal complications has

not been clearly identified, concern regarding fetal and neonatal risk with prolonged use of nonsteroidal anti-inflammatory drugs, especially at later gestational ages (>32 weeks), has limited their use to a short duration of no longer than 2 days.

Oxytocin Receptor Antagonists

OT receptors are present in myometrial cells and myoepithelial cells in mammary glands, and relatively limited other peripheral sites. In theory, a specific OTR blocker should be quite effective for inhibition of labor with limited maternal side effects. One OTR blocker, atosiban, has been investigated for the prevention of preterm birth in several studies. A systematic review of randomized trials found that atosiban was not associated with a reduction in the rate of preterm birth or an improvement in maternal or neonatal outcomes. Although it caused fewer adverse maternal drug reactions, it was not found to be superior to other tocolytic agents.[652] In addition, a small but increased rate of infant deaths in the atosiban group identified in this meta-analysis led to safety concerns contributing to the US Food and Drug Administration's (FDA) decision to not approve it for tocolytic use in the United States.[653]

Beta-Adrenergic Receptor Agonists

Beta-sympathomimetics such as terbutaline and ritodrine have been widely used to treat preterm labor for over four decades. They inhibit uterine contractility by binding to β_2 receptors on myometrial cells, activating adenylyl cyclase and PKA and ultimately suppressing myometrial contractility.[653] These beta-adrenergic receptor agonists also stimulate β_1 receptors in the heart, vascular system, and liver, causing significant adverse maternal side effects that limit their tolerability and safety. Common maternal side effects include tachycardia, palpitations, tremor, chest discomfort and dyspnea, and hyperglycemia.[654] In addition, these agents cross the placenta and may cause adverse fetal effects such as fetal tachycardia, neonatal hypoglycemia, hypocalcemia, and ileus. Ritodrine is the only FDA-approved tocolytic medication; however, it is no longer available in the United States. Risks of potentially fatal complications of cardiac toxicity and death associated with prolonged terbutaline use led the FDA to issue a black-box warning in February 2011 stating that it should not be used for more than a 48–72 h period. These safety concerns, in addition to lack of superior efficacy compared to other tocolytics with preferable safety profiles, such as nifedipine, have limited the use of terbutaline in the United States in recent years.[654]

Labor Induction

Some maternal and fetal conditions may develop during pregnancy that increase the chance of adverse perinatal outcome if pregnancy continues. When delivery is felt to increase the likelihood of good perinatal outcome compared to allowing the pregnancy to progress, interventions to expedite the process of parturition may be indicated. When delivery is medically indicated, for either maternal or fetal benefit, in a pregnancy that has not begun the process of labor, artificial means to initiate labor are commonly employed. A variety of pharmacologic and nonpharmacologic interventions have proven efficacious to initiate parturition in pregnancies that have not begun the labor process. It has been estimated that over 20% of births in the United States result from induction of labor.[655]

Pharmacologic agents used for labor induction: PGs are often used for cervical ripening prior to labor induction when the cervix is unfavorable. A variety of different PG preparations have been studied, most with proven efficacy for yielding cervical ripeness. However, as a class, they have not been shown to decrease the frequency of failed induction or reduce cesarean delivery rates in nulliparous women.[655] Nevertheless, it is standard practice for women with an unfavorable cervix undergoing labor induction to receive either a mechanical or pharmacologic agent for cervical ripening prior to induction with oxytocin.

Intravaginal or intracervical PGE_2 (dinoprostone) or intravaginal PGE_1 (misoprostol) are commonly used cervical-ripening agents. Administration of PGE_1 tablets is the most common approach for cervical ripening given its low cost and ease of administration, in addition to some evidence of superior efficacy for achieving cervical ripening or delivery within 24 h compared to other agents.[656] Although PGE_1 has clinical and cost advantages compared to PGE_2 and OT, it is associated with more frequent complications related to uterine hyperstimulation (uterine tachsystole) in most studies performed to date.

Synthetic OT is the most frequently utilized medication for induction of labor. Uterine response to OT is very rapid, with uterine contractility demonstrated within 3–5 min of administration. The half-life of OT is 3 min, and discontinuation of infusion often results in decreased frequency of uterine contractility within a short period of time. Although frequently used on labor and delivery units globally, rare complications such as water intoxication and inadvertent overdose of OT have been reported with serious consequences. OT should be administered only by individuals adequately trained in proper dosing and in monitoring for adverse maternal and fetal effects.[655]

CONCLUSION

Pregnancy is a temporary state in the viviparous reproductive cycle that ends in a controlled manner and at a specific time in gestation (i.e., usually term) by the process of parturition. In general, the gravid uterus is highly proficient at expelling its contents, and as such dysfunctional parturition is mainly due to errors in timing rather than process. Major problems arise for the neonate when parturition occurs before term because it may be born before organ systems needed to maintain homeostasis outside of the uterus are mature. In contrast, a postterm fetus will be mature enough to survive as a neonate, but becomes too large to pass through the birth canal. In this case, parturition that is initiated postterm may not progress to delivery and instead puts the survival of both the fetus and the mother at risk. The timing of parturition is therefore critical for the success of pregnancy (and reproduction), and as such has been subjected to significant selective pressure through evolution. Consequently, considerable diversity exists among viviparous species in the normal length of gestation (i.e., term) and neonatal maturity at birth.

Examination of the comparative biology of birth timing[248] across various species demonstrates how natural selection has acted so that term for each species—and, by implication, the mechanisms that initiates parturition—matches a reproductive strategy to maximize overall reproductive efficiency. Thus, in addressing the subject of this chapter, the physiology of parturition was considered in a species-specific context. This approach is especially relevant for understanding human parturition because the mechanism for its timing was likely affected by a constellation of traits unique to the hominid lineage (e.g., encephalization and bipedalism), the most important of which is encephalization. We argue that the extant mechanism for initiating human birth represents natural selection in response to the benefits of encephalization, which increased fetal brain and head growth, balanced against the cost of reproductive failure (i.e., neonatal and maternal loss) due to the difficulty of delivering a large-headed fetus through the limited pelvic outlet and/or the nutrient demand of the large fetal brain exceeding maternal nutrient provision. This problem seems to have been solved by the selection of a trigger mechanism for hominid parturition that shortened the length of gestation so that the fetus is born at a time when it is capable of surviving ex utero but before its head becomes too large to pass through the pelvic outlet. The implication of this evolutionary paradigm is that the fidelity of animal models to mimic the physiology of human parturition, particularly the initiating mechanism, is poor.

Nonetheless, certain elements in the hormonal control of parturition appear to be conserved in most viviparous species. The general consensus is that the hormonal interactions that promote pregnancy maintenance and the process of labor and delivery generally involve a common group of uterotropic (progesterone and estrogens) and uterotonic (OT and PGs) hormones. It is also generally accepted that parturition is blocked by progesterone and triggered by any interruption of progesterone actions mediated by the nuclear PRs (i.e., progesterone withdrawal). A major conundrum, however, derives from the fact that human parturition occurs without a systemic progesterone withdrawal, and this continues to be a major criticism of the progesterone block hypothesis. An equally valid alternative hypothesis is that human parturition does not require progesterone withdrawal but instead is promoted by pro-labor stimuli that overcome the progesterone block. Nonetheless, clinical studies of nuclear PR antagonists show that PR-mediated progesterone signaling is essential for the maintenance of human pregnancy and that disruption of PR signaling alone is sufficient to induce the full parturition cascade. In addition, studies of nuclear PR isoform signaling in myometrial cells suggest that progesterone withdrawal is mediated by multiple redundant mechanisms that desensitize the gestational tissues (myometrium, cervix, decidua, and fetal membranes) to PR-mediated progesterone actions, a process referred to as functional progesterone withdrawal. A key issue for future research will be to identify the upstream hormonal interactions that induce functional progesterone withdrawal in each of the gestational tissues. These mechanisms will likely reflect the human-specific pathways that determine the timing of birth. Importantly, this understanding will likely reveal therapeutic strategies to maintain progesterone signaling in the various gestational tissues and prevent preterm birth.

A general theme that is emerging from research in multiple species is that the hormonal control of parturition involves positive-feedback loops at the paracrine level within each of the gestational tissues and at the endocrine level between the uterus and extrauterine sites, including the maternal hypothalamus (Figures 42.7 and 42.9). Tissue-level inflammation appears to be a major contributor in this regard, and myometrial and cervical distention may also be involved. CRH, glucocorticoids, OT, and PGs may all contribute to the positive-feedback acceleration of labor. This paradigm implies that the drive to empty the uterus is a reflexive response driven by positive-feedback interactions. Based on this model, the success of pregnancy depends on repression of the positive-feedback interactions until term. Future research should be targeted to unravel the dynamics and interconnectivity of the various positive-feedback loops in each of the gestational tissues, and between the uterus and the maternal pituitary, and determine the mechanisms by which those interactions

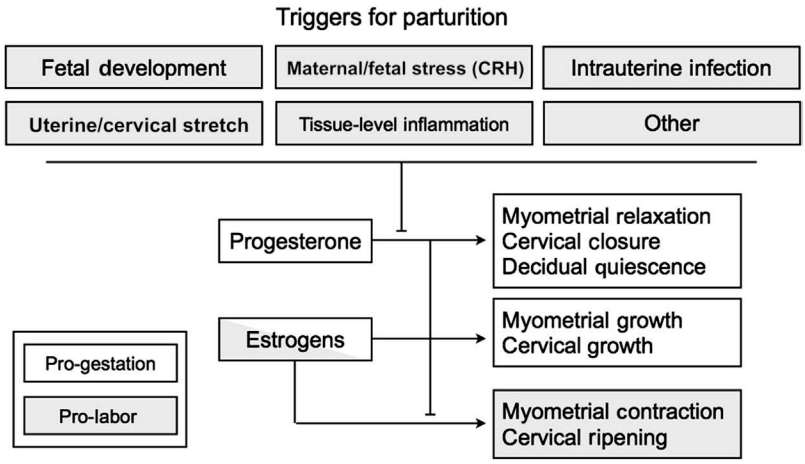

FIGURE 42.9 Schematic representation of the triggers for parturition. Uterine quiescence and growth are promoted by the combined actions of progesterone and estrogens. Estrogens also promote pro-labor gene expression at the time of parturition, but this activity is inhibited by progesterone for most of pregnancy. Multiple physiological triggers for parturition function primarily by inhibiting the pro-gestational actions of progesterone.

are controlled by progesterone and other hormones involved in pregnancy maintenance and the induction and process of parturition.

INTRODUCTION

A variety of reproductive strategies are found among vertebrates ranging from groups with relatively small maternal energy investment, as for some reptiles, to mammals that nurture offspring within the intrauterine environment and invest in costly postnatal care for extended periods of time. Mammals are also unique in their ability to nurture after birth in the form of milk from the maternal mammary gland that provides all nutritional requirements for a period of time. Lactation provides the opportunity for bonding and physical stimulation that is important in postnatal brain maturation.[1] This form of reproduction exacts a high energy cost from the mother in the form of remodeling of the maternal body, growing and maintaining augmented mammary tissue, carrying the weight of the developing fetus for the entire gestational period, and providing nutritional substrate in the form of milk to offspring as well as attending to the offspring for times ranging from weeks to months during the postnatal period.

This chapter will cover the current knowledge of major physiological changes that accompany pregnancy in women. Perhaps the most important adaptations of pregnancy are imperceptible even to a woman carrying a child, yet essential for a successful pregnancy. An inadequate adaptation to pregnancy can lead to improper fetal development or even fetal demise.

One must only review the state of knowledge a century ago to appreciate the amazing progress in our understanding of the physiology of pregnancy. In 1910 Marshall wrote, "What constitutes the original stimulus for the changes that occur in pregnancy remains still outside our ken." He further reported that "the blood pressure is not affected in normal pregnancy, but is always raised in labor as a result of uterine contractions".[2] At that time, the estrogenic sex steroid hormones had not been isolated and cardiovascular adaptations to pregnancy were little studied. But by the late 1960s a general understanding of the primary respiratory and cardiovascular changes in pregnancy were known and well described. For example, increases in blood volume and changes in respiratory function were known, as were basic aspects of metabolism in pregnancy and energy requirements. In 1968 Hytten coauthored a review of the known adaptations to pregnancy,[3] which were then detailed in a monograph.[4] Yet, in spite of decades of research on the mechanisms that underlie changes during pregnancy, the most fundamental cellular and molecular mechanisms remain beyond reach. Pregnancy-related changes in the cardiorespiratory and renal systems have been studied most and are, thus, best understood. This chapter will emphasize cardiovascular–respiratory–renal changes as examples of the elaborate modifications of the human body that make childbearing possible and will highlight crucial areas that need further investigation. Recent

findings will be especially noted. Much of what we know about pregnancy has come from animal experimentation. However, the next decade should bring an avalanche of new data from human pregnancies as it becomes increasingly clear that population health is largely driven by the quality of growth in the womb and as noninvasive imaging methodologies become widely available.

Definitions

Fortunately, most of the terminology used in the pregnancy literature is not controversial. There has been a longstanding debate over the use of the term *adaptations* when applied to the pregnant condition because changes in body function during pregnancy are not adaptations as defined by evolutionists, such as a biological trait that confers biological advantage to an organism. Rather, in the case of pregnancy, adaptations are defined as those anatomic and functional changes in the female body that are believed to have physiological benefit to the growing embryo and fetus. This controversy has, over the decades, led authors to use other phrases, like "adjustments to pregnancy" or "physiological changes in pregnancy," both of which continue to be occasionally used. However, from the authors' view, there is no longer a need to apologize for this specialized use of *adaptation* since it has been firmly entrenched in the pregnancy literature for decades.

METABOLIC ADAPTATIONS

Energy Costs of Pregnancy

The total energy cost of a human pregnancy over its full-term duration has been estimated at some 80,000 kcal.[5,6] The average weight gain during pregnancy is about 12.5 kg and includes the increased weight of the fetus, amniotic fluid, uterine tissue, breast tissue, and blood, as well as extravascular and intracellular water. Changes in maternal body composition over the course of gestation have been studied.[7,8] Measuring the composition of body compartments during pregnancy is difficult, and no method has gained complete acceptance. Traditional methods like skin-fold thickness[9] are helpful but not well validated across populations. Newer methods like bioelectric impedance analysis, underwater weighing, air displacement plethysmography, and nonradioactive isotope dilution methods are likely to improve the accuracy of such measurements as they become standardized for pregnant women. Studies over the past few decades suggest that approximately 1 kg protein, 4 kg fat, and 7 kg water are gained during pregnancy.[4,10] Half of the protein weight accrues in the fetus and placenta. Pregnancy weight gain varies considerably among individuals, with very low or very high weight gains being related to poorer fetal outcomes compared to moderate weight gains.[11]

Thus, in 2009 the National Institute of Medicine updated guidelines for weight gain based upon the category in which a woman's prepregnancy body mass index (BMI) (weight per height squared, in kg/m^2) is found (Table 43.1). Less weight gain is recommended with each step increase in prepregnancy BMI.[8] Categories of recommended weight gain include: underweight, normal weight, overweight, and obese.

The basal metabolic rate (BMR) of the mother increases during pregnancy. It is the level of metabolism of an individual at rest, often determined by measuring oxygen consumption per minute. BMR increases from about 1300 kcal/day to about 1700 kcal/day over gestation in women of average prepregnant BMI.[11] Figure 43.1 shows the increases in BMR above prepregnant levels over gestation for three groups of women with different body mass indices. In reality, the total daily energy expenditure includes not only the BMR but also additional energy expended by daily activities (Figure 43.2). Total energy expenditure ranges from some 2700–3000 kcal/day at 36 weeks depending upon BMI at the time of conception and the degree of activity of the members in the three BMI groups.[11] Hytten and Leicht proposed that the increased energy costs of pregnancy could be met by a reduction of activity energy expenditure without an increase in food energy consumption.[4] While this proposal might be correct, it has not been tested. It is clear that most women expend excess energy from a high level of activity during pregnancy and require a significant increase in food intake.[11] There is evidence that metabolic rate is regulated differently in pregnant women compared to nonpregnant women. Before pregnancy, metabolic rate is most closely related to fat-free body mass whereas during the third trimester metabolic rate is most closely related to body fat mass.[16] This may mean that maternal metabolic rate is uniquely regulated by adipose reserves during pregnancy.[17]

Oxygen consumption ($\dot{V}O_2$) increases by some 50 ml/min in pregnant women by term.[18] Figure 43.3 shows the increases found in individual organs. As expected, the gravid uterus accounts for the largest increase in oxygen consumption. Term women sitting upright show increases in resting $\dot{V}O_2$ over nonpregnant women by some 33%, reflecting increased metabolism. There is evidence of a fundamental change in the regulation of the oxygen consumption threshold during pregnancy in sheep.[19] It is not known whether this occurs in humans. However, it is known that physiological conditions will affect oxygen consumption in pregnant women. For example, resting oxygen consumption is decreased by 15% in first trimester women who suffer from hyperemesis gravidarum, severe "morning sickness", and are unable to consume a normal daily calorie intake.[20]

TABLE 43.1 New Recommendations for Total and Rate of Weight Gain during Pregnancy, by Prepregnancy BMI[12]

	Total Weight Gain		Rates of Weight Gain[a] 2nd and 3rd Trimester	
Prepregnancy BMI	**Range in kg**	**Range in lbs**	**Mean (range) in kg/week**	**Mean (range) in lbs/week**
Underweight (<18.5 kg/m^2)	12.5–18	28–40	0.51 (0.44–0.58)	1 (1–1.3)
Normal weight (18.5–24.9 kg/m^2)	11.5–16	25–35	0.42 (0.35–0.50)	1 (0.8–1)
Overweight (25.0–29.9 kg/m^2)	7–11.5	15–25	0.28 (0.23–0.33)	0.6 (0.5–0.7)
Obese (≥30.0 kg/m^2)	5–9	11–20	0.22 (0.17–0.27)	0.5 (0.4–0.6)

[a]*Calculations assume a 0.5–2 kg (1.1–4.4 lbs) weight gain in the first trimester.*[13–15]

The first group with a below-average body mass index before conception (BMI < 19.8 kg/m^2, hatched bar); the second group, a normal BMI (19.8–26.0 kg/m^2, unfilled bar); the third group, a high BMI (>26.0 kg/m^2, filled bar). *Source: Data from Ref. 11.*

Diet, Maternal Body Composition, and Fetal Programming

There is increasing evidence from animal[21–23] and human[24] studies that maternal diet affects the growth patterns of the placenta, fetus, and offspring. It is also clear that fetuses that experience growth faltering before birth are at risk for chronic diseases as adults.[25] Thus, evidence for links between maternal diet, fetal growth, and adult disease is becoming solidified. Shiell and coworkers studied the blood pressures of 626 young men and women of Motherwell, Scotland, whose mothers were recommended to eat a high meat, low carbohydrate diet during pregnancy.[26] The offspring of mothers who had the highest consumption of meat and fish had the highest mean systolic pressures. These findings point to the importance of maternal diet and body composition in establishing the health of their offspring in later life. The nutritional flow that is made available to a fetus depends on many aspects of the mother's nutrition and physiology, including her nutritional stores in the form of fat and muscle mass, her diet, and her metabolism, which is the product of her lifetime's nutrition.[27] Little is known about the fascinating increased drive for specific foods reported by many women during pregnancy.

Maternal appetite increases during pregnancy in a sex-specific way. Women carrying boys consume more calories from all macronutrient sources, protein, carbohydrate, and lipid.[28] Boys grow faster than girls with less relative placental mass and thus have placentas that are more efficient. The growth of boys is more closely linked to maternal body composition than is the growth of girls.[29] Because of the robust growth strategy of male fetuses, they are more vulnerable to nutrient deprivation.[30,31]

The powerful influence of the size and shape of the placenta on offspring risk for disease in later life has become apparent in recent years. Studies from Finland,[32] the United Kingdom,[33] the Netherlands,[31,33] Saudi Arabia,[34] India,[35] and the United States[36] have brought new emphasis to the importance of placental growth patterns as predictors of disease. Figure 43.4 shows placental phenotypes that are related to offspring disease.[37]

Not only is placental size and shape important but also the combination of placental and maternal phenotype may have even greater predictive value. These relationships suggest the presence of biological processes by which maternal body composition interacts with fetal/placental development leading to constraints on fetal organ development. Placental morphological studies have shown that placental breadth, length, thickness, and the better-known effects of placental weight are each associated with specific chronic diseases in the adult.

CARDIOVASCULAR ADAPTATIONS

Blood Volume

Maternal blood volume increases over time beginning at 6–8 weeks gestation, reaching a maximum at approximately 32–34 weeks, and changing little thereafter.[38–42] Maternal blood volume expansion supports fetal growth. Pregnancies complicated by fetal intrauterine growth restriction have lower mean maternal plasma

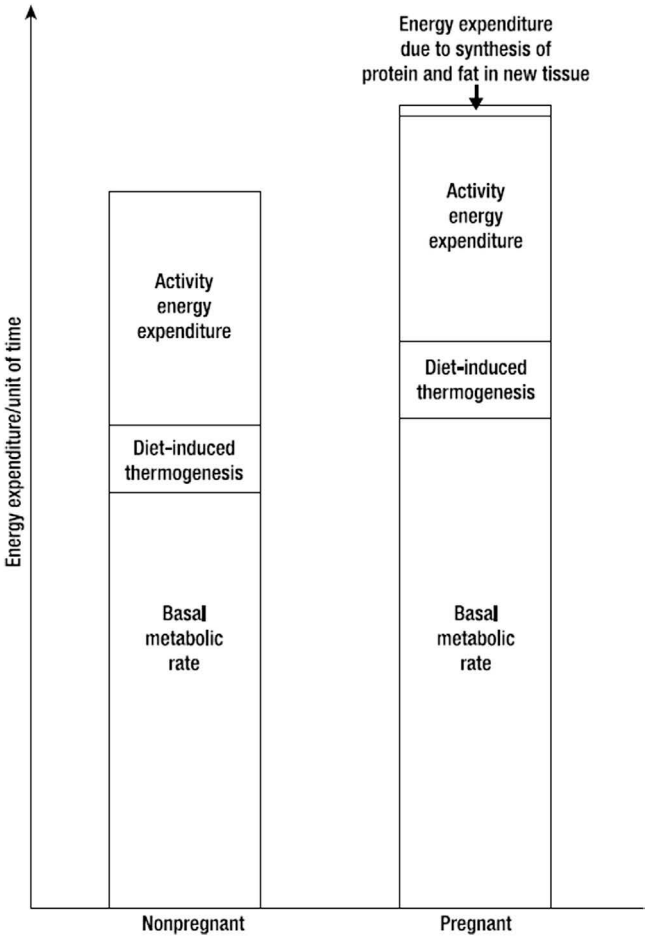

FIGURE 43.2 Increases in energy expenditure during pregnancy. *Source: Data from Forsum E, Lof M. Energy metabolism during human pregnancy.* Annu Rev Nutr *2007;***27***:277–292.*

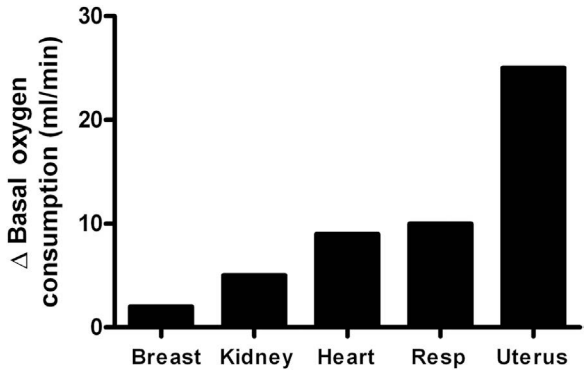

FIGURE 43.3 Increases in basal oxygen consumption (ml/min) for individual organs in near-term pregnancy compared to nonpregnant consumption rates. *Source: Data from Ref. 18.*

volumes than do pregnancies with normal fetuses (2976 ± 76 ml versus 3594 ± 103 ml, respectively).[31] The increase in blood volume serves at least two purposes: (1) it facilitates maternal and fetal exchanges of respiratory gases, nutrients, and metabolites, and (2) it reduces the impact of maternal blood loss at delivery. Blood losses of 300–500 ml for vaginal births and 750–1000 ml for Caesarean sections are typical and are compensated to some degree by the so-called "autotransfusion" of blood from the contracting uterus. Further blood losses tap the resources of maternal stores.

Bernstein and associates detected plasma volume expansion in pregnancy during the sixth week following a woman's last menstrual period.[43] By 12 weeks, plasma volume had expanded by approximately 14 ± 12% (mean ± standard deviation, SD) over follicular phase estimates. While the average blood volume increases from a prepregnant 6.5 l to 8.5 l during pregnancy, increases vary considerably among women, ranging from 30% to 50% in proportion to the number of fetuses[44,45]; increases have been estimated in a singleton pregnancy at 1570 ml and 1960 ml in a twin pregnancy.[44] Women show a similar plasma volume expansion pattern in their subsequent pregnancies.[40,44] Most of the added volume of blood is found in the uterus, breast, kidney, striated muscle, and skin.

The increase in plasma volume during pregnancy is relatively greater than that of red cell mass (20–30%) resulting in a decrease in hemoglobin concentration. Figure 43.5 shows that the decrease in hemoglobin concentration is not the result of simple hemodilution; both red cell mass and blood volume are increased. Thus, the popular term *hemodilution of pregnancy* is an oversimplification. Supplemental iron and folic acid intakes are necessary to restore hemoglobin levels to normal pregnant levels (~12 g/dl) if a woman has been iron deficient. Leukocyte counts are variable during gestation but remain at the upper limits of normal; leukocyte production appears to be regulated independently of red cell production. Like red cell concentration, plasma protein concentrations and total plasma osmolality decrease during pregnancy.

The mechanism by which blood volume increases is not fully understood, yet there are a number of physiological changes that are thought to be important. The role of the kidney is discussed in detail following. There is evidence that systemic vascular resistance is decreased under the influence of gestational hormones, which leads to activation of the renin–angiotensin–aldosterone system causing increases in sodium retention and blood volume.[46–48] There is evidence from experiments in baboons that systemic vasodilation precedes the measured increase in maternal blood volume as pregnancy progresses.[49]

The placenta may also contribute to the hormonal milieu that affects maternal blood volume regulation. Placental estrogen synthesis is dependent upon the estrogen precursor (dehydroepiandrosterone) from the fetal adrenal gland. Estrogen stimulates the renin–angiotensin system and thus promotes aldosterone production. Plasma

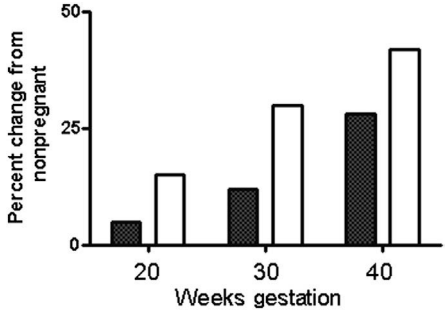

FIGURE 43.5 Average red cell mass (filled bar) and blood volume (open bar) increase over the course of pregnancy. *Source: Data from Ref. 41.*

renin levels, which are high during pregnancy, ensure high levels of angiotensin II (Ang II) that stimulate arginine vasopressin (AVP) release and water retention.[46,48,50,51] In the kidney, increased mineralocorticoid activity may also be important in the regulation of renal function during pregnancy.[52] Extra-adrenal conversion of progesterone to deoxycorticosterone also increases mineralocorticoid activity.[53] There is a net accumulation of sodium during pregnancy of some 500–900 mEq.[54,55] Further studies are needed to integrate these physiological features of pregnancy. (There are a number of interesting features of the physiological adaptations to pregnancy.)

Altitude

The hypobaric hypoxia of altitude causes an increase in hematocrit and hyperviscosity in long-term residents. Pregnant women adjust to altitude (~4400 M) differently from women at sea level in that they show blunted adaptive hematological adaptations in general.[56] Hematocrit and viscosity decrease with gestation in women at altitude but much less than for women at sea level. Thus, women at altitude have a higher blood viscosity than women at sea level even during pregnancy.

Circulating Factors with Cardiovascular Effects

A number of circulating factors are important in blood volume regulation. Many of these are also powerful regulators of vascular tone and of vessel remodeling. Atrial natriuretic peptide (ANP) is maintained at normal levels during pregnancy or is increased depending upon posture.[57,58] Figure 43.6 shows plasma ANP levels from 15 healthy women as a function of gestational age and posture.[59] In healthy men and nonpregnant women, plasma osmolality, plasma renin activity, and plasma concentrations of AVP, ANP, and aldosterone all increase with increasing exercise intensity. However, in nonpregnant individuals, high intensity exercise has an antidiuretic and antinatriuretic effect, opposite to the effects expected when plasma ANP levels are elevated.[60] Heenan and colleagues studied the responses to exercise in pregnant women, expecting that their hypervolemic state would attenuate the normal increases in Ang II and AVP.[61] Thirteen pregnant women of 37 weeks gestation were studied at rest and at two intensity levels as a percentage of the estimated anaerobic threshold (VT value). Figure 43.7 shows that plasma Ang II levels were high in these pregnant women but tended to decrease with increasing exercise intensity; in contrast, nonpregnant women had lower initial Ang II levels that increased with exercise. The AVP response to exercise was completely blunted in the pregnant women. However, plasma levels of ANP were elevated with exercise.

Verkeste and associates found that the increase in plasma volume during pregnancy in rats results from fluid retention rather than from a shift within the extracellular fluid volume (ECFV) from the interstitium to the intravascular compartment.[62] They found a gradual synchronous increase in all fluid compartments, without consistent change in their relative distributions. Chapman and associates found that peripheral vasodilation occurs in the luteal phase of the normal menstrual cycle in association with an increase in renal plasma flow and filtration.[63] They found increased activation

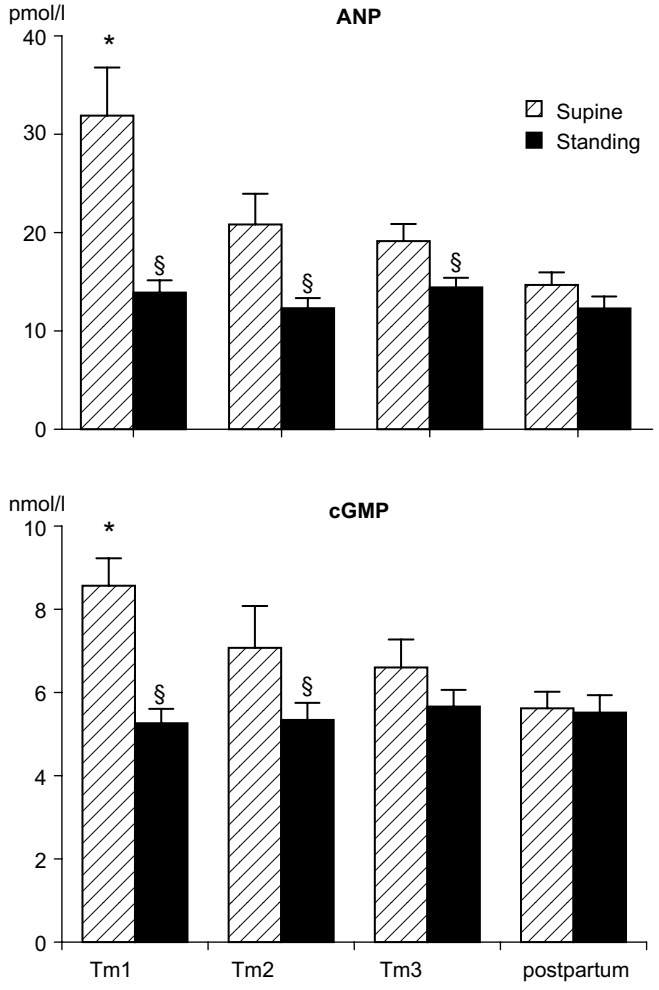

FIGURE 43.6 **Plasma atrial natriuretic peptide (ANP) and cGMP at each trimester (Tm) of pregnancy and postpartum in 15 healthy women in the supine and upright positions (mean ± SEM).** *$P < 0.05$ versus postpartum in the same position; §$P < 0.05$ versus corresponding supine value. *Source: From Ref. 59, with permission.*

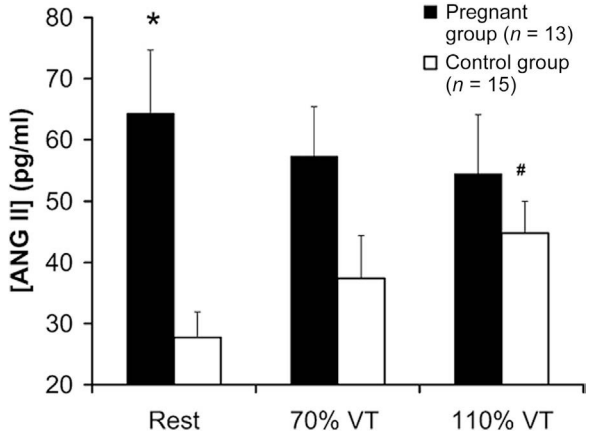

FIGURE 43.7 **Plasma angiotensin II concentration ([ANG II]) at rest and at two work rates as a percentage of the estimated anaerobic threshold or ventilatory threshold (VT).** *Significant difference ($P < 0.05$) between groups. #Significant change ($P < 0.05$) within group from rest. *Source: From Ref. 61, with permission.*

of the renin–angiotensin–aldosterone system indicating that vasodilating mediators may be responsible for the observed hemodynamic changes. The authors suggest that hormonal changes during the normal menstrual cycle mimic changes seen in early pregnancy. This would argue for changes in hormonal environment as the primary driving force for changes in blood volume regulation.

Atrial Distension

The role of atrial distension in regulating maternal blood volume has been investigated and is controversial. Some scientists have suggested that the maternal atrium grows to accommodate increased blood volume, which, in turn, decreases the degree of stretch and blunts the stretch-ANP release response. That explanation is not likely to be true for two reasons: (1) an increase in systemic blood volume would not necessarily increase atrial transmural pressure, and (2) an increase in the radius of curvature of the atrial wall would increase wall stress and presumably make the atrium more sensitive to ANP release unless there was a disproportionate increase in wall thickness. Thus far, no study has provided convincing evidence for an increase in atrial stretch during pregnancy. Kaufman used a rat model to study whether pregnancy affects the sensitivity of atrial distension in the release of ANP and whether neural input from the atrial volume receptor is altered.[64] Atrial distension was achieved by implanting small balloons positioned at the superior vena caval/right atrial junction of rats; inflation of the balloon did not impede blood flow through the heart. In virgin rats, atrial stretch caused increased urine production, urine sodium and potassium output, and decreased free water clearance; plasma ANP levels also increased. No such response was observed in pregnant animals. Distension of isolated atria derived from unmated and 7-day pregnant rats resulted in an increase in secretion of ANP into the perfusate, whereas atria from 14- to 21-day pregnant rats were unresponsive to distension. The authors concluded that there is attenuation of both hormonal and neural responses to atrial distension in the pregnant rat. The sensitivity of ANP release from the heart may accommodate blood volume increases in pregnant women without eliciting homeostatic mechanisms to eliminate the extra fluid.

Deng and Kaufman found that atrial distension caused an increase in c-fos expression in the paraventricular nucleus of the lateral hypothalamus in rats.[65] During pregnancy, this response was markedly attenuated. Zhang and Kaufman sought to determine whether nitric oxide (NO) was involved in cardiovascular homeostasis in pregnancy.[66] They found that nitric oxide synthase (NOS) inhibition selectively reduced plasma volume in pregnant rats. Lo and Kaufman found that plasma levels of 5 alpha-pregnan-3 alpha-ol-20-one (pregnan), a potential regulator of NOS, is increased during pregnancy in rats.[67] One

milligram of pregnan given to rats over a two-day period stimulated NO biosynthesis and an increase in plasma volume in nonpregnant rats. These data are interesting in that while NO is known to be a powerful vasodilator in pregnancy, it may also affect cardiac function.[68]

During pregnancy in most species, the resting levels of plasma ACTH (corticotropin), aldosterone, cortisol, and Ang II are increased.[69,70] Cortisol is undoubtedly important in blood volume regulation. For example, when maternal cortisol is decreased experimentally, blood volume during pregnancy is reduced in sheep.[71]

Lindheimer and Davidson have shown that the osmotic thresholds for thirst and antidiuretic hormone release simultaneously decrease in pregnancy so that water intake is increased, retained, and body fluids are diluted.[50] In pregnancy, AVP release is not suppressed at the usual level of body tonicity so that ingested water is retained. With increased body water, plasma osmolality declines until it is beneath the osmotic thirst threshold, and a new steady state is established. Pregnancy is characterized by increments in intravascular volume, but volume-sensing mechanisms appear to accommodate as gestation progresses so that each new volume increment is "sensed" as normal. The metabolic clearance of AVP increases several fold, due to rising plasma cystine aminopeptidase (vasopressinase), which is produced by the placenta.

Vasopressin and ACTH responses to hypotension are altered in pregnant ewes,[69,72,73] and the relationship between mean arterial pressure and vasopressin or ACTH response shifts, consistent with a change in set point for regulation of mean arterial pressure. The decrease in hormone responses to hypotension is stimulus specific; ACTH responses to hypoglycemia are increased in the pregnant ewe and AVP responses to hyperosmolality are not altered in the pregnant ewe.[69,72]

The heart rate responses to hypotension are also decreased in pregnant ewes, consistent with the observations in the rat that baroreflex responses are decreased in the pregnancy. Recent studies suggest that the decrease in baroreceptor gain in pregnancy is related to decreases in central insulin concentrations in rabbit and rat.[74] The vasopressin and cortisol responses to hypotensive hemorrhage are also altered in the pregnant dog[75,76]; the relation between mean arterial pressure and hormone concentration is depressed. These data indicate that pregnant animals have a reduced ability to maintain arterial pressure during hemorrhage compared to nonpregnant animals. In addition, increases in heart rate, renal sympathetic activity, vasopressin, ACTH, and cortisol that are mediated by the baroreceptor reflex are reduced during pregnancy.[76]

Circulatory Adaptations

Remodeling of the entire maternal circulation begins within a few weeks following implantation. Circulatory changes continue through parturition, after which most of the changes are reversed. Table 43.2 summarizes many of the changes that occur. Among the most profound changes are the early decreases in systemic vascular resistance and increases in cardiac output. These changes occur even before there is an increase in metabolic rate.[77] The heart is remodeled with increased left ventricular chamber dimensions and increased left ventricular mass, reminiscent of changes observed in athletes.[78–81]

Cardiac Output

Cardiac output increases by more than 50% during pregnancy (Figure 43.8). It peaks by mid-third trimester, but half of that increase takes place within the first 8 weeks, long before $\dot{V}O_2$ has increased. Thus, the increase in cardiac output is not the sole result of increased tissue demand.

$$\dot{Q}_{CO} = SV \times HR$$

Because cardiac output is the product of stroke volume and heart rate, each has the potential to augment cardiac output in pregnancy; Figure 43.8 shows that both are important. Heart rate and stroke volume increase early in gestation and both reach their peak at mid-gestation. Stroke volume reaches a plateau by about 20 weeks and appears to gradually decrease over the remaining course of gestation. The magnitudes of change in stroke volume and heart rate are quite variable between individuals, and some studies have shown somewhat different patterns for these changes.

For any given chamber volume, stroke volume is regulated through increases in end diastolic pressure, which changes cardiac chamber wall stress (preload, the force/area in the myocardium), by decreases in systolic load (afterload, the force/area acting on the muscle wall during ejection), and by contractility (the contractile state within the myocardium). Of these three, only the decrease in afterload is a well-accepted mechanism for increasing stroke volume during pregnancy. While there are many investigators who have found increases in

TABLE 43.2 Hemodynamic Changes in Pregnancy[17]

Increased	Decreased
Blood volume	Systemic vascular resistance
Uterine blood flow	Pulmonary vascular resistance
Red cell mass	Hematocrit
LV diastolic dimension	Arterial blood pressure
Stroke volume	Plasma albumin concentration
Heart rate	Arterial carbon dioxide tension
Arterial oxygen tension	Arterial hydrogen ion concentration
Arterial compliance	Colloid osmotic pressure

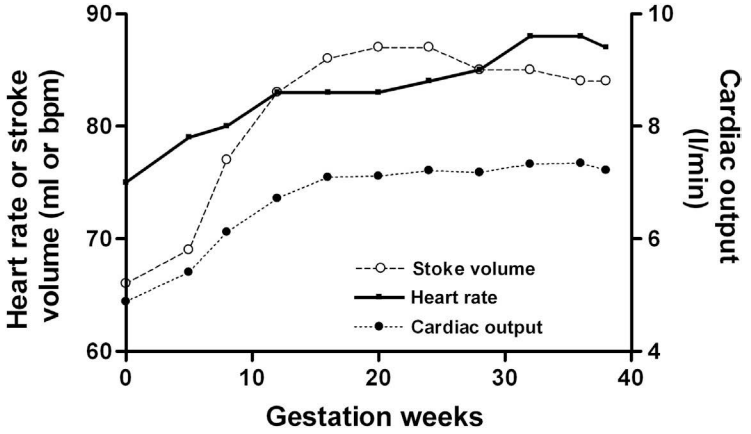

FIGURE 43.8 Cardiac output (closed circles) increases over gestation as the product of increased stroke volume (open circles) and heart rate (solid line). *Source: Data from Ref. 80. Reproduced from Ref. 17, with permission.*

surrogate measures for preload, an equal number have not seen increases. However, the heart of the pregnant woman may be quite sensitive to changes in preload so that profound alterations in cardiac anatomy could be driven by preload changes that are hardly measurable. One important factor that must be considered when measuring central venous or end diastolic pressure is maternal posture. As for all adults, preload increases in the supine position compared to sitting upright. However, in the later stages of pregnancy, the weight of the uterus may compress the inferior vena cava in the supine posture and can change filling pressures of the heart in a dramatic way. The importance of posture in determining plasma ANP levels is shown in Figure 43.6.

There is an even greater controversy over the role of contractility as an adaptation to pregnancy. Some authors have found increases,[82] others have agreed with the Poppas study[83] that there is no change,[84] and yet others have found a decrease in contractility.[85,86] Differences in contractile state are notoriously difficult to measure in humans using noninvasive methods in which estimates are affected by the loading conditions of the heart. In the Poppas and Mone studies, contractility was estimated from a method believed to be load and heart rate independent, the velocity of circumferential fiber shortening relative to the stress in the wall at end systole. Yet the findings of these two groups remain different. Thus, the degree to which preload and contractility are changed during pregnancy requires further study.

Cardiac output also increases during labor. Increases may reach 30% in the first stage and more in later stages, with variability dependent on posture and anesthesia.[87] Cardiac output increases are more related to stroke volume, through increases in venous filling than to increases in heart rate.[88]

Arterial Blood Pressure

Mean arterial blood pressure decreases over the course of pregnancy and is lowest at mid-gestation. Systolic and diastolic pressures, as well as pulse pressure, drop modestly during pregnancy and reach their lowest values at about 20 weeks. This drop in pressure is the result of decreased systemic vascular resistance (Figure 43.9). The behavior of the cardiovascular system can be understood in simplified form by applying a form of Ohm's law for direct current in a simple circuit. Under such conditions, current I is equal to the ratio of applied voltage divided by total resistance. In equation form:

$$I = \Delta V / R.$$

Following the same form for the systemic circuit of the cardiovascular system, the total flow through the system, cardiac output ($\dot{Q}_{CO}$) is equal to the driving pressure across the systemic circuit, aortic pressure minus right atrial pressure ($P_{ao} - P_{ra}$) divided by the total vascular resistance of the circuit (TVR). In equation form:

$$\dot{Q}_{CO} = (P_{ao} - P_{ra}) / \text{TVR}$$

Systemic arterial pressure decreases during the first trimester of pregnancy. Systolic, diastolic, and mean arterial pressure decrease about 10% by the seventh week of pregnancy.[42] Because, in an oversimplified view, arterial pressure is determined by the product of cardiac output and TVR, one or both of these factors must decrease to explain a decrease in arterial pressure.

$$\text{BP} = \dot{Q}_{CO} \times \text{TVR}$$

Because cardiac output is increased early in pregnancy, it cannot account for a decreased arterial pressure in pregnancy. However, TVR is the change that leads to decreased blood pressure. Thus, total resistance to flow must be decreased to a greater degree than cardiac output is increased, leading to a drop in arterial pressure. It has been argued that the reduction in TVR is due to the presence of the dilated uterine bed. However, the contribution of the gravid uterus, at its peak in flow, has been estimated to contribute

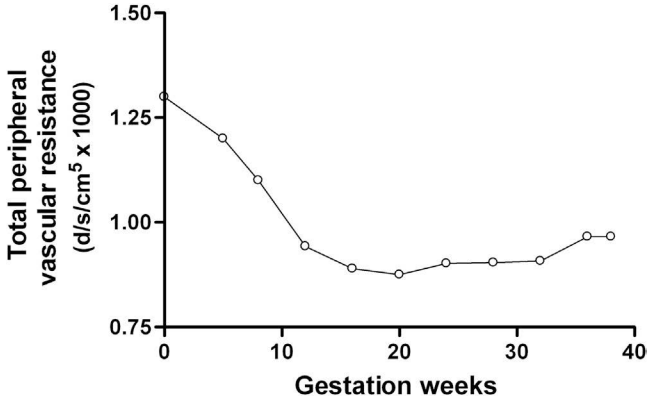

FIGURE 43.9 **Total peripheral resistance decreases dramatically over the first 16 weeks of pregnancy.** *Source: Data from Ref. 80. Reproduced from Ref. 17, with permission.*

about 20% to the decrease in TVR. Both systolic and diastolic blood pressure decrease until about 28 weeks and then gradually approach prepregnant values by term.[46] Blood pressure values are sensitive to the methods used to make the measurement. Ginsberg and Duncan found that mean systolic and diastolic blood pressures were lower by 6 and 15 mmHg, respectively, when determined by catheter in the radial artery compared to sphygmomanometry.[89] Similarly, Kirshon and associates found a lower systolic blood pressure by automated sphygmomanometry compared with a direct radial arterial measurement, but diastolic pressure was not different.[90]

It is well known that hypertensive disorders are a leading cause of maternal and perinatal morbidity and loss of life.[91] It has been estimated that some 25% of cases of intrauterine growth retardation are associated with inadequate cardiovascular adaptations to pregnancy and especially insufficient remodeling of the uterine arterial vascular bed.[92] There are a number of known causes of hypertension in pregnancy, and there are undoubtedly causes that remain undiscovered. Steer and coworkers have shown that both hypertension and hypotension during pregnancy are associated with babies who are undergrown and who suffer high mortality.[93]

Among the adaptations to pregnancy are a reduced pressor response to vasoconstrictors such as Ang II, AVP, norepinephrine, and phenylephrine. A number of studies in whole animals and isolated vessels have sought to determine the underlying mechanisms for this adaptation.[94–99] D'Angelo and Osol found an increased sensitivity to vasoconstrictors within uterine arcuate arteries in late-pregnant rats compared to nonpregnant rats.[99] Clearly, more investigation is required for clarification of the sensitivities of resistance vessels to constrictor-dilator substances in the pregnant woman.

Changes in central venous pressures during pregnancy have been difficult to prove, but lower body venous pressures are known to rise under the influence of mechanical factors. From mid-pregnancy, the enlarged uterus compresses both the inferior vena cava and the lower aorta in the supine position. Obstruction of the inferior vena cava reduces venous return to the heart leading to a fall in cardiac output by as much as 24% toward term when a woman is lying in the supine position. Most women compensate for the resultant decrease in stroke volume by increasing systemic vascular resistance and heart rate. Obstruction of the lower aorta and its branches can cause diminished blood flow to kidneys, uteroplacental unit, and lower extremities. During the last trimester, maternal kidney function is often lower in the supine than in the lateral position. Rarely, obstruction of the lower aorta and its branches can cause diminished blood flow to the placenta, which can result in insufficient transplacental gas exchange.[18]

Vascular Changes

Changes in vascular behavior with pregnancy have been studied in a number of animal models and in humans. Most studies show that arterial distensibility is increased over the duration of pregnancy. Whether veins behave in the same way is more controversial. The early literature suggests that venous compliance is increased under the influence of sex steroid hormones and that venous pressures in the lower limbs are elevated during pregnancy and prone to stasis.[100] Edouard and coworkers found that the distensibility and viscoelastic components of the lower limb veins decreased with duration in pregnancy and that upper limb veins made no such changes.[101] Vasodilator substances that are known to be important in pregnancy include estrogen,[102] NO,[103] prostacyclin,[102] relaxin,[104] and calcitonin-gene-related peptide.[105] These vasodilators have effects in a number of vascular beds including cerebral,[106] mesenteric,[105] coronary,[107] and uterine vessels.[102]

In sheep, vasodilatory prostacyclin and associated enzymes for its production are increased in the uterine arteries. Rupnow showed that estrogen and progesterone have independent effects on the production of prostacyclin-regulating enzymes in endothelium and vascular smooth muscle of uterine, renal, coronary, and omental vessels.[102] However, the combination of increased estrogen and progesterone, as seen with pregnancy, causes an increase in phospholipase 2 and cyclooxygenase in the uterine artery. Thus, changes in vascular remodeling and behavior are vessel specific.

The mechanisms that underlie the remodeling of the uterine vascular bed are the subject of intense investigation because the stakes in terms of fetal health are so profound. It is now well recognized that the uterine arteries of pregnant animals are extensively remodeled, being profoundly dilated in pregnancy compared to the nonpregnant state.[97,103,108]

Twin Pregnancies

Maternal cardiovascular responses to pregnancy are exaggerated in twin pregnancies compared to singletons. Twin pregnancies carry a higher risk for gestational hypertension and preeclampsia.[109,110] Kametas and coworkers reported that cardiac output is 20% greater, stroke volume is 15% greater, and heart rate is slightly higher in twin pregnancies than in singleton pregnancies.[111] Left atrial diameter and left ventricular end diastolic dimension are also larger. Others have found similar increases in cardiovascular hemodyamics.[79,82,109,110]

Pulsatile Characteristics of the Cardiovascular System in Pregnancy

As mentioned previously, the use of Ohm's law to characterize the circulation, as one would an electrical circuit, is the most straightforward way to understand the relationships between steady flow, driving pressure, and resistance to flow. Using these relationships, we are able to understand changes that occur in the cardiovascular system under steady load conditions during pregnancy. However, because an intermittent pump drives blood flow, many of the characteristics of the circulatory system can be understood only by analyzing the relationships of pulsatile pressure and flow.

Poppas and coworkers have assessed both steady and oscillatory aspects of the cardiovascular system using noninvasive measurements in 14 pregnant women during each trimester of pregnancy and postpartum.[83] They used instantaneous subclavian artery pulse tracings, Doppler flow velocities, and left ventricular M-mode echocardiography (Figure 43.10). Their measurements of steady hemodynamics and cardiac anatomy fit with previous reports. They found a pregnancy-related increase in left ventricular muscle mass and end diastolic chamber dimension. They did not detect changes in myocardial contractility.

Poppas and coworkers found that global compliance in the subclavian artery increased with gestational age as TVR decreased.[83] Global arterial compliance is the relationship between volume and pressure change during exponential diastolic pressure decay in an arterial segment ($\Delta V/\Delta P$).[112,113] This finding is undoubtedly related to well-documented changes in distensibility of arteries and veins during pregnancy under the influence of estrogen and relaxin as discussed earlier.[101,114–117] There are two mechanisms that could alter the distensibility of the arterial tree at a given transmural pressure: (1) the vascular wall might be remodeled so that matrix elements have an altered behavior, and (2) vascular smooth muscle tone might be reduced. Unfortunately, simply testing the pressure volume characteristics of specific vessels does not adequately distinguish between these possibilities under in vivo conditions.

One of the most important contributions of the Poppas study was the finding that oscillatory power (time related work, $\dot{W}$) was progressively increased in pregnancy compared to the nonpregnant state (Figure 43.11). This suggests that an ever increasing fraction of the energy expended by the muscle pump to circulate blood through the vascular tree is spent on overcoming the oscillating resistance offered by its vascular elements. Thus, as pregnancy proceeds, the circulation of blood requires extra energy by the heart, which has adapted to the pregnant condition.

Hematological Factors

Blood volume gradually increases by an average of some 50% by term but with great individual variability.[40] Pritchard reported an average increase in red blood cell mass of around 30% (450 ml) in both singleton and twin pregnancies as determined by the chromium (^{51}Cr)-labeled red blood cell technique.[44] Thus, it has been known for decades that plasma erythropoietin levels and consequent erythropoiesis increase during pregnancy.[118] However, recent studies have shown that red cell mass is suppressed in the first trimester as is erythropoiesis.[119,120] Figure 43.12 shows that hematocrit decreases with gestational age even as erythropoietin increases. The "set point" for

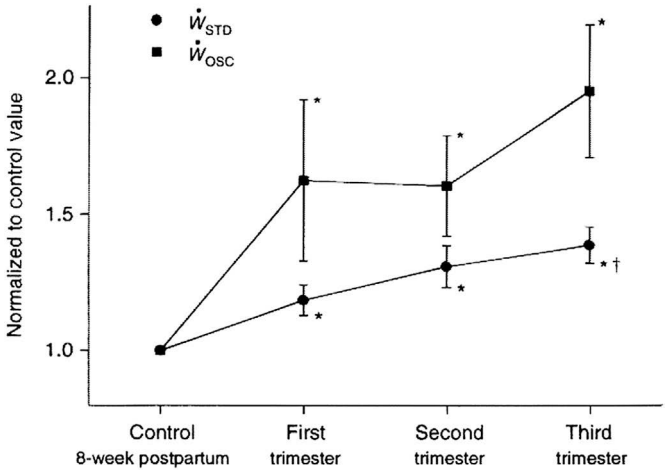

FIGURE 43.11 Increases in steady ($\dot{W}_{STD}$) and oscillatory ($\dot{W}_{OSC}$) power during gestation. Data are normalized to 8-week postpartum control values (mean ± SEM $^{*}p < 0.05$ versus control, $^{\dagger}p < 0.05$ versus first trimester). *Source: From Ref. 83, with permission.*

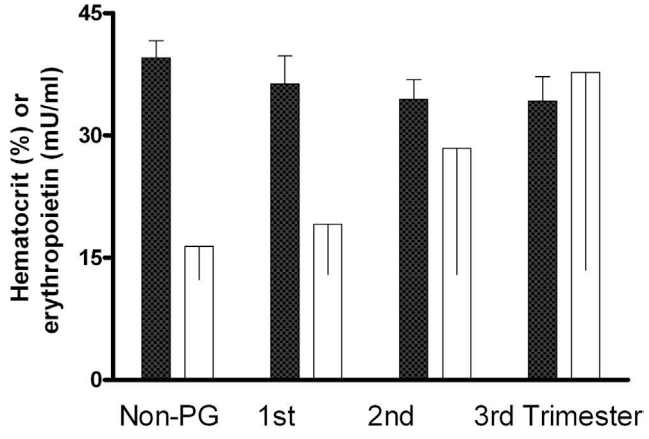

FIGURE 43.12 Hematocrit (filled bars ± SD) and plasma erythropoietin concentrations (unfilled bars) in nonpregnant women and in pregnant women in each trimester. *Source: Data from Ref. 119.*

red cell production appears to be altered with pregnancy because the rate of erythropoiesis is never adequate to maintain hematocrit at prepregnant levels. Thus, the increase in red cell mass during pregnancy is less than the increase in plasma volume and leads to the so-called "anemia of pregnancy".[40,121] It has been suggested that the availability of iron may limit erythropoiesis. Iron stores may be suboptimal in up to two-thirds of reproductive-age women before pregnancy because of recurrent iron loss from menstruation.[122] However, virtually all women have depressed hematocrits during pregnancy, regardless of iron stores.[119] Therefore, the iron limitation hypothesis is unlikely to explain the decrease. It is important to emphasize that the decreased hematocrit is not by simple hemodilution as is often stated in textbooks. As mentioned, red cell production rate increases during pregnancy, but increases less than required to maintain red cell concentration in the face of increased plasma volume. Like red cell concentration, plasma protein concentrations, and total plasma osmolality also decrease during pregnancy, which decreases blood viscosity.

Hemostasis

There is a commonly held view that maternal blood clots more easily during pregnancy. Some have argued from a teleological view that this hypercoagulability is related to the need to prevent excess hemorrhage with delivery of the placenta. However, a more important factor in stemming hemorrhage at birth is contraction of uterine smooth muscle, which occludes blood vessels in the uterus as the placenta is delivered. Regardless, the alteration in hemostasis with pregnancy carries an increased risk of thromboembolism. Thus, pregnant women are thought to be at increased risk for fatal pulmonary embolism and coronary occlusive disease.[123,124] The hypercoagulability is related primarily to changes in coagulant and anticoagulant proteins in the blood.[125] Table 43.3 shows coagulation proteins that are increased or decreased with pregnancy. Of note, procoagulant activity in the blood is primarily due to increases in factors VII, VIII, X, as well as fibrinogen and von Willebrand factor. Factor VII increases dramatically, up to 10-fold, whereas plasma levels of fibrinogen may double. von Willebrand factor and factor VII increase late in pregnancy, while factor XI usually decreases.[126] In spite of the view that pregnancy is a relatively hypercoagulable state, neither clotting nor bleeding times are outside the normal range. Thus, there is controversy regarding the importance of the known changes in hemostasis. In pregnant women there are a number of conditions that may lead to pathological hypercoagulability and to fetal loss.[127,128] These thrombophilias include antithrombin III deficiencies, protein C and S deficiencies, dysfibrinogenemias, activated protein C resistance, factor V Leiden mutation, and antiphospholipid syndrome.[127]

Cardiovascular Responses to Exercise in Pregnancy

The evolution of advice regarding exercise from physicians to their pregnant patients over the past 50 years has been interesting. Mid-twentieth century advice was based not only on ignorance of the physiology of exercise in pregnancy but also on fear that the cardiovascular fatigue and hyperthermia associated with exercise might harm the fetus. In the 1950s, sports activities were discouraged for pregnant women and only light housework was recommended. But by the 1980s, moderate exercise was recommended by the American College

TABLE 43.3 Coagulation Proteins in Pregnancy[125]

	Increased	Decreased
Procoagulants	I, V, VII, VIII, IX, X	XI
Anticoagulants	Soluble thrombomodulin, TM	Protein S
Adhesive proteins	von Willebrand factor, vwf	
Fibrinolytic proteins	Plasminogen activator inhibitors, pai-1, pai-2	Tissue plasminogen activator, tpa
Placental trophoblast	Tissue factor	Tissue factor pathway inhibitor

Modified from Brenner. Thromb Res *2004;**114**:409.*[125]

of Obstetricians and Gynecologists.[129] While only a half dozen studies have been published, it appears that maternal maximal oxygen consumption ($\dot{V}O_{2max}$) is not different between pregnant and nonpregnant women even with regular weight-bearing exercise. These findings have been summarized.[130] Care providers who might advise against exercise during a normal pregnancy now face an extensive literature on the physiological responses to exercise in pregnancy that show clear benefit. Thus, it is no longer controversial to suggest that moderate, nonexhaustive exercise during pregnancy will bring many health benefits, including less maternal weight gain, reduced risk of preeclampsia, a potentially more efficient placenta (rat), and a heavier baby with a healthy body composition.[130,131]

RESPIRATORY SYSTEM ADAPTATIONS

It is not surprising that the respiratory system must accommodate the energy demands of pregnancy. The single fetus consumes ever increasing amounts of oxygen, and multiple gestations require even more at any corresponding age. Oxygen flow into the maternal blood must then increase not only because of increasing fetal oxygen consumption but also because of increased maternal tissue mass and metabolic demand. Many of the respiratory adaptations have been the subject of published studies and reviews.[132–149] The most profound pregnancy-induced adaptations of the respiratory system arise from two maternal changes:

1. increases in progesterone/estrogen that drive alveolar ventilation during pregnancy;
2. reconfiguration of the chest wall and the elevation of the diaphragm in accommodation of growth of the gravid uterus and mobility of the rib cage.[149]

Hyperventilation

Minute ventilation, $\dot{V}_E$, and alveolar ventilation, $\dot{V}_A$, each increase by about 50% during pregnancy as a result of the central influence of progesterone and perhaps depressed osmolality, augmented Ang II, and AVP.[132,139,141,144,145,147,150] Hyperventilation begins at least by 8 weeks of gestation and depresses alveolar/arterial PCO_2 from its normal resting prepregnant value of ~38 torr (menstrual cycle dependent) to about 30 torr at term; even lower values would not be unusual. The increased alveolar ventilation of pregnancy is maintained mostly by an increase in tidal volume (TV) without much change in respiratory rate. Depressed alveolar carbon dioxide pressure is accompanied by an increase in the partial pressure of oxygen in arterial blood to at least 108 torr early in gestation. Some investigators report a small decrease in PaO_2 to about 104 torr at the very end of term. As the fetus grows and produces more carbon dioxide, the mother must excrete the extra carbon dioxide produced by the fetus in addition to her own. The changes in maternal arterial gas pressures improve the transplacental gradients across the placenta for oxygen, facilitating oxygen flux into the fetal compartment, and for carbon dioxide, facilitating the net carbon dioxide flux from the fetus to the mother. The decreased maternal arterial PCO_2 results in a mild respiratory alkalosis with appropriate renal compensation. Maternal serum pH is maintained at or below 7.45 during pregnancy with a depressed bicarbonate ion level of 18–21 mEq/l.

Lung Volumes and Function

Figures 43.13 and 43.14 show the primary changes in lung volumes and flows that begin after the second half of pregnancy and become pronounced during the third trimester.[132,138,143] These changes include the following:

1. Vital capacity (VC, the amount of gas that can be expelled from the lungs following inspiration to total lung capacity (TLC)) is unchanged.
2. TV (the amount of gas inhaled each breath) is increased by some 40%.
3. Functional residual capacity (FRC, the gas volume remaining in the lungs at rest following exhalation of a tidal breath) is reduced by 20%.

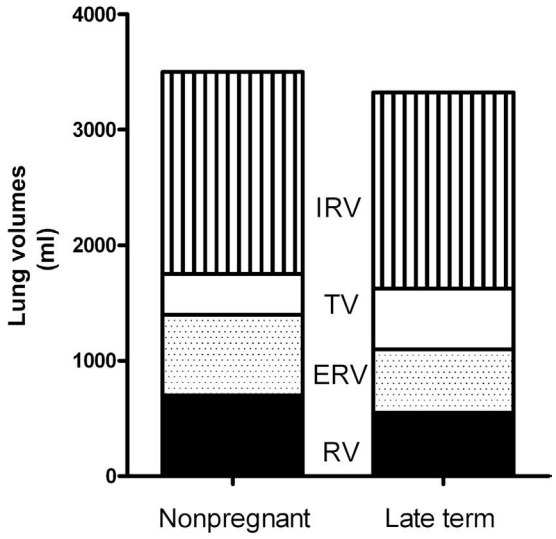

FIGURE 43.13 Lung volumes before and during term pregnancy. IRV = inspiratory reserve volume; TV = tidal volume; ERV = expiratory reserve volume; RV = residual volume. *Source: Data from Ref. 104.*

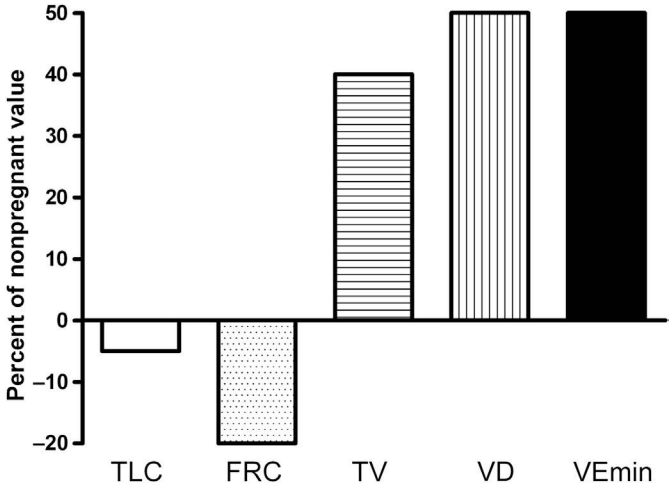

FIGURE 43.14 Maximal percent changes in respiratory parameters during pregnancy compared to the nonpregnant state. TLC, total lung capacity; FRC, functional residual capacity; TV, tidal volume; VD, dead space volume; VEmin, minute volume, rate of expired gas per minute. *Source: Data from Ref. 105.*

The component volumes of the FRC are the expiratory reserve volume (ERV, the volume of gas remaining after a tidal breath that can be exhaled with effort) and the residual volume (RV, the volume remaining in the lung following maximal expiratory effort). Each is reduced approximately equally by some 20%.

4. The sum of all volumes, TLC, is reduced by a modest 5%.
5. Dead space (V_D) increases by about 50%, but the resting dead space to TV ratio (V_D/V_T) does not change because of the increase in TV.

Virtually all respiratory adaptations of pregnancy resolve soon after delivery.[148] Total airway resistance may be reduced during pregnancy, by unknown mechanisms, but overall lung compliance does not change. There are no major changes in standard respiratory functional indices using spirometry-based measurements. Forced expiratory flow in 1 s (FEV_1), mean peak expiratory flow rate (~450 ml/min), and VC are virtually unchanged in U.S. women at sea level.[151] However, ventilatory drive appears to be increased.[140,146]

In 2004 McAuliffe and coworkers reported on respiratory physiological measurements in each trimester of women with singleton pregnancies at sea level (Lima, Peru) and at altitude (Cerro de Pasco/4300 m).[152] They made three interesting findings: (1) nonpregnant and pregnant women alike who lived at altitude had larger lung volumes by about 11 than did sea level women in spite of a 4 cm deficit in height for Cerro de Pasco women, (2) women living at sea level had greater TLC and RV in the third trimester compared to the first trimester, (3) women living at altitude showed a lower FEV_1 in the third trimester compared to the first. These data suggest that pregnancy at altitude demands additional adaptations in respiratory function that are not needed in populations that have lived for generations at sea level.

In normal women, the oxygen cost of breathing is increased in late gestation by some 50%. This is due, in part, to the decreased chest wall compliance that accompanies the reconfiguration of the wall due to the increased intra-abdominal pressure as the growing uterus impinges on abdominal contents and the diaphragm. As pregnancy progresses, the circumference of the abdomen increases, the diaphragm is elevated by some 5 cm, and the chest configuration is altered. One aspect of the reconfiguration is the increase in the average costal angle that accompanies pregnancy earlier than can be explained by increased abdominal pressure with uterine growth. The transverse and anterior–posterior dimensions of the chest increase, which leads to a circumferential increase in the lower thorax of about 5–7 cm.[136,140,146,147]

Diffusing Capacity

The degree to which diffusing capacity of the lung for oxygen changes during pregnancy is controversial. Diffusing capacity for carbon monoxide (DLCO) measurements have been made in women during pregnancy. Because decreasing hemoglobin concentrations in pregnancy affect the measurement of the DLCO, one would expect decreased DLCO values even without any change in the physical attributes of the pulmonary barrier. Milne and coworkers reported an early increase (11 weeks) and a mid-gestation decrease in DLCO.[139] Thus, there may be

changes in barrier function, but further investigation is required to clarify this issue.

RENAL ADAPTATIONS

Overview

Early in pregnancy, well before the human embryo is of significant size, the maternal kidney undergoes dramatic changes in structure, hemodynamic regulation, and tubular handling of solute and water. The primary renal responses to pregnancy have been well documented in previous studies and summarized.[153–158] These well-established changes in the kidney during pregnancy can be briefly summarized as follows:

Glomerular Filtration Rate and Effective Renal Plasma Flow (Figure 43.15)

Glomerular filtration rate (GFR), as measured by creatinine or inulin clearance, increases by approximately 40–65% by the end of the first trimester to a peak of around 180 ml/min[159–162] and is subsequently sustained until term.[161] Effective renal plasma flow (ERPF), as measured by para-aminohippurate (PAH) clearance, also increases by 150–185% above normal at its peak during early pregnancy; it then slowly declines over the second and third trimesters to reach ~10% above the normal nonpregnant level at term.[157] An important caveat applies: a valid comparison of ERPF in normal versus pregnant states via PAH clearance requires that the fractional PAH extraction (EPAH) across the kidney (normally 0.92) remains constant in the pregnant versus nonpregnant kidney.[163] To our knowledge, the renal extraction of PAH has never been measured in human pregnancy but is known to vary up to 20% in various physiological and experimental conditions in other studies.[163]

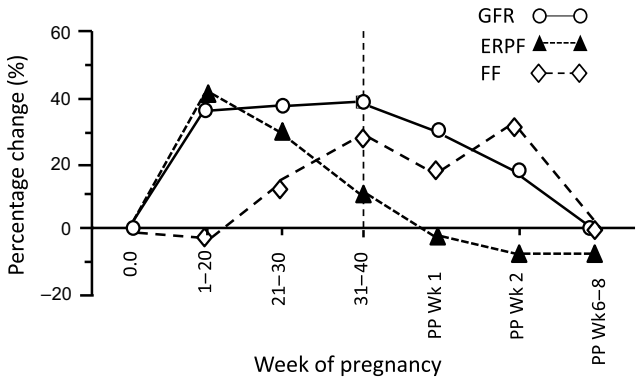

FIGURE 43.15 Changes in renal plasma flow and glomerular filtration rate in normal human pregnancy. Percent changes in glomerular filtration rate (GFR; black line), effective renal plasma flow (ERPF; red line), and calculated filtration fraction (FF; GFR/ERPF) over the course of gestation and early postpartum are shown relative to the nonpregnant state. Data were drawn from published studies based on clearance of inulin or iodothalamate for GFR and on clearance of PAH for ERPF. *Source: From Ref. 157, with permission.*

Blood Urea Nitrogen and Creatinine

Serum urea nitrogen and creatinine levels decrease during pregnancy to values averaging 9.0 and 0.5 mg/dl, respectively, from nonpregnant values of 13.0 and 0.8.[154] A serum creatinine value of greater than 0.8 mg/dl may therefore indicate abnormal renal function in pregnancy.[164]

Protein Excretion

Increases in total urinary non-albumin protein excretion of up to 260 mg/day are normal during pregnancy.[165] Urinary albumin excretion often increases but remains within the normal pregnant range.[157]

Sodium Handling

Renal tubular function is also changed during pregnancy.[155,156,158,166] The filtered load of sodium increases significantly due to the increased GFR. Despite this, a concomitant increase in tubular reabsorption of sodium results in a net retention of up to 1 g of sodium per day.[167,168] Retention of sodium is accompanied by proportional amounts of water, yielding expansion of ECFV up to 1–2 l in the intravascular space plus 4–7 l in the interstitial space.[166]

Renin Release

Renin release and plasma renin activity increase approximately two-fold early in pregnancy, are sustained through the second trimester, and then plateau.[161,169–171] This reflects reduced vascular filling,[172] lower blood pressure, and sympathetic nervous system (SNS) neural activation,[161] as well as hormonal changes.

Water Retention

Pregnancy is also a period of marked water retention.[158,167,168] This reflects sodium-free water, is a consequence of a lowered osmotic threshold for ADH secretion,[173] and yields a mildly lower body-fluid osmolality and serum sodium in normal pregnancy.[173] Intravascular volume expands by around 1–2 l and extravascular volume by approximately 4–7 l.[166]

Glycosuria, Aminoaciduria

Loss of glucose in the urine (glycosuria) is a common finding during normal pregnancy, resulting from increased glomerular filtration and coupled with decreased distal tubular glucose reabsorption.[157,174–178] Similarly, aminoaciduria in normal pregnancy is believed to reflect altered reduced tubular reabsorptive activity.[179]

Structural Changes

Kidneys increase in length and volume during pregnancy, reflecting increased vascular volume and interstitial fluid as well as nephron hypertrophy.[155,158] "Physiologic hydronephrosis" describes the typical pelvic and collecting system dilatation of pregnancy commonly attributed to hormonal influences.[158]

Recent Progress in Understanding Renal Adaptations to Pregnancy

Recent investigations now address the cellular and molecular mechanisms that underlie renal modifications associated with pregnancy.[154,180]

Renal Hemodynamic Changes in Pregnancy

A number of studies in normal rat,[153,181,182] rabbit,[183,184] sheep,[185] and human[164,186–188] pregnancies have established that ERPF and GFR progressively increase over the course of gestation as renal vascular resistance (RVR) declines. In women, GFR peaks in the first trimester and maintains elevated levels of 40–60% above nonpregnant levels until delivery.[186,189] ERPF also increases early but plateaus after 8–12 weeks of gestation. In the rat, both ERPF and GFR peak in midgestation at ~30% above virgin levels.[159] These hemodynamic changes are induced by maternal factors, as they do not require the presence of the feto-placental unit. Similar hemodynamic responses are observed in pseudopregnancy.[190,191]

Chapman and colleagues recently reexamined the time course of renal hemodynamic changes in normal human pregnancy ($n = 13$), using serial measurements of women in the left lateral decubitus position, employing gold standard classic methods (clearances of inulin and PAH), and including a preconception baseline and postconception measurements spanning 6–36 weeks gestation.[161] In agreement with prior work, ERPF was increased by six weeks, reached a maximum at eight weeks, and declined slightly by 36 weeks. RVR decreased in a mirror-image pattern as expected.[161] In contrast, GFR rose in parallel to renal plasma flow over about the first 6 weeks and then continued to increase until 12–24 weeks. Peak renal plasma flow increased to ~50% above nonpregnant levels at 8 weeks; the GFR increased by an average of ~27% by 12 weeks and ~55% by 36 weeks. Filtration fraction (fraction of RPF filtered at the glomerulus) remained below prepregnancy values throughout gestation. In a separate study, Roberts and coworkers estimated 72% and 45% increases in RPF at 16 and 36 weeks gestation, respectively.[192] They also mostly generally agreed with the Chapman study with a ~55% increase in GFR at both time points in normal pregnancy ($n = 11$). Based on a review and resynthesis of data from multiple studies, Odutayo and Hladunewich reached similar conclusions (Figure 43.15).[157]

Mechanisms of Increased GFR: Does Hyperfiltration in Pregnancy Convey Risk of Renal Injury?

Understanding the increased GFR in pregnancy is important in considering whether pregnancy can induce injury to the normal kidney.[159] GFR is determined by the average net filtration pressure within the glomerular capillary (Figure 43.16). An increase in glomerular capillary pressure (Pgc) is the typical mechanism underlying glomerular hyperfiltration in pathological states of nephron loss when sustained chronically.

The net filtration pressure at any point along the glomerular capillary is determined by the algebraic sum of hydrostatic and osmotic pressures across the filtration barrier. The net hydrostatic pressure is the pressure difference (ΔP) between the capillary pressure (Pgc) and the tubular hydrostatic pressure (PT); the oncotic pressure component is determined by plasma oncotic pressure (πgc) alone. The net hydrostatic pressure across the capillary wall favors fluid flow out of the capillary and into the renal tubule; at any point along the capillary, ΔP is offset by the oncotic pressure that opposes water flow from the capillary. The formula for glomerular filtration rate can be expressed as:

$$\mathrm{GFR} = (\Delta P - \pi\mathrm{gc})\,\mathrm{Kf}$$

where Kf is a filtration constant that incorporates the filtration surface area and intrinsic hydraulic conductivity of the glomerular capillary wall. The average ultrafiltration pressure is the summation of pressures along the capillary length, represented in Figure 43.16 as the shaded area. An additional factor influencing GFR is the renal plasma flow, which determines the rate of rise of πgc along the capillary length (Figure 43.16). Thus, an increase in renal plasma flow, when changed in isolation, slows the rate of rise of πgc, enhancing the net filtration pressure. When comparing across species, the degree to which changes in renal plasma flow affect GFR is believed to differ substantially in rats versus humans. Under basal conditions, the rat kidney is in "filtration pressure equilibrium," that is, the rise in oncotic pressure leads to cessation of filtration at a point prior to the end of the capillary length (Figure 43.16; solid line for πgc). Plasma flow has a large influence on GFR in the rat because flow increases (e.g., dotted line in Figure 43.16) allow filtration to occur along a greater fraction of the capillary length, thereby substantially increasing filtration surface area. In the human kidney, where "filtration pressure disequilibrium" pertains (Figure 43.16), filtration occurs along the entire capillary length under

basal conditions; thus, increases in renal plasma flow alone cannot recruit additional filtration surface area in the normal nonpregnant human kidney and thus have a more modest effect on GFR.

Glomerular Hemodynamics in Rat Pregnancy

Micropuncture studies in the rat, where GFR is substantially dependent on renal plasma flow, have shown that the pregnancy-associated increase in single-nephron GFR is accounted for by the increase in renal plasma flow.[193,194] Directly measured pressure in the glomerular capillary, Pgc, was unchanged by pregnancy in rats, indicating that: (1) hyperfiltration in rat pregnancy does not require glomerular capillary hypertension, and (2) renal vasodilation involves proportional reductions in resistances in the afferent (RA) and efferent (RE) arterioles.[194] Because a value for the filtration coefficient, Kf, could not be determined, a change in Kf could not be excluded in the normal pregnant rat.

To directly address the potential for renal injury with repetitive pregnancies, Bayliss and Rennke tested the long-term effect of five consecutive closely spaced pregnancies in normal Munich-Wistar rats.[195] No increase in Pgc was apparent as compared to age-matched virgins, and no adverse effects of repeated pregnancies on kidney function or structure were observed.[195] Although Reckelhoff found a greater tendency for renal functional decline in Sprague Dawley rats after eight successive pregnancies, no proteinuria or renal structural pathology was noted.[196] Studies in the rat indicate that the renal adaptation to pregnancy does not involve intracapillary hypertension, that pregnancy-induced changes fully resolve during the postpartum period, and that renal hyperfiltration during repetitive pregnancies does not appear to impose a risk of renal injury.[153]

Intraglomerular Hemodynamics in Human Pregnancy

Renal micropuncture is not possible in humans. Furthermore, since rat intraglomerular hemodynamics differ significantly from the human (see previous discussion), interspecies inferences are potentially unreliable. Therefore, recent investigations have attempted to estimate determinants of GFR in human pregnancy using computerized mathematical modeling approaches. ERPF, GFR, πgc, and clearances of neutral dextrans across a range of sizes were measured and combined with estimates for unmeasurable parameters such as mean pressure of the glomerular capillary and Kf.[189,192,197,198] Roberts and coworkers suggested that the mid-gestation increase in GFR of 55% could be fully explained by increased renal plasma flow; whereas the late GFR increases are likely due to additional factors, including a reduction from peak renal plasma flow as well as a fall in πgc of 5.9% in early gestation and 19.7% in late gestation.[192] Results did not support glomerular capillary hypertension as the primary driver for increased GFR across a range of feasible Kf and Δ*P* values. In response to technical criticisms, this group repeated their studies with improved protocols using two different mathematical models.[197] They again concluded that the 38% increase in GFR observed in late pregnancy reflected increased renal plasma flow, reduced πgc, and increased Kf with no increase in the net driving pressure (Δ*P*) across the capillary wall (Figure 43.16).

Postpartum Glomerular Hemodynamics in Human Pregnancy

Postpartum observations in women add perspective to our understanding of the mechanisms that lead to the resolution of renal adaptive responses during pregnancy and to the timing of these mechanisms. Lafayette and coworkers studied women immediately after Cesarean delivery, using computer models of glomerular

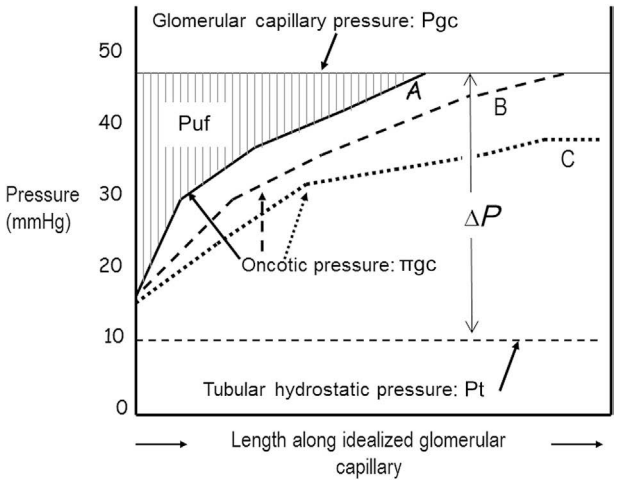

FIGURE 43.16 Regulation of glomerular ultrafiltration. At any point along the length of a glomerular capillary, the force driving filtration is a function of net hydrostatic pressure favoring filtration (Δ*P* = glomerular capillary pressure Pgc minus the opposing intratubular pressure Pt) less the net colloid osmotic pressure (πgc) which also opposes filtration. Increased GFR can be induced by increase in plasma flow, by decrease in oncotic pressure, or by increase in glomerular capillary pressure. GFR is proportional to net ultrafiltration pressure (Puf), defined as the area dilineated by the, Pgc and πgc profiles (e.g., shaded area for πgc profile A). "Filtration equilibrium" refers to an oncotic pressure profile (e.g., solid line A or dashed line B) where filtration ceases prior to the end of the capillary. The rat operates in filtration equilibrium under basal conditions: With increased plasma flow rate, the πgc profile can shift to e.g., line B or line C; The parallel increase in Puf area reflects the increase in GFR due to elevation of plasma flow. In "filtration pressure disequilibrium" (πgc profile C), πgc rises sufficiently slowly that it never reaches Δ*P*; thus filtration continues to occur along the entire capillary length. Humans, in contrast to rat, are believed to operate basally in filtration disequilibrium. An increase in RPF thus cannot increase filtration surface area and thus has much more limited impact on GFR. *Source: Adapted from Ref. 158.*

parameters.[199] They reported a persistent glomerular hyperfiltration without hyperperfusion; the former was attributed entirely to the persistent decrease in plasma oncotic pressure after delivery. The same group recently reported similar studies at 1 day and at 2 weeks postpartum in 22 uncomplicated pregnancies.[189] On the first day after delivery, the model again supported reduced capillary oncotic pressure as the predominant factor in maintaining a 41% increase in GFR. By 2 weeks postpartum, GFR was still increased by 20% even though renal plasma flow and oncotic pressure had returned to normal nonpregnant levels; thus, only unmeasurable parameters could be postulated to maintain GFR, such as an increase in ΔP, Kf, or both. Milne and coworkers reported that GFR and renal plasma flow had returned to prepregnancy values by 4 months after delivery.[197]

Despite these careful efforts to enhance our knowledge of renal hemodynamic changes in human pregnancy, caution is in order. The unverified assumption of constant EPAH underlying estimation of ERPF changes by PAH clearance has already been noted; it remains feasible that the apparent ERPF decline following the midpregnancy peak reflects progressively reduced tubular extraction of PAH with consequent underestimation of ERPF. Inferences about ΔP necessarily involve modeling based on rat data and require assumptions that cannot be validated at the present time. Moreover, these theoretical considerations do not address the possibility that the glomerular hypertrophy of pregnancy, via increased glomerular capillary length, might create glomerular filtration pressure equilibrium in the human kidney as in the rat. This would enhance the flow dependence of GFR. Glomerular hypertrophy might also increase filtration surface area. Either the pregnancy-induced increase in capillary length or the increased infiltration area could obviate the need to postulate for either increased PGC or increased permeability (Kf). It should also be emphasized that while renal adaptations in pregnancy are normally safe, even modest impairment of renal function in human pregnancy (GFR < 50 cc/min) is known to impose a substantial risk of further renal functional loss.[200–202] Finally, it is not yet known in humans whether successive pregnancies increase risk of renal injury to the human kidney.

Glomerular Capillary Permselectivity to Neutral Macromolecules in Human Pregnancy

An estimate of glomerular capillary wall porosity to macromolecules in human pregnancy has been made, utilizing fractional clearance of neutral dextrans spanning a wide size range. This measurement is independent of hydraulic permeability. Neutral dextrans are not restricted in their passage across the glomerular filter by charge or configurational factors, nor are they absorbed or secreted by the renal tubule. Thus they are classically used to assess the glomerular size-selective barrier function. It was a surprise when Lindheimer's group found reduced fractional clearance of dextrans at the lower size ranges during late gestation.[192,197] This finding points to an altered structure of the glomerular capillary membrane. Their findings could be explained by (1) an increase in molecular movement through a nondiscriminatory "shunt" pathway or (2) an increased range of pore sizes in the late-gestation glomerular capillary wall.[197]

Urinary Protein and Albumin Excretion in Pregnancy

Protein that is present in normal urine derives from filtered protein that escapes proximal tubular reabsorption and/or from secreted protein, primarily Tamm–Horsfal protein formed by the distal nephron segments. Urinary albumin excretion rate can increase due to a decrease in the discriminatory capacity (permselectivity) ion of the glomerular capillary wall or to a reduced tubular reabsorption of normally filtered proteins. The latter leads to an increased excretion of non-albumin low molecular weight (MW) proteins—below MW 10,000 Da—together with small increases in albumin. Several studies report that total urinary protein (but not albumin) increases by about two-fold by late gestation.[197,203–205] Higby and coworkers reported an average total protein excretion of 117 mg/day with an upper 95% confidence limit of 260 mg/day in 270 healthy pregnant subjects.[165] In normal pregnancy, albumin excretion increased minimally to an average of 12 mg/day with an upper limit of 29 mg/day, thus remaining within the normal nonpregnant range. Collectively, this suggests that proximal tubular reabsorption of normally filterable low MW proteins (but not albumin) may be selectively reduced. Alternatively, increases in plasma levels of filterable smaller-molecular-weight proteins or increased tubular synthesis/secretion of Tamm–Horsfall protein could account for the increase.

Changes in albumin excretion in human pregnancy remain controversial. Misiani and coworkers measured albumin by radioimmunoassay in healthy pregnant women and found a reduction in urinary albumin excretion to below nonpregnant levels throughout gestation.[204] This was in distinct contrast to cases with pregnancy-induced hypertension, where albumin excretion began increasing by 28 weeks gestation.[204] Milne and coworkers found that urinary albumin was higher than nonpregnant levels in 11 healthy women in late gestation and persisted at 4 months postpartum.[197] But, once again, these changes were within the normal nonpregnant range. Furthermore, whereas the increase in glomerular permselectivity to small neutral dextrans fully normalizes by 12 weeks postpartum, urinary albumin remains at late-pregnant levels.[192,197]

These findings suggest that additional factors favoring increased albumin excretion may be operative. Of note, increased urinary amino acid excretion during pregnancy has been documented and could indicate a more generalized impairment of proximal tubular reabsorptive capacities.[179]

Structural Changes of Kidney and Genitourinary Tract

During the course of normal pregnancy, the kidneys enlarge by up to 30%. In one large autopsy series, kidney weights during or shortly after delivery (ranging 300–310 g) exceeded the nonpregnant norms; glomerular size, but not cell number, was increased.[206] X-ray[155,158] and ultrasound[207] studies have shown that kidneys increase in length by approximately 1 cm during human gestation. In rats, kidney dry weight during pregnancy has been found to increase along with increases in proximal tubular length, changes resembling those in compensatory renal hypertrophy.[208,209] In other studies, increased renal weight was attributed to renal water content.[210] These changes, seen in >90% of gravidas, are associated with dilation of the renal calyces, pelvices, and ureters,[155,211–213] the latter often more marked on the right due to dextrorotation of the uterus.[214] Dilation of the renal calyces is accompanied by ureteral smooth muscle hypertrophy and connective tissue hyperplasia. The mechanisms that lead to these remarkable changes are unknown. Of note, renal structural changes may persist up to 4 months postpartum.[212] It is unknown whether increased compliance of these structures in pregnancy reflects the actions of relaxin on smooth muscle, as described for the vasculature and uterus in the rat,[104,215] the actions of relaxin to alter connective tissue structure of the rodent cervix,[216] or other hormone-related mechanisms.

The Kidney and ECFV and Blood Pressure Regulation in Pregnancy: The Relaxin Paradigm in the Pregnant Rat

Investigators have long struggled to understand how the regulatory system for renal sodium reabsorption and ECFV is co-opted to retain sodium and produce a positive sodium balance, while avoiding the expected feedback suppression of sodium retention. It is not clear, for example, whether observed renal changes are secondary to systemic signals, or whether they are initiators of systemic responses. One view holds that primary systemic vasodilatation induces secondary renal sodium and water retention, driving the expansion of ECFV and blood volume that is characteristic of pregnancy from its early stages.[48,154,217] An alternative view is that the kidney vasodilates early in pregnancy and acts as an arteriovenous shunt, which secondarily activates systemic sodium/water retaining pathways.[154] Neither view alone fully reconciles renal responses in pregnancy with known principles of hemodynamic regulation. In the nonpregnant state, the introduction of extrarenal vasodilation leads to vasoconstriction of renal circulation as a key feature of its response to circulatory underfilling. In contrast, the renal circulation undergoes a remarkable vasodilation from early in pregnancy, concomitantly with systemic vasodilation.[48] We propose another option: that systemic and renal resistances are reduced proportionally by a common stimulus.

Candidate Vasoactive Mediators in Rat Pregnancy

Attempts to identify specific systemic or locally active vasodilators that account for all the hemodynamic changes in pregnancy have failed. Factors such as estrogen, progesterone, prolactin, and vasodilatory prostaglandin species may be important but do not explain all of the vasodilator actions needed for adaptation to pregnancy.[154,155] However, in elegant studies in the pregnant rat, Conrad and colleagues have documented a major role for relaxin, a TGF-beta family member with systemic vasodilating capacity.[154,218] Relaxin is produced by the corpus luteum, and levels rise in temporal association with the early progressive fall in systemic vascular resistance as pregnancy progresses.[219] In the nonpregnant rat, Conrad and coworkers found that relaxin reproduces many of the characteristics of the pregnant vasculature: reduced vasomotor tone, increased global arterial compliance, modification of vascular extracellular matrix structure, and reduced vascular stiffness (measured independently of tone).[117,175,219,220] These effects of relaxin were found in small renal arteries[117] and the uterine artery of the rat,[157,220,221] as well as in numerous arteriolar, capillary, and postcapillary venular sites throughout the body.[215] In the pregnant rat, relaxin was shown to mediate maternal renal vasodilation and hyperfiltration,[218] to reduce the myogenic activity of small renal arteries, and to reduce their reactivity to Ang II.[222]

Subsequent work by this group elucidated downstream roles of endothelin[223] and NO[224,225] in mediating the renal vasodilation and hyperfiltration effects of relaxin in rat pregnancy.[154] Specifically, the vascular effects of relaxin, normally acting via its RXFP1 receptor,[157,226] were mediated by endothelin 1 (ET1), through its endothelin B (ET_B) receptor to stimulate NO production.[117,223,227] Moreover, relaxin was found to increase the ET_B:ET_A receptor ratio. In recent work, relaxin was additionally shown to upregulate[157,228] and activate vascular gelatinases,[219] which likely convert Big ET1 to a smaller version, ET1-32.[157,229,230] Relaxin was also found to require both vascular endothelial growth factor and placental growth factor in order to attenuate myogenic constriction in rodent renal arteries and human

subcutaneous arteries.[157,231] Jeyabalan and coworkers showed that increases in the vascular gelatinase MMP2 are essential for relaxin-induced renal vascular effects, possibly via conversion of Big ET1 to ET1-32.[230] This work establishes a novel mechanism underlying classic pregnancy-induced renal hemodynamic changes in the rat, and concomitantly unveils a unique MMP-2 gelatinase-linked vasodilatory pathway with potentially broad relevance for renal vascular regulation.

Renal Tubular Changes during Pregnancy

Before considering the implications of this novel vasodilatory mechanism for pregnancy-associated hemodynamic adaptations, it is important to first revisit recently recognized factors acting on tubular sodium handling during pregnancy. There are both antinatriuretic (sodium ion retentive) and natriuretic (promoting sodium loss in urine) forces that are present during pregnancy. What allows the former to predominate is not clear, but pregnancy is unequivocally associated with net renal sodium retention.[155,158] The positive balance in women over the course of gestation averages 2–6 mEq of sodium daily with cumulative gains of 500–950 mEq.[155,158] Studies in humans using lithium clearance as a sodium marker document enhanced proximal tubular sodium reabsorption in pregnancy.[232] Micropuncture studies in the rat have also shown that sodium delivery to the end of the accessible proximal tubule is normal in pregnancy, indicating that the excess glomerular filtrate is fully reabsorbed proximally.[233] Paradoxically, this increased reabsorptive work in the proximal tubule is not accompanied by increases in renal microsomal sodium-potassium-adenosine-triphosphatase (Na-K-ATPase) activity, the primary energy source for tubular reabsorption throughout the nephron.[234]

Recently, a mechanical factor has been shown to influence proximal tubular sodium retention in pregnancy. Khraibi and coworkers documented a reduction in intrarenal interstitial hydrostatic pressure (RIHP) in the pregnant rat,[235–237] a feature that should enhance sodium reabsorptive capacity.[238] In the nonpregnant rat, increased renal perfusion pressure or volume expansion is associated with an increase in RIHP and subsequently natriuresis[238]; if the increase in RIHP is prevented by stripping the renal capsule, no natriuresis ensues. In pregnant rats, basal RIHP was found to be low and failed to increase normally following raised renal perfusion pressure or saline expansion[236,237]; however, an expansion of the ECF volume with saline did induce a normal natriuretic response, while an increase in perfusion pressure did not. It is useful to consider how reduced basal RIHP might influence sodium-retaining forces (elevated Ang II, norepinephrine) versus the natriuretic forces (variably increased ANP[161] and reduced renal cortical Na-K-ATPase activity and abundance[234]). Low RIHP would be expected to reduce the passive intercellular back leak of sodium (with Cl^- and H_2O) in the normally leaky proximal tubule, causing more reabsorbate to be retained and thereby passively enhancing net reabsorptive flux. Sodium reabsorptive activity of Ang II and SNS traffic in the proximal tubule could thereby be substantially amplified. In contrast, the natriuretic response to ANP was blunted in pregnant rats.[239] RIHP would seem less likely to influence more distal tubular segments due to their greater water impermeability.

In the distal tubule, additional factors are believed to modulate sodium/H_2O retention during pregnancy. The mineralocorticoid hormone, aldosterone, which is secreted from the adrenal cortex, is essential for normal renal sodium and potassium balance, and thus indirectly regulates blood volume. The rate of aldosterone secretion and its consequent plasma levels are increased in normal gestation, frequently approaching levels associated with primary hyperaldosteronism.[155,161] In addition, it is known that a specific mutation in the mineralocorticoid receptor leads to enhanced hypertension during pregnancy.[240] Experiments in sheep suggest that loss of aldosterone or cortisol lead to a decrease in blood volume during pregnancy.[240] The sex steroid progesterone has both agonistic and antagonistic activity at the mineralocorticoid receptor. However, in vivo, efficient renal enzymes metabolize progesterone, effectively protecting the mineralocorticoid receptor.[241,242] However, pregnancy also increases intrarenal enzymes that metabolize progesterone.[243,244] The net effect of hormone action is not yet clear. Nonetheless, the kidney effectively retains 2–6 mEq sodium daily during gestation, establishing ECF volume increases of 5–7 l. The increased levels of aldosterone appear necessary to achieve this critically important adaptation.

The relaxin story offers a potential solution to one major pregnancy conundrum: how to entice the kidney to generate and maintain an expanded ECFV in anticipation of future feto-placental needs. The key elements of the solution in the rat are now discernible.[154] First, a single systemic hormone (relaxin) simultaneously mediates vasorelaxation at multiple systemic sites and in the kidney. Second, the downstream vasodilatory effect of relaxin is ensured by upregulation of a classic vasoconstrictor system (ET1) while concurrently enhancing its vasodilatory activity via an increase in ET_B receptor relative to ET_A receptor. Third, the final common pathway of this hormonal system is NO, a potent vasodilator that also has known effects on capillary permeability and structure. Finally, relaxin has been shown to have widespread effects on tissue

structure to increase compliance, a recurring theme in tissue responses to pregnancy.[154,215,245]

Proposing an Integrated View of the Renal Response to Pregnancy

The actions of relaxin in the pregnant rat create a physiologically unique set of intrarenal conditions. We propose the following canonical model to explain many of the features of mammalian pregnancy and associated changes in the kidney. First, primary vasodilation of both systemic and renal vasculatures generates systemic vascular underfilling via increased vascular capacity, a change normally expected to activate central venous stretch receptors. The increased SNS traffic, together with its subsequent stimulation of renal renin release, initiates renal salt and water retention; if these stimuli were unopposed, they would simultaneously cause both pre and postglomerular renal vasoconstriction and renal tubular sodium/H_2O reabsorptive capacity. However, Relaxin-ET_B receptor-induced NO concomitantly mediates resistance to the pressor effects of Ang II and norepinephrine. This ensures that both renal preglomerular and postglomerular vasodilation are sustained and proportional, maintaining normal glomerular capillary pressure. In the systemic circulation, resistance to pressors ensures that the reduced stretch at central venous receptors cannot be relieved via the usual compensatory pressor actions of Ang II and SNS to reduce the volume capacity of the vascular tree. Thus, the vascular underfilling signal is perpetuated even as ECFV increases. In the kidney, this persistent relaxin-mediated preglomerular vasodilation leads to greater transmission of aortic mean arteriolar pressure (MAP) to the afferent arteriole. Thus, the lower systemic blood pressure can now sustain a normal afferent arteriolar pressure, thereby shifting the renal set point downward to accept and sustain a lower MAP. In effect, despite systemic vascular underfilling, preglomerular vasodilation that is resistant to Ang II and norepinephrine permits the kidney to accept the lower MAP of early pregnancy as "normal". The concomitant resistance to ANP (see previous discussion) suggests that its potential to counteract these forces is effectively neutralized.

As outlined earlier, the renal tubular sodium retention limb of the feedback loop remains intact. This may have important effects on the behavior of the macula densa to regulate GFR in pregnancy. Normally, elevated GFR, despite an increased absolute proximal reabsorption (i.e., glomerulo-tubular balance), will also deliver excess sodium/H_2O to the thick ascending limb. The higher thick ascending limb flow rate would limit NaCl capture and create a higher concentration of sodium chloride sensed by the specialized epithelial cells of the macula densa. This stimulus would normally activate tubular glomerular feedback, causing macula densa cells to release basolateral ATP and activate afferent arteriolar constriction at a discrete sphincter-like site located just within the glomerulus. The outcome would be to reduce Pgc and GFR.[246] In contrast, the pregnant state is accompanied by normal fluid/sodium delivery measured in the late proximal tubule and is compatible with the view that, despite high GFR, stimulated sodium reabsorption proximally—together with low RIHP/reduced back leak—prevents any increase in [NaCl] at the macula densa.[233] The latter is thus rendered blind to the high GFR of pregnancy. This is precisely compatible with the observations of Baylis and Blantz that macula densa function in pregnancy is reset to a higher level of GFR but operates normally around that set point.[233]

Another factor of potential importance in promotion of proximal tubular reabsorptive capacity and modifying macula densa activity during pregnancy is proximal tubular hypertrophy. In early chemically induced diabetes in rats, Thompson and coworkers have provided compelling data to support the idea that hyperglycemia-mediated proximal tubular hypertrophic growth directly enhances sodium reabsorption, reduces [NaCl] at the macula densa, induces afferent-sphincter dilation, and causes a compensatory increase in GFR.[247,248] According to this view, tubular hypertrophy is a primary event that directly leads to enhanced proximal reabsorption and glomerular hyperfiltration by activating (rather than silencing) the macula densa. Evidence in the pregnant rat that proximal tubule length is increased lends support to the potential for proximal-tubular-growth-dependent initiation and perpetuation of glomerular hyperfiltration in pregnancy.[208,209] Of note, hyperfiltration due to proximal hypertrophy/hyperabsorption in diabetes is typically dependent on increased glomerular capillary pressure. In pregnancy, the Ang II pressor resistance of the postglomerular capillary would prevent increased Pgc and require additional intraglomerular changes to achieve GFR elevation.

Mediators of Renal Hemodynamic Adaptations in Human Pregnancy

Available early data based on maternal relaxin levels in human pregnancy suggested that relaxin, at least in circulating form, may mediate the systemic and renal vasodilation.[154] However, the similarities in hemodynamic responses of rat and human suggest that there will be homologous systemically active vasodilatory molecules and common downstream pathways in human pregnancy. In support of that, there is limited evidence that NO may be increased in pregnant women.[161,249] Goodrum and coworkers found higher arginine and NO production in mid-gestation.[249] On the other hand, von Mandach and coworkers found NO increased predominantly in the fetal compartment.[250] Similarly, Schiessl and coworkers detected no changes in either NO metabolites or cGMP levels in plasma or urine over the course of gestation in 49 healthy pregnancies.[251] In the first

study to carefully control for dietary nitrate and nitrite, Conrad and coworkers found no increase in whole body NO production but marked increases in cGMP production during pregnancy, especially during the period of rapid vasodilatation in the first trimester.[252] Recent work has shown that human subcutaneous arteries respond to relaxin via molecular pathways comparable to those of rat small renal arteries.[231] More compellingly, in pregnant women who were recipients of donated eggs and who therefore lacked a corpus luteum (the dominant source of relaxin in human and rat pregnancy[224]) and measurable circulating relaxin, glomerular hyperfiltration of early pregnancy was attenuated.[226,253,254] As these intriguing results do not exclude participation of other corpus luteum factors, the question of whether and how relaxin contributes to the human renal and hemodynamic adaptations to pregnancy remains unanswered.

Role of Angiotensin 1–7 and/or Angiotensin AT2 Receptors

If relaxin is not a mediator of pregnancy-associated hemodynamic change in human pregnancy,[158] we wonder whether there is a human molecule that is equivalent in action to relaxin. (One would expect multiple layers of regulation of blood volume and blood pressure during pregnancy.) Brosnihan and coworkers have recently reported increased levels of the vasodilator Ang 1–7 in plasma and urine of normal pregnant women.[255–257] This vasodilatory metabolite is formed via conversion of Ang II by angiotensin converting enzyme 2 (ACE 2) or by a two-step reaction converting Ang I to Ang 1–9 by ACE2, then to Ang 1–7 by ACE (Figure 43.17). Also, in pregnant rats, increased renal and urinary levels of Ang 1–7 were observed, together with enhanced ACE 2 expression in kidney.[256] These observations suggest a role for vasodilatory components of the renin-Ang II system in human and rodent pregnancy. It is interesting to speculate that, whereas relaxin co-opts the endothelin pressor system and converts it to vasodilatory action in the pregnant rat, the Ang II system might be co-opted to a vasodilatory system in human pregnancy, potentially via increased Ang 1–7, via shift to AT_2 Receptor > AT_1 Receptor ratio, and/or via enhanced Ang II-induced endothelial vasodilatory factors. Evidence already available indicates functional resistance to AT_1R in pregnancy. Like the upregulated endothelin ETB receptor in rat pregnancy, AT_2 Receptor-mediated vasodilation is linked to bradykinin and NO,[258] and thus its upregulation in pregnancy could potentially mimic the relaxin role in the rat. The relaxin paradigm in the rat may provide a valuable template for reassessing the human response to pregnancy.

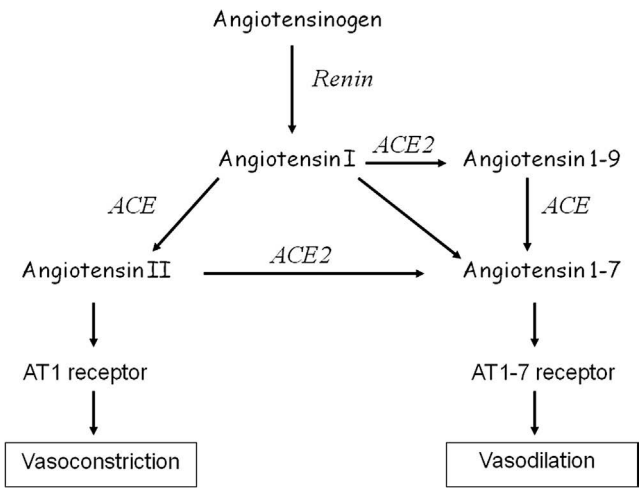

FIGURE 43.17 Enzymatic pathways for formation of the vasodilator angiotensin 1–7. Ang 1–7 can be formed from either Ang II by the action of angiotensin converting enzyme ACE2 or from angiotensin I via a two-step reaction requiring ACE 2 followed by ACE. Ang 1–7 has been reported to increase in the 3rd trimester of normal pregnancy, whereas levels in preeclamptic pregnancies were significantly reduced as compared to normal pregnancy. *Source: From Ref. 256.*

PHARMACOKINETICS OF PREGNANCY

Because of ethical concerns associated with the experimental administration of drugs during pregnancy, less is known about drug pharmacokinetics for pregnant women than for nonpregnant women. However, the application of standard pharmacokinetic principles has provided insight as to how drug handling and metabolism are different in women who are pregnant.

The absorption of a medication from the gastrointestinal tract may be altered during pregnancy. In general, gastric emptying and small intestine motility are reduced in pregnancy, in part due to effects of progesterone.[259–270] In addition, intravascular fluid volume and total body water increase during pregnancy, augmenting the volume of distribution—the body fluid volume within which a substance distributes—for any dissolved drug.

Plasma protein concentrations, including albumin, decrease in pregnancy. As a result, there is less protein available for binding drugs, and the plasma concentrations of albumin-bound drugs decrease.[271,272] However, because less drug can be bound by albumin during pregnancy as its concentrations decrease, an increased concentration of unbound "free" drug becomes available to produce an effect. Thus, while a drug may have a lower concentration in the blood because of low protein binding, more of it may become available to cells.

Several steroid hormones, including estrogens and progesterone, increase during pregnancy. The increasing concentrations of steroid hormone levels can displace drugs from their bound state on albumin resulting in increased concentration of free drug while decreasing the drug's biological half-life.[272] Thus, the drug may

have a greater effect because of its higher concentration at the cell but for a shorter duration. This is because an increased concentration of circulating free drug facilitates its metabolism and excretion. The overall magnitude of these effects is not known for most drugs.

Along with increases in total body water, total protein and fat mass generally increase during pregnancy.[273] The increase in total fat mass provides a larger volume of distribution for lipophilic drugs, those that dissolve easily in lipids. However, the increase in the volume of distribution for lipophilic drugs does not appear to be of great clinical significance for most drugs.

Most medications are metabolized in the liver to forms that are then excreted by the kidneys. Several enzymes of the hepatic cytochrome P-450 system are induced by estrogen and progesterone, resulting in a higher rate of metabolism for some medications, while other enzymes are competitively inhibited by estrogen and progesterone, leading to decreased metabolism and impaired elimination.[274–276] Maternal cardiac output, renal blood flow, and GFR all increase substantially during pregnancy.[164,188,277] These increases may lead to an enhanced elimination of drugs that are normally excreted unchanged. An example of enhanced elimination during pregnancy is penicillin.

Drugs move from the maternal circulation to the fetal circulation mainly by diffusion across the placenta.[278–280] Their rate of transfer depends on their lipid solubility and size. Polar hydrophilic drugs cross the placenta slowly. Highly protein bound drugs, highly charged drugs, and large MW drugs also cross the placenta slowly. On the other hand, lipophilic medications move across the placental barrier to the fetus rapidly because they have the entire trophoblastic surface area available for diffusion. Their drug transfer is influenced by maternal and fetal placental blood flows. Ethanol is an example of a drug in this category. Protein binding is an important consideration for the transplacental transport of lipophilic drugs too because it influences the amount of free drug available for diffusion.

Even though the fetal liver is metabolically active,[281] the metabolic enzyme activity of the immature fetal liver metabolic is low. In addition, some 50% of the fetal blood flow from the placenta bypasses the fetal liver via the ductus venosus and travels directly to cardiac and cerebral circulations. As a result the fetus metabolizes drugs less rapidly than the mother. The fetal liver can metabolize drugs by sulfate conjugation and glucuronidation; such drugs then undergo renal excretion into the amniotic fluid. Drugs in the amniotic can be reabsorbed into the fetal circulation. This process can contribute to drug accumulation in the fetus. Drug metabolites are often ionized, impairing diffusion. As a result, they can accumulate within the fetus as a result of "ion trapping". Fetal blood is slightly more acid than maternal blood. Lipophilic, nonionized drugs that are weakly basic, move by diffusion back and forth across the placenta in a balanced fashion, driven by their concentration gradients. On the other hand, acidic drugs that are ionized in the more acidic fetal plasma favor movement from the mother to the fetus.[282] The placenta itself contains many metabolizing enzymes.[282,283] Some drugs are metabolized by the placenta and are converted into either active or inactive metabolites, depending on the drug in question. In summary, the adaptations to pregnancy made in a woman's body, combined with the biological contributions of the placenta and fetus, alter the distribution and metabolism of drugs compared to the nonpregnant state.

CONCLUSION

Looking backward in time is valuable because it generates an appreciation for the progress that has been made in understanding the physiology of pregnancy. It is clear that the concomitant development of precise physiological measurements of the actions of the cardiovascular, renal, pulmonary, and endocrine systems allowed the field to blossom over the past four decades. Nevertheless, one cannot assess the gains made in this field without a sense of frustration for its slow progression compared to other fields of human biology and medicine. Studies on pregnancy have been relatively few. There is a driving reason for that to change in the near future. It has recently become clear that adaptations to pregnancy are key to determining the developmental integrity of the growing embryo and fetus. Maternofetal nutrient flow plays a major role in determining the risk for chronic disease in a woman's offspring and thus the health of each and every member of the population. Thus, maternal health and the appropriate adaptation to pregnancy will determine the health of the next generation.

In addition to the numerous loose ends that need to be solved in every area of physiology as noted in each section of the chapter, intense research is needed in three major additional areas: (1) the role of maternal body composition and metabolism in regulating adaptations to pregnancy and providing nutrients for offspring; (2) the mechanisms by which the maternal milieu signals and regulates placental growth and function; and (3) the molecular mechanisms by which steroid and protein hormones modify maternal organ structures and their function at different stages of pregnancy. Any enterprising young scientist should recognize this as a gold mine from which a lifetime of treasure can be extracted.

CHAPTER

44

Maternal Brain Adaptations in Pregnancy

Paula J. Brunton

Division of Neurobiology, The Roslin Institute and Royal (Dick) School of Veterinary Studies, University of Edinburgh, Easter Bush, Midlothian, UK

John A. Russell

Centre for Integrative Physiology, University of Edinburgh, Edinburgh, UK

INTRODUCTION

We have selected aspects of this topic that concern the most profound changes in physiology that are a consequence of pregnancy and are regulated by the brain, and the most important changes that prepare for a successful outcome of pregnancy. These changes are driven by actions on the brain of hormones of pregnancy: the steroids estradiol and progesterone and its neurosteroid metabolite, allopregnanolone, and peptide hormones from the placenta (placental lactogen), corpora lutea (relaxin), or anterior pituitary (prolactin) (Figure 44.1). In addition, altered secretion of oxytocin, and actions of oxytocin released in the brain have key roles. Most of the studies referred to in this chapter have been performed on laboratory rats, in which pregnancy lasts for c. 22 days, as such studies allow analysis of mechanisms in detail and depth. Nonetheless, studies on this rodent reveal core principles that can be tested in, and generally applied to, other species, though there are differences in detail.

An important aspect of a successful pregnancy outcome is that adverse programming of the fetus and infant should be minimized, which is an issue of great current interest following the pioneering epidemiological studies of Barker et al.[1] Adverse programming in pregnancy can be a result of exposure to maternal stress hormones or be associated with excessive and imbalanced maternal food intake and obesity, despite appropriate physiological adaptations in the neuroendocrine systems considered here. Postpartum, the quality of maternal care is important for coping with stress in later life, as shown in many studies in the past 30 years,[2] hence understanding the mechanisms that enable rapid and intense expression of maternal care in response to the appearance of the young at birth is providing the basis for understanding variability in its quality. Coping with maternity involves cognitive abilities, and there are changes in performance as a result of pregnancy, with evidence for increased complexity of neural connectivity in the hippocampus.

We begin (see the section Osmoregulation in Pregnancy) by considering the role of the brain in driving the large expansion of blood volume, and reduced blood sodium chloride (NaCl) concentration in pregnancy, a consequence of actions of relaxin on the neural circuitry in the brain hub comprising the lamina terminalis and the hypothalamus, which controls vasopressin and oxytocin neurons and thirst. Relaxin was identified originally as an insulin-like peptide produced predominantly by the corpora lutea of pregnancy that relaxes the pubic ligament but also induces uterine quiescence directly and indirectly via inhibition of oxytocin secretion.[3–6] Its importance, through its actions on the brain, in increased water intake and blood volume expansion in pregnancy was recognized more recently.[7,8] The outcome of these actions of relaxin is resetting of osmoregulatory mechanisms in the hub that controls body fluid homeostasis so the hyponatremic hypervolemia of pregnancy results.

We next review the neural networks in the hypothalamus, brain stem, and reward circuitry that control appetite and metabolism (see the section Food Intake and Metabolism in Pregnancy). It has become clear in the last decade that these networks are complex, involve many groups of neurons organized into several interconnected hubs (in the hypothalamus, brain stem, and midbrain) and utilize many different transmitters and neuromodulators, especially neuropeptides.[9] We have aimed to give a current account of these networks, hubs, and the signaling molecules without pregnancy and indicate

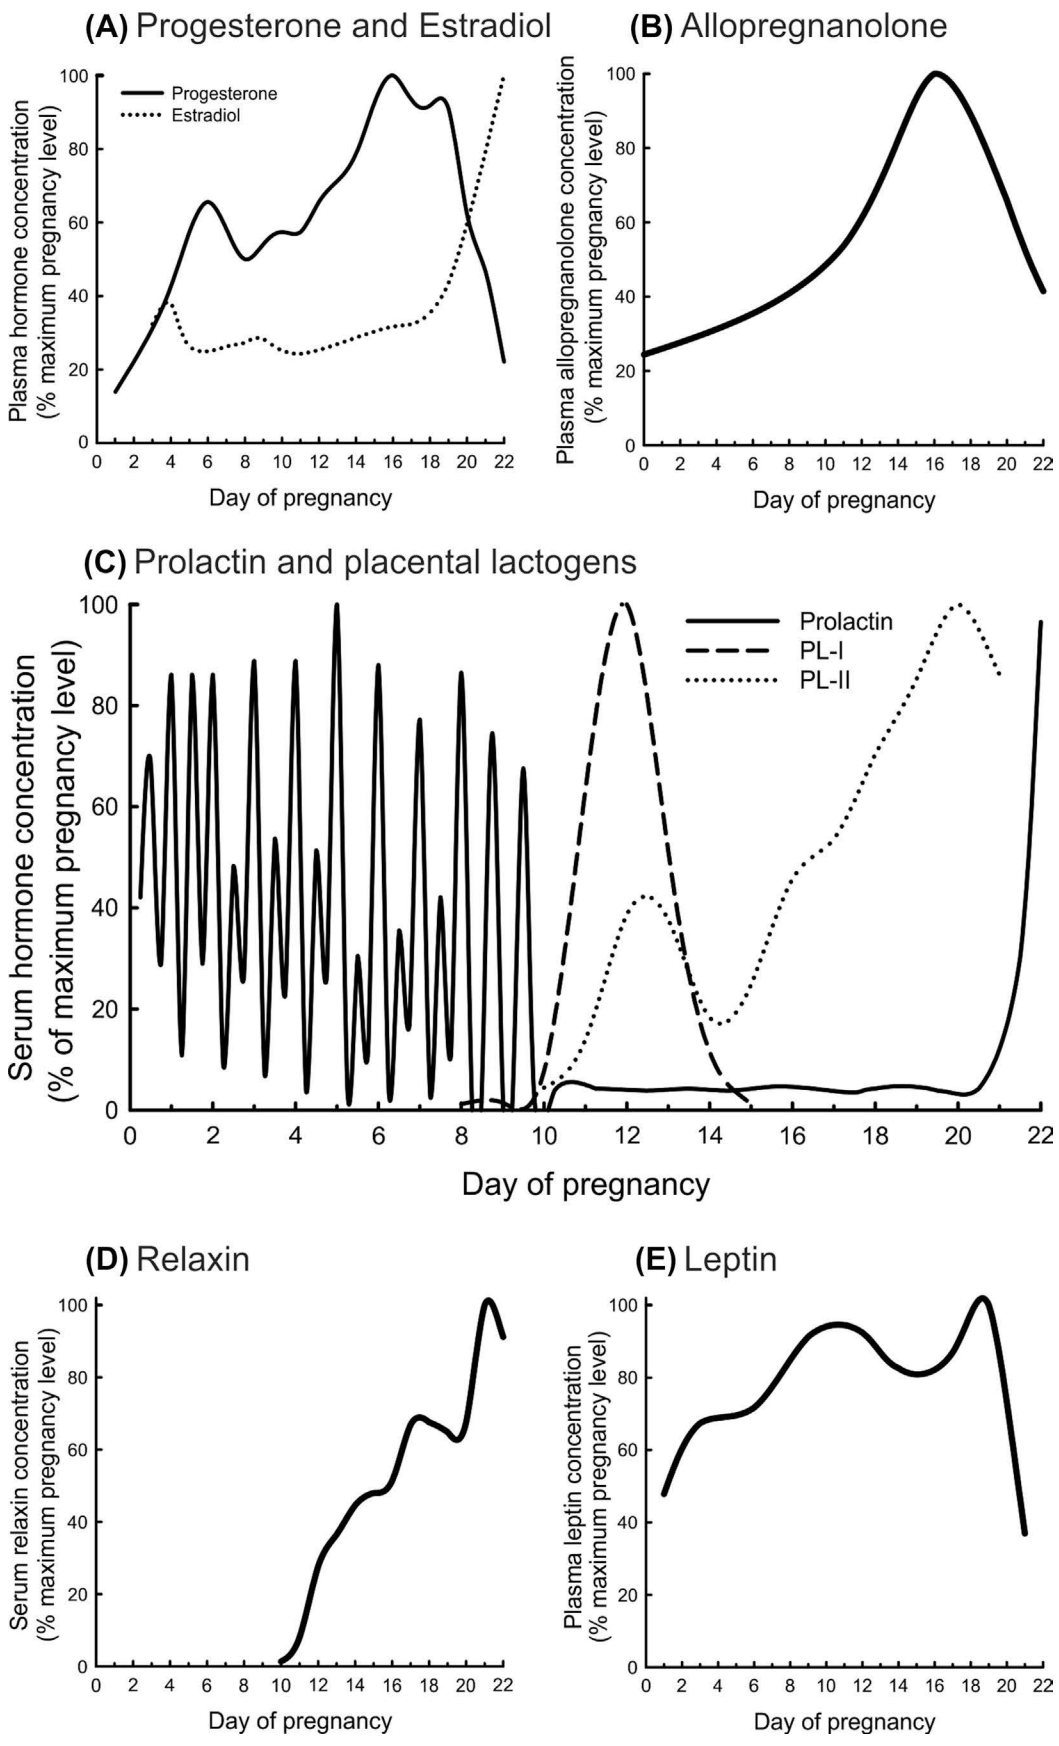

FIGURE 44.1 Hormone secretion profiles during pregnancy in the rat. Circulating concentrations of (A) progesterone and estradiol, (B) allopregnanolone, (C) prolactin and placental lactogen I and II, (D) relaxin, and (E) leptin, across pregnancy in the rat. Hormone concentrations are expressed as a percentage of the maximum levels found in pregnancy. *Sources: Data are derived as follows: progesterone and estradiol;[854] allopregnanolone;[29] prolactin;[424,855] placental lactogen;[856,857] relaxin;[858] and leptin.[859] Reproduced from Brunton & Russell (2010)[860] with permission from Elsevier.*

how they may change in pregnancy. But this is a rapidly advancing field, and while there is a large amount of detail with several dimensions, there are obvious large gaps in present understanding, and these are likely to be filled rapidly. Actions of progesterone have long been considered to be important in driving the increased food intake and energy storage in pregnancy,[10] but with the discovery of leptin,[11] and several other peripheral peptides that signal to the brain and are involved in regulation of appetite and metabolism, attention has focused on changes in these hormones in pregnancy and altered interactions with and adaptations within these central networks. In particular, the importance of resistance to leptin, recognized soon after the discovery of leptin[12] and recently shown to be evident in pregnancy, likely involving prolactin action,[13] and changes in other anorexigens are discussed. Recent evidence for upregulated expression of orexigens (e.g., neuropeptide Y)[14] and uncertainties about downregulated expression of anorexigens in the brain are considered. Hence, this section aims to explain how processing of information about energy supply in the neuronal networks governing regulation of food intake and energy storage may be modified in pregnancy by shifts in the balance between predominance of orexigenic or anorexigenic signals, resulting in increased food intake and energy storage. An important consequence of increased energy storage in pregnancy is that this is available for milk production after birth.

In the prolactin section we discuss changes through pregnancy in the control of prolactin secretion by the brain (see the section The Prolactin System: Preparation for Lactation). With availability of a radioimmunoassay, Friesen and colleagues in 1971[15] found prolactin secretion to be markedly increased in human pregnancy. The main regulation of prolactin secretion without pregnancy, as established in many studies since the early 1970s, is inhibition by dopamine, secreted into the hypothalamo-adenohypophysial portal system by hypothalamic neurons.[16] There are several peptides that are candidate prolactin releasing factors (PRFs), and in early pregnancy increased prolactin secretion (initially pulsatile as identified also in the early 1970s) involves increased PRF actions, then secretion is suppressed by dopamine, but finally increases near the end of pregnancy.[17] Overall, this neuroendocrine system develops changing patterns and levels of prolactin secretion during pregnancy, alongside increasing placental lactogen secretion,[18] appropriate for stimulating appetite, maternal behavior, and lactogenesis.

Responsiveness of the maternal hypothalamo-pituitary-adrenal (HPA) axis to stressors is reduced in pregnancy. The glucocorticoid secreted by this system has powerful effects on metabolism (mobilizing glucose), the cardiovascular system, and immune responses, and on the brain, raising alertness. Attenuation of HPA axis responses in pregnancy, first reported in the 1990s,[19,20] is considered to be beneficial in terms of conserving energy as well as protecting fetuses from adverse programming by excess glucocorticoid (see the section The Hypothalamo-Pituitary-Adrenal Axis). The mechanisms of this adaptation in pregnancy involve activation of an endogenous opioid peptide (EOP) inhibitory mechanism, which has recently been shown to be activated by allopregnanolone,[21] a neurosteroid metabolite of progesterone formed in the brain and in high concentrations near the end of pregnancy, as first reported 20 years ago.[22]

A successful outcome of pregnancy involves functioning oxytocin neuron systems, based in the supraoptic (SON) and paraventricular (PVN) nuclei in the hypothalamus, to support parturition and enable milk transfer after birth (see the section Magnocellular Oxytocin Neuron System in Pregnancy). We discuss their role as a hub for regulation of parturition, the neural inputs that regulate their activity, and how the actions of these inputs are modulated in pregnancy. We detail the autoregulatory mechanisms, inhibitory and excitatory, which are of crucial importance in organizing the coordinated activity of these neurons that leads to secretion of pulses of oxytocin from the posterior pituitary gland, as first described for the milk ejection reflex 40 years ago.[23] A predominant aspect in pregnancy is restraint of oxytocin neurons by several mechanisms that prevent premature activation, including an EOP mechanism in the brain detailed in 1995.[24]

Enhanced cognitive performance in pregnancy is seen in tests of several memory processes, relevant to learning necessary for successful mothering, and focused on the hippocampus, which is a target for several hormones of pregnancy (see the section Cognition during Pregnancy). Testing roles of specific hormones in nonpregnant rats indicates that estrogen actions are important in enhanced cognitive performance in pregnancy, and in underlying changes in long-term potentiation (LTP) at hippocampal synapses that have been revealed in the last few years.[25] Progesterone and allopregnanolone actions are also implicated in hippocampal changes, as is oxytocin, which some 25 years ago was deduced to be important in forming olfactory memory for the young postpartum.[26] Prolactin has recently been shown to play a role in stimulating neurogenesis in the brain in pregnancy,[27] while functional hippocampal synaptic changes in pregnancy were reported in 2006 to be reflected in an increase in number of dendritic spines.[28]

The high levels of progesterone in the brain fall dramatically near the end of pregnancy in the rat, as documented by Concas et al.,[29] and this is an important step permitting the emergence of maternal behaviors, as first reported in 1978,[30] which is stimulated by the high level of prolactin at this time, as first implicated around 50 years ago[31,32] (see the section Maternal Behavior). The

medial preoptic area (mPOA), rostral to the hypothalamus, is the key hub in the neural networks that organize the several elements of maternal behavior, and prolactin acts here, as first reported in 1974[33] and 1990,[34] respectively. Also important is oxytocin, as controversially reported in 1979,[35] but consistent with subsequent evidence for release in the brain and action in the mPOA and at several nodes in the maternal behavior networks.[36]

OSMOREGULATION IN PREGNANCY

Central Control of Decreased Blood Osmolarity and Increased Volume in Pregnancy

Homeostatic mechanisms regulating extracellular fluid osmolality and blood volume are reset in pregnancy. By the end of pregnancy this adaptation increases blood volume by c. 55%, and plasma volume is increased by c. 40%, enabling large increases in blood flow through the placenta and maternal organs supporting the pregnancy.[37,38] The volume increases are accompanied by decreases of c. 4% in plasma [Na^+] and osmolarity.[37] Clearly, there is a large retention of water and NaCl in pregnancy, though the increase in NaCl retention is proportionally less, leading to the hyponatremic hypervolemia of pregnancy.

The brain governs these changes through altered regulation of drinking, and water retention and sodium excretion by the kidneys. Relaxin, a pregnancy hormone, has an essential role in driving this adaptation through its actions on the brain.[39] The altered regulation involves central osmoreceptors, vasopressin (antidiuretic hormone; ADH), and in the rat, oxytocin, secreted from the posterior pituitary gland. These mechanisms interact with regulation of blood volume and sodium ion concentration ([Na^+]) by other mechanisms, in particular actions of angiotensin II and atrial natriuretic peptide (ANP).[40] In the nonpregnant state, stimulation of vasopressin and oxytocin secretion by increased blood osmolarity will lead, through respective actions of vasopressin and oxytocin, to antidiuresis and, in rodents, to natriuresis, hence normalizing osmolarity and blood volume. In pregnancy, the hormone relaxin intercedes to modulate this homeostatic mechanism.

Vasopressin and Oxytocin

Vasopressin and oxytocin are closely related nine–amino acid peptides produced by separate magnocellular neurons in the PVN and SON nuclei, which project their axons to the posterior pituitary gland.[41] The large size of the cell bodies of these neurons reflects the large amount of peptide hormone that they produce; hormone newly synthesized in the cell bodies in the PVN and SON is transported within the axons to the posterior pituitary. Large amounts of these peptide hormones are stored in the axon terminals, and some of the stored hormone is released into the systemic circulation when axon potentials invade the terminals. The rate and pattern of hormone release is determined by the frequency and patterning of action potentials, which is a result of the sum of inhibitory and excitatory synaptic input on the cell bodies, interacting with the intrinsic electrical properties of the magnocellular neurons; typically, vasopressin neurons fire action potentials in phasic bursts, and oxytocin neurons fire continuously and irregularly.[41] However, oxytocin neurons fire in high frequency synchronized bursts during parturition and suckling, which results in the intermittent secretion of pulses of oxytocin to effect parturition and milk ejections (see the section Magnocellular Oxytocin Neuron System in Pregnancy and Chapter 13).

Other neurons in the PVN, but not the SON, that produce either oxytocin or vasopressin have smaller cell bodies. Hence these are designated as parvocellular neurons, which reflects that they produce less peptide than magnocellular neurons as they do not secrete into the systemic circulation. Instead, vasopressin parvocellular PVN (pPVN) neurons, which coproduce corticotropin releasing hormone (CRH), project to the median eminence and release their peptides into the hypothalamo-hypophysial portal system to regulate adrenocorticotropic hormone (ACTH) secretion from the anterior pituitary gland (see the section The Hypothalamo-Pituitary-Adrenal Axis). Parvocellular oxytocin neurons by contrast project their axons within the brain to the brain stem, spinal cord, or to rostral brain regions concerned with emotionality and behaviors, and have important roles in the control of appetite, and maternal and social behaviors (see the section Food Intake and Metabolism in Pregnancy and Maternal Behavior). The central actions of oxytocin released by pPVN neurons may be complemented by the release of oxytocin from the dendrites of magnocellular oxytocin neurons, which certainly has a key role in autoregulating magnocellular oxytocin neurons during parturition and lactation (see the section Magnocellular Oxytocin Neuron System in Pregnancy and Chapter 13).

MAGNOCELLULAR OXYTOCIN AND VASOPRESSIN NEURONS ARE OSMORECEPTORS

Verney demonstrated that osmoreceptors controlling vasopressin secretion and hence water excretion are located in the brain.[42] In the context of regulation of plasma osmolarity and [Na^+], an important factor is the direct sensitivity of the magnocellular neurons to changes in extracellular fluid osmolarity, i.e., these neurons are osmoreceptors.[43,44] This osmosensitivity results in depolarization when extracellular osmolarity increases, and conversely in hyperpolarization when it decreases,[44]

as in pregnancy. However, this direct osmosensitivity requires support from excitatory synaptic input to increase action potentials.[45,46] In particular, the relevant input is from the osmosensitive osmoreceptor complex in the lamina terminalis (Figure 44.2). In addition, glial cells in the magnocellular nuclei release taurine, which enhances tonic inhibition of the neurons by glycine, and this release is reduced with increased extracellular osmolarity;[47] hence, this inhibitory mechanism is expected to be enhanced in pregnancy as osmolarity is decreased. Vasopressin neurons are also stimulated by reductions in blood pressure or volume,[48] and such changes augment responses to hyperosmotic stimulation. This augmentation persists in pregnancy,[38] which may protect the hyponatremic hypervolemia of pregnancy.

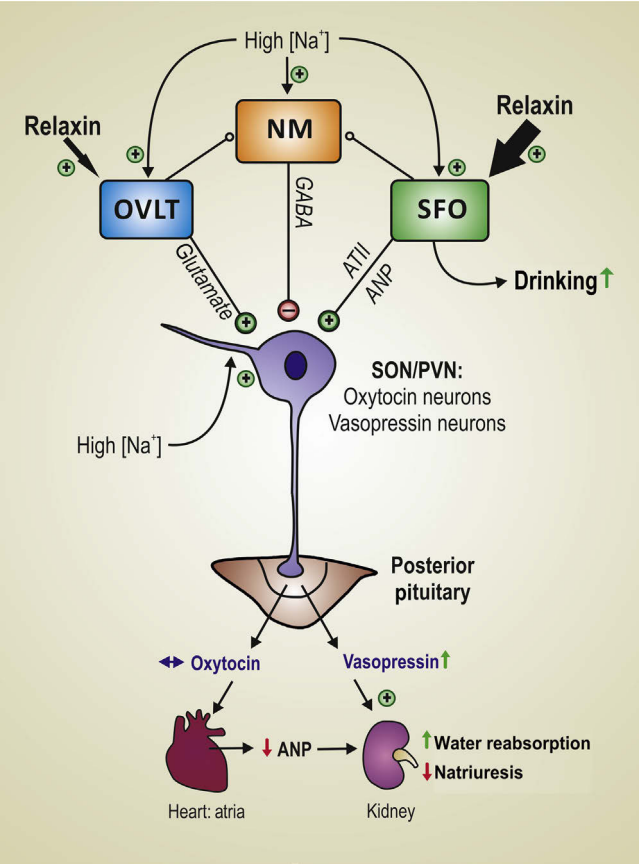

FIGURE 44.2 Mechanisms of hyponatremia and hypervolemia in late pregnancy. The organum vasculosum of the lamina terminalis (OVLT) and the subfornical organ (SFO) are both strongly interconnected with the nucleus medianus (NM) in the lamina terminalis. Together these structures comprise the AV3V region (the region anterior and ventral to the third ventricle), which plays a key role in regulating fluid and electrolyte balance. Hypernatremia (high [Na^+]) stimulates magnocellular oxytocin and vasopressin neurons in the paraventricular (PVN) and supraoptic (SON) nuclei directly, but also indirectly via osmoreceptive neurons in the OVLT, SFO, and NM. AV3V neurons project to the SON and PVN to regulate the activity of the magnocellular neurons. The projections from the AV3V region involve glutamate (excitatory) and GABA (inhibitory) transmission, atrial natriuretic peptide (ANP), and angiotensin II (ATII). In late pregnancy, relaxin from the corpora lutea acts on subfornical organ (SFO) neurons to stimulate drinking. Relaxin also stimulates magnocellular vasopressin neurons via relaxin receptors in the OVLT and SFO. In early, but not late, pregnancy, relaxin similarly stimulates oxytocin neurons. Increased vasopressin secretion (stimulated by relaxin) acts on the kidney via V2 receptors to increase water retention. This together with increased drinking and reduced natriuresis, as oxytocin secretion is not increased and ANP secretion is decreased, leads to the hyponatremia and hypervolemia of pregnancy.

Lamina Terminalis Complex

The lamina terminalis complex (or AV3V region; the region anterior and ventral to the third ventricle) includes neurons that are osmosensitive. Some of these neurons, in the subfornical organ (SFO) and organum vasculosum of the lamina terminalis (OVLT), are outside the blood–brain barrier (BBB) and are responsive to circulating angiotensin II, which reflects renal blood flow,[49] and to relaxin.[39] These neurons form an osmoregulatory network, which includes GABAergic and glutamatergic neurons, and neurons that use angiotensin II and ANP as excitatory transmitters.[39,50] They project to the magnocellular oxytocin and vasopressin neurons, and to brain regions that control drinking (Figure 44.2).

The lamina terminalis has an essential role in the regulation of Na^+ excretion as lesion of this brain region strongly reduces excretion of a Na^+ load.[51,52] This has been attributed to failure of ANP release by the brain, or loss of the ANP input from the lamina terminalis to the oxytocin neurons, with resulting reduced oxytocin secretion.[51] ANP mRNA expression in the preoptic area is decreased in late pregnancy,[53] which may contribute to the reduced effectiveness of stimulating the lamina terminalis to increase oxytocin secretion in late pregnant rats.[54]

Vasopressin Neurons and Relaxin

In pregnancy, relaxin secreted by the corpora lutea acts on the brain to reset the osmoregulatory networks and drive water drinking.[49] This is achieved by reduction of the osmotic threshold at which vasopressin secretion is stimulated, without changing the slope relating osmolarity increase to vasopressin secretion.[55] Hence relaxin overrides the inhibitory mechanisms, outlined before, that would otherwise operate. The increased vasopressin secretion induces water retention by renal actions, via V2 receptors,[56] and plasma volume is thereby increased and osmolarity is reduced. This, together with water drinking governed by relaxin and the reduced osmotic threshold in pregnancy,[37,57] accounts for the increased plasma volume. Infusion of relaxin to nonpregnant rats, or central injection of a viral vector to upregulate relaxin expression in the brain, results in increased vasopressin secretion, and drinking, sustained over 3 weeks, and reduces plasma osmolarity as in pregnancy.[58,59]

Relaxin(s) and Receptors in the Brain

Relaxin was originally discovered as a circulating factor in the pregnant guinea pig that softens the pubic ligament, permitting birth of the young in this species.[3] In the pig and rodents it softens the cervix and promotes mammary gland development;[60] in its absence, parturition in rats is prolonged.[61] In addition, relaxin produced by the corpora lutea in early pregnancy has vasodilator actions, which may be important in increasing uterine blood flow as well as being involved in the normal reduction in plasma osmolality and increased cardiac output in pregnancy.[62–65] A proposed role in offsetting preeclampsia in late pregnancy has so far failed to be supported by evidence.[66]

The source of relaxin in pregnancy varies between species, but the corpora lutea are the source in women, pigs, and rats.[60] Relaxin is a peptide, showing some species differences: in women the relaxin secreted in pregnancy is designated human (H) relaxin-2, with biological activity like rat (R1) or porcine (P1) relaxin (in this account all called "relaxin"),[67] and evidently these are the only forms that are secreted into blood. Blood levels increase steadily from the first third of pregnancy[60] (Figure 44.1). Relaxin acts via a leucine-rich guanine nucleotide-binding (G-protein)-coupled receptor, LGR7,[68] now called RXFP1,[69] via stimulation of the G_s-cAMP–protein kinase A pathway.[68,70]

There are two other closely related peptides, products of different genes, relaxin-3 (expressed in the brain, in GABA neurons in the nucleus incertus),[71] and relaxin-1 (expressed in the decidua, placenta, and prostate).[72] The relaxins are members of the insulin superfamily.[60] It has been proposed that relaxin-3 is the evolutionary ancestor of relaxin (e.g., H-2, R1, and P1),[73] but it now seems that the modern vertebrate forms arose from a common ancestral gene.[74] Of interest here, central relaxin-3 administration activates the osmoregulatory network in the brain and increases water intake in rats.[75] Such actions could be through RXFP1.[76] Whether relaxin-3 contributes to increased water drinking and the hyponatremic hypervolemia of pregnancy is not yet clear.

Mechanisms regulating RXFP1 receptor expression in the brain and in the SFO in particular are not known, although progesterone is a positive regulator in the pregnant myometrium,[64] and estradiol treatment decreases relaxin receptor binding in the cerebral cortex.[77]

Relaxin and Water Drinking

Relaxin, tested in nonpregnant rats, acts on subfornical organ (SFO) neurons to stimulate drinking,[49] and the OVLT is more involved in mediating stimulation by relaxin of the magnocellular PVN and SON neurons.[49] In vitro, SFO neurons are electrically activated by relaxin.[49] RXFP1 is quite widely expressed in the brain, and strongly in the SFO, especially its outer part, but not in the OVLT.[78] In pregnancy, increased angiotensin 1A (AT1A) receptor expression in the SFO is expected to increase sensitivity to the dipsogenic action of angiotensin, and hence support water drinking induced by relaxin.[79]

The lamina terminalis structures project widely to interact with defined brain regions concerned with thirst and regulation of drinking, from anterior cingulate cortex and insula to thalamus, midbrain, and hindbrain regions.[44,80] Presumably, relaxin actions on the SFO in pregnancy are transmitted through these projections; whether there are any changes in these regions in pregnancy that increase thirst is not clear.

Oxytocin and Sodium Balance

Oxytocin secretion is stimulated in the rat by increased plasma osmolarity and has natriuretic actions.[81] Magnocellular oxytocin neurons and oxytocin secretion are also stimulated by blood volume expansion.[51,82] The natriuretic action of oxytocin is exerted partly on the kidney,[83] and also via the heart by stimulating ANP release by the atria.[84]

In late pregnancy, oxytocin receptor mRNA level in the heart and kidney, circulating ANP levels, and renal sensitivity to ANP are all reduced.[85–87] Hence the oxytocin-ANP axis that would normally oppose Na^+ retention and blood volume expansion is less active in pregnancy. In addition, in pregnancy, as a result of the reduced osmolarity caused by the stimulation of vasopressin secretion by relaxin, the threshold for osmotic stimulation of secretion of oxytocin is normally not reached; indeed, a hyperosmotic stimulus that does not increase osmolarity above the nonpregnant level is ineffective in pregnant rats.[88] Consequently, under normal conditions in pregnancy, Na^+ excretion is reduced, to an extent that enables the hyponatremia seen in pregnancy. Nonetheless, a sufficiently large hyperosmotic or hypervolemic stimulus in pregnant rats does stimulate oxytocin secretion, as the threshold is exceeded, and the stimulus-response relationship is then similar to that without pregnancy.[89,90]

Relaxin and Oxytocin Neurons

In nonpregnant rats relaxin infusion can stimulate oxytocin neurons, partly via angiotensin II actions.[91,92] However, in late pregnancy relaxin does not stimulate oxytocin secretion, while vasopressin responses to relaxin are retained.[93] Also, ovariectomy on day 15 of pregnancy to remove relaxin (pregnancy maintained with estradiol and progesterone implants) does not restore oxytocin responses to a hyperosmotic challenge, indicating that this lack of response is independent of relaxin actions at this stage.[94] However, initiation of reduced hyperosmotic responses of oxytocin neurons by relaxin in nonpregnant rats, but not increased water drinking or hyponatremia,

requires pregnancy levels of estradiol and progesterone;[95] these experiments were performed in the presence of naloxone to remove any induction by relaxin of inhibition of secretion by endogenous opioid.[61] The mechanisms of this estrogen–progesterone dependent action of relaxin need further study.

Salt Appetite

In rats salt appetite is increased in pregnancy,[37,96] yet with excessive intake, the hyponatremia of pregnancy is maintained.[97] The mechanism of increased salt appetite in pregnancy is not clear. Salt intake is not increased by relaxin in nonpregnant rats,[98] while pregnant mice with inactivation of the serum- and glucocorticoid-inducible kinase (*Sgk1*) gene, important in salt appetite stimulation by mineralocorticoids, show reduced sodium appetite.[99]

Circulating angiotensin II is a signal acting on the brain that can increase salt intake, and angiotensin II produced in the brain is important in stimulating salt appetite, which is usually associated with hypovolemia;[100] this is not the situation in pregnancy as blood volume is increased.

Angiotensin II acts in the lamina terminalis, from where neurons project to regions concerned with salt appetite, though the role of angiotensin II actions in the lamina terminalis, and the SFO in particular, is controversial.[100] Angiotensin II can stimulate and inhibit salt appetite, and the latter action has been shown to be via a central oxytocin action.[100–103] Any role for circulating angiotensin II in increased salt appetite in pregnancy is not clear. However, oxytocin clearly has actions in the brain to reduce food intake and salt appetite.[104–107] Hence, if in pregnancy central release of oxytocin by parvocellular oxytocin neurons is inhibited as well as from magnocellular oxytocin neuron dendrites,[108,109] increased salt intake could be explained, perhaps by unopposed angiotensin II action.

Inhibition of salt appetite is associated with inhibitory action of serotonin from dorsal raphe neurons released in the lateral parabrachial nucleus (lPB), which is a key node in a regulatory network involving brain stem and forebrain structures, including lamina terminalis components.[110] It is not clear whether the lPB is a site of oxytocin action.

Adrenomedullin

This is a potent hypotensive 52–amino acid peptide that has important actions in the periphery in pregnancy (e.g., in implantation and uterine vascular changes).[111,112] It is expressed in reproductive tissues and production, especially by the placenta, and circulating levels increase through pregnancy.[111] Adrenomedullin is also co-expressed in magnocellular oxytocin and vasopressin neurons,[113] and it acts centrally to excite oxytocin neurons.[114,115] Given centrally, adrenomedullin is hypertensive and inhibits water drinking and sodium appetite.[116,117] Brain adrenomedullin is important in mediating stimulation of oxytocin secretion by hypernatremia, and the inhibition of sodium appetite by adrenomedullin involves oxytocin action in the brain.[118] Although changes in pregnancy in the adrenomedullin system in the brain have not been reported, reduced activity and consequent reduced stimulation of oxytocin neurons clearly could have a role in maintaining the hyponatremia of pregnancy.

Sex Steroids

There are several possible sites of action of female sex steroids in the osmoregulatory complex. Estrogen receptor-alpha (ERα) is expressed by neurons in the lamina terminalis (SFO, OVLT, and median preoptic nucleus), and only estrogen receptor-beta (ERβ) is expressed in the magnocellular oxytocin and vasopressin neurons.[119–121] The lamina terminalis neurons expressing ERβ, which project to the magnocellular neurons,[119] respond to osmotic stimulation.[120] Magnocellular oxytocin neurons express G-protein coupled receptor 30 (GPR30),[122] which is a nongenomic estrogen receptor mediating rapid estrogen actions.[123] Only a few neurons in the lamina terminalis express progesterone receptors, but magnocellular neurons lack these.[124]

Summary and Conclusions

In pregnancy relaxin acts on the lamina terminalis and hence the magnocellular oxytocin and vasopressin neurons, together comprising the hub for regulating body fluid osmolarity. Relaxin reduces the threshold for osmotic stimulation of vasopressin neurons, causing water retention and hyponatremia, compounded by increased water drinking, notwithstanding increased sodium appetite. These changes make osmotic and hypervolemic regulation of oxytocin neurons less effective, attenuating any natriuretic action of oxytocin, supported by reduced atrial natriuretic peptide secretion.

Increased oxytocin secretion during parturition and by suckling following parturition, the loss of relaxin at the end of pregnancy, and increased ANP secretion postpartum[86] all contribute to enhanced natriuresis and reversal of the central adaptations in control of osmolarity and blood volume.

Future Perspectives

Mechanisms regulating RXFP1 expression in the brain need to be clarified. The discovery of relaxin-3, its expression in the brain, and that it stimulates water drinking raises questions about possible roles in pregnancy. The explanation for increased salt appetite in pregnancy is not clear, but may involve changes in the neural circuitry controlling salt appetite, or involve angiotensin II actions, or inhibition of central oxytocin or adrenomedullin release.

FOOD INTAKE AND METABOLISM IN PREGNANCY

Increased appetite and adipose storage are important accompaniments of pregnancy. The increase in food intake in women is less than 10% in developed countries and more in less-developed countries.[125] However, there is concern about the impact on pregnancy outcome in preexisting obesity, or obesity that develops during pregnancy.[126] By contrast, in rats food intake is increased in pregnancy by about 60%.[109,127] Increased intake supplies the growing placenta(e), fetus(es), and uterus, and increased maternal metabolism, as well as providing surplus for storage as adipose tissue[128] and preparation of the mammary gland for lactation.[129] Meeting these demands involves resetting of complex neural circuitry involving the hypothalamus, brain stem, and reward circuitry in particular. The mechanisms are not fully understood, but resistance to some normal physiological signals from the periphery that control appetite has been demonstrated, and changes in metabolic control are implicated.[130]

Interest in the regulation of maternal appetite and metabolism in pregnancy has been driven recently by concerns about obesity before and during pregnancy on the mother's health, and about long-term consequences for the health of offspring experiencing an overabundance of nutrients and other food constituents in utero.[131] Increased incidence of obesity in pregnant women, with increased birth weight, over the past 20 years in the United States is a major health concern.[132] This is because obesity in the mother is associated with metabolic disease, including gestational diabetes mellitus, and with programmed metabolic disorder in the offspring,[133,134] as modeled, for example, in sheep,[135,136] mice, and rats.[137–143]

Appetite and Metabolic Regulation

Principles

Calories eaten in excess of current need (i.e., for basal metabolism, exercise, and in pregnancy to supply the fetus(es)) are stored as glycogen in liver (a short-term store), or in muscle (which is only available for use by muscle), or predominantly as adipose tissue (white and brown; a long-term store). Adipose tissue can accommodate by far the largest amounts of stored energy.[144]

The size of this adipose store is a result of the balance (or imbalance) between calories consumed (carbohydrate or fat, with a smaller contribution from protein) and calories used, over a long period of time. In the recent past, the adipose store in human populations was quite stable, and evidently well regulated, but in the last few years the prevalence of obesity (most simply defined as excess body fat, measured by a body mass index [BMI: weight kg/height m^2] >30) has dramatically increased in many prosperous countries (e.g., United States), but not all (e.g., Sweden; World Health Organisation; http://www.who.int/gho/ncd/risk_factors/overweight/en/). In general, this epidemic of obesity is considered to be a result of eating too much and exercising too little; hence the mechanisms that control appetite and metabolism are a focus of much interest. The mechanisms that integrate signals about metabolic status and organize the sensations of hunger and satiety are in the brain, in a neuronal network involving groups of neurons in the hypothalamus and brain stem, in particular, interacting with the mesolimbic dopaminergic reward network in the midbrain and limbic system.[145,146] These networks also exert control over metabolism, especially in brown adipose tissue. A multitude of specific chemical signals in the brain (endocannabinoids (eCBs), monoamines and many neuropeptides) and signals from the periphery (conveyed by the vagus, or circulating peptide hormones) inform the appetite and metabolism controlling networks about metabolic state, which then organize appropriate behavioral and autonomic metabolic regulation (see also Chapter 35).

Understanding of these mechanisms has developed rapidly during the past 20 years, driven especially by the discovery of leptin in 1994[11] and by subsequent discovery, partly through molecular genetics, genome sequencing, and neuropeptidomics, of more peptides with actions on appetite and metabolism.[147] It is clear that most obese people do not have disturbance in function of only a single gene, so the dysregulation of appetite and metabolism in obesity is a result of changes in the settings in the regulatory networks in the brain. These networks are governed by signals that stimulate appetite and energy storage (orexigens) and by opposing signals that restrain appetite and promote metabolism (anorexigens), and by the reward network. Research has been focused on identifying these signaling mechanisms and evaluating their importance.[148] These controls operate over different time domains: the control of eating behavior involves short-term appetite and satiety signals, acting in a context of longer-term regulation of food intake and metabolism.

In pregnancy, there is a clear shift in the operation of the regulatory networks in the brain to favor increased appetite and increased energy storage, while the uterine contents (i.e., fetuses, placentae, membranes), are metabolically highly active. Multiple mechanisms are involved, contrasting with the relaxin-lamina terminalis-vasopressin neuron circuit that is primarily responsible for the hyponatremic hypervolemia of pregnancy (see the section Osmoregulation in Pregnancy). In principle, increased food intake in pregnancy could be a consequence of resistance to anorexigens or increased actions of orexigens; there is evidence for both types of change.

Network Components, Mediators and Modulators

Hypothalamus

More than 70 years ago, the hypothalamus was recognized as containing neural circuits that control appetite; researchers showed that lesions of the lateral hypothalamus led to suppression of eating, and that lesions of the ventromedial nucleus (VMN, or ventromedial hypothalamus) or PVN in the hypothalamus have opposite effects, leading to obesity.[149–152] Hence the medial hypothalamus has been considered a "satiety center" and the lateral hypothalamus a "hunger center" (Figure 44.3).

Neuropeptide Mediators

It was soon established after neuropeptide Y (NPY) was discovered in 1982 that this 36–amino acid neuropeptide is a highly potent orexigen in the brain.[153] The finding that a set of arcuate nucleus neurons express NPY led to focus on this region in appetite regulation (Figure 44.3). NPY neurons co-express agouti-related peptide (AgRP), another orexigen that is longer acting.[154] Pro-opiomelanocortin (POMC) neurons are also clustered in the arcuate nuclei and release α-melanocyte stimulating hormone (α-MSH), an anorectic peptide derivative of POMC, which stimulates metabolism, via melanocortin-4 receptors (MC4), expressed in several brain regions, including the PVN, nucleus tractus solitarii (NTS), lateral hypothalamus, and VMN.[155,156]

AgRP is an antagonist at MC4 receptors, so it blocks α-MSH actions.[157,158] POMC neurons also produce cocaine and amphetamine regulated transcript (CART) in the rat,[159] but not in humans, in which CART is found only in a minority of NPY neurons and is absent in POMC neurons.[160] Overall, CART has anorexigenic and thermogenic actions,[159,161] but applied to the PVN CART is orexigenic.[163]

It is clear that the NPY/AgRP and POMC/CART arcuate nucleus neurons in the base of the hypothalamus, adjacent to the median eminence, where the blood–brain barrier is deficient, are the major first order hypothalamic neurons in the control of appetite and metabolism, positioned to respond to blood-borne metabolic signals.[9] Hence, when stimulated, NPY/AgRP neurons alter activity of second-order neurons in the regulatory network that results in stimulated feeding, and reduced metabolism, in particular neurons in the PVN and dorsomedial hypothalamus (DMH)[163] and, thence, melanin concentrating hormone (MCH) neurons and orexin neurons in the lateral hypothalamus (Figure 44.3).[164,165] These lateral hypothalamic neurons increase feeding[164,166] and affect peripheral metabolism and fat storage via autonomic (sympathetic) outflow.[167] The actions of NPY/AgRP from arcuate neurons on MCH neurons are evidently indirect, via the PVN or DMH.[163,168,169]

Stimulated arcuate nucleus NPY/AgRP neurons release GABA, which inhibits nearby POMC/CART neurons.[170] Conversely, when POMC/CART neurons are stimulated they inhibit feeding, partly through releasing α-MSH to act on MC4 receptors in the PVN to stimulate oxytocin and CRH neurons,[171] and by also inhibiting MCH and orexin neurons they increase metabolism. Actions of α-MSH on MCH neurons are indirect as they do not express MC4 receptors.[169,172]

Fine details of the relative importance of the different components of these networks are being clarified by application of optogenetics (channelrhodopsin-assisted circuit mapping), which involves viral transfection of neurons expressing a specific peptide with the channelrhodopsin gene, which then allows excitation of the cell bodies or axons of these neurons by light pulses from a laser source via an implanted optical fiber. This approach is combined with recording of electrophysiological responses of identified neurons to test whether they are targets for the light-stimulated neurons, and with recording eating behavioral responses.[173] With this combination, it has been shown that stimulation of AgRP neurons (also producing NPY and GABA) in the arcuate nucleus inhibits POMC neurons, but that this connection is not important for acute feeding responses;[173] however, stimulating AgRP inputs to the PVN is important in evoking feeding, and this is mediated by inhibition (via GABA) of oxytocin neurons in the PVN, hence indicating a key role for these neurons in appetite regulation,[173] with implications for the explanation of increased appetite in pregnancy, as discussed following.

Modulators

ENDOCANNABINOIDS

The activity of neurons in the network is modulated by eCBs, generally in such a way that appetite is stimulated; hence a cannabinoid receptor 1 (CB1) antagonist (rimonabant) reduces energy intake, acting on orexigenic and anorexigenic neurons in the hypothalamus, in particular in arcuate neurons decreasing NPY production and increasing α-MSH and CART production.[174] To date, roles in appetite and metabolism regulation in pregnancy have not been explored.

SEROTONIN

Serotonin (5-HT) depletion or inactivation of specific serotonin receptor subtypes leads to obesity. Consequently, drugs that increase serotonin availability (e.g., D-fenfluramine or sibutramine) and a serotonin 2_C-receptor (5-HT_{2C}R) agonist (lorcaserin) have antiobesity actions.[147] The 5-HT_{2C}R mediates the stimulatory actions of serotonin on POMC neurons, independently of leptin, while the 5-HT_{1B}R mediates the inhibitory actions on AgRP neurons; the actions on POMC neurons lead to anorectic effects via MC4R in the PVN.[147] Any

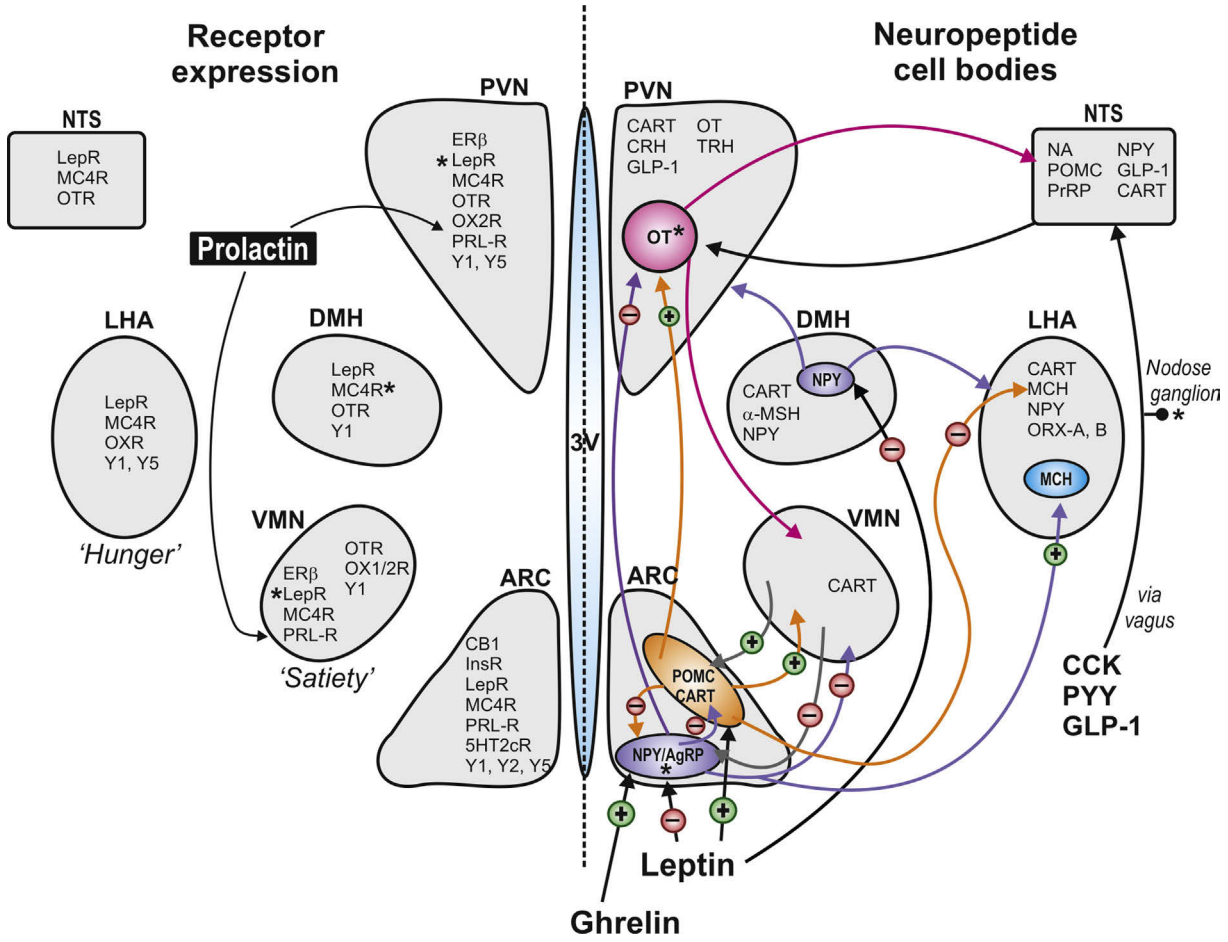

FIGURE 44.3 Hypothalamic neuropeptides and networks regulating appetite and metabolism. The arcuate nucleus (ARC) contains NPY/AgRP neurons that increase food intake and energy storage via inhibition of adjacent POMC neurons (producing anorexigens-α-MSH and CART) and anorexigenic neurons in the PVN (OT, CRH) and via antagonism of α-MSH action on MC4 receptors that mediate inhibition of MCH neurons in the LHA ("hunger center"), with actions in the VMN ("satiety center"). POMC/CART neurons in the arcuate nucleus decrease food intake and increase metabolism by inhibiting NPY/AgRP neurons, stimulating oxytocin neurons, and inhibiting MCH neurons in the LHA. Arcuate NPY/AgRP neurons are inhibited by leptin and stimulated by ghrelin. Leptin stimulates POMC/CART neurons. Leptin can act at all sites in the network (note leptin receptor distribution, LepR). There are reciprocal connections between PVN anorexigenic oxytocin neurons and the nucleus tractus solitarii (NTS). The NTS processes input via the vagus from gut hormones signaling satiety (CCK, GLP-1, PYY). Noradrenaline, α-MSH (from POMC neurons), PrRP, and GLP-1 are transmitters in the NTS to PVN pathway. In mid- to late pregnancy several changes that alter the network balance in favor of increased food intake and energy storage have been identified to date (*): (1) NPY/AgRP neurons are more active, and evidently leptin resistant as leptin levels are high in pregnancy; (2) LepR expression in the hypothalamus (but not arcuate nucleus) is reduced; (3) leptin resistance (with reduced LepR expression and signaling) develops in the PVN and VMN (induced by prolactin/placental lactogen), and vagal nodose ganglion; (4) activity of PVN oxytocin neurons may be suppressed—they develop resistance to CCK action, and central resistance to anorectic OT actions develops; (5) central resistance to α-MSH develops. Symbols: arrows indicate targets; +: represents excitatory action; –: represents inhibitory action. Regions: 3V, 3rd ventricle; ARC, arcuate nucleus; DMH, dorsomedial nucleus; LHA, lateral hypothalamic area; NTS, nucleus tractus solitarii; PVN, paraventricular nucleus; VMN, ventromedial nucleus. Left: R, Receptors: 5HT2cR, serotonin 2c; CB1R, cannabinoid 1; ERβ, estrogen; InsR, insulin; LepR, leptin; MC4R, melanocortin; PRL-R, prolactin; OTR, oxytocin; OXR, OX1R, OX2R, orexin; Y1, Y5, neuropeptide Y. Right, Neuropeptides: α-MSH, melanocyte stimulating hormone; AgRP, agouti-related peptide; CART, cocaine and amphetamine regulated transcript; CRH, corticotropin releasing hormone; GLP-1, glucagon-like peptide; MCH, melanocyte concentrating hormone; NPY, neuropeptide Y; ORX-A, B, orexins; OT, oxytocin; POMC, pro-opiomelanocortin; PrRP, prolactin releasing peptide; TRH, thyrotropin releasing hormone. Monoamine- NA, noradrenaline. Blood-borne: CCK, cholecystokinin; PYY, peptide YY; GLP-1: glucagon-like peptide. *Source: Diagram adapted from Parker & Bloom.*[163]

role for changes in these central serotonin mechanisms regulating appetite and metabolism in pregnancy has evidently not been investigated.

Adipose Signaling to the Networks Regulating Appetite and Metabolism

Adipokines

Adipokines are peptides produced by adipose tissue with regulatory actions, some of which act on the brain. The adipokines include leptin, adiponectin, resistin, visfatin (from visceral fat), retinol-binding protein 4 (which induces insulin resistance), and vaspin (found in visceral fat and has insulin-sensitizing actions).[175]

Leptin

Leptin is produced by adipose tissue in amounts that reflect fat mass, hence its concentration in the circulation reflects fat stores.[12] It is distinguished by its role in inhibiting appetite and promoting metabolism through actions in the brain, on the network outlined earlier (Figure 44.3).

LEPTIN RECEPTORS

There are two types of leptin receptor in brain, the long form (LEPRb), which mediates the actions of leptin, and the short form (LEPRa), expressed in the choroid plexus and mediating transport of leptin across the BBB into brain.[176] LEPRb is expressed in arcuate POMC and AgRP/NPY neurons, and leptin stimulates the former and inhibits the latter.[177] Hence leptin reduces eating and stimulates metabolism by actions on the neurons at the portal of the network regulating appetite and metabolism. However, there are also neurons in the PVN, VMN, lateral hypothalamus, dorsomedial hypothalamus, and NTS that express LEPRb, and these contribute importantly to the actions of leptin on appetite and metabolism.[178–182] Leptin excites most neurons in the PVN, which has an inhibitory role in appetite regulation.[183] Lack of leptin or LEPRb results in hyperphagia and extreme obesity.[184] Leptin and insulin interact on POMC neurons to regulate glucose homeostasis.[185,186]

Leptin also acts on other central nervous system (CNS) sites to regulate energy balance. For example, leptin can act directly on dorsomedial hypothalamic neurons to stimulate brown adipose tissue (BAT) thermogenesis, by activating sympathetic outflow;[179] and in vitro it acts directly on vagal ganglion afferent neurons (through which cholecystokinin [CCK], for example, signals to terminate a meal),[187,188] and in the NTS. Neurons in the reward circuitry (discussed following) also express leptin receptors, and leptin regulates effort-based feeding.[189]

Insulin Signaling to the Brain

Arcuate NPY/AgRP and POMC/CART neurons express insulin receptors (InsR) as well as leptin receptors.[190] Insulin, secreted by pancreatic islet β-cells, signals plentiful energy like leptin, and it has similar central actions to leptin: it reduces appetite and stimulates metabolism[191] by increasing activity of sympathetic outflow to BAT.[192] These actions contrast with its peripheral actions to drive glucose into tissues for use or storage, as fat or glycogen.

Leptin Resistance

Leptin resistance is the state of increased circulating levels of leptin and decreased inhibitory actions on appetite and decreased stimulatory actions on adipose tissue metabolism. Typically this is the situation in obesity, in which circulating leptin levels are increased as a result of the increased body fat mass.[193] Such leptin resistance essentially describes the failure of leptin to control or reverse obesity. An issue is whether leptin resistance leads to obesity, or vice versa.[194] A common laboratory model to study leptin resistance is diet-induced obesity (DIO) in rats or mice susceptible to obesity if fed a high fat diet.[195] The model has complex elements (e.g., low-grade inflammation, including of the hypothalamus),[194,196] that make detailed comparisons with changes in pregnancy difficult, though obesity models have given leads.[197,198]

Leptin (and insulin) resistance in DIO involves activation of a protein kinase (inhibitor of nuclear factor kappa-B kinase [IKKβ]) and endoplasmic reticulum stress while interleukin-6, an anti-inflammatory cytokine released from exercising muscle, reduces appetite and reduces hypothalamic inflammation in DIO.[196] These issues are presently unexplored in the maternal hypothalamus in pregnancy.

Leptin Resistance in Pregnancy in Women

Pregnancy is a state in which appetite is increased, fat is stored (but mobilized near the end of pregnancy), and circulating leptin levels are increased.[199,200] It is likely that the placenta contributes significantly to circulating leptin levels as plasma concentrations fall rapidly after birth.[199]

In women, these findings have been interpreted to indicate physiological leptin resistance in pregnancy.[201,202] However, in healthy women studied before and during pregnancy, no change in the correlation between leptin level and body fat store is found. Rather, fat store size in pregnancy is more steeply correlated with the homeostasis model assessment of insulin resistance (HOMA-IR), indicating insulin resistance in late pregnancy,[199] which would make

glucose more readily available for the fetus. Nonetheless, more direct indicators of leptin actions in cerebrospinal fluid (CSF) samples, taken just before term in healthy women and from healthy nonpregnant women, have shown signs of reduced entry of leptin into the brain (reduced ratio of CSF: plasma levels) despite increased plasma concentrations. Importantly, CSF levels of AgRP are higher in pregnancy, with no change in POMC levels, hence the AgRP:POMC ratio is increased. These findings indicate reduced leptin transfer across the BBB, perhaps related to increased circulating levels of the soluble form of leptin receptor (LEPRe; OBRe), and reduced inhibition of AgRP release (but unaltered action on POMC), together consistent with increased appetite (via AgRP/NPY release in the brain) and increased fat storage (via inhibition of α-MSH action by AgRP).[200] LEPRe is produced by the placenta and acts to bind circulating leptin, reducing its availability to neural tissues.[203]

Leptin Resistance in Pregnant Rodents

Details of mechanisms of leptin resistance in pregnancy have been studied in detail in rats, in particular, and in mice. Food intake in rats increases early in pregnancy, and this is generally found before leptin levels rise, i.e., before leptin resistance develops, and hyperphagia is sustained through pregnancy despite increasing leptin levels.[204,205] However, as 32 different candidate genes have been identified as contributing to human obesity,[147] changes in pregnancy in the activity of a similar large number of genes in the brain regulating appetite and metabolism is possible.

Early Pregnancy in Rats

Pseudopregnant rats (i.e., rats with a prolonged luteal phase consequent on sterile mating) have modestly increased estrogen, high progesterone, and high but pulsatile prolactin levels, and rapidly become hyperphagic and store fat, but show no changes in leptin levels or in arcuate nucleus NPY, AgRP, or POMC mRNA expression, so are not considered leptin resistant.[130,198,205] Moreover, pseudopregnant rats on day 9 show unaltered hypothalamic intracellular signaling responses (see following) to intravenous leptin.[205]

Hence hyperphagia in early pregnancy is due to early pregnancy hormones. But the mechanisms are not clear—only subsequently are leptin resistance and hypothalamic neuron changes important. By contrast with pulsatile prolactin secretion in early or pseudopregnancy, in the second half of pregnancy placental lactogen is continually produced (Figure 44.1), and this pattern, as modeled by continuous intracerebroventricular (i.c.v.) prolactin infusion with progesterone supplementation, induces leptin resistance.[130]

Estradiol, Food Intake and Metabolism

It is well established that energy intake decreases during the ovarian cycle when estrogen levels peak. Moreover ovariectomy increases food intake and fat deposition in several species, and estrogen replacement prevents this.[206–208] Hence, estradiol is an anorexigen and increases energy expenditure, by acting centrally in the appetite and metabolism regulatory network via first-order arcuate neurons, inhibiting NPY/AgRP neurons and stimulating POMC neurons[209–211] and via second-order neurons in the medial hypothalamus (whether in the PVN or VMN is controversial, although tamoxifen, an estrogen receptor modulator, has anorectic actions via inhibitory actions on fatty acid synthase in the VMN),[212] lateral hypothalamus, and NTS.[206,207,213–216] Estradiol given to ovariectomized rats blocks the orexigenic effect of administration of ghrelin (an orexigenic peptide hormone secreted by an empty stomach, production of which is evidently greater in pregnancy),[217] enhances anorexigenic effects of CCK and CCK-induced stimulation of neurons in the PVN and NTS,[207,218] enhances actions of leptin on food intake,[219] and increases LEPRb mRNA expression in the hypothalamus,[220] without changing plasma or CSF leptin levels.[221] In addition, estrogen and progesterone do not alter leptin transfer across the choroid plexus.[205] As central actions of estrogens without pregnancy are evidently anorexigenic, they are unlikely to increase appetite and energy storage in pregnancy. However, estrogens have essential actions by increasing PR expression in the brain,[222] hence enabling orexigenic actions of progesterone, as discussed next.

Progesterone, Food Intake and Metabolism

A stimulatory effect of progesterone on body weight and fat storage was shown long ago in female mice and rats,[10,223] and in women weight gain in pregnancy correlates with progesterone levels.[224] Progesterone does not affect food intake in the absence of estrogen,[206] but food intake in women during the ovarian cycle is greatest in the luteal phase, when progesterone levels are high.[208] Evidently, progesterone overcomes the inhibitory effects of estradiol.[225]

Chronic progesterone administration in ovary-intact rats increases (for the first 2 weeks) food intake and fat storage while reducing thermogenesis, without changing plasma or CSF leptin levels for up to 30 days.[226] Similarly, in early pregnancy such effects of progesterone do not lead to leptin resistance as an orexigenic mechanism.[130] However, chronic estrogen and progesterone treatment in ovariectomized rhesus monkeys blocks short-term anorexic actions of peptide YY ($PYY_{(3\text{-}36)}$; a 36–amino acid anorectic peptide, related to NPY, that is secreted by the distal intestine after a meal

and acts on Y2 inhibitory autoreceptors, which arcuate NPY neurons express, through which PYY/$PYY_{(3-36)}$ can suppress further feeding after a meal).[227,228,229]

The actions of progesterone on food intake and fat deposition may involve the progesterone receptors that are expressed in VMN and arcuate neurons.[124]

Allopregnanolone, Food Intake and Metabolism

Levels of this neuroactive steroid metabolite of progesterone are high in late pregnancy,[29] and given acutely it stimulates food intake in male rats.[230] Although allopregnanolone is an allosteric modifier at $GABA_A$ receptors, its stimulatory action on food intake in male rats is evidently not mediated by these receptors.[230] However, in female rats stimulation of feeding by allopregnanolone (an effect that is maximal at diestrus; i.e., with low estrogen and progesterone levels), is attenuated by a $GABA_A$-receptor antagonist.[231] Hence, high levels of allopregnanolone in pregnancy may contribute to increased food intake, perhaps via actions on GABA receptors on arcuate POMC neurons and/or on PVN and SON oxytocin neurons: reinforcing inhibition by GABA from NPY/AgRP neurons. This remains to be tested.

Mid-to-Late Pregnancy in Rodents

Changes in Leptin Availability

As in women, leptin levels in blood increase in pregnant rats and mice after the first week of pregnancy, as a result of the increased fat mass[13,198] and a possible contribution from the placentae.[203,232,233] However, more circulating leptin is bound to circulating LEPRe, which seems especially important in mice.[234] Leptin bound to LEPRe is less effective at binding to LEPRb, and in activating postreceptor signaling, i.e., STAT-3 tyrosine phosphorylation.[235] Leptin resistance in pregnancy (from day 13) involves reduced entry into brain through the BBB.[205] This may be a result of action of prolactin on leptin transport across the choroid plexus.[205]

LEPTIN RECEPTORS

Leprb mRNA expression in the hypothalamus is reduced[232,233] or not changed in late pregnant rats or mice,[204,236,237] although reduced hypothalamic LEPRb protein level has been reported on gestation day 18 but not 13.[205] LEPRb expression in the arcuate nucleus is not reduced in pregnancy.[238]

Leptin Resistance in Pregnancy: Functional Evidence

Reduced effects of the high circulating levels of leptin with respect to its central appetite suppressing actions and enhancing actions on adipose tissue metabolism is a feature of the second half of pregnancy in rats and mice. This can support an anticipatory increase in food intake and a positive energy balance.[13,198,239,240] Leptin resistance is revealed by finding that i.c.v. or systemic infusion of leptin fails to reduce food intake in mid-pregnant rats.[13,205,241] Consequently, in rats near the end of pregnancy, *Npy* mRNA expression in the arcuate nucleus is increased, despite increased circulating leptin levels.[14,205,242] A similar pattern in arcuate *Npy* mRNA levels has been reported in pregnant mice,[237] though other studies suggest it is unaltered.[236] In rats, *Agrp* mRNA level has been found to be unaltered[242] or increased, as in mice,[205,236] and *Pomc* mRNA expression has been found to be reduced[205] or not significantly reduced,[242] as in mice.[236] However, the level of *Pomc* mRNA in the arcuate, or the number of arcuate *Pomc* mRNA expressing neurons in the caudal part of the arcuate, is increased in the last week of pregnancy.[243,244] But the arcuate shows increased density of fibers containing β-endorphin, an opioid peptide product of POMC, and α-MSH density has not been assessed in this way.[244] In another species (Brandt's vole) there is no change in hypothalamic *Leprb*, *Npy*, *Agrp* or *Cart* mRNA levels, but a decrease in *Pomc* mRNA is found.[245]

Leptin Signaling and Resistance

Intracellular Mechanisms of Leptin Action

Leptin acts on arcuate neurons to reduce *Npy*/*Agrp* gene expression and to increase *Pomc*/*Cart* expression.[246] Post-LEPRb signaling mechanisms for leptin actions on neurons first involve Janus family kinases (Jak2) and phosphorylation of specific tyrosines in the receptor-Jak2 complex (Figure 44.4), of which: Tyr_{985} on the receptor recruits SH2-containing tyrosine-phosphatase (SHP-2), which activates extracellular signal-regulated kinase (ERK); receptor Tyr_{1138} recruits signal transducer and activator of transcription 3 (STAT3). pSTAT3 is a transcription factor, but also induces suppressor of cytokine signaling 3 (SOCS3), the negative feedback regulator of LEPRb-STAT3 signaling,[247] and positive regulators for leptin actions, e.g., POMC;[248] Tyr_{1077} phosphorylation recruits STAT5[249] (Figure 44.4). pSTAT3 has the major role in mediating leptin actions.[250] The Tyr_{1138} -to- STAT3 path increases *Pomc* gene expression in arcuate neurons[247] and inhibits *Agrp* gene transcription.[251] Leptin also decreases activity of MCH neurons in the lateral hypothalamus, although leptin action is through inputs (perhaps from the arcuate nucleus) rather than directly on the MCH neurons.[252,253] In contrast, orexin neurons in the lateral hypothalamus receive inhibitory input from local neurons expressing LEPRb.[253] Hence leptin signaling in these different neurons, or their inputs, mediates inhibition of appetite and stimulation of metabolism. However, pSTAT3 actions on POMC expression require removal, by phosphorylation,

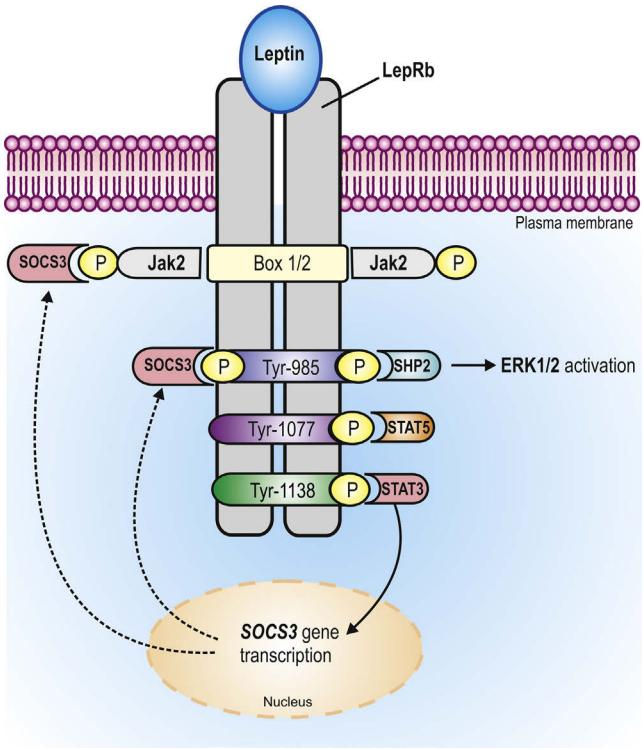

FIGURE 44.4 Intracellular leptin receptor signaling. Binding of leptin to the long form of the leptin receptor (LepRb) results in activation of Janus kinase (Jak2) at the Box 1/2 motif on the LepRb. Activated Jak2 auto-phosphorylates and also phosphorylates (P) tyrosine (Tyr) residues on the LepRb at positions 985, 1077, and 1138. Phosphorylated Tyr-985 is a docking site for SH2 domain-containing phosphatase (SHP2). Phosphorylated Tyr-1077 is a docking site for signal transduction and activation of transcription 5 (STAT5), and phosphorylated Tyr-1138 is a docking site for signal transduction and activation of transcription 3 (STAT3). Activated SHP2 activates the extracellular-regulated kinase 1/2 (ERK1/2) signaling pathway that results in increased EGR-1 gene transcription. Activated STAT3 translocates to the nucleus and induces the expression of suppressor of cytokine signaling 3 (SOCS3). SOCS3 negatively feeds back to inhibit leptin signaling by binding to phosphorylated Tyr-985 and phosphorylated Jak2. Functional leptin resistance in pregnancy may be associated with reduced pSTAT3 formation in response to leptin in neurons that mediate anorectic actions of leptin; this may not simply involve increased SOCS3 induction.

of inhibition by forkhead box protein O1 (FOXO1). Indeed, sustained activation of STAT3 can, by increasing SOCS3, lead to leptin resistance in POMC neurons.[247,254]

In addition, leptin receptor phosphorylation activates, via phosphatidylinositol (3,4,5)-triphosphate (PIP3), phosphatidylinositol 3-kinase (PI3-K),[254] hence converging leptin signaling with insulin signaling (see following). This pathway has been suggested to be important in the regulation of NPY expression by leptin.[198] FOXO1 is one target of p-protein kinase B (a serine/threonine specific kinase, p-Akt), and FOXO1 phosphorylation enables pSTAT3 stimulation of POMC gene expression, suppression of AgRP expression, and stimulation of PVN neurons.[255] Whether there are changes in pregnancy in FOXO1 mechanisms has not been reported.

Insulin Signaling

Occupation of the insulin receptor by insulin activates the insulin receptor substrate (IRS) protein to PI3′-K path by Jak2 and leads to altered membrane potential in appetite regulating neurons; in POMC neurons leptin and insulin activate this pathway but have opposite actions on electrical activity (leptin depolarizes; insulin hyperpolarizes).[256] In AgRP neurons insulin also activates this path, but actions of leptin on POMC neurons lead, via synaptic connections, to inhibition of this particular path in AgRP neurons,[257] perhaps by GABA, which POMC neurons also produce.[258]

Intracellular Mechanisms of Leptin Resistance

From obesity models leptin resistance was proposed to follow exposure of neurons to high levels of leptin that cause continual activation of pSTAT3 and the inhibitor SOCS3.[197] Studies of leptin resistance in pregnancy have tested this mechanism of leptin resistance in different components of the appetite and metabolism regulating networks. There are major differences from obesity models.

At the level of the whole hypothalamus, by contrast with actions in virgins, peripheral leptin injection in rats and mice fails, from gestation day 13, to increase hypothalamic pSTAT or pAkt (a proto-oncogene product: a serine–threonine protein kinase related to PKC) content (reflecting reduced activity of the PI3′-K, -Akt cascade).[205] I.c.v. leptin injection from day 13 also fails to increase hypothalamic pSTAT3 and SOCS3, or pAkt (excepting day 13), although basal SOCS3 levels in pregnancy are greater than in nonpregnant rats.[205] Measurements on micropunch samples indicate that leptin does not increase pSTAT3 in the arcuate nucleus, but induction is decreased in the VMN.[13] However, immunohistochemical studies revealed that arcuate α-MSH (POMC) neurons do not develop leptin resistance in pregnant rats or mice as they show normal pSTAT3 responses to leptin; instead, in late pregnant rats and mice, VMN neurons do not show a pSTAT3 response to leptin, and in rats VMN neurons show reduced LEPRb mRNA expression.[238,240,242] Moreover, the anorectic actions of α-MSH are lost, so the intact pSTAT3 responses of arcuate POMC neurons to leptin in pregnancy are nonetheless ineffectual.[240,242] Evidently, leptin resistance in pregnancy of α-MSH mechanisms resides in targets for α-MSH and not in POMC neurons. These findings contrast with obesity models in which arcuate POMC neurons develop leptin resistance and, tested with MCR3/4 receptor agonist or antagonist, α-MSH signaling in the appetite and metabolism regulating circuitry is maintained or even enhanced.[197]

The loss of anorectic action of α-MSH in pregnancy contrasts with maintained eating responses to i.c.v. NPY or orexin in late pregnant rats, despite loss of oxytocin and HPA axis responses.[259,260]

Prolactin and Leptin Resistance

Prolactin and leptin are members of the cytokine class superfamily of peptides and have similar receptor-mediated intracellular signaling mechanisms.[261,262] However, prolactin has opposite effects to leptin on food intake: infusion of prolactin into the PVN in virgin rats increases food intake,[263] and i.c.v. infusion for 10 days increases food intake and prevents acute anorectic effects of i.c.v. leptin.[264] This effect of prolactin is associated with reduced Fos (an immediate early gene product, marking recent neuronal activation) and pSTAT3 induction by leptin in the PVN and VMN, with no effects of prolactin in the arcuate (Figure 44.3).[264]

Rats in pseudopregnancy (extended by progesterone implants and given chronic i.c.v. prolactin to mimic continuous high levels of placental lactogen seen in pregnancy) (Figure 44.1), show resistance to suppression of food intake by leptin, as in pregnancy.[130] The mechanisms of this action of prolactin are not clear, although prolactin targets many neuron types in the brain, in which it activates pSTAT5.[265] Perhaps relevant is that oxytocin has anorectic actions, oxytocin neurons are excited by leptin[266] and express the long-form prolactin receptor (PRL-R_L), and that prolactin has an opposite action, inhibiting the electrical activity of magnocellular SON oxytocin neurons (although it stimulates Fos and oxytocin gene expression in these neurons).[267] If leptin resistance develops in specific neurons as a result of chronic exposure to prolactin, it seems likely that this will involve interference between prolactin and leptin postreceptor signaling mechanisms. In the PVN the same neurons express LEPRb and PRL-R, and leptin resistance is seen in lactation, as leptin does not induce pSTAT3.[268] However, direct testing of cross-resistance in a cell line expressing both receptors shows that leptin or prolactin overexposure induced homotypic resistance, examining STAT3 or STAT5 signaling, respectively, but cross-resistance was not seen. This finding leads to the suggestion that direct stimulation of PVN NPY neurons, rather than SOCS3 induction, may counteract inhibition by leptin.[268]

Adiponectin in Pregnancy

Adiponectin is insulin-sensitizing, anti-inflammatory, and anti-atherogenic.[175] High leptin levels and low adiponectin levels are associated with gestational diabetes mellitus.[175] Insulin resistance develops[270] and leptin levels increase,[271] while circulating adiponectin levels decrease in late pregnancy, as adipose tissue expands.[272,273] In obese individuals adipose tissue shows markers of chronic inflammation, which persist into pregnancy in pregravid obese women.[274] In women, changes in the adipose transcriptome, including increased expression of inflammatory markers, are evident in early pregnancy, long before insulin resistance in late pregnancy.[275] Mice in late pregnancy show insulin resistance and markers of low-grade inflammation in adipose tissue.[276]

Direct central actions of adiponectin are indicated by expression of adiponectin receptors in arcuate NPY and POMC neurons.[277] Given centrally in mice, adiponectin stimulates energy expenditure and decreases body weight.[278] However, there is evidence for stimulatory effects of adiponectin on food intake: chronic i.c.v. infusion in rats increases energy intake (but increases expenditure by fat),[279] and given systemically, adiponectin increases food intake and decreases energy expenditure in fasted mice, while mice deficient in adiponectin show decreased food intake.[280] Also, adiponectin inhibits magnocellular and parvocellular (those projecting to the NTS) PVN oxytocin neurons, which may increase appetite (see following).[281,282] However, such actions of adiponectin in the increased appetite of pregnancy are unlikely as circulating levels of adiponectin are low in late pregnancy.[283] Nonetheless, it is possible that the reduced level of adiponectin in pregnancy leads to central insulin resistance, which would diminish central anorexigenic actions of insulin.[191]

Oxytocin and Appetite

It has been known for over 25 years that CCK stimulates oxytocin secretion via the vagus, and for 20 years that accompanying decreased food intake is a result of oxytocin release into the brain, specifically from PVN neurons projecting to the dorsal vagal complex (Figure 44.3).[284–286] Hence, oxytocin given into the brain has anorectic actions.[285,287] Oxytocin has rather subtle actions in the brain that reduce appetite, in particular in terminating a meal;[288] in its absence or with an oxytocin receptor (OTR) antagonist, appetite for carbohydrate is increased.[289–291] In rats, oxytocin neurons in the SON are activated during a meal,[292] as shown by Fos expression, and in mice PVN oxytocin neurons are activated at the end of a liquid meal.[291] The importance of PVN oxytocin neurons in food intake regulation is indicated by studies on mice heterozygous for inactivation of the single-minded 1 (*SIM1*) gene (essential for normal PVN development), which show hyperphagic obesity that is rescued by central oxytocin administration, and mice homozygous for conditional postnatal *SIM1* knockout as adults develop hyperphagic obesity and have very low oxytocin mRNA levels in the PVN.[152,293,294] Moreover, mice with oxytocin neurons overexpressing synaptotagmin-4 (which negatively regulates oxytocin exocytosis)

are obese.[295] However, specific deletion of oxytocin neurons in adult mice does not affect food intake or energy expenditure on a regular diet but reduces expenditure on a high fat diet.[296]

Oxytocin circulating at physiological concentrations cannot enter the brain, because entry is effectively prevented by the blood–brain barrier,[297] and it has not been shown to act directly on circumventricular organs, which evidently lack OTRs, although *Oxtr* mRNA is expressed in the lamina terminalis.[298–300] However, oxytocin is released within the brain by axon terminals of PVN parvocellular neurons,[301] and by dendrites of SON and PVN magnocellular neurons, from which it may diffuse to nearby nuclei containing neurons that express oxytocin receptors.[108]

In relation to appetite regulation, oxytocin receptors are expressed by neurons in the VMN,[298,299,302] and the NTS.[303] Estradiol alters architecture of dendrites extending from the VMN, enhancing oxytocin innervation, while progesterone has opposite action.[304] Any such change in pregnancy due to high progesterone level would be expected to reduce inhibition of appetite by oxytocin.[304]

Arcuate POMC (α-MSH) and Oxytocin Neurons

Oxytocin plays a key role in mediating the anorectic actions of α-MSH as they are blocked by central administration of an oxytocin antagonist.[305] Arcuate POMC (β-endorphin/α-MSH) neurons project to the dorsal SON, where oxytocin neurons are predominant[244,306] and to the non-magnocellular division of the PVN (Figure 44.3).[307]

α-MSH acts via MC4R on magnocellular oxytocin neurons to inhibit their firing and consequently oxytocin secretion from the posterior pituitary. The action on firing rate is mediated by locally produced eCBs.[308,309] Remarkably, at the same time, α-MSH acts on these neurons to induce Fos expression and stimulate the release of oxytocin from the dendrites of these neurons, in a Ca^{2+} dependent manner, as intracellular Ca^{2+} mobilization by α-MSH primes the dendritic store of oxytocin for release and then triggers release.[308,310] It has been proposed that oxytocin released from the dendrites of magnocellular oxytocin neurons can diffuse in brain extracellular fluid to reach nearby neurons in the VMN, where OTR are abundantly expressed, and alter their electrical activity.[311–313] Actions of oxytocin in the VMN have been suggested to contribute to regulation of appetite;[314] however, this remains to be established.

Leptin and Oxytocin Neurons

Leptin, secreted by adipose tissue and reflecting fat store size, can enter the brain via the choroid plexus, and oxytocin neurons express leptin receptors.[315]

DIO in rats, induced by feeding a high fat diet, involves reduced numbers of arcuate neurones,[269] and leptin resistance (i.e., obesity despite high circulating leptin levels, and lack of effect of administered leptin on food intake).[316] In such rats, i.c.v. injection of oxytocin (1 μg) before lights out reduces overnight food intake and body weight similarly in normal and DIO rats, as does intraperitoneal injection of up to 1000 μg/kg oxytocin,[a] which stimulates neurons in the NTS and area postrema in both DIO and control rats; this treatment is similarly effective in reducing food intake in obese rats genetically deficient in leptin signaling.[316] These findings are interpreted as reflecting failure, in DIO rats, of leptin to signal via α-MSH from arcuate nucleus POMC/CART neurons to parvocellular oxytocin neurons that project to the NTS.[316] It seems possible that leptin resistance involves failure to activate central oxytocin mechanisms, and that in pregnancy, a similar situation could be important in permitting increased food intake.

Appetite Peptides and Oxytocin Neurons in Pregnancy

The effects on oxytocin neurons of peptides that are involved in appetite regulation are altered in pregnancy.

LEPTIN

Given acutely by intravenous injection, leptin stimulates the electrical activity of magnocellular oxytocin neurons; this action is lost in late pregnant rats that are fasted overnight but not in fasted virgin rats.[266] Hence, leptin may normally recruit magnocellular oxytocin neurons to augment its anorectic actions and to stimulate postprandial natriuresis.[318] The loss of the oxytocin neuron responses to leptin in the fasted state in late pregnancy may contribute to increased appetite and sodium retention (see the section Osmoregulation in Pregnancy).

NEUROPEPTIDE Y (NPY)

NPY, a 36–amino acid peptide produced by arcuate nucleus neurons, is a potent orexigen when given centrally.[319] It also stimulates oxytocin neurons, which express NPY receptors;[320] this action is lost in late pregnancy in rats, yet its orexigenic action is intact.[259] Hence, this loss of oxytocin neuron responses to NPY with maintained orexigenic action will favor increased food intake in pregnancy.

[a] for comparison, i.v. infusion of 1 μg over 2 h is sufficient to drive delivery of the litter in a late pregnant rat.[317] At the supraphysiological ECF concentrations of oxytocin expected after an intraperitoneal injection of 1000 μg/kg oxytocin (c. 5000 ng/ml: >5000-fold greater than maximal endogenous concentrations[297]) a small (but physiologically significant) percentage may cross the blood–brain barrier.[297] It needs to be tested whether effects of peripherally administered oxytocin in the brain are through central oxytocin receptors.

NESFATIN-1

Nesfatin-1 (also called nucleobindin 2, NUCB2-encoded satiety and fat-influencing protein) is a recently identified potent anorexigenic 82–amino acid peptide.[321–323] It is expressed in neurons in brain regions involved in regulation of appetite and metabolism,[323] in subcutaneous adipocytes, and in gut;[322] it is also present in the circulation and can cross the BBB.[324]

Released from arcuate nucleus POMC/CART neurons, probably by dendrites,[325] nesfatin-1 inhibits nearby NPY/AgRP neurons.[305,326] Nesfatin-1 is also co-expressed in oxytocin neurons and PVN CRH neurons, and expression in oxytocin neurons decreases with fasting and increases with refeeding.[327] Melanocortin signaling is involved in nesfatin's anorexic actions, and these are blocked by central administration of an oxytocin or a CRH-R2 antagonist, indicating mediation of nesfatin actions by α-MSH and oxytocin and CRH (or a urocortin).[305,328] Clearly, reduced production and action of nesfatin-1 on networks regulating appetite could support increased food intake in pregnancy, but this has not been reported.

RELAXIN-3

This peptide, a member of the relaxin family (see the section Osmoregulation in Pregnancy),[73,74] is expressed in the brain[329] and acts via the RXFP3 receptor, inhibiting adenylate cyclase—opposite to relaxin actions via RXFP1.[69,70,330] Relaxin-3 increases food intake and weight gain, acting via the PVN, possibly via reduced oxytocin production[331]; while human relaxin-2 (rat relaxin has similar reproductive biological activity)[332] has opposite effects.[333] Any role of relaxin-3 in increased appetite in pregnancy is presently unknown, however, the inhibitory actions of relaxin-2 on eating cannot explain increased food intake in pregnancy.

Oxytocin and Food Intake in Pregnancy: Oxytocin Resistance?

When food is returned after 24 h food deprivation, mid-pregnant rats start to eat more quickly, eat more, and spend more time eating than virgin rats.[109] Central infusion of an oxytocin antagonist before food is returned increases food intake over the next 24 h in virgin, but not in pregnant, rats.[109] Conversely, i.c.v. oxytocin infusion (1 μg; n.b. 500-fold greater than the dose that triggers coordinated burst firing of oxytocin neurons in suckled lactating rats[334]) reduces food intake in virgin rats after fasting for 24 h, but has no such effect in pregnant rats.[109] Together, these experiments indicate a lack of oxytocin anorectic activity in pregnancy. This may be the result of a lack of stimulation of oxytocin neurons during eating (e.g., by circulating leptin or CCK, or by NPY released in the brain, reduced OTR expression, or post-OTR signaling mechanisms in appetite-regulating regions).

OXYTOCIN RECEPTORS (OTR)

Expression of OTR (*Oxtr*) mRNA or oxytocin binding sites in the VMN are not altered in mid-pregnancy but are increased by the completion of parturition, probably consequent on estradiol/interleukin-6 (IL-6) action.[313] OTR are also expressed in the NTS, PVN, and SON, and *Oxtr* mRNA expression in the SON and NTS (but not in the PVN) is increased by the end of pregnancy.[303] OTR binding is increased in the PVN and SON after mid-gestation, compared with ovariectomized controls (in which estrogen and progesterone treatment mimic the changes observed in the SON but not the PVN in late pregnancy).[335] However, intact rather than ovariectomized controls are appropriate to seek changes due to pregnancy. Evidently, there is no reduced OTR expression in the VMN, NTS, PVN, or SON that might explain increased appetite in pregnancy.

NUCLEUS TRACTUS SOLITARII (NTS)

Some PVN oxytocin neurons project to the NTS, where oxytocin receptors are expressed,[298,303,336] and oxytocin release here interacts with CCK to enhance satiety (Figure 44.3). This release of oxytocin in the NTS following a meal is stimulated by noradrenergic neurons in the NTS that are excited by CCK and project to the oxytocin neurons in the PVN.[288,337,338] Interruption of this NTS-PVN circuit by ablating NTS neurons expressing OTR with a toxin (oxytocin-saporin conjugate) attenuates anorectic effects of CCK.[339] In late pregnancy, this NTS-PVN circuit may be suppressed by enhanced production of enkephalins by NTS neurons that presynaptically inhibit noradrenaline release in the PVN, so that CCK less effectively stimulates oxytocin neurons.[24,340]

Gastrointestinal Peptides

Cholecystokinin (CCK)

CCK secreted by the I cells in the small intestine acts centrally after a meal to limit meal size, synergizing with leptin to reduce food intake.[341] The central short-term anorectic (satiety) actions of CCK are mediated by vagal afferents and the area postrema and NTS in the medulla oblongata (Figure 44.3). CCK and leptin each electrically excites nodose ganglion neurons, and they synergize via separate receptors (CCKAR and LEPRb) on their peripheral nerve terminals and via converging postreceptor signaling mechanisms expressed by these neurons.[342]

In the NTS, CCK excites A2 noradrenergic neurons[343–347] and several types of neuron that produce peptides that modify eating, e.g., PRP, NPY, POMC, glucagon-like peptide-1 (GLP1, an anorexigen).[348] A2 neurons are important for the anorectic actions of CCK, and for activation of PVN oxytocin neurons by CCK.[337]

Prolactin-Releasing Peptide

Prolactin-releasing peptide (PrRP; 20 amino acids) is a member of the arginine and amidated phenylalanine (RFamide) peptide family.[349,350] It was identified originally as a ligand for an orphan G-protein coupled receptor (GPR 10, hGR3, or UHR-1).[349] PrRP was so named because it was found to stimulate the secretion of prolactin from lactotrophs in vitro,[351] but this is now not considered to be its function (see the section The Prolactin System: Preparation for Lactation). Instead, the function of PrRP in the brain is to negatively regulate appetite.[352–354] PrRP is produced by A1 and A2 noradrenergic neurons in the NTS, which project to the hypothalamus (including the PVN, SON, and dorsomedial region) and limbic regions, and it is also produced by neurons in the dorsomedial hypothalamus.[350,355]

Notably, PrRP-expressing neurons are activated by food intake or i.v. CCK,[345,353] and blocking central PrRP actions leads to hyperphagia.[345] There is evidence that the inhibitory actions of PrRP are mediated by CRH and oxytocin neurons.[356–358] When given by i.c.v. injection, PrRP stimulates secretion of prolactin, but it also stimulates the secretion of several other pituitary hormones including oxytocin.[359] Interestingly, NTS PrRP neurons express ER, and estradiol positively regulates NTS PrRP expression.[360,361] Hence NTS PrRP neurons might mediate the inhibitory actions of estrogen on appetite. PrRP mRNA expression in the NTS has been reported to be increased substantially in pregnancy in the rat[360] but not in the mouse,[362] and, in contrast, expression in the NTS is reduced in lactation.[353] As PrRP reduces appetite, and mRNA expression is increased in pregnancy, it seems that increased appetite in pregnancy is not explained by decreased PrRP production.

Projection targets of PrRP neurons include the PVN and SON, and they provide the route for circulating CCK to activate, for example, oxytocin neurons.[358] In nonpregnant rats, CCK given intravenously excites SON magnocellular oxytocin neurons, via a noradrenergic (A2) input from the NTS,[41,363] which stimulates somato-dendritic oxytocin release in the SON; this may be important in mediating anorectic actions of CCK.[364] In the PVN, systemic CCK also activates neurons expressing CART,[365] p-mammalian target of rapamycin (p-MTOR, associated with appetite suppression), a serine/threonine-kinase (expressed in oxytocin neurons)[366] and nesfatin (co-expressed with CRH or oxytocin).[367]

Activation by CCK of pPVN oxytocin neurons that project to the NTS is important in reinforcing the satiety actions of CCK, and these neurons are important in potentiating the anorectic actions of CCK by leptin.[288,338] CCK also alters the firing activity of VMN neurons, predominantly inhibiting, but whether this involves oxytocin is not known.[368]

Leptin-CCK Interactions

Synergy between CCK and leptin, as seen in vagal afferents, does not extend to actions in the PVN or SON, indicating that leptin acts also by another pathway[369] or perhaps directly on magnocellular oxytocin neurons.[266]

CCK is consistently found not to activate arcuate neurons, but leptin signaling in the arcuate nucleus is important for normal satiety actions of CCK via the NTS, perhaps via α-MSH/MCR4 signaling in the PVN or lateral hypothalamus.[370] Also important for satiety actions of CCK are interactions between α-MSH/MCR4 signaling and vagal input, via N-methyl-D-aspartate (NMDA) receptors, in the NTS.[344,371] CCK activates the ERK cascade in NTS neurons, which is necessary for the satiety effects of CCK[372] and for convergence with α-MSH/MCR4 signaling.[373] Notably, leptin evidently acts directly on NTS POMC neurons,[374] which, together with neurons expressing GLP1 or CCK, are the only NTS neurons that express LEPRb.[375] Leptin does not interact with CCK at the level of the VMN.[368]

CCK Resistance in Pregnancy

In the context of leptin resistance, CCK does not reduce food intake in pregnancy.[376] This may be because CCK is less effective in activating oxytocin neurons in late pregnancy,[377] which likely involves reduced noradrenaline release in the SON.[378] The reduced activation of NTS neurons by CCK in day 14 pregnant rats and the absence of activation of SON and PVN neurons (contrasting with CCK's actions in nonpregnant rats)[376] support this explanation. Importantly, CCK activates only oxytocin neurons in the SON,[41] and in the PVN it activates parvocellular and magnocellular oxytocin neurons, but not in day 14 pregnant rats.[376] Central (possibly in the NTS) or vagal leptin resistance (as seen in DIO),[187,188] may underlie the lost action of CCK on oxytocin neurons in late pregnancy. It is also possible that this is explained by μ-opioid inhibition acting on oxytocin neurons, or on the noradrenergic input from NTS A2 neurons, which emerges in late pregnancy and inhibits dendritic oxytocin release as well as firing rate responses.[24,340] This inhibited stimulation of oxytocin neurons by CCK in late pregnancy may have the same consequences for increased appetite (and sodium retention) as the reduced leptin sensitivity of oxytocin neurons discussed previously.[266]

Like CCK, peptide YY (PYY) is an anorexigen secreted by the intestine after a meal, and PYY levels are increased in pregnant rats.[217] The finding in pregnancy of increased circulating levels of PYY (an anorexigen), together with increased food intake, indicate evident resistance to the anorexic actions of PYY in pregnancy; whether this involves altered responsiveness of NPY neurons to inhibitory actions of PYY is not known.

Reward Circuitry: Opioids and Food Intake

Hedonic appetite is motivation that may be a coping response to stress to eat preferentially palatable, energy-rich food for pleasure, in excess of need to maintain metabolic homeostasis.[379,380] Hedonic appetite is regulated by the mesolimbic dopaminergic reward system, comprising the ventral tegmental area (VTA) and nucleus accumbens (NAc) with connections to the central nucleus of the amygdala (CeA), frontal cortex, and bed nucleus of the stria terminalis (BNST) (see the section Maternal Behavior).[381] This network nonetheless has important interactions with the homeostatic networks, based in the NTS and hypothalamus. Hence, for example, ghrelin has appetite-stimulating actions through both the reward and hypothalamic networks.[146] The reward network is also key in organizing maternal behavior (see the section Maternal Behavior).[382]

It has been known for over 40 years that endogenous opioids are involved in short-term positive regulation of appetite, following reports of inhibitory actions of naloxone, an opioid receptor antagonist, and subsequent reports of stimulatory actions of centrally administered opioid peptides.[383,384] Although all three opioid receptor types are involved, predominant actions via μ-opioid receptors at multiple sites in pathways regulating hedonic appetite have been identified.[381] Within the hedonic reward system, a μ-selective synthetic enkephalin-like opioid [D-Ala(2), NMePhe(4), Gly-ol(5)]enkephalin (DAMGO) acts in both the VTA and NAc to increase feeding, and naltrexone (long-acting form of naloxone) given into either site blocks the effects of DAMGO in the other.[385] Similar experiments demonstrate μ-opioid-mediated interactions between the VTA and PVN to increase feeding.[386] Moreover, DAMGO given into the CeA inhibits CeA neurons, then excites NAc (shell) neurons and increases feeding.[387] In particular, DAMGO injection into the NAc stimulates high fat diet intake, but this effect involves excitatory projections to hypothalamic orexin neurons and requires orexin action in the NAc or VTA;[388] these findings illustrate the interaction between hypothalamic homeostatic and mesolimbic hedonic regulation of food intake.[381]

Opioids and the NTS

Importantly, the reward network connects to the hypothalamic network via the lateral hypothalamus (LHA) and the NTS (Figure 44.3). Microinjection experiments have shown reciprocal interactions between μ-opioid actions on feeding in the NTS and VTA.[389] In the NTS, POMC neurons (identified by green fluorescent protein (GFP) expression in transgenic mice) are activated by CCK (local or systemic) and inhibited by met-enkephalin. These POMC neurons may have local effects, via α-MSH and MCR4 in the NTS, and their inhibition by enkephalin could contribute to stimulation of feeding through NTS connections to the CeA and NAc.[343] As discussed elsewhere (see the sections The Hypothalamo-Pituitary-Adrenal Axis and Magnocellular Oxytocin Neuron System in Pregnancy), pro-enkephalin-A (*Penk-a*) gene expression is increased in the NTS in late pregnancy,[21] but any impact on hedonic food intake has not been studied.

Opioids and Hypothalamic Circuitry

Stimulation of feeding by NPY injection into the PVN is inhibited by naltrexone injection into the medial NTS, reflecting opioid support of NPY actions via reciprocal PVN-NTS interactions.[390] Moreover, microinjection studies of effects of naltrexone and DAMGO on feeding show reciprocal μ-opioid-mediated stimulation in the PVN and VTA.[386] The powerful stimulatory action on feeding of centrally administered NPY is reduced by μ, δ, and κ-opioid receptor antagonists.[391] Similarly, stimulation of feeding by i.c.v. administration of orexin, but not MCH, is reduced by naloxone.[392] In late pregnancy, i.c.v. injection of NPY still evokes an eating response similar to that in virgin rats,[259] and the inhibition by naloxone of NPY-stimulated feeding seen in nonpregnant rats[391] is exaggerated in late pregnancy (Bales J, Brunton PJ, Russell JA, unpubl.). This may reflect upregulation of endogenous opioid mechanisms in the brain, including in the NTS, in late pregnancy.[21,24,340,393,394]

ARCUATE NUCLEUS

The number of arcuate neurons expressing POMC mRNA (in the caudal arcuate) or immunoreactive for β-endorphin is increased near the end of pregnancy, and the number of β-endorphin fibers in the SON is also increased. Estradiol and progesterone actions may underlie this change as arcuate β-endorphin neurons express PR.[244,395–397] Whether this reflects a switch to processing POMC to β-endorphin, with reduced α-MSH production is not known. Such a switch could enhance opioid inhibition of oxytocin neurons, including dendritic release, as emerges near the end of pregnancy,[24] and might reduce stimulation of dendritic oxytocin release by α-MSH.[308] However, β-endorphin knockout mice are hyperphagic, and retain normal feeding responses, respectively, hyper- and hypophagic, to other opioids and to the antagonist naloxone.[398] Together, these findings do not indicate a role for β-endorphin regulation of oxytocin neurons in appetite control, at least without pregnancy.

ENKEPHALINS

Another way in which opioids may increase appetite is by inhibiting oxytocin release in response to anorexigens. During the last half of pregnancy, in rats, magnocellular oxytocin neuron responses to input from the NTS (including stimulation of this input by CCK) are inhibited by

emergence of opioid inhibition.[24,394,399] Importantly, central release of oxytocin is restrained by an endogenous μ-opioid mechanism in late pregnancy.[24] This is likely to be a result of stimulation by allopregnanolone of increased expression of *Penk-a* and μ-opioid receptor (MOR, *Oprm1*) mRNAs in NTS neurons, with consequent presynaptic inhibition of noradrenaline release in the PVN and SON.[21,340]

In addition, allopregnanolone, present in the brain at high levels in late pregnancy, directly inhibits activity of magnocellular neurons.[400] Clearly, this could contribute to reducing oxytocin neuron responses to anorexigens; however, testing an allopregnanolone-opioid link by systemic naloxone administration results in reduced food intake, similar to that seen in nonpregnant rats.[109] This outcome is not conclusive, as systemic naloxone reduces hedonic appetite, as discussed earlier, which may obscure a selective action on food intake of blocking the established inhibitory action of opioid on dendritic oxytocin release in pregnancy.[24]

Summary and Conclusions

Possible changes in pregnancy to explain increased food intake and consequent increased energy storage have been considered in the context of the neural circuitry in the hypothalamus and brain stem that homeostatically regulates appetite, the mesolimbic circuitry regulating hedonic appetite, and the actions of circulating hormones on or in this circuitry. In early pregnancy, increasing progesterone secretion stimulates food intake (offsetting an inhibitory action via stimulation of arcuate POMC neurons by estrogen). The hypothalamic circuitry involves neurons that use many signaling peptides and GABA to increase or decrease food intake and energy storage and utilization. In mid- to late pregnancy, first-order arcuate NPY/AgRP neurons (which increase food intake and energy storage) may be more active. These neurons are normally negatively regulated by leptin, secreted in increasing amounts as the adipose store increases. At the level of the hypothalamus there is leptin resistance (reduced postreceptor signaling) in pregnancy, but contrary to expectation, signaling (STAT3 induction) by leptin is evidently intact in the arcuate NPY/AgRP and POMC (α-MSH) neurons (which decrease appetite and increase energy expenditure). Other post-LEPRb signaling pathways still need to be examined. Instead, leptin resistance (with reduced LEPRb expression) is found in second-order neurons (i.e., targets for α-MSH), in the PVN and VMN (satiety center) during pregnancy, which seems to be induced by the high levels of prolactin. Importantly, the anorectic actions of α-MSH are lost (α-MSH resistance) in pregnancy. Oxytocin has central anorectic actions; pPVN neurons project within the brain, including to the NTS, while magnocellular oxytocin neuron dendrites release oxytocin (when stimulated by α-MSH), which may diffuse to target neurons expressing OTR. In pregnancy, suppression of responses of pPVN and magnocellular PVN and SON neurons to feeding stimuli (e.g., NPY, CCK) and leptin is a strong candidate mechanism for increased food intake in pregnancy, as is resistance to the anorectic actions of oxytocin. The NTS integrates vagal input (e.g., conveying signals about circulating CCK) and input from the PVN (e.g., from oxytocin neurons), and NTS neurons signal satiety via noradrenaline, GLP1, and PrRP to the hypothalamus (e.g., to oxytocin neurons). Oxytocin neurons are evidently resistant to excitation by CCK signaling via the NTS in late pregnancy, which will act to increase eating. This resistance may involve reduced CCK action on vagal afferents as a consequence of leptin resistance and loss of synergy with leptin. Also, CCK resistance may be a result of activation of an endogenous opioid inhibitory mechanism on NTS inputs to oxytocin neurons.

Future Perspectives

Many aspects of altered appetite regulation in pregnancy remain to be investigated. These include the possibility of: altered serotonin and eCB actions in the hypothalamic homeostatic circuitry regulating appetite and metabolism; a role for low adiponectin levels in pregnancy in central control of altered energy balance; a role for the high levels of allopregnanolone; reduced nesfatin and increased relaxin-3 production in the brain; and reduced GLP1 production in the NTS and plasticity of PVN-NTS connections in pregnancy, especially of oxytocin actions. The significance of reported increased expression of PrRP (an anorectic peptide) in the NTS in pregnancy needs clarification. Testing roles for upregulated endogenous opioid expression in resetting the homeostatic and hedonic neural networks regulating appetite and metabolism is difficult because of opposite, but complementary, opioid actions on these networks. This will need focal exploration of possible roles of opioids at specific nodes in these networks with available novel techniques. It is possible that the experience of increased food intake and metabolic changes in pregnancy leaves epigenetic traces in hypothalamic and mesolimbic circuitry as in DIO, with enduring effects on appetite and metabolism.[401]

THE PROLACTIN SYSTEM: PREPARATION FOR LACTATION

In the 1920s, several researchers studying several species established that anterior pituitary extracts could induce lactogenesis.[402] Subsequently, Riddle et al.[403] isolated prolactin from the anterior pituitary and reported that it acted distinctly differently from other hormones known at the time. Prolactin is a peptide hormone (197 amino acids in rats; 199 amino acids in humans)[17,403] produced by lactotroph cells in the anterior pituitary gland.

Prolactin has an essential role in lactation by stimulating milk production and secretion in the mammary gland alveoli; in pregnancy prolactin acts on the alveoli to prepare for milk production. Accordingly, the secretion of prolactin is greatly increased in late pregnancy in the rat (Figure 44.1), and in women prolactin secretion increases continually through pregnancy (in late pregnancy by c. 20-fold from prepregnancy values).[404]

In the rat prolactin has an essential role in early pregnancy in preventing luteolysis, and hence in sustaining progesterone secretion for the pregnancy. Prolactin has many other actions,[17,405] of which a role in the initiation of maternal behavior and in appetite regulation are relevant to this chapter (see the sections Food Intake and Metabolism in Pregnancy and Maternal Behavior).

Prolactin secretion is under the control of the brain through the production and release of prolactin release inhibiting (PIF) and prolactin releasing factors (PRF; Figure 44.5). Unlike other anterior pituitary hormones, the predominant control of prolactin secretion is by a PIF. This is well established to be dopamine, produced and secreted by hypothalamic dorsomedial arcuate nucleus neurons (A12, tubero-infundibular dopamine: TIDA neurons; tubero-infundibular refers to this brain region in humans). Without pregnancy and lactation, the secretion of prolactin is restrained by tonic dopamine secretion into the hypothalamo-hypophysial portal system.[16] Dopamine is synthesized from tyrosine, which tyrosine hydroxylase (TH; rate-limiting enzyme, constitutively active in TIDA neurons) converts to L-dihydroxyphenylalanine (L-DOPA), from which dopamine is formed by DOPA decarboxylase action. DOPA is stored in secretory granules and released by exocytosis from axon terminals in the median eminence when the neurons are active. Dopamine is inactivated enzymatically by monoamine oxidase (MAO) and catechol-*O*-methyl transferase (COMT), and there is a reuptake mechanism.[16] In the anterior pituitary dopamine acts primarily on D2 receptors (a 7-transmembrane domain G-protein linked receptor) on lactotrophs, which mediate continual inhibition of prolactin production.[16] Hence, prolactin secretion is stimulated when dopamine secretion by TIDA neurons is inhibited, or when secretion of a PRF is increased, or both occur (see also Chapter 12).

There are major adaptive changes in the brain in pregnancy in the mechanisms regulating prolactin secretion that permit exposure of peripheral and brain targets to high levels of prolactin in early and late pregnancy, while there are high levels of placental lactogen from mid-pregnancy (Figure 44.1).[406]

Regulation of TIDA Neurons

Multiple neurotransmitters and modulators are involved in regulating TIDA neurons (Figure 44.5),[17] as is

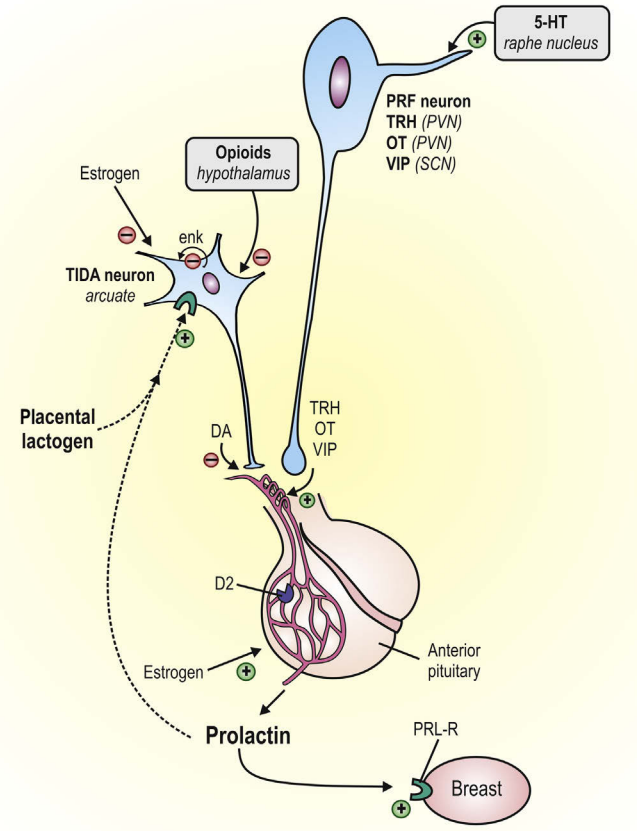

FIGURE 44.5 The hypothalamo-pituitary prolactin system. In nonpregnant, nonlactating animals prolactin secretion is under tonic inhibition by dopamine (DA) produced by tubero-infundibular dopamine (TIDA) neurons in the hypothalamus and secreted into the hypothalamo-hypophysial portal system to act on dopamine D2 receptors on the lactotrophs. TIDA neurons are inhibited by endogenous opioid peptides, which can thus stimulate prolactin secretion. There are several candidate prolactin releasing factors (PRFs), including thyrotropin-releasing hormone (TRH) and oxytocin (OT) produced in the parvocellular division of the paraventricular nucleus (PVN) and vasoactive intestinal peptide (VIP) produced by neurons in the suprachiasmatic nucleus (SCN), which stimulate prolactin secretion. PRF neurons are activated by serotoninergic (5-HT) inputs from the raphe nucleus. Estrogen sensitizes the pituitary to release prolactin and also inhibits dopamine synthesis in TIDA neurons. Prolactin can enter the brain by being transported across the blood–brain barrier via a specific transport mechanism. Prolactin feedback is important in maintaining the rhythm in prolactin secretion once it is established in early pregnancy (see Figure 44.1). Prolactin acts via prolactin receptors (PRL-R) in a short feedback loop to stimulate dopamine production by TIDA neurons. From mid-pregnancy increasing production of placental lactogen (not controlled by the brain) acts like prolactin to stimulate TIDA neurons, which eventually become resistant to stimulation, so that prolactin secretion surges near the end of pregnancy (Figure 44.1). Enkephalins (enk) produced by the TIDA neurons near the end of pregnancy may contribute to this surge by auto-inhibiting the TIDA neurons. In late pregnancy prolactin prepares the mammary glands for milk secretion.

the case for other hypothalamic neuroendocrine neurons. Hence, many of these agents given into the brain may alter prolactin secretion through such actions on TIDA neurons.

Prolactin Receptor

There is a single prolactin receptor (PRL-R, found as the long or short form), which is a membrane-bound protein of the cytokine receptor superfamily.[407] The long form (PRL-R_L, the active signaling form) and the short form of the PRL-R (PRL-R_S), result from alternative mRNA splicing from a single gene; the two forms of the receptor have different intracellular domains.[407] Prolactin has important "short-loop" feedback actions on TIDA neurons, via PRL-R_L, increasing *Th* mRNA expression and resulting in increased dopamine production and hence decreased prolactin secretion.[408] Phosphorylated signal transducer and activator of transcription 5b (pSTAT5b) is an essential mediator of prolactin actions on TIDA neurons,[409,410] and, assessed by pSTAT5 induction, these neurons show greater sensitivity to prolactin than all other neurons that respond to prolactin.[265]

Placental Lactogen

In late pregnancy, placental lactogen action results in a sustained increase in dopamine secretion, hence inhibiting prolactin secretion.[406]

Endogenous Opioid Peptides

TIDA neurons are inhibited by endogenous opioid peptides, which thus stimulate prolactin secretion; both μ- and κ-opioid receptors are involved in pregnancy.[411,412] Indeed, in early pregnancy nocturnal prolactin surges are blocked by naloxone, indicating an important role for an endogenous opioid mechanism in permitting the surges.[413] The identity of the opioid peptide mediating this action is not clear: TIDA neurons are contacted by dynorphin and met-enkephalin axons, especially the former.[414]

Estrogen

Exposure to estrogen induces a prolactin surge in the rat, which involves inhibition of TH in TIDA neurons.[415]

Prolactin Releasing Factors

By definition, a hypothalamic releasing factor is secreted from neuroendocrine neuron axon terminals adjacent to primary capillaries in the median eminence of the hypothalamo-hypophysial portal vessel system and acts in the anterior pituitary gland to regulate secretion of an anterior pituitary hormone.[416,417] Hence a range of criteria, including functional importance, must be satisfied to identify a hypothalamic product as a releasing factor or a release-inhibiting factor. There are several candidate PRFs: thyrotropin releasing hormone (TRH), oxytocin, vasoactive intestinal peptide (VIP), and prolactin releasing peptide (PrRP).[17]

Thyrotropin Releasing Hormone

Besides being a hypothalamic-releasing factor that stimulates thyrotropin (thyroid stimulating hormone; TSH) secretion from the anterior pituitary (and the first releasing factor to be characterized),[416] TRH also stimulates prolactin secretion and the secretion of several other hormones.[418] In mammals TRH is produced by neurons in several hypothalamic areas, but TRH neurons in the pPVN are those involved in control of PRL secretion.[419,420] As a PRF, TRH is distinctive as it can stimulate prolactin secretion in the presence of dopamine inhibition.[421]

Oxytocin and Vasoactive Intestinal Peptide

These peptides are both present in portal blood and can stimulate prolactin secretion from lactotrophs in the absence of dopamine inhibition.[421] Vasoactive intestinal peptide (VIP) is also produced by suprachiasmatic nucleus (SCN) neurons that project to TIDA and oxytocin neurons, and these central projections may mediate the important actions of VIP in the regulation of prolactin secretion, acting via the oxytocin neurons.[422]

Prolactin Releasing Peptide

PrRP was so named because it was found to stimulate the secretion of prolactin from lactotrophs in vitro,[351] but this is a misnomer as it is not present in the ventral hypothalamus, where classical releasing factors are found, and it does not satisfy criteria for a releasing factor.[350] However, PrRP has important functions in the brain; it is produced by NTS neurons[355] and is involved in HPA axis stress responses and in appetite control (see the section Food Intake and Metabolism in Pregnancy).[354,423]

Control of Prolactin Surges in Early Pregnancy

As a result of copulation in the rat, the lifespan of the corpora lutea is extended by the reflex stimulation of secretion of a luteotropic complex (luteinizing hormone and prolactin) by the anterior pituitary gland. A circadian pattern of once-daily (diurnal) and once-nightly (nocturnal) pulses of prolactin is triggered, which contributes to maintenance of the corpora lutea for the first half of pregnancy (10–12 days; Figure 44.1). If the mating is sterile, the same events occur, leading to pseudopregnancy.[424] This stimulation of prolactin secretion in early pregnancy is considered to require action of PRF(s) as well as withdrawal of inhibition by dopamine.[17]

Studies to understand the mechanisms controlling prolactin secretion in early pregnancy in the rat have involved experimental models with normal or sterile mating, cervical stimulation (simulating mating), and hormone manipulations in ovariectomized rats. Measurements in hypothalamo-hypophysial portal blood in ovariectomized rats made hyperprolactinemic by implanting donor anterior pituitaries under the renal capsule indicated

stimulation of dopamine and oxytocin release, and inhibition of VIP release.[425] Outcomes of studies on the aforementioned models indicate that several mechanisms are involved in the control of prolactin release in early pregnancy. Experimental data from studies on VIP, oxytocin, and TIDA dopamine neuron activities have been mathematically modeled to understand how interactions among these neurons act as a pacemaker and organize the circadian pattern of prolactin secretion that is seen during early pregnancy or in pseudopregnancy.[426–428]

Oxytocin

A key response to copulation is secretion of oxytocin from the posterior pituitary gland, and simulation of this oxytocin release (5 μg i.v., a large dose, see footnote a) triggers the daily and nightly surges of prolactin seen in early pregnancy.[427,429] However, it seems unlikely that oxytocin action on the lactotrophs is responsible for triggering formation of the central "memory" that sustains this pattern; nor is central action of prolactin likely, nor an action of TRH on lactotrophs.[430,431] Evidently, the action of oxytocin in triggering this neuroendocrine memory depends on intact pelvic nerves, as does the triggering of the luteotropic prolactin pulses.[431] Whether this means that uterine responses to oxytocin are necessary for triggering the diurnal prolactin pulses by copulation is not clear. The central pathway for effects of cervical stimulation involves brain stem noradrenergic input to the PVN.[432] The central mechanism for the "memory" that patterns prolactin secretion in early pregnancy in the rat is not yet clear,[428] although central release and action of oxytocin in the VMN is evidently important.[433]

Vasoactive Intestinal Peptide

The prolactin secretory pattern induced by pharmacologically reducing dopamine tone that is similar to the pattern in early pregnancy is determined by changes in circadian VIP release by SCN neurons in the hypothalamus (i.e., VIP not acting as a releasing factor), which project to and inhibit TIDA dopamine neurons.[434,435] Importantly, the diurnal and nocturnal prolactin increases involve VIP stimulation of oxytocin secretion, and the diurnal prolactin surge involves stimulation of oxytocin secretion also by serotonin (acting in the hypothalamus).[426,436]

Thyrotropin Releasing Hormone

Exogenous TRH has been reported to most effectively stimulate prolactin during the peaks in early pregnancy, and is less effective from mid-pregnancy.[437] However, the circadian prolactin pattern in early pregnancy is not induced by TRH.[431]

Negative Feedback by Prolactin

Prolactin can enter the brain by being transported across the blood–brain barrier into CSF via a specific transport mechanism, involving PRL-R expressed in the choroid plexus.[438,439] PRL-R (long isoform) expression in the choroid plexus is increased by high levels of estrogen in pregnancy, which facilitates the entry of prolactin into the brain.[440,441]

TIDA Neurons

Acting via TIDA neurons, such that prolactin stimulates dopamine production, prolactin feedback is well established to be important in maintaining the rhythm in prolactin secretion once it is established in early pregnancy.[427,429,430] Prolactin acts by upregulating TH gene expression, and by inducing phosphorylation of TH, prolactin prevents inhibition of TH by dopamine.[410] Although the "memory" triggered by oxytocin administration in ovariectomized rats does not involve central prolactin action,[431] in mated rats central prolactin action does seem to be responsible for triggering the surges of prolactin.[430]

Oxytocin Neurons

The models of regulation of oxytocin neurons in the context of control of prolactin secretion involve prolactin stimulating[429] or inhibiting oxytocin neurons.[428] Neurons in the PVN and SON, and specifically most oxytocin neurons, express PRL-R,[427,439,442] with increased numbers of oxytocin neurons in the PVN expressing PRL-R in pregnancy.[267] Prolactin has direct prolonged inhibitory actions on the electrical activity of PVN and SON magnocellular oxytocin neurons, in vivo and in vitro;[267,443] hence prolactin will act to inhibit oxytocin secretion from the posterior pituitary as this is tightly related to action potentials arriving from the oxytocin neuron cell bodies. Nonetheless, in vitro prolactin has been found to increase oxytocin mRNA content in the basal hypothalamus.[444] There may be other prolactin actions on oxytocin neurons via postreceptor signaling mechanisms; the long form of PRL-R signals via the JAK/STAT pathway, and magnocellular oxytocin neurons, express STAT5.[445] However, at least without pregnancy, oxytocin neurons demonstrate less sensitivity to prolactin than TIDA neurons, as assessed by STAT5 induction; interestingly, pPVN oxytocin neurons are more sensitive to prolactin than magnocellular oxytocin neurons.[265]

Control of Prolactin Secretion from Mid-Pregnancy: Preparation for Lactation in Late Pregnancy

Placental Lactogens Take Control

In mid-pregnancy the placenta begins to produce lactogens (I and II; Figure 44.1, Figure 44.5), which are chemically similar to prolactin, with similar actions via prolactin receptors, and henceforth placental lactogens predominate.[17] As placental lactogen production is not regulated by

the maternal brain, its actions on the maternal mechanisms regulating prolactin secretion become important. Hence central actions of increasing levels of lactogens on TIDA neurons, stimulating dopamine release, lead to suppression of prolactin secretion from around mid-pregnancy (Figure 44.1).[446] Such stimulation of TIDA neurons by placental lactogen[447] is incorporated in a mathematical model of changes in prolactin control in pregnancy.[427]

Prolactin Secretion Returns in Late Pregnancy

During the night before parturition, prolactin secretion surges again (Figure 44.1). This late pregnancy pattern in the rat is more like that seen throughout pregnancy in women.[448]

ESCAPE FROM INHIBITION

This prolactin surge in the rat indicates escape from the sustained inhibition by dopamine, due to reduced responsiveness of TIDA neurons to stimulation by placental lactogen, and consequent lack of increased dopamine production with the increased prolactin secretion.[449–451] This reduced sensitivity to feedback actions of prolactin, involving loss of STAT5b induction by prolactin, and hence reduced dopamine production, is attributable to upregulation of suppressors of cytokine signaling (SOCS) proteins in the TIDA neurons.[452] Estrogen and progesterone are importantly involved in these changes: TIDA neurons express ERα and PR, without significant changes near the end of pregnancy.[453] Progesterone withdrawal near the end of pregnancy permits the high levels of estrogen and prolactin at this time to upregulate expression of three SOCS mRNAs (*Socs1*, *Socs3*, and cytokine-inducible SH2-containing protein, *Cish*) in the arcuate nucleus.[454] As STAT5b signaling is suppressed, induction by prolactin of SOCS mRNAs at this stage may involve signaling by alternative post-PRL-R mechanisms, for example, by MAPK.[454]

ENDOGENOUS OPIOID ACTIONS

Hyperprolactinemia, with progesterone support as in pregnancy, results in enkephalin gene expression in TIDA neurons, which may be involved in autoregulation of these neurons.[455,456] There are also dynorphin and β-endorphin fibers in the vicinity of TIDA neurons that may mediate opioid inhibition.[414] Strikingly, naloxone infusion in late pregnancy enhances TIDA neuron activity and blocks the prepartum surge in prolactin secretion.[457] Hence, opioid action on TIDA neurons has an important role in permitting the prolactin surge at the end of pregnancy, as well as permitting nocturnal surges at the beginning.[413]

POSSIBLE PRF ROLE

Removal of the posterior pituitary (including the intermediate lobe) prevents the prolactin surge at the end of pregnancy; this indicates that a PRF from the posterior pituitary might be important in driving the surge. This is not oxytocin but might be VIP.[458,459]

The mechanisms governing the final surge of prolactin secretion at the end of pregnancy appropriately ensure that sufficient prolactin is circulating to trigger bulk milk secretion and, after entry into the brain, with other mechanisms, promote maternal behavior after birth of the young.

Summary and Conclusions

The TIDA neurons form the hub in the hypothalamus through which prolactin secretion is predominantly regulated, with dopamine acting as a PIF. Without pregnancy, TIDA neurons are tonically active and prolactin stimulates these neurons, hence inhibiting its own release via this negative feedback loop. However, in early pregnancy in rats, TIDA neurons are inhibited by endogenous opioids, and PRF neurons are recruited to the hub. These oxytocin and VIP neurons sustain pulsatile prolactin secretion, which has important luteotropic actions (Figure 44.1). This pattern continues for a few days, reflecting a neuroendocrine memory for the initial trigger, copulation. Later in pregnancy, increasing placental lactogen secretion, which is not regulated by the brain, intercedes to stimulate TIDA neurons and thus suppress prolactin secretion. Subsequently, the TIDA neurons develop lactogen and prolactin resistance, which involves estrogen and progesterone actions, and in late pregnancy TIDA neurons express opioids, which are presumptively auto-inhibitory. Hence prolactin secretion finally surges at term.

Future Perspectives

PRP can stimulate prolactin release, but the location of PRP neurons in the brain does not fit a physiological role for PRP in direct regulation of prolactin secretion. It is an open question whether in pregnancy a specific prolactin-releasing factor is involved other than oxytocin and VIP (TRH is evidently not important). The importance and direction of prolactin actions on oxytocin neurons in pregnancy needs clarification, as does whether enkephalins expressed by TIDA neurons in late pregnancy auto-inhibit these neurons. The mechanisms in the hypothalamus involved in the neuroendocrine memory of mating await exploration. Computer-based modeling should continue to aid understanding of the changing control of prolactin secretion in pregnancy.

THE HYPOTHALAMO–PITUITARY–ADRENAL AXIS

The hypothalamo–pituitary–adrenal (HPA) axis plays a crucial role in restoring homeostasis following stressful stimuli. The concept of biological stress was first introduced

by Hans Selye in 1936,[460] who described the general adaptation syndrome, defined as "the sum of all non-specific, systemic reactions of the body which ensue upon long continued exposure to stress." In the early 1950s, Geoffrey Harris demonstrated in rabbits that stress-induced adrenocorticotropic hormone secretion was controlled by the hypothalamus acting through the hypophysial portal vessels of the pituitary stalk,[461] and soon after Guillemin (a former student of Selye) demonstrated the existence of a hypothalamic factor, coined corticotropin-releasing factor (CRF), that elicited ACTH release from the anterior pituitary gland in rats.[462] However, it was not until the early 1980s that the 41-amino acid peptide, CRF (or corticotropin releasing hormone; CRH) was finally identified and characterized by Wylie Vale and colleagues.[463] We now know that in response to stressors, whether physical or emotional, neurons in the medial parvocellular division of the PVN that synthesize CRH (and in some cases co-express arginine vasopressin; AVP) are activated and secrete CRH and/or AVP from their nerve terminals in the median eminence into the hypothalamo-hypophysial portal blood (Figure 44.6). CRH and AVP act synergistically on their receptors (CRH-R1 and V1b, respectively) in the anterior pituitary to stimulate ACTH secretion, which in turn triggers glucocorticoid (corticosterone or cortisol, depending on species) synthesis and secretion from the adrenal cortex. Glucocorticoids facilitate appropriate stress responses by promoting energy mobilization,[464] cardiovascular,[465] immune,[466] and behavioral responses,[467] as well as exerting negative feedback via glucocorticoid (GR; *Nr3c1*) and mineralocorticoid receptors (MR; *Nr3c2*) in the brain, or anterior pituitary (GR), to terminate the HPA axis response.[468]

Exposure to stress during pregnancy can affect the development of physiological systems in the offspring, resulting in increased susceptibility to cardiovascular[469] and metabolic disease[470] and to affective disorders in adulthood,[471] a phenomenon termed *fetal programming*. There are, however, "in-built" mechanisms that protect the fetus from this potentially detrimental programming. As a last line of defense, the placenta expresses 11β-hydroxysteroid dehydrogenase type 2,[472] an enzyme that by converting corticosterone to inert 11-dehydrocorticosterone, acts as a barrier to limit exposure of the fetus to circulating maternal glucocorticoids. A first line of defense is provided by reduced responsiveness of the maternal HPA axis. This acts to buffer the impact of stress, hence reducing fetal exposure to excessive glucocorticoids and minimizing the risk of detrimental programming,[471] while also promoting the anabolic adaptations in the mother necessary for successful pregnancy.[129]

Basal Activity of the HPA Axis in Pregnancy

During early pregnancy in rats, the circadian variation in ACTH and corticosterone secretion is suppressed

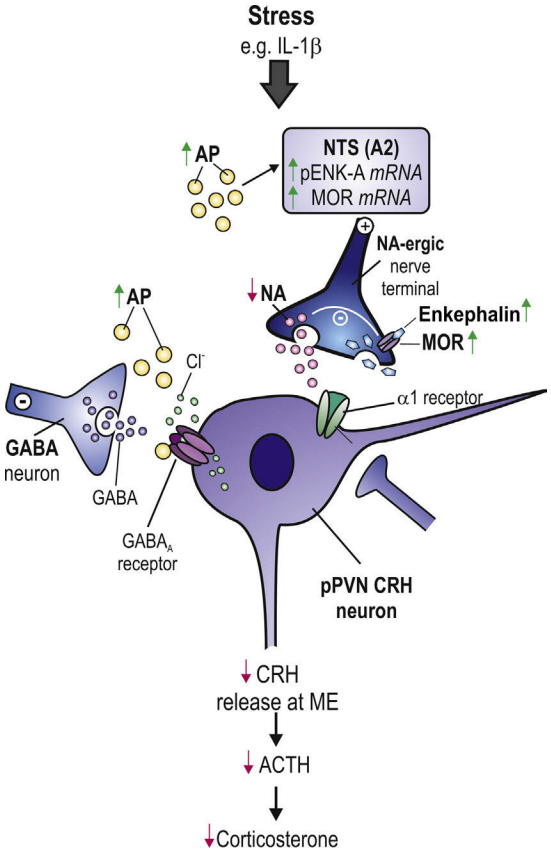

FIGURE 44.6 Allopregnanolone-opioid mechanisms involved in suppressed hypothalamo-pituitary-adrenal (HPA) axis responses to stress in pregnancy. Brain and circulating levels of allopregnanolone (AP) are increased (↑) in pregnancy (see Figure 44.1). In brain stem nucleus tractus solitarii (NTS) neurons, mRNA expression for proenkephalin-A (*Penka*) and μ-opioid receptor (MOR; *Oprm1*) is increased in pregnancy, as a result of increased AP production. Noradrenergic A2 neurons in the NTS project to parvocellular corticotropin-releasing hormone (CRH) neurons in the paraventricular nucleus (PVN). Noradrenaline (NA) released in the PVN excites the CRH neurons via α1 adrenoceptors, CRH is released at the median eminence (ME) and is carried in the hypothalamo-hypophysial portal system to stimulate anterior pituitary corticotrophs to secrete adrenocorticotropic hormone (ACTH), which stimulates glucocorticoid secretion (corticosterone in rodents; cortisol in humans) by the adrenal glands. In pregnancy, systemic interleukin-1β treatment (a stressor) fails to evoke noradrenaline release from the terminals in the PVN, hence ACTH and corticosterone secretion are not stimulated, unlike before pregnancy. This is a result of increased opioid inhibition (by enkephalin) acting presynaptically on the upregulated MOR, presumptively on the noradrenergic nerve terminals. In addition, AP may inhibit CRH neurons by positively modulating GABA inputs to the PVN via actions on $GABA_A$ receptors; AP prolongs the opening time of chloride (Cl^-) ion channels, enhancing inhibitory GABA neurotransmission.

and levels at the daily midpoint of the circadian range are reduced.[473] Salivary cortisol levels are also generally lower in women during early pregnancy compared with late pregnancy.[474,475] Reduced glucocorticoid secretion in early gestation has been suggested to facilitate implantation since elevated salivary cortisol levels in women at 1–3 weeks post conception have been associated with miscarriage.[476]

In the second half of pregnancy in the rat, basal levels of circulating corticosterone steadily increase, despite ACTH secretion remaining strongly suppressed.[473] This is a result of increased sensitivity of the adrenal gland to ACTH, probably as a consequence of estrogen actions on the adrenal cortex.[477,478] Similarly, basal cortisol levels progressively increase in the second half of gestation in women.[479]

Metabolic clearance of corticosterone is sustained at prepregnancy levels throughout gestation,[480] however, the total amount of free corticosterone declines in pregnancy, as a result of an increase in circulating corticosterone binding globulin (CBG), an adaptation seen in rats[481] and mice.[482]

In the brain, *Crh* and *Avp* mRNA expression in the PVN and *Gr* (*Nr3c1*) and *Mr* (*Nr3c2*) mRNA expression in the PVN and hippocampus are unaltered in early pregnancy.[483] Anterior pituitary ACTH content and the expression of mRNA for its precursor, POMC, is also unaltered in the first half of pregnancy.[484] However, in late pregnancy, basal expression of *Crh* mRNA and *Avp* mRNA in the pPVN are reduced,[483] concomitant with reduced median eminence CRH content and anterior pituitary *Pomc* mRNA and CRH receptor-type 1 (CRH-R1; *Crhr1*) mRNA expression.[484] These adaptations reflect reduced forward drive of the HPA axis in late pregnancy.

HPA Axis Responses to Stress in Pregnancy

In the first half of pregnancy in rodents, ACTH and corticosterone responses to acute stressors remain similar to those of nonpregnant females,[20,485,486] even though CRH release may already be reduced.[20] In contrast, the experience of "chronic stressful life events" during early pregnancy in women blunts peak salivary cortisol levels in morning samples, without affecting evening (nadir) levels.[474]

The responsiveness of the HPA axis to stress is markedly reduced in late pregnancy. In rodents, this is found for psychological stressors such as exposure to a novel environment[20,482] or restraint;[19] physical stressors, including those that mimic infection, e.g., endotoxin[340] or cytokine administration;[340] and stressors that comprise both psychological and physical elements, e.g., forced swimming,[20,482,484,487] including those with ethological relevance, e.g., social stress.[488] In each case, reduced responsiveness of the HPA axis is indicated by attenuated ACTH and corticosterone secretion,[19,20,340,482,487] and where tested, is associated with reduced, or absent, stimulation of *Crh* and/or *Avp* mRNA expression in the pPVN neurons,[340,489] indicating reduced central drive of the HPA axis by the CRH/vasopressin neurons in late pregnancy. In rats reduced HPA axis responses to stress are evident from around day 15 of pregnancy and persist through pregnancy,[20] parturition,[490] and lactation, until weaning.[491] Altered responsiveness in late pregnancy involves adaptations in the anterior pituitary, hypothalamus, and higher brain centers; the mechanisms are discussed following. The mechanisms in lactation are different and are dependent on suckling.[94]

While the majority of evidence for reduced HPA axis responses in pregnancy has come from rodent studies,[94] there is also evidence for reduced HPA axis responses to stress in pregnant women.[492,493] Exogenously administered CRH fails to increase ACTH or cortisol secretion during late pregnancy in women,[494] and suppressed salivary cortisol responses are observed following exposure to the cold pressor test.[492]

Adaptations at the Anterior Pituitary in Late Pregnancy

Adaptations at the anterior pituitary contribute to reduced HPA axis responses to stress in late pregnancy in the rat. CRH is less effective in stimulating ACTH secretion and cAMP production by anterior pituitary corticotrophs in late pregnancy.[20] The reduced pituitary response to CRH is likely to be a consequence of a reduction in CRH receptor binding in the anterior pituitary in the second half of gestation.[20] Similarly, vasopressin given alone is also less effective in evoking ACTH release from anterior pituitary corticotrophs and *Avpr1b* (V1b) mRNA expression is reduced in late pregnant rats.[484] However, when administered together, ACTH responses to combined CRH and vasopressin are indistinguishable from those in virgin rats.[484] Thus any reduced responses to stress in pregnancy likely result from reduced central drive to the anterior pituitary corticotrophs.

Central Mechanisms Regulating Reduced HPA Axis Responses to Stress in Late Pregnancy

The PVN receives a rich and diverse afferent supply, including potential routes by which stressful stimuli may influence the HPA axis. The stress-processing circuit activated by a particular stressor is dependent upon the nature of the stressor. Generally stressors are divided into two categories, referred to as physical (also termed physiological or systemic) and psychological (also referred to as emotional, processive, or neurogenic).[495] Psychological stressors (e.g., restraint, novel

environment) involve sensory processing and a distinct cognitive component. They rely on the individual perceiving and appraising the situation as being stressful and are processed predominantly via rostral corticolimbic brain regions. Whereas physical stressors (e.g., immune challenge, hypoxia) are generally conceived as real physiological threats to homeostasis, which the individual need not consciously appreciate. In these situations it is advantageous to bypass cognitive processing and rapidly relay information to the PVN, thus these stressors are processed primarily through caudal brain stem regions.[496] Regardless of the stressor, they all converge, by different central pathways, on the CRH/AVP neurons in the pPVN. However, it is important to note that there are reciprocal, indirect, connections between the rostral primary stressor processing structures and the brain stem stressor processing neurons, which function to integrate HPA axis responses to stress.[496–498]

Forebrain Inputs to the HPA Axis in Late Pregnancy

The rostral networks involved in stress processing and signaling to the PVN are complex.[499] Subregions of the medial prefrontal cortex, BNST, amygdala, and hippocampus are involved in integrating stressor information and regulating HPA axis responses to acute stress. Glutamate and GABA are the key transmitters that regulate CRH neuron responses to rostral inputs,[500] however, little is understood about their regulation in response to stress in pregnancy. Studies mapping Fos protein or *c-fos* mRNA expression, as an indicator of recent activation of neurons, have reported Fos induction following acute stress is similar in several forebrain limbic structures including the hippocampus and amygdala in virgin and pregnant rats.[19,394]

Brain Stem Inputs to the HPA Axis

The brain stem catecholamine system innervates brain regions involved in regulating stress responses and plays a major role in activating the HPA axis (Figure 44.6). Brain stem A2 noradrenergic neurons located in the NTS and A1 ventrolateral medulla (VLM) project both directly and indirectly (via the parabrachial nucleus or central nucleus of the amygdala and BNST) to the medial parvocellular region of the PVN and provide excitatory input to the CRH neurons.[501,502] Neurons in the pPVN express α_1 adrenergic receptors,[503] and noradrenaline and selective α_1 agonists have been shown to excite CRH neurons[504,505] and stimulate CRH gene transcription,[505] while α_1 antagonists block HPA axis activity.[504] Furthermore, electrical stimulation of the A1 and A2 input pathways increases HPA axis activity.[504] Physical stressors, including forced swimming, and systemic administration of CCK or interleukin-1β (IL-1β; an immune challenge) exert their effects on the HPA axis by activating the A2 noradrenergic neurons in the NTS, evoking noradrenaline release from their terminals in the PVN.[506–509] Thus, neurotoxic or surgical lesions of the noradrenergic input to the PVN prevent activation of the CRH neurons in response to stressors, such as systemic immune challenge.[510]

In contrast to nonpregnant rats, HPA axis responses to forced swimming,[20,487] systemic administration of CCK[506] and IL-1β[340] are suppressed in late pregnancy, reflected by attenuated ACTH and corticosterone secretion, and reduced stimulation of *Crh* mRNA expression in the pPVN.[340] This seems to be a result of reduced activity or effectiveness of excitatory noradrenergic input to the CRH neurons in late pregnancy, since immune challenge with IL-1β[340] and forced swimming[506] fail to evoke noradrenaline release in the PVN in late pregnancy (day 21). At least in the case of IL-1β, this does not appear to be a result of impaired signaling from the periphery to the brain stem noradrenergic neurons in pregnancy, as cell bodies in the A2 region of the NTS are similarly activated (using Fos as a marker of neuronal activation) in virgin and pregnant rats.[340] In late pregnancy, mRNA expression for the $\alpha 1_A$ adrenergic receptor (*Adra1a*) is modestly decreased in the pPVN.[506] This may contribute to reduced basal HPA axis activity; however, reduced noradrenergic drive to the CRH neurons is evidently of primary importance in explaining suppressed HPA axis responses to stressors relying on the noradrenergic input to the PVN neurons and is discussed following.

Inhibitory Endogenous Opioid Mechanism in Late Pregnancy

As well as regulating prolactin and oxytocin secretion (see the sections The Prolactin System: Preparation for Lactation and Magnocellular Oxytocin Neuron System in Pregnancy), endogenous opioids have a modulatory role in HPA axis regulation (Figure 44.6). In males and nonpregnant females, opioids, such as morphine, potentiate, while naloxone suppresses HPA axis responses to stress.[511] Furthermore, naloxone treatment reduces Fos induction in CRH neurons in the pPVN following systemic IL-1β administration.[512]

However, in late pregnancy opioids switch to having a net inhibitory effect on HPA axis activity, hence pretreatment with naloxone restores ACTH responses to forced swimming,[487] IL-1β,[340] and CCK[340] in late pregnant rats, and to parturition-related stimuli.[490] Opioids exert these inhibitory actions centrally, since systemic naloxone administration before IL-1β challenge results in enhanced *Crh* mRNA expression levels in the pPVN of late pregnant rats that do not differ from those in nonpregnant rats.[340] Moreover, naloxone infused directly into the PVN restores IL-1β-evoked noradrenaline release in the PVN and the IL-1β-stimulated increase in

Crh gene transcription.[340] In this case it is presumed that naloxone blocks the inhibitory actions of opioids that act presynaptically on noradrenergic nerve terminals in the pPVN, as has been demonstrated for CCK,[513] resulting in disinhibition of the excitatory input to the CRH neurons.

Several central sources of opioids could potentially restrain the responses of CRH neurons in pregnancy. Met-enkephalin is co-expressed with CRH in pPVN neurons, but *Penka* mRNA levels are not increased here in late pregnancy.[340] Beta-endorphin cells in the arcuate nucleus project directly to the PVN,[514] and *Pomc* mRNA and β-endorphin levels in the arcuate are increased in late pregnancy.[244] However, β-endorphin is unlikely to mediate opioid actions on responses to acute stress as activation of these neurons following stress is delayed.[515] Instead, the likely source of the opioids that restrain the CRH neuronal responses in late pregnancy is the NTS neurons that project to the pPVN. NTS neurons synthesize enkephalins and dynorphins,[516,517] and mRNA expression for both *Penka* and *Oprm1* is increased in the A2 region of the NTS in late pregnancy.[340] Moreover, these neurons are rapidly activated by acute stressors, such as immune challenge.[501] Thus, in late pregnancy activation of NTS neurons by IL-1β is expected to release more enkephalin from their terminals in the PVN to act on upregulated μ-opioid receptors and presynaptically inhibit noradrenaline release, affording a mechanism through which excitatory noradrenergic drive from the brain stem to the CRH neurons in the PVN can be selectively autoinhibited in late pregnancy.

In contrast to the rat, enhanced endogenous opioid inhibition does not appear to underpin suppressed HPA axis responses to acute stress during late pregnancy in the mouse,[482] and the mechanisms involved in this species are as yet not known.

Role of Pregnancy Hormones in HPA Axis Hyporesponsiveness

In contrast to lactation where maintenance of attenuated HPA axis responses to stress relies upon the suckling stimulus provided by the pups,[518] in late pregnancy the adaptations are induced by the actions of hormones in the brain.

Role of Sex Steroids: Estrogen, Progesterone, and Allopregnanolone

During the last week of pregnancy in the rat, plasma concentrations of the female sex steroids, estradiol and progesterone, are dramatically increased,[519,520] (Figure 44.1) implicating them as candidate inducers of pregnancy-related adaptations in HPA axis responsivity. However, treatment of virgin rats with estradiol alone,[521] progesterone alone,[21] or combined estrogen and progesterone (with and without progesterone withdrawal)[521] at levels that mimic pregnancy does not result in reduced HPA axis responses to stress.[521] Thus, while these sex steroids play a role in induction of opioid inhibition over oxytocin[521] and prolactin[522] secretion during late pregnancy (see the sections The Prolactin System: Preparation for Lactation and Magnocellular Oxytocin Neuron System in Pregnancy), they are not directly involved in HPA axis hyporesponsiveness at this time.[521] The progesterone metabolite and neuroactive steroid, allopregnanolone (3α-hydroxy-5α-pregnan-20-one), does however play a crucial role.[21]

In rats, progesterone secretion by the corpora lutea is essential for establishing and maintaining pregnancy. Increased plasma and brain levels of progesterone during pregnancy are accompanied by increased levels of allopregnanolone both in the circulation and in the brain.[29] While circulating and central progesterone peaks at levels around 10 times greater than prepregnancy by day 15 of pregnancy, allopregnanolone concentrations in the brain do not peak until day 19 or 20.[29]

The majority of allopregnanolone found in the brain is likely synthesized in the periphery by the liver, ovaries, placenta, and adrenal glands,[523] however, allopregnanolone is also produced in the brain. The enzyme 5α-reductase (the rate-limiting enzyme) converts progesterone into dihydroprogesterone (DHP; 20α-hydroxy-4-pregnen-3-one), which is in turn converted into allopregnanolone by 3α-hydroxysteroid dehydrogenase (3α-HSD). Both of these enzymes are expressed in the brain by astroglia,[524] although 5α-reductase activity also occurs in neurons.[524] Thus the brain can produce neurosteroids de novo,[525] and metabolize steroids produced in the periphery into neuroactive steroids.

In late pregnancy the capacity of the brain to generate neurosteroids is increased. Activity of 5α-reductase is increased in the hypothalamus,[21] and 5α-reductase (*Srd5a1*) mRNA expression is upregulated in the NTS.[21] There is also an increase in *3α-HSD* (*Dhrs9*) mRNA expression in the PVN in late pregnancy.[21] This is expected to lead to increased allopregnanolone generation for local action on neurons.

The factor(s) responsible for regulating the expression of these enzymes in the brain in pregnancy are unclear. It has been shown that 3α-HSD activity in the hypothalamus is regulated by ovarian hormones,[526] and estrogen, but not progesterone, increases hippocampal *3α-HSD* mRNA expression.[527] There is currently no evidence to indicate that estrogen or progesterone regulates 5α-reductase expression in the brain in pregnancy, however, increased levels of prolactin may play a role.[528]

ALLOPREGNANOLONE AND HPA AXIS ACTIVITY IN PREGNANCY

In pregnancy, increased allopregnanolone levels suppress HPA axis responses to stress (Figure 44.6). Studies

have shown that blocking allopregnanolone production in pregnant rats with administration of finasteride (a 5α-reductase inhibitor that reduces brain allopregnanolone content by up to 90%)[29] substantially restores HPA axis responses to IL-1β;[21] whilst allopregnanolone administration attenuates HPA axis stress responses in nonpregnant female rats[21] and in males.[529] Any stimulatory actions of elevated estrogen levels in pregnancy on HPA axis stress responses to stress, like those reported in nonpregnant rats,[530] are presumably outweighed by the suppressive actions of allopregnanolone.

As mentioned before, progesterone is ineffective in suppressing HPA axis responses to IL-1β in nonpregnant rats. Notably, the other allopregnanolone precursor, DHP, is also ineffective,[21] which highlights the importance of upregulation of both of the allopregnanolone synthesizing enzymes in the brain in late pregnancy.

ALLOPREGNANOLONE AND ENDOGENOUS OPIOID SYSTEM INTERACTIONS IN PREGNANCY

The suppressive effect of allopregnanolone on stress-induced HPA axis activity reported in pregnancy is dependent upon the actions of endogenous opioids.[21] In virgin rats, allopregnanolone treatment induces opioid inhibition over ACTH responses to systemic IL-1β,[21] and allopregnanolone treatment upregulates *Penka* mRNA expression in the NTS of virgin rats by c. 35%, comparable to the increase reported at the end of pregnancy.[340] Furthermore, finasteride treatment reduces *Penka* mRNA expression in the NTS in late pregnant rats.[21] The mechanism by which allopregnanolone upregulates *Penka* gene expression in the NTS remains unclear, however, an interaction with $GABA_A$ receptors is a possibility,[531] as has been described for *Crh* and *Avp* mRNA expression in the PVN[532] and for oxytocin gene expression in the hypothalamus at the end of pregnancy (Figure 44.6).[531]

ALLOPREGNANOLONE AND POTENTIATION OF INHIBITORY GABA ACTIONS

As mentioned before, allopregnanolone is a potent allosteric modifier at postsynaptic $GABA_A$ receptors (including those in the PVN), where it acts to enhance the effectiveness of GABA inhibition by prolonging the opening time of chloride ion (Cl^-) channels within $GABA_A$ receptors and maintaining activity of these receptors during late pregnancy.[533–535] Parvocellular CRH neurons in the PVN are under direct inhibitory GABAergic control,[536] however, it is not known whether the effectiveness of the GABA innervation of CRH neurons is enhanced in late pregnancy, as has been described for the magnocellular oxytocin neurons (see the section Magnocellular Oxytocin Neuron System in Pregnancy).[537] Action of allopregnanolone on the $GABA_A$ receptor depends upon the subunit composition,[533] with higher efficacy at δ subunit-containing receptors than on receptors containing the γ_2 subunit.[538–540] In late pregnancy in the rat, increased central levels of allopregnanolone are associated with altered expression of $GABA_A$ receptor isoforms in the hippocampus, with an increase in the expression of the δ subunit-containing $GABA_A$-R and a decrease in those containing the γ_2 subunit.[541] The resultant increase in tonic GABAergic inhibitory transmission may be important to reduce excitability in pregnancy.

Hence, in pregnancy increased levels of allopregnanolone in the brain may act to enhance the action of GABA in the PVN or on afferent inputs to the CRH neurons to suppress HPA axis stress responses.

Role of Neuropeptide Hormones: Oxytocin and Prolactin

Oxytocin is released within the brain, including in the PVN, in response to stress,[542] indicating oxytocin may be involved in modulating stress responses. Indeed, in nonpregnant rats centrally released oxytocin reduces HPA axis responses to stress.[543–546] However, in late pregnancy, an oxytocin antagonist fails to reverse the suppressed HPA axis responses to stress,[546] indicating that endogenous intracerebral oxytocin does not maintain HPA hyporesponsiveness at this time. Similarly, intracerebral infusion of prolactin suppresses stress-induced ACTH secretion in nonpregnant female rats[547] and during lactation,[548] however, it is not known whether prolactin or placental lactogen influences HPA axis activity in pregnancy.

Glucocorticoid Negative Feedback in Pregnancy

Glucocorticoids acting via GR and MR exert negative feedback control over HPA axis activity via rapid (nongenomic signaling) and slow mechanisms (genomic).[549,550] CRH neurons in the pPVN respond to glucocorticoids by releasing eCBs, which inhibit excitatory glutamatergic synaptic inputs.[551] Moreover, glucocorticoids facilitate synaptic GABA release,[551] further enhancing inhibition of pPVN neurons. The effectiveness of these mechanisms has not been tested in pregnancy, however, as corticosterone is less effective in rapidly inhibiting ACTH secretion in late pregnant rats,[521] enhanced rapid glucocorticoid negative feedback is unlikely to be involved in reduced responsiveness of the HPA axis to stress in late pregnancy.

Nonetheless, reduced basal activity of the HPA axis in late pregnancy may involve enhanced delayed glucocorticoid negative feedback since *Nr3c1* mRNA expression (indicative of increased number of GRs) in the dentate gyrus is modestly increased on day 21 of pregnancy.[483] Furthermore, activity of the enzyme that reactivates corticosterone from inert 11-dehydrocorticosterone, 11β-hydroxysteroid dehydrogenase type-1 (11β-HSD1),

is increased in the PVN and anterior pituitary in late pregnancy[483] potentially amplifying the glucocorticoid negative feedback signal, which may contribute to the reduction in basal expression of *Crh* and *Avp* mRNA in the pPVN[483,489] and reduced *Pomc* mRNA in the pituitary[484] observed in late pregnancy.

Adrenomedullary and Sympathetic Responses to Stress in Pregnancy

In response to stress, the sympathetic and adrenomedullary systems are also activated, stimulating the release of catecholamines,[552] i.e., adrenaline from the adrenal medulla and noradrenaline from sympathetic nerve terminals. Glucocorticoids and catecholamines act together to mobilize energy stores and redistribute resources: they increase blood pressure and cardiac output and promote the delivery of substrates to tissues that are critical to the immediate defense of the animal, thus enabling them to cope with emergency situations and facilitate "fight or flight" responses.[553]

Few studies have investigated the responsiveness of the sympathetic-adrenomedullary system in pregnancy. In women, plasma noradrenaline concentrations are similarly increased in pregnant and nonpregnant participants following acute thermal stress (exposure to a heat chamber at 70 °C); however, adrenaline responses to the same stressor are suppressed in pregnant women.[554] Consistent with this is the finding in late pregnant rats of attenuated adrenaline responses, but normal noradrenaline responses to air-puff startle.[555] It is unlikely that there is a reduction in the capacity of the adrenal medulla to produce adrenaline, as *Th* (gene encoding the rate-limiting enzyme in adrenaline synthesis) mRNA expression in the adrenal medulla is increased in late pregnant rats (Douglas AJ and Gooding H, unpubl., pers. comm.). Adrenal chromaffin cells co-synthesize and co-secrete enkephalins with adrenaline;[556,557] while air-puff startle increases met-enkephalin content in the adrenal medulla of nonpregnant rats, it has no such effect in late pregnant rats (Douglas AJ, Pierzchała-Koziec K, and Russell JA, unpubl.), further supporting the prospect of reduced adrenomedullary responses to stress in pregnancy. However, the mechanisms underlying attenuated adrenaline secretory responses to stress in late pregnancy in rats and women remain to be elucidated.

Summary and Conclusions

Attenuated HPA axis responses to stress emerge in the second half of gestation in the rat. This involves adaptations at the level of the anterior pituitary and upregulation of an inhibitory endogenous opioid mechanism in the brain that is driven by increased levels of the progesterone metabolite, allopregnanolone. Progesterone treatment alone (to mimic pregnancy levels) is not sufficient to suppress HPA axis responses to stress in nonpregnant rats, indicating that an increase in the activity of 5α-reductase (which converts progesterone into allopregnanolone) in pregnancy is a prerequisite. This adaptation is expected to provide a first line of defense to protect the fetuses from any adverse programming by glucocorticoids, thus withdrawal of these mechanisms or failure to maintain them appropriately might predispose the fetuses to disease in later life.[471]

Future Perspectives

Whether the mechanisms shown to suppress HPA axis responses to the physical stressor IL-1β in late pregnancy represent a global mechanism through which HPA axis response to all types of stress are attenuated requires further investigation. The pathway by which allopregnanolone upregulates *Penka* gene expression in the NTS remains unclear, though an interaction with $GABA_A$ receptors is a possibility. Moreover, whether the effectiveness of the GABA innervation of the CRH neurons is enhanced in late pregnancy and whether this contributes to HPA axis hyporesponsiveness also remains to be elucidated. There is currently no evidence to indicate whether allopregnanolone of peripheral origin (e.g., synthesized in liver) or central origin is of greatest importance in suppressing stress-induced activity of the HPA axis in pregnancy. Increased activity of 5α-reductase in the brain in late gestation indicates that allopregnanolone generated centrally is important. However, the mechanisms that regulate 5α-reductase gene expression in the brain in pregnancy are also unclear.

MAGNOCELLULAR OXYTOCIN NEURON SYSTEM IN PREGNANCY

The most important outcomes of pregnancy for successful nurturance of the offspring are the initiation of maternal behavior and lactation. Oxytocin has important actions when released in the brain in supporting the initiation of maternal behavior. Secreted from the posterior pituitary gland by the axon terminals of magnocellular PVN and SON oxytocin neurons (Figure 44.7), oxytocin has essential actions on the mammary glands to drive transfer of milk from the mammary alveoli through the milk ducts and out from the nipples into the mouths of the suckling young. Similarly, oxytocin released into the circulation has an important ancillary role in stimulating uterine contractions during parturition to promote births. To be ready to perform these functions, oxytocin neurons themselves undergo subtle, though important, changes in pregnancy, but major changes emerge in their immediate environment in the PVN and SON, and in their

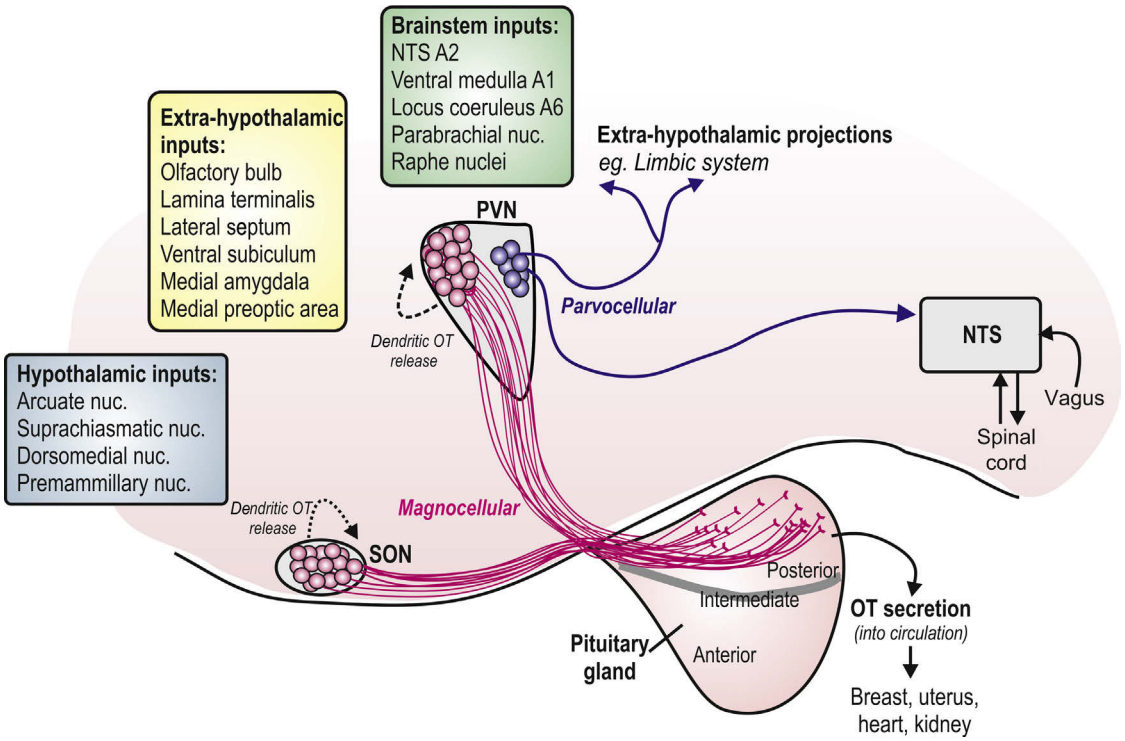

FIGURE 44.7 Oxytocin neuron projections and afferents. Magnocellular oxytocin (OT) neurons located in the supraoptic nucleus (SON) and the paraventricular nucleus (PVN) send axons to the posterior lobe of the pituitary gland. Oxytocin is secreted into the systemic circulation to act at distant organs, e.g., uterus, mammary glands. Oxytocin is also released from dendrites in the SON and PVN, where it can act locally on the oxytocin neurons themselves, but may also diffuse to influence other hypothalamic neurons, and extrahypothalamic brain regions. Parvocellular oxytocin neurons in the PVN project caudally to the nucleus tractus solitarii (NTS) and spinal cord. They also project rostrally to limbic brain regions and release oxytocin from their axon terminals. Magnocellular oxytocin neurons receive afferent inputs from hypothalamic, extrahypothalamic, and brain stem regions. Sources of input to the parvocellular oxytocin neurons include other hypothalamic nuclei (e.g., the arcuate nucleus) and the NTS.

inputs. As pregnancy progresses, oxytocin neurons show increases in auto-inhibitory mechanisms and the effectiveness of inhibitory inputs is enhanced; such changes and consequent quiescence of oxytocin neurons ensure that the oxytocin store in the posterior pituitary is enlarged and that premature activation of oxytocin neurons is prevented. The inhibitory mechanisms become less effective at the end of pregnancy, permitting their strong excitation during parturition. Oxytocin released by the dendrites of these neurons has a key role in this excitation.

Oxytocin has important actions in the brain in the context of pregnancy: oxytocin released by the dendrites of magnocellular neurons has an essential role in organizing coordinated burst firing of oxytocin neurons during parturition and suckling, which results in intermittent secretion of pulses of oxytocin; released by centrally projecting pPVN neurons (and possibly by dendrites of magnocellular oxytocin neurons, or by scarce centrally projecting axons of these neurons), oxytocin actions in rostral structures are important in initiating maternal behavior. Such actions are akin to the social affiliative actions of oxytocin, but may also involve aggressive defensive behavior. In some species, oxytocin has important peripheral actions in the control of blood volume and osmolarity (see the section Osmoregulation in Pregnancy), and is secreted in response to stressors, and in response to several metabolic signals (see the section Food Intake and Metabolism in Pregnancy).

Oxytocin and Parturition

The early finding that a posterior pituitary extract stimulated uterine contractions[558] led to the eventual identification of a nine–amino acid peptide, similar to vasopressin, that stimulates uterine contractions and milk ejections.[559] Extensive worldwide obstetric use of oxytocin for more than 50 years in humans and domestic or companion animals amply confirms the efficacy of oxytocin in initiating or promoting births. Many studies have shown that oxytocin secretion increases during parturition, as a reflex response to the passage of the fetus(es) through the birth canal (Ferguson reflex)[560] (Figure 44.8), and that the pattern of secretion is pulsatile.[561] Moreover, an oxytocin antagonist can be effective in delaying threatened preterm labor.[562,563] In rats,

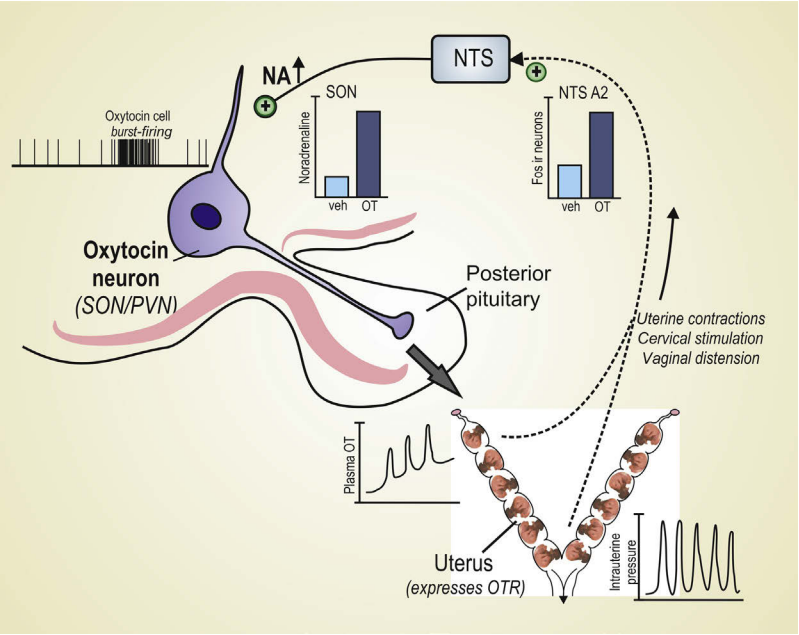

FIGURE 44.8 Oxytocin neuron activation at parturition. Coordinated burst-firing of magnocellular oxytocin neurons triggers pulsatile oxytocin (OT) secretion into the blood from the nerve terminals in the posterior pituitary. OT acting on upregulated OT receptors (OTR) in the uterus stimulates uterine contractions and increases intrauterine pressure, resulting in pup expulsion. The stretching of the birth canal activates neural pathways to noradrenergic neurons in the A2 region of the nucleus tractus solitarii (NTS). Activation of these noradrenaline (NA)-producing neurons in the NTS can be mimicked experimentally with intravenous infusion of OT pulses in day 22 pregnant rats, which causes Fos (protein product of *c-fos*, an immediate early gene and indicative of recent activation) induction in the NTS cell bodies. The noradrenergic neurons project to oxytocin neurons in the supraoptic (SON) and paraventricular (PVN) nuclei, where they release noradrenaline, which excites the OT neurons. Experimentally, in late pregnant rats intravenous OT pulses stimulate NA release in the SON. This pathway is a classic positive feedback loop, designated as the "Ferguson reflex."

inhibiting oxytocin secretion in established parturition (by opiate administration) stops births, which can be restored by oxytocin infusion,[564,565] and an oxytocin antagonist prolongs parturition.[566] However, the importance of oxytocin in parturition is challenged by the finding that mice with inactivation of the oxytocin or oxytocin receptor gene do not show deficits in parturition.[567,568] Nonetheless, magnocellular oxytocin neurons are activated during parturition in mice, an oxytocin antagonist slows parturition in mice, as does stress, and this effect is reversed by oxytocin administration.[569] Hence oxytocin, the most potent uterotonic agent, has a role in parturition in mice, but there is redundancy, and other mechanisms are also important.[570]

Oxytocin Neuron Electrical Properties

Magnocellular oxytocin neurons discharge action potentials (spikes) in a slow, irregular pattern in resting conditions (at around 4 spikes/s: in vivo, usually measured in anesthetized rats; in vitro in thin slices of the hypothalamus), which contrasts with the phasic firing pattern of vasopressin neurons.[571] When these oxytocin neurons are stimulated by, for example, increased plasma [Na^+] or intravenous (i.v.) cholecystokinin (CCK), they increase their firing rate and maintain the irregular pattern.[46,572] The irregular pattern of oxytocin neurons is a result of the balance of excitatory (e.g., glutamate, noradrenaline, and oxytocin) and inhibitory (e.g., GABA and opioids) inputs.[41,573–575]

Strikingly, during parturition and suckling magnocellular oxytocin neurons show high frequency bursts of activity (around 50–100 spikes/s for 1–2 s) a few minutes apart, and importantly these bursts happen almost simultaneously in the whole population[334,576,577] (Figure 44.8). This behavior is a result of the electrophysiological properties of the neurons and coupling among them, the actions of transmitters, and the interactions between signals emitted by the neurons, especially including oxytocin, on synapses on the dendrites.[578,579]

The Ferguson Reflex Pathway

The afferent neural pathway of the Ferguson reflex[560] has been shown to involve signals from the contracting uterus and the birth canal (uterine cervix and vagina), when it is stretched as each fetus is pushed through the canal by expulsive uterine contractions (Figure 44.8). These signals are relayed by somatic spinal afferents and by vagal afferents[580,581] to A2 noradrenergic neurons in the nucleus tractus solitarii (NTS) that project to the magnocellular oxytocin neurons in the SON and PVN. NTS neurons are also activated during parturition in mice.[569] Noradrenaline acts via α1 receptors to activate the oxytocin neurons,[573,582–584] which consequently show induction of Fos and oxytocin gene transcription[569,585,586] (Figure 44.8). In addition to release of noradrenaline in the SON, which begins an hour before the first pup is born, release of glutamate is increased transiently just before the first birth.[583] Some of the NTS neurons that project to the SON and are activated in parturition express somatostatin, which may contribute to the regulation of oxytocin neurons at this time through direct inhibitory or indirect excitatory actions.[587] The NTS neurons that are activated by vaginal distension, as in parturition, are a different population from those activated by

CCK, so there is no convergence in the pathways to oxytocin neurons of signals about parturition with satiety signals.[588] Nonetheless, CCK (and IL-1β) have been used as peripheral stimuli that act via NTS noradrenergic neurons to excite oxytocin neurons to probe adaptations in this pathway in pregnancy (discussed following).

Through this noradrenergic pathway, uterine contractions excite the electrical activity of magnocellular oxytocin neurons, increasing their continuous firing rate, hence increasing oxytocin secretion, readily measurable in blood samples.[589] Their intermittent coordinated activation during parturition, when they show brief high frequency discharge of action potentials, excites release of pulses of oxytocin from the posterior pituitary.[576] The high frequency bursts of action potentials by oxytocin neurons are only seen during parturition and, more strikingly, during suckling, when each burst is followed by secretion of a pulse of oxytocin, which causes a milk ejection, as established 40 years ago.[23] The oxytocin pulses during parturition are optimally efficient for the stimulation of uterine contractions and births, including in women.[317,590–592] However, in humans measurement is made difficult by circulating placental "oxytocinase" (placental leucine aminopeptidase; P-LAP), which has been known for over 50 years to rapidly inactivate oxytocin.[561,593] As a consequence of the intermittent pulsatile and increased continuous secretion of oxytocin, a substantial proportion of the oxytocin stored in the posterior pituitary is depleted during parturition.[594]

Provision of Oxytocin for Parturition (and Lactation)

An enlarged store of oxytocin in the posterior pituitary at the end of pregnancy is evidently the result of reduced release of oxytocin during pregnancy.

Storing Oxytocin

A result of reduced strength or activity of inputs to oxytocin neurons that mediate control of oxytocin secretion by homeostatic signals, related to osmoregulation and food intake (see the sections Osmoregulation in Pregnancy and Food Intake and Metabolism in Pregnancy), is reduced functional demand for oxytocin secretion in pregnancy. Hence, the store of oxytocin in the posterior pituitary can gradually increase through pregnancy by about 75% in rats.[393,594] This accumulation occurs without consistent findings of increased oxytocin gene expression in magnocellular neurons in pregnancy,[570,579,586,595] although such an increase does follow parturition.[586]

Sex Steroid Regulation of Oxytocin Gene Expression

The high levels of estrogen and progesterone in late pregnancy have led to studies of possible effects on oxytocin gene expression in pregnancy, but without consistent findings.[570,579] Any genomic action of estradiol could only be via ERβ,[596] as magnocellular oxytocin neurons do not express ERα.[597] Even so, the oxytocin gene promoter contains a complex composite hormone response element, with homology to a consensus estrogen response element (ERE), which shows marked species differences in binding to ERα or ERβ.[598] The response element binds orphan receptors, including steroidogenic factor-1 (SF-1), chicken ovalbumin upstream promoter transcription factor (COUP-TF),[599] and variably among species estrogen-related receptor α (ERRα),[600] and retinoic acid and thyroid hormone receptors.[598] The significance of the finding that androstanediol (3β-diol), a testosterone metabolite, briefly stimulates occupancy of the oxytocin promoter by ERβ and consequent oxytocin gene expression[601] is not clear for oxytocin synthesis during or after pregnancy. Estrogen and progesterone treatment followed by progesterone withdrawal increases *oxytocin* mRNA level in the SON and PVN, which is prevented by allopregnanolone, likely via $GABA_A$ receptors, and is consistent with no change in neuronal oxytocin gene expression in pregnancy but may explain postpartum increases.[531]

Preventing Early Oxytocin Release

Auto-Inhibition: Posterior Pituitary Opioid

Without pregnancy, μ-opioids can act on oxytocin-containing axon terminals in the posterior pituitary to inhibit voltage-gated Ca^{2+} channels (VGCC) and hence modulate bursts of oxytocin secretion.[602] However, a κ-opioid mechanism in the posterior pituitary is predominantly responsible for restraining continual oxytocin secretion, evidently mediated by a pENK-A-derived peptide produced by oxytocin neurons.[603] Importantly, this mechanism is downregulated in late pregnancy, enabling greater stimulation of oxytocin secretion by arriving actions potentials.[393]

Retrograde Signaling

Magnocellular oxytocin neurons produce and release retrograde chemical signals into the dendritic microenvironment when stimulated: these include nitric oxide (NO), eCBs, and oxytocin, which act on inputs to the neurons and inhibit transmitter release (Figure 44.9).

NEURONAL NITRIC OXIDE SYNTHASE

Oxytocin neurons express neuronal nitric oxide synthase (nNOS) and produce NO when activated.[604] In general, NO exerts its effects via cGMP-mediated increase in inhibition by GABA, and in the PVN, cGMP is expressed in oxytocin neurons and nearby GABAergic neurons and axon terminals.[604] However, in the magnocellular

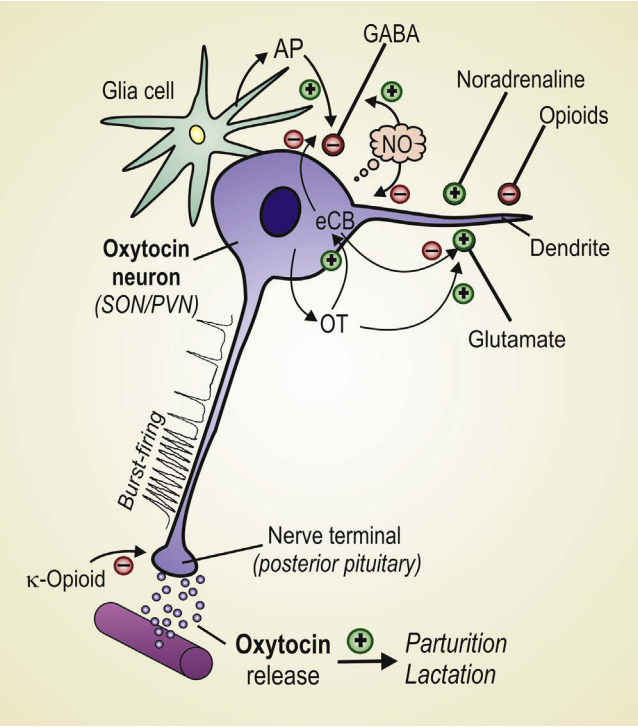

FIGURE 44.9 Microenvironment of a magnocellular oxytocin neuron: changes near the end of pregnancy. The dendrites and cell bodies of magnocellular oxytocin (OT) neurons in the supraoptic (SON) and paraventricular (PVN) nucleus receive excitatory (glutamate and noradrenaline) and inhibitory (GABA and opioids) inputs. The noradrenergic input is restrained by endogenous opioids during late pregnancy. Oxytocin is also released from the dendrites, which stimulates endocannabinoid (eCB) production by the oxytocin neurons. In turn, eCBs inhibit glutamatergic and GABA inputs to the oxytocin neurons, while oxytocin directly stimulates glutamate terminals. Allopregnanolone (AP; present in increased concentrations in pregnancy and produced by glial cells) potentiates the inhibitory actions of GABA via actions on $GABA_A$ receptors. Allopregnanolone levels decline at the end of pregnancy, and its potentiating effect on GABA inhibition of oxytocin neurons is lost. Oxytocin neurons also produce nitric oxide (NO) when activated, and NO can inhibit the oxytocin neurons both directly and by acting presynaptically on GABAergic inputs. At the end of pregnancy, the NO system in the oxytocin neurons is downregulated, thus oxytocin neurons are more responsive to excitatory inputs, and oxytocin released by the dendrites exerts a predominant control of oxytocin neuron activity. At the posterior pituitary, a κ-opioid mechanism restrains oxytocin secretion in pregnancy. This mechanism is downregulated in late pregnancy, enabling greater stimulation of oxytocin secretion by arriving actions potentials. Synchronized or burst-firing of oxytocin neurons at parturition and in lactation causes secretion of pulses of oxytocin.

oxytocin system, NO signaling has been found not to be by cGMP,[605] and electrophysiological studies show that oxytocin neurons are inhibited by NO acting directly, but also presynaptically, on GABAergic neurons (Figure 44.9).[606]

Increased capacity to produce NO in oxytocin neurons has been reported in late pregnancy, and attributed, from studies in nonpregnant rats, to stimulation by increased local oxytocin released as a result of local prolactin action.[607] However, at the end of pregnancy, *nNOS (Nos1)* mRNA expression and the inhibitory activity of the NO system on the oxytocin neurons are downregulated.[89] This attenuation of the powerful NO system restraining oxytocin neurons leaves these neurons more responsive to excitatory inputs. The importance of downregulation of NO mechanisms in oxytocin neurons is indicated by the adverse impact of i.c.v. administration of sodium nitroprusside (SNP; an NO donor) on the progress of established parturition.[608]

ENDOCANNABINOIDS AND OXYTOCIN

Release of eCBs is stimulated by increased intracellular calcium ion concentrations ($[Ca^{2+}]_i$) or depolarization, and eCBs act via G-protein-coupled CB_1 receptors. Excitatory (glutamatergic) and inhibitory (GABAergic) synapses on SON oxytocin neurons are inhibited by a CB_1 agonist, and similar actions of oxytocin are mediated by eCBs, as shown by blocking the oxytocin actions with a CB_1 antagonist.[609,610] It has been proposed that oxytocin released from dendrites will act back on OTR on the dendrites, increase $[Ca^{2+}]_i$ and hence stimulate production of eCBs, which then act on the presynaptic glutamate and GABA terminals[609,610] (Figure 44.9). Such a local cascade during parturition could serve to organize bursting activity of oxytocin neurons by quelling excitation and synchronizing inhibition. However, oxytocin also has an excitatory action on presynaptic glutamate release, which is not via eCB action.[609] Hence, if eCB production is suppressed at the end of pregnancy, dendritically released oxytocin could stimulate excitatory input. However, changes in eCB production by oxytocin neurons in pregnancy have to date not been reported.

Progesterone

In species in which progesterone in pregnancy is predominantly produced by the corpora lutea (e.g., rodents), by contrast with production by the placenta (as in women), luteolysis near term and consequent progesterone withdrawal are essential to enable uterine OTR responsiveness to oxytocin.[592,611,612] Consequently, oxytocin administration does not activate neurons in the NTS or magnocellular oxytocin neurons if progesterone withdrawal is prevented; however, eventual progesterone withdrawal after such a delay at the end of pregnancy progressively permits activation of NTS and then SON neurons.[590] Hence, progesterone has multistage actions to restrain oxytocin neurons in late pregnancy, some of which are not via progesterone receptors (PR); for example, there are no PRs in oxytocin neurons, and very few NTS neurons express PR.[124,590] Instead progesterone actions on these neurons

are mediated by allopregnanolone, a neurosteroid progesterone metabolite.

Allopregnanolone

Two types of inhibitory action by allopregnanolone have been identified: a direct action via potentiation of inhibitory actions of GABA, and an indirect action via induction of an inhibitory opioid mechanism, involving NTS A2 noradrenergic neurons (discussed following).

ALLOPREGNANOLONE AND GABA SYNAPSES

Inhibition by GABA released at synapses and acting on postsynaptic, or potentially extrasynaptic $GABA_A$, receptors[613,614] plays an important role in regulating the continuous activity of oxytocin neurons. There are GABA neurons around the magnocellular nuclei,[615,616] and the input from the lamina terminalis osmoregulatory complex includes an important GABA component.[41,46] $GABA_A$ receptors comprise five subunits, and the complex is subject to positive allosteric modulation by allopregnanolone.[613] Allopregnanolone is present in the brain in high concentrations in pregnancy,[29] and SON oxytocin neurons express predominantly α1, α2, β2, and γ2 $GABA_A$ receptor subunits,[617] of which α1 is critical for positive modulation by neurosteroid.[618] In oxytocin neurons allopregnanolone slows the closure of the $GABA_A$ receptor Cl^- channel after activation; this action is G-protein mediated, and involves protein kinase C (PKC).[619] As progesterone and consequently allopregnanolone levels fall at the end of pregnancy (in the rat), the possibility that resulting reduced GABA inhibition of oxytocin neurons may contribute to activation of oxytocin neurons at parturition has been investigated in several studies. Remarkably, the initial finding was that the potentiating effect of allopregnanolone actions on inhibition by GABA of SON oxytocin neurons is essentially lost at the end of pregnancy.[619] The initial explanation was a change in $GABA_A$ receptor subunit composition,[534] but subsequently allopregnanolone insensitivity was attributed to an action of oxytocin in the SON to activate PKC in oxytocin neurons.[400] The consequent change in balance between serine/threonine phosphatase and PKC in the neurons leads to phosphorylation of $GABA_A$ receptors, and consequent insensitivity to allopregnanolone.[400] More recently, altered α1, α2, and α3 subunit composition of clusters of $GABA_A$ receptors on SON oxytocin neurons around parturition was found, but this is not due to altered mRNA levels.[620] This change in receptor cluster composition is perhaps related to the increased numbers of GABA synapses at this time, which can be induced by exposure to oxytocin and estradiol, with action of oxytocin via OTR.[621] The observed reduced number of $GABA_A$ receptors with non-α1 subunits will reduce sensitivity to allopregnanolone, as shown in SON neurons in mice with α1 subunit gene inactivation.[400,614] Clearly, the loss of sensitivity of $GABA_A$ receptors on oxytocin neurons at the end of pregnancy will result in potential greater excitability, even if allopregnanolone level in the SON remains high, as in other brain regions.[29]

ALLOPREGNANOLONE AND ENDOGENOUS OPIOID INHIBITION

In late pregnancy magnocellular oxytocin neuron responses to i.v. CCK or IL-1β are inhibited by the endogenous opioid mechanism in the brain that emerges at this time, is induced by allopregnanolone, and also inhibits HPA axis stress responses (see the section The Hypothalamo-Pituitary–Adrenal Axis).[21,24,340,394] Both CCK and IL-1β act via noradrenergic neurons in the NTS[363] to increase the firing rate of oxytocin neurons,[24,399] in the continuous firing mode, hence increasing oxytocin secretion. CCK acts via vagal afferents and is a physiological stimulus from the small intestine signaling active digestion, acting centrally as a satiety signal, in part via oxytocin (see the section Food Intake and Metabolism in Pregnancy). IL-1β imitates immune cell activation in response to infection. It acts via interleukin receptors on endothelial cells in the dorsal medulla oblongata, initiating local prostaglandin synthesis and consequent excitation of A2 noradrenergic neurons via prostaglandin receptors.[501,510,622] Stimulation of oxytocin neurons by IL-1β is relevant to involvement of utero-cervical infection in threatened preterm labor.[623,624] Study of changes in responses of oxytocin neurons to i.v. CCK or IL-1β in pregnancy has provided information about mechanisms that may govern control of oxytocin neurons during pregnancy and parturition.

Changes in Oxytocin Neuron Responses to IL-1β in Pregnancy

In contrast with its stimulatory actions on oxytocin neurons in virgin rats, i.v. IL-1β fails to excite oxytocin neurons in late pregnancy, unless naloxone is given a few minutes before i.v. IL-1β; hence the excitation of oxytocin neurons is inhibited by an endogenous opioid mechanism at this time.[394,399] In virgin rats, i.v. IL-1β increases noradrenaline release in the PVN, as a consequence of stimulating NTS A2 neurons; but in late pregnancy, although IL-1β still activates the cell bodies of A2 neurons, noradrenaline release in the PVN is prevented by a local opioid mechanism.[340] This may involve upregulated production of presynaptic μ-opioid receptors and enkephalin in the noradrenergic input, auto-inhibiting noradrenaline release.[340] Importantly, overnight treatment of virgin rats with allopregnanolone (but not with allopregnanolone precursors, progesterone, or dihydroprogesterone) reduces oxytocin neuron responses to IL-1β as in pregnancy, and this is naloxone reversible, indicating that allopregnanolone induces opioid inhibition of oxytocin neuron responses to IL-1β.[394] Moreover, allopregnanolone treatment upregulates *Penka*

mRNA level in the NTS, a known source of enkephalin input to the PVN.[625] In late pregnant rats, blocking allopregnanolone production with finasteride reduces the upregulated expression of pENK-A mRNA.[21] Notably, expression of *5α-reductase* and *3α-HSD* mRNAs in the NTS are increased in late pregnancy, which indicates increased local allopregnanolone production.[21] Hence, increased levels of allopregnanolone in the brain, or more particularly in the NTS, in pregnancy induce the opioid inhibitory mechanism in late pregnancy that prevents oxytocin neurons from being stimulated by systemic IL-1β. The mechanisms involved in upregulation by allopregnanolone of *Penka* mRNA expression in the NTS in pregnancy are not known.

Oxytocin secretion is stimulated by other types of stressors, including forced swimming, but the response is barely altered in late pregnancy; however, the oxytocin response is much more enhanced by naloxone in late pregnant than in virgin rats, consistent with the just-discussed actions of allopregnanolone and inhibition by endogenous opioids.[487] However, estradiol and progesterone treatment for 17 days to simulate pregnancy in virgin rats leads to exaggerated oxytocin responses to forced swimming, compared with sham-treated rats, but only after opioid inhibition is removed.[487,521] Whether the sex steroid treatment leads to increased allopregnanolone production is not known.

Changes in Oxytocin Neuron Responses to CCK in Pregnancy

In late pregnancy, i.v. CCK stimulates magnocellular oxytocin neuron electrical activity and oxytocin secretion to an extent similar to that seen in virgin rats.[24] However, this conceals strong opioid inhibition of the firing rate and secretory responses in late pregnancy as these responses are much greater after naloxone, but not in virgin rats.[24] The explanation for the exaggerated responses of oxytocin neurons to i.v. CCK after naloxone seems likely to be that at the end of pregnancy, even without naloxone, CCK stimulates the release of more noradrenaline onto oxytocin neurons,[378] but the excitatory effects of this are inhibited by local opioid action. Increased noradrenaline release onto oxytocin neurons at the end of pregnancy is likely to involve the action of local oxytocin, released from the dendrites.[378,579] Moreover, noradrenaline has presynaptic excitatory actions on glutamate release onto magnocellular neurons in the SON and PVN, as well as inhibitory actions on GABA release.[626,627] In addition, glutamate as well as oxytocin and eCBs may be released by the dendrites of oxytocin neurons, as they express vesicular glutamate transporter 2 (VGLUT2).[628,629] Hence, at the end of pregnancy, in the dendritic environment of magnocellular oxytocin neurons, positive feedback mechanisms are set to be activated at the start of parturition.

Importance of Allopregnanolone and Endogenous Opioid Actions for Normal Delivery

The importance of opioid restraint of magnocellular oxytocin neurons in parturition is indicated by finding that naloxone administration in parturition increases oxytocin secretion and accelerates birth, meaning that there is insufficient time between births for full maternal behavior.[630] Conversely, the stress of moving a rat or pig from its nest during parturition leads to reduced circulating oxytocin levels and suspension of births; these effects are prevented by naloxone, and are thus due to heightened opioid inhibition of oxytocin neurons in response to stress.[630,631] The sensitivity of oxytocin neurons to inhibition by endogenous opioid inhibition is reflected in the potent inhibitory actions of μ- and κ-receptor agonists;[632] consequently, exogenous opiate drugs (e.g., morphine) strongly inhibit oxytocin neurons and births during established parturition in rats.[564] By contrast, opioid control of oxytocin neurons is not evident in pregnant mice, and stress interrupts parturition in mice by a β-adrenergic mechanism.[569]

The importance of allopregnanolone actions is indicated by finding that blocking allopregnanolone synthesis in late pregnancy by administering finasteride, which reverses the upregulation of *Penka* expression in the NTS seen in late pregnancy,[21] leads to preterm births and high neonatal mortality.[624]

Removal of Restraints and Readiness to Burst-Fire

Somato-Dendritic Release of Oxytocin in Parturition

Oxytocin released in the SON and PVN during parturition has an important role in the magnocellular nuclei in positive feedback regulation of oxytocin neuron activity, including stimulating further dendritic oxytocin release.[633] The importance of this action is revealed by the disruption of normal parturition in rats receiving an oxytocin antagonist into the SON.[633] Continuous i.c.v. infusion of an oxytocin antagonist for a week before parturition, except for the day before birth, does not affect parturition or maternal behavior but does interfere with the appropriate patterning of oxytocin secretion postpartum for a successful lactation.[634] Hence, while it is important that central oxytocin release is inhibited during pregnancy, it must be able to act at the start of parturition.

The sensitivity of oxytocin release in the PVN to an α1-adrenergic agonist increases in mid-pregnancy, evidently in preparation for stimulation of release during parturition, and subsequently during suckling in lactation, when oxytocin release in the PVN depends on local noradrenaline release, via α- and β-adrenergic receptors.[579,635] However, such increased sensitivity is not evident in late pregnancy.[579]

ENDOGENOUS OPIOID PEPTIDES

Endogenous opioid inhibition seems a likely explanation for the lack of increased sensitivity of dendritic oxytocin release to an α1-agonist in late pregnancy, as naloxone reveals that there is opioid suppression of even basal oxytocin release in the SON at this time.[24] This opioid may be either β-endorphin from arcuate POMC neurons[244] or an enkephalin produced in NTS neurons that project to the PVN and SON.[21] Notably, this important local opioid inhibition mechanism restraining somatodendritic release of oxytocin through late pregnancy is not evident during parturition, allowing enhanced oxytocin release.[636]

ALLOPREGNANOLONE

Although allopregnanolone positively modifies GABA action at $GABA_A$ receptors, in vitro allopregnanolone has a weak stimulatory effect on dendritic oxytocin release from the SON.[637] High levels of allopregnanolone in the SON in late pregnancy might thus contribute to the extracellular pool of oxytocin needed to trigger local changes in synaptic input.[579,621]

Oxytocin Receptors in the Brain in Pregnancy

Specific OTR binding sites in the PVN and SON increase in late pregnancy. In the SON (but not the PVN) this may be a result of estrogen and progesterone action, while preventing progesterone withdrawal has no effect in pregnancy.[335] Only one *Oxtr* gene has been identified,[638] and *Oxtr* mRNA expression in the SON and NTS (but not the PVN) increases in late pregnancy and is maximal at parturition.[303] Many neurons immunolabeled for OTR are activated during parturition, as shown by co-expression of Fos; this includes neurons in the SON and NTS.[303] Most NTS neurons activated in parturition and projecting to the SON express OTR, indicating that the NTS might be an additional site of positive feedback action of oxytocin.[303] Clearly, increased expression of OTR by magnocellular oxytocin neurons at the end of pregnancy is expected to increase autostimulatory actions of oxytocin in parturition.

The oxytocin receptor is a seven-transmembrane G-protein-coupled receptor that binds promiscuously to G proteins when occupied by oxytocin. Hence it directly binds G_q and $G_{i/o}$ subtypes.[639] Thus oxytocin can have diverse actions on different cell types, depending on intracellular organization of subsequent signaling pathways. In oxytocin neurons, stimulation of phospholipase C (PLC) follows G-protein binding, and triggers generation of IP3, which liberates Ca^{2+} from endoplasmic reticulum stores,[640] and this promotes exocytosis of oxytocin from dendrites.[310] In addition, synthesis of eCBs is triggered via MAP kinase or increased $[Ca^{2+}]_i$ actions.[641] Oxytocin can also modulate some K^+ channel subtypes in neurons, in a direction dependent on the type of G-protein coupled.[642] Clearly, there are multiple ways in which oxytocin may act on oxytocin neurons and their inputs (GABAergic, glutamatergic, noradrenergic, as discussed earlier) following release into the dendritic microenvironment in the PVN or SON.

Morphological Plasticity in Pregnancy

Ultrastructural studies carried out over 30 years ago showed remarkable changes in the magnocellular nuclei in the last few days of pregnancy that have been interpreted as enabling the burst-firing of oxytocin neurons during parturition and suckling post-partum. These changes include withdrawal of glial processes from between adjacent oxytocin neurons, consequent closer apposition of adjacent dendrites and cell-bodies, and evident increased numbers of synapses.[643] Such changes can be induced in virgin rats by estrogen and progesterone treatment, mimicking changes in pregnancy, provided oxytocin is given chronically by i.c.v. infusion.[644] Whether this reflects the mechanism of the changes in pregnancy is questionable as oxytocin release in the brain is not increased in pregnancy, but rather is suppressed by an opioid mechanism,[24] although remaining allopregnanolone might stimulate sufficient local oxytocin release.[637] However, preventing the neuro-glial morphological changes does not impact on parturition or burst-firing of oxytocin neurons during suckling in lactation, so the functional importance of these changes is not clear.[645]

Changes in Oxytocin Neuron Electrophysiological Properties

In late pregnancy, as in lactation, oxytocin neurons show more depolarizing afterpotentials (DAPs) after a train of action potentials, which is expected to increase excitability (see Chapter 13).[646] Oxytocin neurons also show exaggerated Ca^{2+}-dependent afterhyperpolarizations (AHPs) following a burst of action potentials, which are considered to limit the size of the burst.[579,647] Pursuing the question of the importance of oxytocin in bringing about changes in the electrical properties of oxytocin neurons in pregnancy, it has been found that central administration of an oxytocin antagonist in midpregnancy reduces the AHP changes,[648] and in vitro treatment of hypothalamic slices from late pregnant rats with oxytocin and estradiol enhances the slow AHP. However, how this, or any of these changes, occur is not clear.[579] A network of genes is proposed to underlie reorganization of SON neurons in established lactation;[649] whether this network is active in pregnancy is not yet known.

Oxytocin Neuron Burst Firing

Our understanding of the mechanisms of synchronized burst-firing by magnocellular oxytocin neurons that generate pulses of oxytocin secretion during parturition is based largely on elegant studies on the behavior of these neurons during suckling, and complemented by in vitro experiments and computer-based modeling (see Chapter 13). During parturition, burst-firing depends on stimulation by noradrenergic inputs from the birth canal as it is stretched during the passage of a fetus.[576] In lactation, burst-firing depends on the input from the nipples during suckling, although the key transmitters have not been firmly identified, noradrenergic mechanisms[650] and GABA input are important in the local control of burst-firing of oxytocin neurons.[651] Oxytocin released by the dendrites when the neurons are stimulated has an essential role: i.c.v. injection of oxytocin or infusion into the PVN or SON during suckling triggers burst-firing, and this can be stopped by an oxytocin antagonist.[334] The actions of oxytocin are through OTR located on the dendrites of the oxytocin neurons, leading to Ca^{2+} entry and mobilization from intracellular stores.[652] In lactation, oxytocin release from an enlarged pool in the SON dendrites is stimulated by glutamate (via NMDA receptors), and oxytocin released in this way acts (indirectly) as a retrograde messenger on axon terminals around oxytocin neurons in the SON to inhibit GABA release.[653,654] Oxytocin also stimulates noradrenaline release in the SON,[655] and Ca^{2+} entry into dendrites is expected to stimulate eCB production, which may then act presynaptically to modify GABAergic and glutamatergic inputs (as discussed herein).

In a cultured organotypic hypothalamic slice, oxytocin neurons show intermittent burst-firing driven by glutamate synapses and modulated by oxytocin actions.[656] In this model, low oxytocin concentrations increase GABAergic release and hence action on oxytocin neurons, while higher oxytocin concentrations inhibit GABA actions by a postreceptor mechanism.[575] The effect of the low concentration of oxytocin leads to excitation of burst-firing on recovery from GABA-induced hyperpolarization, involving Ca^{2+} influx, which likely contributes to oxytocin neuron burst-firing in vivo during suckling and parturition.[575]

OXYTOCINASE

An important factor that has recently emerged is the regulating action on the availability of extracellular oxytocin by inactivation of oxytocin by P-LAP (also referred to as oxytocinase). Immunocytochemical studies have shown expression of P-LAP in a secretory pathway in magnocellular oxytocin neurons.[656b] At the end of pregnancy P-LAP activity is reduced in the SON, which is expected to prolong the half-life of extracellular oxytocin at parturition. However, during lactation a P-LAP inhibitor, amastatin, given centrally increases the frequency of milk ejections, indicating an important role of P-LAP in curtailing oxytocin neuron bursts.[656b]

COMPUTER-BASED MODELING

This has been used to bring together in a dynamic model the factors (25 variables) that result in the burst-firing behavior of oxytocin neurons in lactation (and presumptively in parturition), in particular: (1) the electrophysiological properties of the neurons, (2) their synaptic inputs, and interactions with retrograde signals, (3) the close apposition of oxytocin neuron dendrites to each other, (4) the weak coupling that is thereby enabled: this is via oxytocin action, but not direct electrotonic coupling as previously envisaged,[657] (5) the priming of dendritic oxytocin stores for release, and (6) the positive feedback actions of oxytocin on oxytocin neurons. This model faithfully replicates the intermittent coordinated burst-firing pattern of oxytocin neurons seen during suckling.[658]

Other Consequences of Sustained Inhibition of Magnocellular Oxytocin Neurons in Pregnancy

Oxytocin has peripheral actions that promote natriuresis, and thus impact the control of extracellular fluid and volume regulation. Reduced oxytocin secretion in response to changes in blood volume and osmolarity (which without pregnancy stimulate oxytocin secretion) contribute to the changes in body fluid regulation in pregnancy (see the section Osmoregulation in Pregnancy). Furthermore, oxytocin released within the brain by magnocellular neuron dendrites may contribute to anorectic actions of oxytocin (see the section Food Intake and Metabolism in Pregnancy). Hence reduced oxytocin release in the brain in pregnancy may be an important factor in increased food intake (see the section Food Intake and Metabolism in Pregnancy).

Summary and Conclusions

Magnocellular oxytocin neurons release oxytocin from their axon terminals in the posterior pituitary in pulses during parturition and subsequently during suckling in lactation. This is the most efficient and effective way in which uterine contractions and milk ejections are driven by oxytocin; hence the magnocellular oxytocin neurons are a hub for driving these processes. Oxytocin is evidently not essential in parturition but is essential in lactation, as seen in experiments on mice with deletion of the oxytocin or oxytocin receptor genes. However, neural signals from the birth canal during parturition certainly act via spinal cord pathways and relays in the brain stem to the PVN and SON to stimulate oxytocin secretion, and oxytocin antagonists have some efficacy in delayed threatened preterm births.

The mechanism that generates pulses of oxytocin, a few minutes apart, is coordinated high-frequency action potential discharge in the whole population of magnocellular oxytocin neurons, which is only seen during parturition and lactation. This behavior is triggered by neural input but is organized by an interaction among the oxytocin neurons and with their synaptic inputs that critically depends on oxytocin released by the dendrites of these neurons. This oxytocin acts on oxytocin receptors on the neurons and increases eCB release, which then modulates excitatory and inhibitory synaptic input, having the effect of coupling the neurons. In addition, local oxytocin actions prime the dendrites for the release of more oxytocin; this positive feedback leads to an explosion of action potentials in all the neurons and secretion of an oxytocin pulse. Until late pregnancy, multiple mechanisms are active to prevent premature activation of oxytocin secretion, including nitric oxide produced by the oxytocin neurons, endogenous opioids in inputs, and allopregnanolone produced in the brain from progesterone. Oxytocinase produced by the oxytocin neurons is likely important in regulating duration of local oxytocin actions.

Future Perspectives

A computer-based model, using the known variables, replicates the coordinated burst-firing of oxytocin neurons seen in vivo. Such models enable understanding roles of new discoveries and the formulation of hypotheses. It is not clear yet which neurotransmitters in the pathway from the brain stem are most important in stimulating burst-firing during parturition; possible roles of eCBs in regulating oxytocin neurons during parturition need to be tested. Only minor changes are seen in the properties of oxytocin neurons in pregnancy, though these facilitate expression and regulation of burst-firing. The store of oxytocin in the posterior pituitary increases because of decreased release rather than upregulation of synthesis. It remains unclear how estrogen, or related steroids, might influence oxytocin gene expression.

COGNITION DURING PREGNANCY

Given the dynamic fluctuations in hormones that the maternal brain is exposed to in pregnancy (Figure 44.1), it is perhaps unsurprising that other brain systems besides those that function to ensure a successful pregnancy outcome and the expression of appropriate maternal behavior are also affected. For example, the hippocampus plays a critical role in certain aspects of learning and memory and expresses receptors for many of the hormones that show marked changes in secretion in pregnancy, such as estradiol,[659–661] progesterone,[662,663] glucocorticoids,[549] oxytocin,[664] and prolactin,[665] indicating the possibility for alterations in cognition during pregnancy. The first record in the literature reporting altered cognitive ability in pregnant women was in 1969,[666] and since then investigators have utilized rodent models to study the mechanisms involved in altered cognition during pregnancy and postpartum.

Rodent Behavioral Tests of Learning and Memory

Cognition is a complex process that comprises several components. Firstly, information must be acquired or learned, then it should be retained or stored, and lastly the stored information must be retrieved when required.

Several behavioral tests have been devised to assess cognitive performance in rodents; commonly used are the Morris water maze,[667] radial arm maze,[668] and object recognition task.[669] The Morris water maze[667] is a hippocampal-dependent task widely used to study spatial learning and memory. It comprises a large circular pool filled with water containing a hidden "escape" platform submerged just below the surface and distal cues around the pool to aid the animal's orientation. Acquisition (learning) and spatial reference memory (long-term, stable memory) can be assessed by measuring how quickly the animal learns the location of the platform over repeated trials. Alterations to the protocol can be used to assess memory retrieval and working memory (memory that is useful for a limited period of time, e.g., information unique to a specific trial). The radial arm maze[668] is another hippocampal-dependent task used to assess spatial learning and memory. In this task animals have to remember where food rewards are located: working memory is tested as the ability to remember where they just found a food reward, and reference memory is tested as the ability to remember the restricted locations of a food reward in a previous session. In the object recognition test,[669] animals are assessed on their ability to discriminate between a familiar object and a novel one. The test is based on the tendency for rodents to spend more time investigating a novel object than one previously encountered, though only if they remember the familiar one. Thus the choice to explore the novel object reflects recognition memory. The object recognition test is sometimes modified to test object place memory (the location of one of the objects, rather than the object itself is changed). Recognition tasks such as these involve processing by the hippocampus, prefrontal cortex, and/or perirhinal cortex.[670–675]

Cognition in Animals during Pregnancy

It is well established that lactation and motherhood are associated with enhanced cognition;[676,677] less is understood about cognition during pregnancy.

Behavioral Tests of Cognition during Pregnancy

Changes in cognitive performance during pregnancy depend upon the stage of pregnancy and the type of memory system being tested. During the first 14–16 days of gestation in rats, spatial memory as assessed by the Morris water maze[678] or by an object placement task[679] is enhanced compared with nonpregnant females. However, in late pregnancy (day 21) change in cognitive ability is less clear, with one study reporting that spatial memory is similar to that seen in virgin rats[680] and another indicating it is impaired,[678] using the water maze. Nevertheless, working memory or cognitive flexibility may actually be enhanced in late pregnancy[680] as pregnant rats, compared with virgin rats, display less perseveration to a previously learned location when the water maze platform is relocated.

Interestingly, prior reproductive experience influences spatial memory as rats in their second or third pregnancy perform better in a spatial memory task (days 2–17) than do primigravid rats,[681] indicating cognitive performance is further enhanced in subsequent pregnancies.

Rodent tests of cognition should however be interpreted with caution, as many tests are aversive, contain stress-invoking elements, or rely on reinforcement by rewards (commonly with food restriction). For example, the water maze, commonly used to assess spatial memory, involves forced swimming—a robust stressor in rodents.[682,683] The test relies on the animals finding the water "aversive" and/or being sufficiently "stressed" by the water in order to motivate them to escape onto the hidden platform. In nonpregnant rats, estrogen potentiates HPA axis responses to stress, while in late pregnancy the responsiveness of the HPA axis to stressful stimuli, including forced swimming, is markedly reduced (see the section The Hypothalamo-Pituitary-Adrenal Axis). Thus, findings from this type of behavioral test could be skewed by the level of stress the animal experiences. Moreover, as trials are repeated, the affective state of the animal should also be taken into account, given that repeated stressful experiences can lead to learned helplessness.[684]

Effects of Pregnancy-Related Hormones on Cognitive Performance

Changes in the hormonal milieu in pregnancy (Figure 44.1) have been proposed to underlie altered cognitive ability; however, the involvement of pregnancy-related hormones (e.g., estradiol, progesterone) on cognition has not been directly tested in pregnant animals (as blocking their action would likely compromise the pregnancy). Instead, inferences must be made from studies investigating the effects of administration of these hormones on cognitive performance in nonpregnant animals.

ESTROGENS

While there is an abundance of evidence supporting a role for estrogens in influencing cognitive performance in nonpregnant animals, findings from behavioral studies are equivocal. Such studies show that estrogens can enhance,[685–688] impair, or have no effect on learning and memory.[689–692] Critically, the effects of estrogen on cognition seem to depend upon several factors, including the nature of the task (e.g., how aversive it is), the type of memory being tested (e.g., spatial working memory, reference memory, recognition), the age[693] and sex of the animal,[694,695] the levels and pattern of estrogen exposure and when it is administered (i.e., pre- or posttraining), and the presence or absence of progesterone. For example, some studies have shown that exogenous estradiol administration to ovariectomized rats enhances memory retention in spatial memory tasks such as the Morris water maze[686,687] or open field tower task,[696] and can enhance recognition and memory retention in object recognition and object place tasks,[688] while other studies where endogenous estradiol levels are naturally higher, such as proestrus, report no effect[689] or even impaired spatial memory in the water maze.[690] Moreover, studies using the radial arm maze have found estradiol improves acquisition and working memory[697,698] but has no effect on reference memory,[697,698] whereas others have found the opposite effect, with estrogen enhancing reference memory but not working memory.[685] Discrepancies like these may result from the different doses of estrogen used (and indeed the type of estrogen used and route of administration), since low levels of estrogen have been shown to facilitate working memory,[691] while high estrogen levels impair working memory on the radial arm maze,[691,692] with similar effects on T maze alternation, a prefrontal cortex-dependent memory task.[699]

Generally, moderate levels of estrogen appear to enhance cognitive processing; however, its effects are not observed under all testing conditions. Indeed the effects of estrogens on cognition appear to be context dependent with stress/adversity and the environment playing pivotal roles in influencing estrogens actions.[696,700,701]

Long-term potentiation is a persistent enhancement in signal transmission or synaptic strength between two neurons and is considered one of the major cellular mechanisms underlying learning and memory.[702] Induction of LTP in the CA1 region of the hippocampus is augmented during proestrus (when estrogen levels are at their highest levels of the cycle) in rats.[25] In contrast, the induction of long-term depression (LTD; a persistent activity-dependent reduction in the efficacy of neuronal synapses) is severely attenuated during proestrus but not during other stages of the cycle.[25] Furthermore, induction of LTP in the hippocampus is augmented in multiparous mice compared with virgin mice.[703] Thus,

estrogen-related changes in hippocampal synaptic plasticity may be involved in altered cognition in pregnancy, however, this requires further investigation.

PROGESTERONE AND ALLOPREGNANOLONE

Although much of the research concerning the role of the female sex steroids in modulating cognition has focused on estrogens, progesterone also plays an important role. In ovariectomized females, administration of progesterone enhances object recognition in rats[704–706] and mice,[707,708] and object place recognition[709,710] and social recognition in rats.[711] Moreover, increased levels of progesterone in the hippocampus and prefrontal cortex are associated with improved Y maze performance.[712] Some of these effects of progesterone may be mediated by its metabolite, allopregnanolone.[704,705,712] Indeed, higher levels of allopregnanolone in the prefrontal cortex and hippocampus are associated with improved object recognition[712] and enhanced performance in the water maze,[704] and allopregnanolone administration improves object recognition,[705] object placement memory,[709] and performance in the water maze,[713] Y maze,[713] and in an inhibitory avoidance task.[714] Whether the fluctuating levels of progesterone and/or allopregnanolone during pregnancy (increasing progressively during early and mid-pregnancy, peaking on around day 16, before a rapid decline 2–3 days before parturition) are involved in the changes in cognition in pregnancy is unclear, though they would seem potential candidates.

OXYTOCIN

The roles of oxytocin in parturition, lactation, and maternal behavior are well established,[715] which may explain why the majority of studies investigating a role for oxytocin in cognitive processing have focused on its role in social memory and recognition. Several studies have demonstrated that central oxytocin facilitates social recognition in male rats[716,717] and mice,[568,718,719] and oxytocin also plays an important role in social recognition in female rodents.[720] Social recognition driven by olfactory cues is mediated by the actions of oxytocin and oxytocin receptors in the medial amygdala (MeA) and olfactory bulb following priming by estrogen[721] (see also Chapter 48).

The "Bruce effect" or "pregnancy block" refers to the tendency for pregnancy in female mice to be terminated by exposure to an unfamiliar male.[722] During pregnancy female wild-type mice are able to discriminate between their mate (pregnancy continues) and an unfamiliar male (pregnancy is terminated) even after a 24 h period of separation.[723] However, pregnant oxytocin knockout ($Oxt^{-/-}$) mice are unable to recognize their mate after the same period of separation, resulting in their pregnancy being terminated when exposed to the mate,[723] hence illustrating the importance of oxytocin in this olfactory memory.

The significance of oxytocin in social memory and recognition is perhaps more obviously apparent after birth. Centrally released oxytocin at parturition in ewes facilitates olfactory lamb recognition and bonding, which is essential for successful maternal behavior in this species.[26,724] In rodents, oxytocin induces LTP in the hippocampus and is critically involved in the enhanced spatial learning and memory associated with motherhood.[703] Thus central oxytocin serves to mediate social recognition before and after birth, as well as enhance spatial memory in the postpartum period, which presumably optimizes foraging for food and navigation to and from the young.

Neuroplasticity during Pregnancy and the Role of Pregnancy-Related Hormones

Estradiol and progesterone influence hippocampal structure and function. In late pregnancy, dendritic spine density in the CA1 region of the hippocampus is increased compared with virgin females (Figure 44.10).[28] This is likely a result of increased levels of circulating sex steroids, as a similar increase in spine density can be induced by a treatment regime that mimics pregnancy levels of estradiol and progesterone in ovariectomized

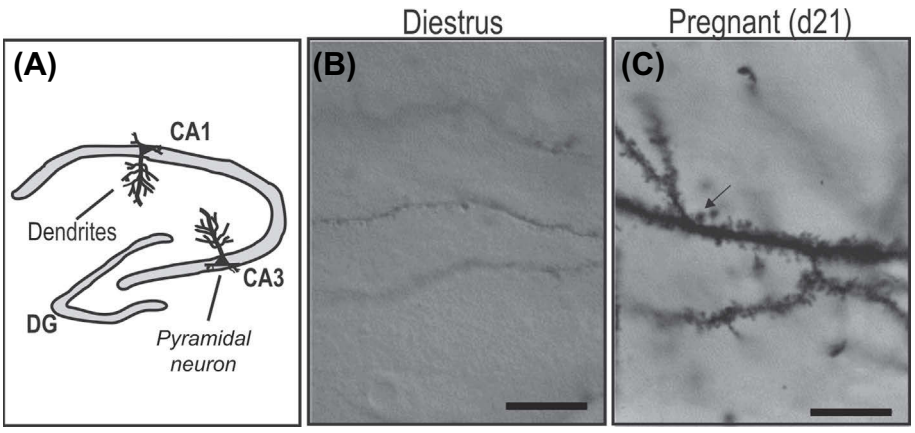

FIGURE 44.10 Dendritic spines in the hippocampus in pregnancy. (A) Diagram illustrating hippocampal pyramidal neurons and their dendritic trees. Photomicrographs of dendritic spines in the CA1 region of the dorsal hippocampus from a (B) diestrus female and (C) late pregnant (gestational day 21) rat. Scale bar = 10 μm. Note the increase in the density of spines on the dendrites (indicated by arrow) in late pregnancy compared with diestrus. As dendritic spines represent potential sites for postsynaptic input, an increase in their number is often interpreted as an increased potential for neurotransmission and information processing. *Source: Adapted from Kinsley et al.[28] with permission from Elsevier.*

virgin rats.[28] As dendritic spines represent potential sites for synaptic input, an increase in their number is often interpreted as an increased potential for neurotransmission and information processing.[725] Estradiol is a potent modulator of dendritic spine modeling, and exposure to either exogenously administered estradiol or increased endogenous levels during proestrus significantly increases the dendritic spine density in the CA1 region of the hippocampus[726–728] in rats and in nonhuman primates;[729] estradiol has been shown to enhance the number of dendritic spines in the prefrontal cortex.[730] Furthermore, in ovariectomized rats estradiol treatment increases spine density in CA1 pyramidal cells and enhances spatial memory in the Morris water maze,[731] an effect that can be augmented by progesterone.[731]

Neurogenesis during Pregnancy and the Role of Pregnancy-Related Hormones

The functional relevance of adult neurogenesis in cognition is unclear,[732] however, there is some evidence that hippocampal neurogenesis can play an important role.[733,734] Moreover, pregnancy-related hormones, in particular estradiol (see following), but also oxytocin,[735] can stimulate adult neurogenesis in the hippocampus. Changes in estradiol levels across the estrous cycle impact upon hippocampal neurogenesis in adult female rats.[736] For instance, estradiol levels in the circulation are directly correlated with cell proliferation and are inversely correlated with cell death.[736] Moreover at proestrus when endogenous estradiol reaches its highest level during the estrous cycle, rats have approximately 50% more newly proliferating cells in the dentate gyrus compared to rats at diestrus, when estradiol levels are at their lowest level,[736] an effect that can be abolished by removing the ovarian source of estradiol.[736] Estrogens evidently exert their action on neurogenesis via both ERα and ERβ, as agonists for both increase cell proliferation in the dentate gyrus.[737] In rats, ERα, ERβ, and PR agonists can enhance spatial learning,[697,709,738] while both *Erα*$^{-/-}$ (*Esr1*) and *Erβ*$^{-/-}$ (*Esr2*) mice show deficits in performing hippocampal-dependent memory tasks.[739,740] Furthermore, administration of an ERβ agonist improves cognitive performance in wild-type, but not in *Erβ*$^{-/-}$, mice.[741]

To date, few studies have directly examined the role of progesterone or allopregnanolone in neurogenesis. Nevertheless, allopregnanolone can induce a dose-dependent increase in the proliferation of neuroprogenitor cells derived from the rat hippocampus and human neural stem cells derived from the cerebral cortex in vitro.[742] In vivo, allopregnanolone promotes neurogenesis in the hippocampus and reverses cognitive deficits in a mouse model of Alzheimer's disease,[743] and furthermore has been shown to restore impairments in hippocampal neurogenesis induced by chronic isolation stress in rats.[744] Whether allopregnanolone is involved in increased neurogenesis in pregnancy remains to be elucidated.

Given these data it may be predicted that neurogenesis would be increased in pregnancy; indeed proliferation is markedly increased in the subventricular zone (SVZ) in late pregnant rats,[745] though not in the hippocampus.[745] Nonetheless, increased neurogenesis in the SVZ is also seen during pregnancy in mice,[27] an effect mediated by prolactin that results in increased incorporation of new neurons into the olfactory bulb.[27] This process is considered to play an important role in subsequent maternal behavior, given that olfactory discrimination is critical for social recognition of the offspring (see the section Maternal Behavior). Thus, in pregnancy neurogenesis may not be critical for alterations in classical hippocampal-dependent cognitive function, e.g., spatial memory, but the hormone-mediated generation of new olfactory neurons (together with the actions of oxytocin, discussed herein) may be important in enhancing social memory, especially postpartum.

Cognition in Women during Pregnancy

There is much anecdotal evidence[746,747] and data from subjective studies[748,749] indicating impaired cognitive performance during pregnancy. In a study by Poser et al.,[749] more than 80% of the women self-reported increased forgetfulness during pregnancy. In another study, two-thirds of women reported experiencing problems with one or more of the following during their pregnancy: concentration, short-term memory loss, and absent-mindedness.[748] Intriguingly, in this study more changes were reported by women who were older, married/living with partner, and had a higher level of education. However, it has been suggested that subjective memory impairments may bear little relationship to objective measures and rather may be linked with low mood (anxiety or depression)[750] or disrupted sleep.[751]

Findings employing objective measures of cognitive performance in women during pregnancy are somewhat ambiguous. Some report deficits in declarative memory (conscious recall of facts or events),[752,753] while others report no impairments in declarative memory but impaired nondeclarative memory (procedural memory, e.g., skills, habits that become automatic)[754] or impaired prospective memory (remembering to perform an intended action at the appropriate time).[755] Whereas other studies report no significant impairments in memory, despite the women in the sample self-reporting increased forgetfulness during pregnancy.[756] These studies indicate that while in women cognitive performance may be impaired during pregnancy, the effects depend upon the specific nature of the memory task employed, the stage of pregnancy, and the affective state of the woman.

Hormonal Modulators of Cognitive Function: Women

ESTROGEN

Despite estrogens having been demonstrated to have beneficial effects on certain aspects of memory in premenopausal women who have undergone ovariectomy[757] and in postmenopausal women administered estrogen replacement therapy,[758] the role of maternal estradiol levels in cognitive function during pregnancy is less clear. For example, women with higher levels of estradiol in early gestation perform less well in a verbal recall memory task in the last trimester.[759] However, other studies have found no discernible association between estradiol levels and performance scores in women in late pregnancy.[760,761]

PROGESTERONE AND ALLOPREGNANOLONE

In nonpregnant women, other sex steroid hormones known to change dramatically in pregnancy have been associated with modulating cognition. Plasma levels of the neuroactive progesterone metabolite, allopregnanolone, correlate with increased measures of confusion and delayed verbal memory recall,[762] though this may be related to the sedative effects of allopregnanolone.[763] Nevertheless, functional magnetic resonance (fMRI) studies have demonstrated that progesterone administration (possibly exerting its actions via allopregnanolone), impairs recognition memory by suppressing recruitment of brain regions such as the amygdala and fusiform gyrus during memory encoding and in the fusiform gyrus and prefrontal cortex during memory retrieval.[764] Other studies have not detected any correlation between progesterone levels and cognitive performance in gestation;[760,761] however, it is not yet known whether increased allopregnanolone level affects cognitive processing in pregnant women.

GLUCOCORTICOIDS

In the absence of pregnancy, effects of glucocorticoids on cognition are well established[765,766] and show an inverted U-shaped function,[767,768] meaning that high and low levels of glucocorticoids have detrimental effects for many cognitive processes, whereas moderate levels are associated with optimal performance. Indeed, one study of pregnant women carried out between 34 and 38 weeks of gestation reported this type of relationship between cortisol levels and performance in a verbal memory test.[761] However, another study described that lower cortisol levels between 14 and 36 weeks of gestation correlated with poorer performance in a verbal recall memory task in the last trimester.[759]

DEHYDROEPIANDROSTERONE

The evidence for effects of dehydroepiandrosterone (DHEA; a weak androgen secreted in large amounts by the adrenal) on cognitive function is inconsistent. While some studies demonstrate positive correlations between DHEA levels and cognitive function,[769,770] others indicate increased DHEA levels contribute to impaired cognitive function[771] or improve cognitive scores only in elderly patients with preexisting mild-moderate cognitive impairment[772] but are without effect in healthy older women.[773,774] Increased levels of DHEA in late pregnancy have been associated with increased performance in a line orientation task,[760] but there is little other evidence currently available.

PROLACTIN AND OXYTOCIN

Increased levels of peptide hormones have also been implicated in modulating cognition during pregnancy. Prolactin levels increase substantially in pregnancy (See the section The Prolactin System: Preparation for Lactation; Figure 44.1).[775] One study has suggested that higher prolactin levels in late gestation are detrimental to executive function.[761] However, moderate prolactin levels are optimal for performing verbal memory recall tasks in pregnancy, whereas both higher and lower levels of circulating prolactin may be detrimental.[761] Studies in women have found no correlation between cognitive performance and plasma oxytocin concentrations.[776] This is perhaps not surprising given that unlike steroid hormones, circulating oxytocin does not cross the BBB in effective concentrations, and, furthermore, any behavioral effects of oxytocin on cognitive processing are likely a result of centrally released oxytocin acting within the brain.[777]

Hippocampal Volume in Pregnant Women

Consistent with reports of impaired cognitive performance in pregnancy in women, there is a temporary decrease in the overall volume of the brain during pregnancy, which returns to prepregnancy size within 6 months postpartum.[778] It has been proposed that elevated cortisol levels may be involved.[779–781]

Summary and Conclusions

There is an apparent inconsistency in the literature when considering the effects of pregnancy on cognition between rodents and humans. The evidence from rodents predominantly indicates enhanced cognition during pregnancy. However, the human literature points toward impaired cognition in pregnancy. It seems that enhanced cognition in rodents during pregnancy ultimately serves to maximize the survival chances of the offspring. The hormones that the brain is exposed to during pregnancy prepare the animal for the challenges of motherhood. More efficient learning and enhanced memory are just one critical aspect of this. Enhanced social memory facilitates recognition of her offspring and mother–infant bonding, as well as aids

in the identification of possibly hostile conspecifics so she can defend her young. Improved spatial learning and memory will aid the efficiency of the mother's navigation to and from the nest while searching for food, thus minimizing the time she must leave the pups unattended and reducing the risk they will be harmed in her absence.

Future Perspectives

Whether the discrepancy between the rodent and the human literature is simply the result of species difference or some other underlying factor(s) requires further investigation. It may be that pregnant women should be tested using more ethologically relevant tasks, such as those more related to the pregnancy and impending motherhood (rather than intelligence quotient-, IQ-based tests), and enhanced cognitive abilities like those seen in rodents may be revealed. In support of this suggestion, pregnant women (at 22–33 weeks gestation) have been shown to have heightened attention scores in response to danger cues compared with nonpregnant controls.[782]

MATERNAL BEHAVIOR

Maternal behavior in mammals is necessarily expressed as the first young are born. This rapid expression of maternal behavior is possible because of the predictive adaptations in the maternal brain that have been organized in late pregnancy by the actions of hormones of pregnancy. These hormones act on mainly preexisting neural circuitry that organizes interactions with other individuals and involves recognition, emotionality, and attachment.[783] The actions of hormones evidently tune and bias this circuitry to favor interactions with the newborn that provide protection and nutrition, and are obviously essential for survival of the offspring and the species. The pregnancy hormones that are involved are prolactin and placental lactogen, and the female sex steroids, estradiol and progesterone; these hormones can all enter the brain from the circulation.

However, some species or strains display maternal behavior spontaneously without pregnancy, and virgin rats will display maternal behavior if repeatedly exposed to neonates over several days; this "sensitization" is independent of ovarian or pituitary hormones.[784] Nonetheless, prolactin accelerates the expression of maternal behavior in virgin rats.[785] Moreover, a substantial proportion of pregnant rats show maternal behavior toward pups on the last day of pregnancy; hence the neural mechanisms for rapid expression of maternal behavior become active before parturition.[786] This activation depends on the prolonged actions of progesterone, estradiol, and prolactin or placental lactogen through pregnancy (Figure 44.1). Hence, rats ovariectomized and hysterectomized at day 16 of pregnancy show rapid induction of maternal behavior,[787] which can be further advanced by a single injection of estradiol.[788] Moreover, treating virgin rats with sequential progesterone (days 1–11), estradiol (days 11–17), and then prolactin to simulate pregnancy changes leads to rapid expression of maternal behavior on exposure to young; progesterone withdrawal is important, as is the presence of prolactin.[32,34,520] Given in combination with progesterone and estrogen, i.c.v. prolactin (days 11–13), which is not effective alone, induces rapid expression of maternal behavior.[34]

Brain mechanisms that organize maternal behavior have been studied in these models as well as in normal pregnancy. Brain circuitry involved in maternal behavior includes the olfactory system, the mPOA, and the mesolimbic dopaminergic reward circuitry. Within the brain, actions of centrally released oxytocin are important, as are dopamine and opioid peptides (Figure 44.11).

Mammalian maternal behavior comprises several distinct components, with species variability in their relative importance. These are: nest building, and maintenance thereafter; immediate care of the young at birth (licking, cleaning, placentophagy); recognition and bonding; nursing; and protective defensive behavior (retrieval of young, aggression against intruders or predators). Some of these behaviors begin to emerge near the end of pregnancy (nest building, aggression), and others require birth to have been completed and the presence of the young.

The expression of maternal behavior at the end of pregnancy involves suppression of the actions of inhibitory factors (especially progesterone), as well as the activation of stimulatory factors (central oxytocin, dopamine). While maternal behaviors can be induced in virgin rats by repeated exposure over several days to neonatal pups,[789] the immediate expression of maternal behavior after birth depends on changes in the maternal brain at the end of pregnancy and immediately postpartum.

There is variability in the quality of maternal behavior within a species, and understanding the neurobiological basis of this has been a recent focus of interest as quality of nurturing impacts on offspring long-term health and welfare.[790] (see also Chapter 51.)

Neural Circuitry for Maternal Behavior

Olfactory Bulbs

Olfactory input in virgin rats evidently conveys stimuli from pups that are aversive and are processed via the MeA to produce defensive responses (Figure 44.11).[791] Suppression of these responses and activation of maternal behaviors postpartum is a function of the hormonally primed mPOA, through connections to the mesolimbic

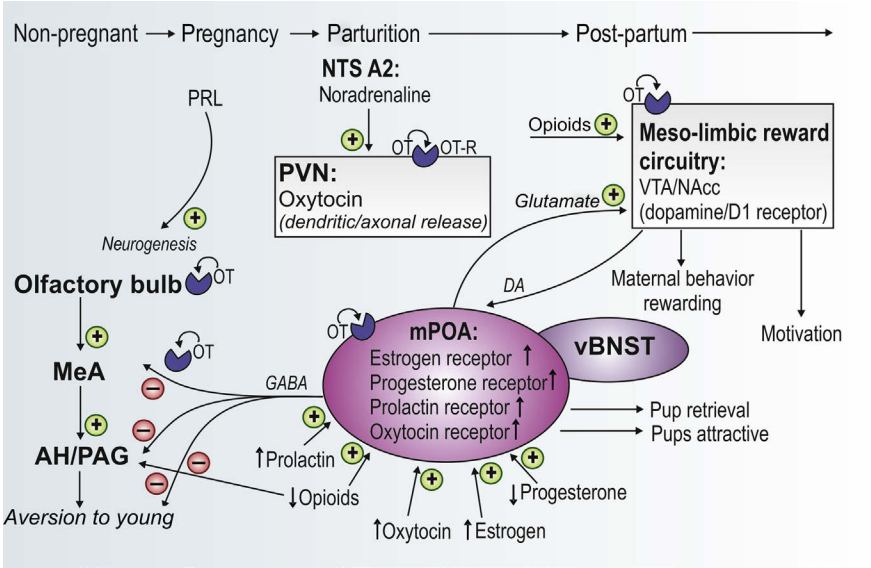

FIGURE 44.11 Neural networks organizing maternal behavior. Before pregnancy, aversion to young or disinterest is predominant, involving olfactory input to the medial amygdala (MeA) and thence to the periaqueductal gray (PAG) via the anterior hypothalamus (AH). Stimulation of neurogenesis in the olfactory bulbs by prolactin in early pregnancy is important for maternal behavior postpartum. At the end of pregnancy the medial preoptic area (mPOA) GABA output, interacting with oxytocin actions in the olfactory bulbs and amygdala, suppresses aversion to young. The mPOA is primed by actions of estrogen, progesterone, and prolactin in late pregnancy. Progesterone withdrawal and downregulation of μ-opioid action, with upregulation of oxytocin action, lead to display of maternal behavior at parturition. Central release of oxytocin stimulated by parturition, involving noradrenergic input from the nucleus tractus solitarii (NTS), promotes maternal behavior through actions at multiple sites, where oxytocin receptor expression is upregulated. mPOA projections to the meso-limbic dopaminergic (reward) circuitry stimulates motivation to perform maternally, and to provide reward via dopamine release in the NAcc. In the VTA dopamine neurons are stimulated (indirectly) by μ-opioid action, which here promotes maternal behavior, with actions on the mPOA. Activation of μ-opioid input to the PAG switches off maternal behavior. AH, anterior hypothalamus; DA, dopamine; D1, dopamine receptor; GABA, γ-aminobutyric acid; MeA, medial amygdala; mPOA, medial preoptic area; NAcc, nucleus accumbens; NTS, nucleus tractus solitarii; PAG, periaqueductal gray; OT, oxytocin; OT-R, oxytocin receptor; PVN, paraventricular nucleus; vBNST, ventral bed nucleus of stria terminalis; VTA, ventral tegmental area.

dopamine system. Hence dopamine release in this system is considered to mediate signaling of readiness to be maternal.[792]

Medial Preoptic Area

It is well-established that the mPOA has a key central role as a hub in the network that organizes and regulates the onset and maintenance of maternal behavior; the adjacent ventral BNST (vBNST) is also important (Figure 44.11).[787,793]

Estradiol, but not prolactin action specifically in the mPOA facilitates maternal behavior in the ovariectomized and hysterectomized pregnant rat model.[787] How estradiol enables neurons in the mPOA to initiate maternal behavior is not clear.[794]

PROLACTIN ACTION IN THE mPOA IN LATE PREGNANCY

As well as being essential for the preparation of the mammary glands for lactation and for milk production, prolactin has important actions in the brain that prepare for maternal behavior and reduce anxious behavior at this time.[795] It is well established that prolactin and placental lactogen actions in the brain near the end of pregnancy are important in the rapid expression of maternal behavior postpartum.[796–798] These actions are mediated by the mPOA, which expresses prolactin receptorsm,[442,799] but are also dependent on female sex steroids.[34,441,797,800–803] Hence, blocking release of prolactin from the anterior pituitary (with a D2 receptor agonist, bromocriptine, CB154) or blocking prolactin action in the brain, with a PRL-R antagonist into the mPOA, respectively, delays the normal rapid development of maternal behavior after parturition or after estradiol and progesterone treatment to simulate pregnancy.[804] More recently, studies on mice have shown prolactin actions in the brain in early pregnancy also to be important, as discussed following.[805]

PROLACTIN RECEPTORS IN THE BRAIN

PRL-R mRNA is distributed quite widely, but focally, in the brain. PRL-R_L, the active signaling form,[806] is found in the choroid plexus, anteroventral periventricular (AVPV) nucleus, arcuate, mPOA, PVN, SON, VMN, limbic regions (BNST, MeA, thalamus, central gray), and parietal cortex (during lactation). PRL-R_S is strongly

expressed in the choroid plexus and also essentially in the same regions as the long-form.[442,807,808] Notably, long-form, but not short-form *Prlr* mRNA expression in whole brain extracts is upregulated in pregnancy or by estradiol or progestogen treatment,[441,809] but the changes are localized: PRL-R_L mRNA expression is increased at the end of pregnancy (or by progesterone and estradiol treatment in virgin rats) in the mPOA and choroid plexus, but not the VMN.[442,810] In the mouse, prolactin increases pSTAT5 expression in most areas expressing PRL-R, excepting the PVN and median preoptic nucleus (MPN), indicating alternative postreceptor signaling in this region.[808]

mPOA and the Mesocorticolimbic Dopamine System

Extensive neuroanatomical studies have shown that the mPOA has connections via the lateral preoptic area with the VTA, and with the intermediate lateral septum, nucleus accumbens, olfactory circuitry, and motor outputs.[811,812] Through connections with the VTA, and hence the mesolimbic dopaminergic reward circuitry involving the nucleus accumbens, the mPOA regulates appetitive aspects of maternal behavior (Figure 44.11).[792,793] The lateral septum is important in maternal aggressive behavior, which is first seen in late pregnancy.[813,814]

mPOA projections to the mesolimbic dopamine system have been shown in a range of studies to be of key importance by evoking motivation (appetite) to behave maternally, and consummation provides reward for doing so via the nucleus accumbens (the "pleasure center").[815] For example, blocking D1, but not D2, receptors in the nucleus accumbens specifically disrupts postpartum maternal behavior.[816] Furthermore, in pregnancy-terminated rats (rats hysterectomized and ovariectomized on day 15 of pregnancy to investigate mechanisms of preparation for maternal behavior), infusion of a D1 agonist into the mPOA or nucleus accumbens facilitates rapid expression of maternal behavior.[817] The role of the mPOA is encapsulated as switching aversion or disinterest in the newborn to intense attraction.[382]

In rats, a tendency to kill young pups is suppressed near the end of pregnancy.[818] In mice, neurotoxic lesion of the central zone of the mPOA, which is crucial for maternal behavior, induces infanticidal behavior postpartum.[819] There are multiple neuronal phenotypes in this zone, and it is not clear which is most important for maternal behavior, although GABA neurons are predominant.[819] Unexpectedly, oxytocin neurons in the mPOA are not activated during maternal behavior.[819]

Ventral Tegmental Area

The VTA consists predominantly of dopaminergic neurons (the A10 group) and GABA neurons; the dopamine neurons form the mesocorticolimbic dopamine system, central to the reward circuitry in the brain. It is a focus for studies of mechanisms of normal (see the section Food Intake and Metabolism in Pregnancy), and abnormal, motivations and hence of drug addiction.[820] Activity in this system is important in the normal motivation for maternal behavior.[382] mPOA neurons project to the VTA, and VTA dopaminergic neurons project to the nucleus accumbens, medial prefrontal cortex and mPOA, where dopamine acts to promote maternal behavior, for example, in pregnancy-terminated rats.[817] The power of the VTA in promoting maternal behavior has been shown in virgin rats by chronically driving the dopamine neurons with an injection of pertussis toxin into the VTA, which then reduces latency to show maternal behavior.[821]

Prolactin and Neurogenesis in Early Pregnancy

The circadian pattern of increased prolactin secretion in early pregnancy in the rat (a diurnal and a nocturnal surge) was discussed earlier (see the section The Prolactin System: Preparation for Lactation). In mice there is only a single diurnal surge through the first 9 days of pregnancy.[822,823] In addition to an essential role of these prolactin surges in the maintenance of the corpora lutea (see the section The Prolactin System: Preparation for Lactation), studies on mice have shown that they have important actions in stimulating neurogenesis in the SVZ of the lateral ventricle, giving rise to new neurons that migrate to the olfactory bulbs,[27,795] as discussed earlier (Figure 44.11; see the section Cognition during Pregnancy). Similar increases in neurogenesis in the SVZ are seen near the end of pregnancy in rats.[745] In virgin rats induced to be maternal, a less-marked increase in neurogenesis in the SVZ is seen, but this seems unlikely to be a result of circulating prolactin action.[824]

In mice, the primary site of action of prolactin in stimulating neurogenesis in the SVZ is not clear: short-form PRL-R have been detected immunocytochemically in the dorsolateral corner of the mouse SVZ,[27] but PRL-R mRNA is not detectable in the SVZ, nor is there a pSTAT5 response to prolactin.[808] An action of growth factors released by the adjacent choroid plexus, which expresses abundant PRL-R and pSTAT5 in response to prolactin, might stimulate neurogenesis in the SVZ.[27,808]

Blocking actions of prolactin on SVZ neurogenesis pharmacologically results in disturbance of postpartum maternal behavior, such that mice are more anxious in a novel environment and show impaired maternal behavior (slow pup retrieval).[795] A similar outcome results from the suppression of prolactin secretion in early pregnancy that follows exposure to unfamiliar female mouse pheromones.[795] By contrast, exposure to male pheromones (over 2 weeks) stimulates prolactin secretion, increases neurogenesis in the SVZ, from which new neurons move to the olfactory bulbs, and eventually advances the emergence of maternal behavior in virgin and pregnant mice. These effects of exposure to male pheromones are dependent on

estradiol and progesterone.[805,825] The two critical actions of prolactin in early pregnancy to reduce anxiety postpartum, and to enable normal maternal behavior, seem to be a result of separate actions of prolactin.[823]

Oxytocin Actions Postpartum

Released centrally, oxytocin facilitates initiation of maternal behavior especially in conditions of environmental stress.[826,827] From studies of projections of oxytocin neurons, central oxytocin release, including by dendrites, changes in oxytocin receptor expression, and localized sites of administered oxytocin action, oxytocin has been found to have actions at several nodes in the networks organizing and controlling expression of maternal behavior (Figure 44.11). These include the mPOA, VTA,[36,828] nucleus accumbens,[829] and MeA,[815,830] where oxytocin acts by enhancing interactions with pups. Changes in pregnancy in oxytocin production and in oxytocin receptor expression in the brain were discussed earlier (see the section Magnocellular Oxytocin Neuron System in Pregnancy). In the present context, oxytocin receptor expression in late pregnancy is increased in the MeA, mPOA, olfactory bulbs, and VTA.[36,303,313,335]

Ventral Tegmental Area and Oxytocin

The VTA is a site of oxytocin action. mPOA neurons project to the VTA, and these include neurons expressing ER or oxytocin.[828,831] Oxytocin receptor binding in the VTA is increased at the end of pregnancy, and an oxytocin antagonist given into the VTA disrupts postpartum maternal behavior.[36] Oxytocin neurons in the pPVN as well as the mPOA project to the VTA, and the number of projecting neurons is greater in those lactating rats showing more intense pup licking and grooming behavior. Moreover, oxytocin infusion into the VTA increases dopamine release in the nucleus accumbens, and an oxytocin antagonist given into the VTA reduces dopamine released in the nucleus accumbens only in the more intensely maternal mothers.[828] Hence, oxytocin neurons mediate mPOA and pPVN modulation of intensity of maternal care via VTA dopaminergic neuron projections to the nucleus accumbens. This variability in maternal behavior is of importance in postnatal programming of the offspring.[790]

Opioids and Maternal Behavior

Administration of morphine, a μ-opioid receptor agonist, disrupts the expression of maternal behavior in ovariectomized and hysterectomized pregnant rats,[832] and in postpartum rats in established lactation, systemic morphine or i.c.v. administration of a selective μ-opioid (but not δ or κ-opioid receptor agonists) temporarily stops maternal behavior.[833,834] These effects indicate a potential inhibitory action of endogenous μ-opioids on maternal behavior. By contrast, if brain μ-opioid receptors are blocked in late pregnancy by i.c.v. β-funaltrexamine infusion, immediate postpartum maternal behavior is normal, but if pups are removed for a few days, memory for the behavior is not retained.[835,836] Furthermore, in early lactation naloxone prolongs nursing bouts,[836] indicating that endogenous opioid activation through nursing may act as a maternal reward, or satiety signal, hence ending a nursing bout. Rhesus macaques with a specific single nucleotide polymorphism (SNP) in the μ-opioid receptor-1 (*Oprm1*) gene show subtly stronger maternal attachment behavior toward their young, indicating a gain of function from this mutation, and an active endogenous μ-opioid mechanism regulating maternal behavior.[837] Explanations for these evidently conflicting findings of inhibitory and facilitatory opioid actions on maternal behavior relate to their multiple sites of action, in the mPOA, VTA, and periaqueductal gray (PAG).

Opioids and the Medial Preoptic Area

The inhibition of maternal behavior in lactating rats by morphine is accompanied by inhibition of Fos expression in the mPOA, which is reversed by naloxone pretreatment.[838] Further studies involving local application of morphine show that it acts in the mPOA.[839] Beta-endorphin content in the mPOA increases in pregnancy, evidently as a result of estrogen and progesterone action.[840] Moreover, μ-opioid receptors are expressed in the mPOA, and the level increases in pregnancy and decreases near term and after parturition, reflecting changing pregnancy hormone levels, and perhaps action of β-endorphin.[841] Consequently, endogenous μ-opioid action in the mPOA near the end of pregnancy can be expected to restrain the performance of maternal behavior, and withdrawal of this opioid inhibition at the end of pregnancy should thus contribute to the rapid expression of maternal behavior postpartum.

Opioids and the Ventral Tegmental Area

Opioid actions on maternal behavior involve the VTA, but here μ-opioid actions stimulate maternal behavior in rats primed to perform it.[842] The explanation for positive opioid actions on maternal behavior via the VTA is that VTA dopamine neurons are stimulated indirectly by μ-opioids, which act by inhibiting local GABAergic interneurons.[843] Any adaptations in pregnancy in opioid mechanisms impinging on dopamine neurons in the VTA have not been reported.

Periaqueductal Gray

This midbrain tegmentum region is important in organizing fear and defensive behaviors, in pain modulation,

and in the context of maternal behavior it is pivotal in switching between behaviors (Figure 44.11).[844] Changes in function are expected as a result of pregnancy as PAG neurons are modulated by progesterone and its neurosteroid metabolites.[845] Expression of maternal behavior requires the fear responses to pups characteristic of virgin rats to be suppressed, and this suppression is evident near the end of pregnancy.[846] Notably, maternal behavior toward pups activates GABAergic neurons in the caudal ventrolateral PAG (cPAGvl),[847] which may indicate active inhibition of fear responses to permit maternal behavior. Furthermore, the cPAG is essential for the kyphotic nursing posture, and lesion of this region increases maternal aggression.[848]

Opioids and the Periaqueductal Gray

The PAG expresses all three types of opioid receptor; changes in expression in a first pregnancy have not been reported, and there are no changes in a third pregnancy in levels of opioid receptor mRNA or protein (except for a decrease in δ-receptor protein).[849] Similarly, changes in pregnancy in opioid peptide content in the PAG have not been reported. Nonetheless there are important actions of opioids in the PAG that affect maternal behavior. The striking action of morphine in switching off maternal behavior in lactating rats is prevented by naloxone infusion into the PAG,[850] and is also prevented in rats with a previously made lesion of the rostral lateral PAG (rPAGl).[844] Moreover, given insect prey, lactating rats treated with morphine show predatory behavior, but not if the rPAGl has been lesioned; in this case maternal behavior is largely intact. Hence, switching by morphine (and presumptively endogenous μ-opioid peptides in the PAG) from maternal to predatory behavior is mediated by the rPAGl.[844] Whether this depends upon the actions of hormones during pregnancy remains to be established.

Postpartum Emotionality

It has been suggested that plasticity in processing in the olfactory bulbs as a result of stimulation of neurogenesis by prolactin in early pregnancy may be important in reducing postpartum anxiety via projections from the olfactory bulbs to the CeA, which has a key role in anxiogenesis.[805,851] Hence, postpartum mood disorders in women[852] might result from disorder of this anxiolytic mechanism, which depends on prolactin action early in pregnancy,[805] rather than being a result of loss of actions of progesterone or estrogen as otherwise supposed.[853]

Summary and Conclusions

As for lactation, changes in the maternal brain in pregnancy prepare for immediate expression of maternal behavior following birth. This behavior has multiple components and many neural circuits are involved. The changes in pregnancy are a consequence of actions of estrogen, progesterone, and prolactin or placental lactogen, especially near the end of pregnancy, when elements of maternal behavior can be elicited. Prolactin and placental lactogen readily enter the brain, and prolactin receptors are widely expressed. After birth, the prepared neural circuitry is activated by stimuli from the pups, mediated, reinforced, or regulated by actions of oxytocin, dopamine, and endogenous opioids in the brain, in the context of progesterone withdrawal. The mPOA is the essential hub in the networks that organize maternal behavior, which include the mesolimbic dopamine (reward) system, olfactory and other sensory, and locomotor systems. The hormonally prepared mPOA, by actions of prolactin and estrogen, switches aversion to the young to intense attraction, via interactions with brain stem networks. Oxytocin acts at multiple sites in the circuitry that organize maternal behavior, where oxytocin receptor expression may be upregulated in pregnancy. Similarly, endogenous opioid peptides have region-specific actions on maternal behavior, and are inhibitory in the mPOA, stimulatory via the mesolimbic dopamine system, and have actions in the PAG that are involved in switching to other behaviors.

Future Perspectives

The quality of maternal behavior has been associated with oxytocin-dopamine interactions, but it would seem appropriate to focus also on investigating possible variability in the activity of opioid mechanisms.

Postpartum disturbances in emotionality are common in women, but the mechanisms are poorly understood; a problem is the lack of validated experimental animal models.

CONCLUSION

We have summarized conclusions and questions to be asked in the future at the end of each section. Here we emphasize some common features of the adaptations in the maternal brain in pregnancy that are associated with physiological coping with pregnancy and preparations for birth and maternity.

The main theme has been that the exposure of the brain in pregnancy to hormones not experienced before (relaxin, placental lactogen), or to increased levels of familiar hormones (sex steroids: estradiol, progesterone, and its neurosteroid metabolite, allopregnanolone; peptides: prolactin, leptin) alters the settings of several neural networks in the brain. These networks regulate vital homeostatic systems (controlling hydromineral balance, appetite and metabolism, endocrine stress responses) that are adjusted to meet the physiological demands of pregnancy (expanded blood volume, energy demands).

These hormones also prepare neural systems that will be important in parturition (oxytocin secretion) or essential for successful motherhood (lactation: prolactin, oxytocin; maternal behavior: estrogen, progesterone, prolactin).

The actions of the hormones are mediated by specific receptors, which may be upregulated in pregnancy as a result of estrogen action, except for allopregnanolone, which acts as an allosteric modifier at $GABA_A$ receptors. Hence, the predominant type of change in the neural networks is at the molecular level, i.e., changes in expression of specific genes that mediate or modulate signaling. There are few indications of structural changes: an increase in neurogenesis in the SVZ (from actions of prolactin) is an example, and increased number of dendritic spines on hippocampal neurons (from actions of estradiol) is another. Nonetheless the changes in pregnancy are predominantly changes in the balance of excitatory and inhibitory signaling in the networks governing the functional output.

Focusing on the changes in signaling within the neural networks we have considered, there are noteworthy recurrences. With regard to the increased salt appetite that accompanies increased water intake and hyponatremic hypervolemia, suppression of central actions of oxytocin by inhibiting its release seems likely to be important, and this seems also important in the increased appetite of pregnancy. Furthermore, restraining release of oxytocin from the dendrites of magnocellular neurons is also important to prevent premature activation of burst-firing of oxytocin neurons that might otherwise trigger parturition. Activation of an endogenous opioid mechanism in pregnancy in the NTS that blocks signaling via the vagus to oxytocin and CRH neurons could account for such inhibition, as well as the attenuation of HPA axis stress responses. Allopregnanolone inhibits magnocellular oxytocin neurons directly, and it may have direct inhibitory actions on other neurons in the networks considered here to alter their outputs. Also, induction by allopregnanolone of the endogenous opioid mechanism in the NTS that inhibits oxytocin and CRH neurons might have wider actions. Moreover, allopregnanolone may have similar actions on opioid activation elsewhere, for example, in TIDA neurons to permit the prolactin surge at the end of pregnancy.

Opioid mechanisms are also important in increasing motivation (to eat or to behave maternally) through actions in the mesolimbic dopamine system, yet restrain the performance of maternal behavior at the end of pregnancy through actions in the mPOA. These opposing actions of opioids nonetheless imply upregulation of opioid mechanisms in pregnancy (as discussed earlier), while the opposing actions can be accounted for by similar inhibitory actions on either inhibitory or excitatory inputs in a network.

There seems to be a remarkable coherence of oxytocin actions through pregnancy, parturition, and the performance of maternal behavior. There is a similar coherence of prolactin actions on the brain, first in interacting with TIDA neurons and prolactin releasing factors to generate pulses of prolactin secretion, then to be involved in appetite regulation and preparation for maternal behavior.

The neural network regulating appetite and metabolism seems the most complex, and much research is focused on this, in the nonpregnant state. In the context of pregnancy we have described how the system may be adjusted by resistance to several inputs that normally reduce appetite and energy storage (such as leptin, CCK, and α-MSH in the brain), with increased activity of orexigenic neurons (e.g., arcuate NPY neurons, whose increased activity in pregnancy is not explained), and decreased activity of anorexigenic neurons (e.g., oxytocin neurons, perhaps restrained by an opioid mechanism, as discussed earlier).

INTRODUCTION

In 1989 observations made by David Barker and colleagues led to an exciting new field of study associating the in utero experience with the susceptibility to disease in adulthood. They found that birth weight was inversely correlated with an individual's blood pressure in adulthood, as well as their susceptibility to the adult onset of cardiovascular disease.[1–3] Studies of individuals exposed in the womb to the Dutch Hunger Winter during World War II further supported Barker's work, revealing that famine exposure in utero has various adverse effects in adulthood.[4] These individuals show a higher risk of having glucose intolerance, obesity, and coronary heart disease.[4] While the associations between an adverse in utero experience and adult disease are strong, the question remains: How is the memory of the in utero exposure maintained until adulthood?

It is unlikely that a change in the genetic code is behind these phenotypes because some of these phenotypes are not transmitted transgenerationally. However, the contribution of fetal epigenetic modifications that may help maintain a molecular memory of an adverse in utero exposure is currently a rapidly expanding field of research. Epigenetic marks are modifiable through interaction with the environment and are altered with development.

While it has been established for more than half a century that disruptions within our genomic DNA can lead to disease, the fact that epigenetic changes can cause profound childhood and later-in-life disorders is a much more recent discovery. Genomic changes such as single nucleotide polymorphisms, copy number variations, insertions, and deletions have all been implicated in the etiology of disease. However, it is becoming increasingly evident that changes to the higher order structure of the genomic landscape, through epigenetics, also play a prevalent role in disease etiology.

Using a mouse model that carries the Agouti gene, elegant experiments have shown that epigenetic changes can lead to a disease phenotype in adulthood. Researchers discovered that the DNA methylation levels of the Agouti gene promoter, which are established in utero, can predispose the animal to obesity in adulthood. The level of DNA methylation within the Agouti promoter region in the fetus can be altered by supplementing the maternal diet with the methyl donors folic acid and vitamin B_{12}.[5] If the maternal diet does not contain the proper levels of the methyl donors, the offspring are prone to obesity in adulthood.[5–7] These data show that the DNA methylation pattern of a single locus, which is established in fetal life, can lead to adult disease. Furthermore, with proper supplementation of the maternal diet, the obesity phenotype can be avoided.

The study of imprinting disorders has also contributed to the understanding that epigenetic changes can cause profound childhood disease. For example, Prader–Willi syndrome (PWS) (discussed in detail later in the chapter) can be caused by an epimutation, where the paternal allele contains an improper maternal imprint.[8] Because this is such a severe childhood disorder, further understanding of how imprinting is established and maintained will help scientists develop treatments for these disorders with an epigenetic etiology.

In this chapter we begin by defining epigenetics and the various epigenetic modifications that have been implicated in the developmental origins of adult disease. We discuss the epigenetics of fertilization, which establishes the fetal

Knobil and Neill's Physiology of Reproduction, Fourth Edition
http://dx.doi.org/10.1016/B978-0-12-397175-3.00045-4

epigenome. At this crucial stage, genomic imprints are being established and protected. We discuss the mechanisms of genomic imprinting, and imprinting disorders, which can arise as a result of aberrant DNA methylation. We further summarize studies showing an association (or lack thereof) between assisted reproductive technologies (ART) and imprinting disorders. We discuss studies of maternal and paternal constraints such as diet and nutrient supplementation, which both alter the fetal epigenome and predispose the offspring to adult metabolic disease. We close the chapter with a discussion on fields of emerging influence in perinatology, which we believe will ultimately be found be crucial modifiers of the temporal and spatial establishment of the fetal epigenome.

EPIGENETICS

Every cell in our body arises from a single cell generated at conception. Each cell, with few exceptions, has the same exact genomic information. However, by the blastocyst stage, two very different cell types have already emerged. The trophoblasts that surround the blastocyst will give rise to the placenta and other extraembryonic tissues necessary to support the pregnancy. The cells of the inner cell mass within the blastocyst are embryonic stem cells (ESCs), which will give rise to the fetus. Both cell types have very different characteristics, and at this point early in gestation, cellular programming has already begun.

If the trophoblasts and ESCs contain the exact same genetic information, what distinguishes the two cell types from each other? How are they programmed to perform two completely separate tasks? The answer lies in the understanding of epigenetic regulation within the two different cell types. First described by Conrad Waddington, epigenetics is the study of alterations to the DNA that lead to changes in gene expression but does not alter the underlying DNA sequence.[9] Such changes can occur through altering the local chromatin structure. In all eukaryotic cells, DNA is packaged into a nucleoprotein structure called chromatin. Modifications that make the surrounding chromatin more compact will inhibit access of transcription factors to the DNA and can inhibit transcription. There are also modifications that can enhance access to the DNA through an opening of chromatin structure.

In this section we will describe the organization of chromatin structure within the eukaryotic genome. We will further discuss the epigenetic modifications that can occur within the chromatin that influence gene expression. Modifications to the histone proteins, methylation of the DNA, and the mechanisms of microRNA silencing will be discussed. Epigenetic modifications that are heritable through the cell cycle are summarized in Figure 45.1.

Chromatin Organization

All eukaryotes maintain their genome as a nucleoprotein complex, which consists of DNA wrapped around four histone proteins (Figure 45.2). The basic repeating unit of chromatin is the nucleosome. The central core of the nucleosome consists of two copies each of four histone proteins. The canonical nucleosome contains two copies of H3 and H4, which form a histone tetramer, as well as two histone H2A/H2B dimers. Together, the histone proteins form an octamer. Around this octamer, 147 base pairs of DNA wrap approximately 1.7 times in a left-handed superhelix to form the nucleosome.[10,11]

The crystal structure of the nucleosome provided much insight into the role of the histone proteins in chromatin organization. The crystal structure revealed that each of the four histones has a globular domain involved in dimer–tetramer interactions within the nucleosome core. However, each histone has an N-terminal domain, often referred to as the histone "tail", which extrudes from the nucleosome surface. While the histone tails do not contribute to the structure of individual nucleosomes, they are involved in organizing the structure of chromatin as a whole.[12] Besides an N-terminal tail, histones H2A and H2B contain C-terminal tails, which also extrude from the surface of the nucleosome.

Nucleosomes are separated from each other by stretches of DNA called "linker DNA". Visualized by cryo-electron microscopy, a simple nucleosomal array looks like beads on a string.[13] This is the primary structure of chromatin. In order to undergo further levels of compaction, the chromatin array employs both linker

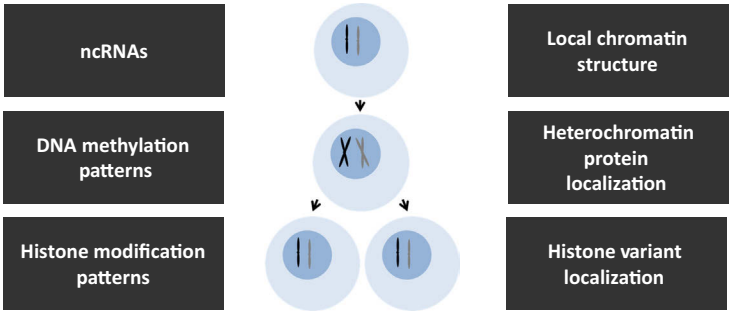

FIGURE 45.1 Epigenetic mechanisms: heritable chromatin state throughout replication and cell division. The epigenetic characteristics of a dividing cell must be passed on to the daughter cell. The mechanisms preserving the epigenetic landscape of the mother cell through cell division are unclear. However, the daughter cell requires that specific chromatin states are maintained, such as the packaging of telomeres and centromeres, in order to preserve genome stability.

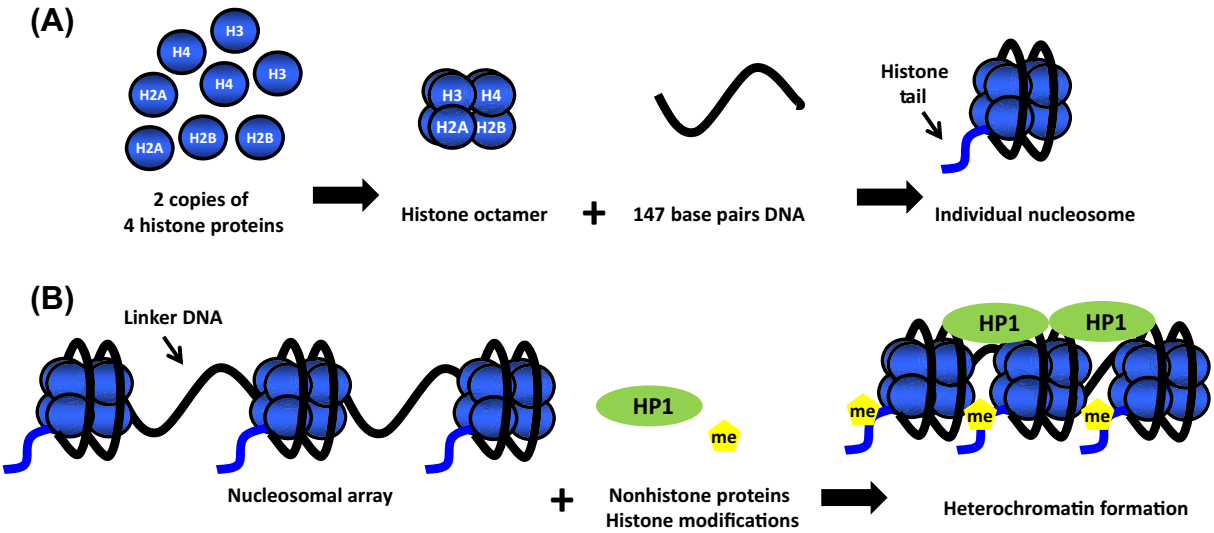

FIGURE 45.2 Chromatin organization. (A) The nucleosome is the basic repeating unit of chromatin in all eukaryotes. The nucleosome consists of two copies of four histone proteins (H3, H4, H2A, and H2B), which form the histone octamer. The nucleosome is formed by 147 base pairs of DNA that wrap around the octamer. (B) Individual nucleosomes are separated from each other by short stretches of "linker DNA" that are not wrapped around the histone octamer. In order to undergo condensation to form heterochromatin, the nucleosomal array is aided by histone modifications such as histone methylation, as well as nonhistone proteins such as HP-1.

histones, which are not part of the canonical nucleosome structure, as well as nonhistone proteins.[14] Through these interactions chromatin can form secondary and tertiary chromatin structures.

While histones H3, H4, H2A, and H2B are the four main histones based on quantity in the eukaryotic cell, there are also variants of H3 and H2A. Some variants are species specific. While crystal structures of nucleosomes with variants have been published, their exact role throughout the cell cycle and in chromatin organization still remains to be elucidated. For example, most eukaryotes have a variant of histone H3, called H3.3, which differs from H3 only by four amino acid residues.[15] This variant is synthesized throughout the cell cycle rather than only during S-phase. Histone H2A also has many characterized variants. H2A.X has a unique C-terminal tail compared with H2A. Within the H2A.X tail resides an important serine residue that is immediately phosphorylated in chromatin following a DNA double strand break.[16] The role this modified serine plays in the detection and repair of double strand breaks has been the subject of hundreds of studies.[17] Of interest to this chapter are the oocyte- and testis-specific histone variants, which will be discussed in detail in the section The Epigenetics of Fertilization.

The histone octamer makes strong contacts with the nucleosomal DNA. Therefore, specific enzymes are necessary to access the DNA, which is tightly wrapped around the octamer: ATP-dependent chromatin remodeling enzymes and histone modifying enzymes. Both are important machineries for transcription, DNA synthesis, and DNA repair. The ATP-dependent remodeling enzymes use the energy from ATP hydrolysis to disrupt histone-DNA contacts. They can do so by creating torsion of the DNA, sliding nucleosomes, and aiding histone dimer exchange.[18] ATP-dependent remodeling enzymes are involved in transcription,[19] DNA replication,[20] and DNA repair.[21]

The histone modifying enzymes add posttranslational modifications, such as phosphorylation, acetylation, methylation, and ubiquitylation to the histone proteins. Amino acids within the histone globular domains, located within the nucleosome core, are subject to modification. However, most of the histone modifications characterized thus far are found on the N- and C-terminal tails that extrude from the nucleosome surface. The importance of these histone modifications is currently an exciting field of research impacting the fields of reproduction and fertility research.

Histone Modifications

Histone modifications are known to play an important role in replication, transcription, heterochromatin formation, chromatin compaction, and DNA damage repair. As we are currently learning, the pattern of histone modifications is also important for fertility and fetal growth. Histone modifications can be altered by different environmental stimuli and may provide a "memory" of previous transcription or activation. While the role of the many histone modifications discovered thus far has not yet been established, many modifications have been associated with specific transcriptional states. For the importance of the work described in this chapter, we will

focus on histone acetylation and methylation, two modifications that have been implicated in the fetal epigenetic origins of disease. The relevant histone modifications are summarized in Table 45.1.

Many hypotheses exist as to the role of histone modifications. The phosphorylation of the C-terminal tail of histone H2A.X immediately after DNA damage is thought to recruit damage repair enzymes directly to the site of the double strand break.[22] Perhaps specific modifications aid in the recruitment of downstream effector proteins, which then aid in DNA damage repair, initiate transcription, or maintain heterochromatin structure. Histone modifications must be inherited through subsequent cell cycles to maintain the viability of the cell. For example, telomeric regions must be maintained as tightly compacted heterochromatin so that the ends of each chromosome are not recognized by the cell as DNA double strand breaks. Telomeres are enriched with histone modifications specific for heterochromatin and will retain these heterochromatic marks after a round of S-phase.[23]

Historically, specific histone modifications have been associated with specific chromatin states. There are certainly exceptions to the rule, and the role of some modifications remains elusive. Histone modifications are dynamic. The cell employs enzymes that can acetylate histones as well as enzymes that remove the acetyl group, making these marks reversible.[24] Histone lysine acetylation is a highly characterized histone modification.

Using high-throughput sequencing technology, localization of acetylated histones has been mapped throughout the genome in many cells and tissues. Using a technique called chromatin immunoprecipitation followed by high-throughput sequencing (ChIP-seq), the genomic location of any modification can be mapped, as long as there is an antibody that recognizes it. Lysine acetylation has traditionally been associated with transcriptionally active, open chromatin structure, called euchromatin.[25] Most studies have focused on acetylation of histone H3, specifically lysines 9 and 14 (H3K9/14ac) as well as acetylation of the four lysines within the H4 histone "tail" (K5, 8, 12, 16).[26] Acetylated histones are found near the transcription start site and within the coding region of active genes throughout the genome.[27]

Not only can histone lysines be acetylated but they can also be mono-, di-, or tri-methylated. Methylation of histone H3 lysine 4 (H3K4) is a conserved modification from yeast to man. Using ChIP-seq, the localization of each form (mon-, di-, or tri-) of methylated H3K4 has been mapped in *Saccharomyces cerevisiae* and mammalian cells,[28] and the data show that localization of trimethylation of H3K4 (H3K4me3) appears to be evolutionarily conserved. Similar to acetylated lysines, H3K4me3 maps to the promoter of active genes. However, mono- and dimethylation do not share the same pattern in yeast and mammals. Where lysine acetylation usually correlates with gene expression, lysine methylation does not show the same trend. The specific lysine in the histone tail that is methylated appears to correlate with specific transcriptional states. While H3K4me3 marks active transcription, trimethylation of lysine 9 of histone H3 (H3K9me3), as well as H3K27me3, appears to localize to silenced genes.[29]

DNA Methylation

DNA methylation is an important epigenetic modification in the regulation of gene expression and chromatin structure. It is a relatively stable modification; however, it is modifiable by environmental exposures. Global changes in DNA methylation have been implicated in cancer etiology.[29] In mammals, DNA is methylated on the C5 position of cytosine residues (5-mC). Most studies to date have studied methylation of "CpG dinucleotides", or a cytosine residue immediately 5′ to a guanine. Regions of compact, silenced heterochromatin, such as telomeres, are hypermethylated.[30] Approximately 70–80% of CpGs within the adult mammalian genome are methylated, with the exception of "CpG islands", which are largely unmethylated.[31] CpG islands are GC-rich stretches of the genome and lie within proximal promoters and enhancer regions of genes. Changes to the methylation status of CpG islands have been found to correlate with changes in gene expression. DNA methylation patterns are heritable through the mitotic cell cycle;

TABLE 45.1 Histone Modifications

Modification	Localization	References

H3K27me3	Promoter and gene body of repressed genes	21

the DNA methyltransferase, DNMT1, travels with the replication machinery and helps to reestablish methylation marks on the newly synthesized strand.[32]

The stability of CpG methylation was long thought to be due to the lack of a DNA demethylase.[33] The only way to "remove" the methyl mark was through active rounds of DNA synthesis without subsequent methylation of the daughter strand, which would dilute the overall levels of DNA methylation. However, this mechanism could not account for the rapid demethylation of the paternal genome following fertilization that occurs in the absence of DNA synthesis (discussed in the section The Epigenetics of Fertilization). Similarly, this mechanism could not account for changes in DNA methylation found in nondividing neurons.[34] The discovery of the modification 5-hydroxymethylcytosine (5-hmC) in the mammalian genome in 2009 has garnered attention as a possible intermediate in an active DNA demethylation process.[35,36]

Evidence for this process is still scarce but is actively being sought. TET1 is an enzyme responsible for converting 5-mCs to 5-hmCs.[36] The authors also showed that overexpression of TET1 in mammalian cells leads to a significant reduction in modified cytosines. TET1 is also important in mammalian cells for maintaining pluripotency; loss leads to increased methylation of *Nanog*, a gene required for pluripotency, as well as loss of *Nanog* gene expression.[37] TET1 overexpression has also been shown to be involved in active demethylation of a methylated plasmid.[38]

The importance of DNA methylation, and a potential process for active demethylation, makes the study of this modification of great importance in the fetal epigenetic origins of disease. In this chapter we highlight many studies where an altered in utero environment leads to changes in DNA methylation in the offspring, in tissues such as liver, pancreas, and brain. These changes in DNA methylation are associated with changes in gene expression in many cases and can lead to the adult onset of metabolic syndrome. However, if there is an active process that could remove the methylation marks, perhaps there is a chance for postnatal intervention, even if the "stage has been set" for an adult disease in utero. These are exciting fields of research that are only beginning to be understood.

Noncoding RNAs

Of all the epigenetic modifications implicated in the fetal origins of epigenetic disease, noncoding RNAs (ncRNAs) are the least understood. Because they have a large role in regulating gene transcription, they are likely to emerge as a major player in fetal epigenetics in the coming decade. Due to the prevalence of large-scale sequencing studies, it has been discovered that ncRNAs account for more RNA than protein coding RNAs in the mammalian transcriptome.[39] They can be classified as small ncRNAs (<200 bps) or large ncRNAs (lncRNAs, >200 bps).[40]

Small ncRNAs are around 20–30 nucleotides long and are associated with the Argonaute (Ago) family of proteins. They act to posttranscriptionally silence mRNA through exonucleolytic processing. Micro RNAs (miRNAs) are 20–23 nucleotides long and are processed from longer RNAs through the actions of Drosha and Dicer.[41] These miRNAs then associate with Ago and the RNA-induced silencing complex (RISC). The miRNA-containing target then finds complementary mRNA sequences and degrades the mRNA through an exonuclease activity.[40] Piwi-interacting RNAs (piRNAs) are similar to miRNAs in that they mediate silencing of mRNAs. They are generally 24–32 nucleotides long and arise from intergenic repetitive elements called piRNA clusters.[42] They do not require Drosha or Dicer, and associate with the PIWI-subfamily of the Argonaute family.[40]

LncRNAs are similar to mRNAs in that they are transcribed by RNA PolII, but they do not appear to code for functional proteins.[43] LncRNAs have different mechanisms through which they regulate transcription. Similar to short ncRNAs, they have been shown to target and degrade mRNA.[44] LncRNAs can also target chromatin modifications to specific regions of the genome to regulate transcription by acting as a scaffold.[45] They have also been hypothesized to compete with and sequester miRNA, inhibiting the repressive function of the miRNA and allowing its target to be expressed.[46]

We have highlighted some of the fundamental properties of chromatin and its organization. Not only do histone modifications, DNA methylation, and ncRNAs play a role in chromatin structure and folding, but they play a role in transcriptional regulation as well. While the DNA sequence will remain unchanged throughout development, the patterns of gene expression are highly dynamic over time. Research into the roles epigenetic marks play in altering gene expression patterns is still a relatively new field of study. Even more recent are studies of epigenetic reprogramming in the developing fetus due to varying environmental constraints. Perhaps these changes contribute to the differing susceptibility of these offspring to the adult onset of adult disease.

THE EPIGENETICS OF FERTILIZATION

Fertilization offers a unique vantage point to appreciate the cell-type specific nature of epigenetic patterning. It is well established that different cell types bear unique epigenetic signatures. Both the sperm and oocyte have very distinct chromatin packaging and epigenetic marks, specific for their purpose as gametes. However, once these two genomes combine at fertilization, a highly coordinated reorganization of both epigenomes must occur to orchestrate the precise needs of the developing embryo. In this section we address the epigenetic

changes that accompany spermatogenesis and oogenesis. We then describe the changes to both the paternal and maternal genomes upon fertilization in order to establish epigenetic marks necessary for proper development within the zygote. This process is summarized in Figure 45.3.

Sperm Epigenetics

It is not surprising that the sperm has a highly specialized and specific chromatin structure given the sperm's highly specialized role in reproduction. During meiosis, the sperm chromatin must undergo compaction to become 6–20 times denser than nucleosome-bound chromatin found in somatic cells.[8,47] It is hypothesized that this compaction allows for sperm mobility and shields the genome from DNA damage.[48] Until recently, it was believed that the paternal contribution to the developing embryo's epigenome was rather limited. However, studies over the past decade reveal that the sperm epigenome plays an important role both in male fertility as well as embryo development.

Although it has been recognized since 1971 that there are testis specific histone variants that can be incorporated into the sperm chromatin in a replication independent manner,[49] the role these variants play in higher-order chromatin structure and spermatagonia is still unknown. For example, the role of the testis-specific H3 variant, H3T, has been studied in vitro. These studies revealed that H3T can be incorporated into nucleosomes with the aid of the histone chaperone Nap2 and that an H3T-containing nucleosome is unstable compared with a canonical nucleosome.[50,51] Similarly, the testis-specific H2A variant, H2AL2, forms nucleosomes with different properties than a canonical nucleosome, including its ability to be remodeled by the ATP-dependent chromatin remodeling enzymes SWI/SNF and RSC.[52] While it appears that most of these variants disappear after fertilization,[53] the importance of the location or modification status of those variants that remain as part of the fetal epigenome has not been elucidated.

In order to achieve such a high level of compaction, sperm chromatin undergoes a complete rearrangement during meiosis. Approximately 85–95% of the sperm histone proteins are removed from the DNA and replaced by protamines.[48] Before the histones are removed they are hyperacetylated, which may ease their removal from the DNA template.[54] In mammals, transition proteins replace the histones, which are then replaced by one of two protamines, P1 and P2.[48] The ratio of P1 and P2 appears to be important for fertility and is approximately 1:1 in most fertile males.[47] The protamine sperm chromatin can now achieve a far greater level of compaction than that afforded by the canonical nucleosome. It is generally thought that the sperm genome is now quiescent, with no transcription occurring until after fertilization.[55]

Notably, even though the bulk of histones are replaced by protamines, paternal histones are retained within the sperm chromatin. It appears that their localization is programmed, and that there are distinct chromatin domains within the sperm genome.[56] Using ChIP-seq it has been found that histones with distinct modifications are located at specific regions throughout the sperm genome, which are important for embryonic development.[57] Histone modifications associated with active

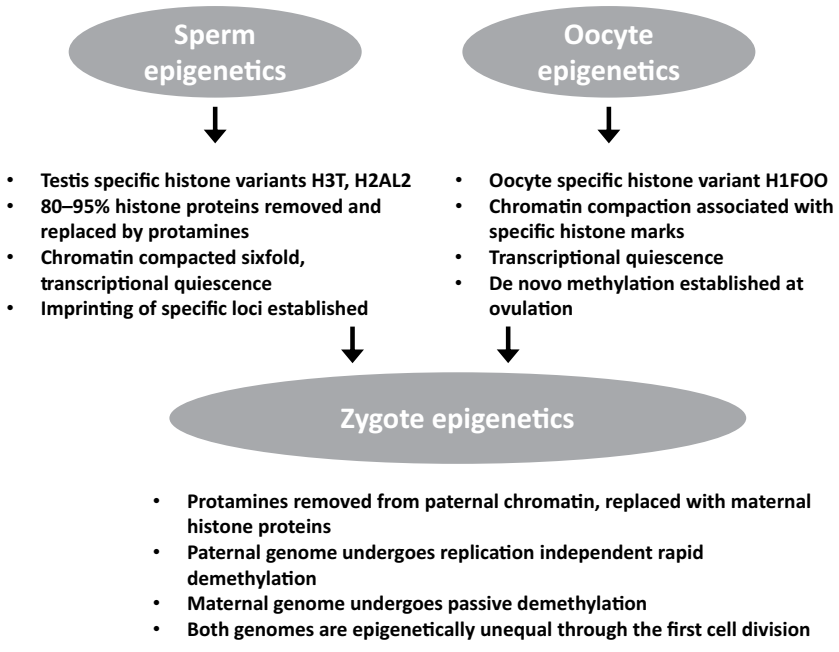

FIGURE 45.3 Epigenetics of fertilization. Both the sperm and the oocyte have distinct epigenetic landscapes that are essential for their role as gametes. However, upon fertilization both parental epigenomes must be reorganized in order to orchestrate the transcriptional program necessary for embryonic development.

chromatin (H3K4me2 and H3K4me3) are enriched at HOX gene clusters and imprinted regions, while the repressive H3K27me3 is enriched in the promoters of genes that are repressed in the developing embryo.[57] Whether these modifications help to either initiate or repress gene-specific transcription within the embryo is still unknown. Yet this data contrasts with the prevailing view that the sperm chromatin is not a player in the establishment of the embryonic epigenome. The importance of the retained histones and their location within the genome is only beginning to be elucidated. Thus, many questions still remain. What is the fate of these paternal histone proteins after fertilization? Do these histones and their associated histone code contribute to the embryonic epigenome?

Aside from the sperm histone code, the role of DNA methylation in the developing sperm is extremely important for fertility and proper embryonic development. Our understanding of DNA methylation changes during gametogenesis and embryogenesis mostly comes from studies of mouse models. In the mouse, germ cell development starts when primordial germ cells (PGCs) arise from the posterior primitive streak at embryonic day 7.5 (e7.5) and migrate to the genital ridge by e11.5. By the time the cells reach the genital ridge, an active demethylation process has removed the methylation marks of the PGCs.[58] The timing of the reestablishment of the genomic imprinting is still unknown. One study showed erasure and reestablishment of methylation before birth at a specific imprinted region in the mouse (IG-DMR), and this methylation status is maintained throughout the lifetime of the individual in the germ line.[59] Another study shows that establishment of methylation patterns of different imprinting regions occurs at different stages of germ cell development and therefore doesn't occur at a specific stage during differentiation.[60] It is generally accepted that in males imprinting is already established in gonocytes.[49]

Many studies have confirmed the importance of the paternal epigenome in fertility and proper embryo development. Using mouse models it is established that knocking out the methyltransferase DNMT1 is embryonic lethal.[61] Mice harboring a germ cell specific knockout of DNMT3a showed decreased methylation at imprinted loci, were infertile, and had decreased spermatogenesis.[62] Furthermore, treatment of mice and rats with a DNA methylation inhibitor, 5-aza-2′-deoxycytidine, led to increased preimplantation loss and decreased pregnancy rates.[63,64]

In humans, epigenetic alterations in the sperm have been shown to be associated with infertility and poor pregnancy outcomes. A study of the P1/P2 ratio in sperm used in IVF revealed that the ratio reveals a relationship with the ability of the sperm to fertilize the oocyte.[65] Another study from an IVF clinic showed that global DNA hypomethylation in sperm is associated with a poor pregnancy rate.[66] Hammoud et al. reported that sperm from infertile men had randomly distributed histone retention, rather than the programmed distribution seen in fertile men.[67]

Oocyte Epigenetics

While studies of DNA methylation patterns in sperm abound, such studies on the oocyte are scarce. This is likely due to the difficulty in obtaining enough material during the oocyte maturation process. Most of what we know about changes in DNA methylation in oogenesis in mammals has been discovered in the mouse. Traditionally, the mouse is superovulated in order to have enough eggs to study. However, such a procedure may alter the methylation patterns.[68]

Similar to the development of the sperm, in the female mouse, methylation marks within the PGCs are erased as they migrate to the genital ridge.[69] This demethylation is achieved between days 10.5 and 13.5 of gestation and is believed to occur through an active process.[70,71] However, while in the male mouse the imprinting marks have been established in the germ line before birth, in the female, de novo methylation occurs prior to ovulation over the life span of the individual.[69] As in the male germ line, establishment of an abnormal methylation pattern in the oocyte similarly disrupts embryonic development.[72]

In 1998, an oocyte-specific DNMT1 (DNMT1o) was discovered.[73] This DNA methyltransferase is abundant in the cytoplasm of the oocyte and preimplantation embryo. While it is not required for establishment of imprints in the oocyte, it is translocated from the cytoplasm to the nucleus of the eight-cell embryo, and homozygous deletion is embryonic lethal.[74,75] DNMT1o may be required for maintenance of imprints in the developing embryo. Along with DNMT1o, DNMT3A, DMNT3B, and DMNT3L are important for the correct DNA methylation patterns within the oocyte.[76] The germ line-specific DNMT3L shares a similar sequence with DNMT3A and DNMT3B but has no catalytic activity.[77] Interestingly, it is only expressed in germ cells when de novo methylation occurs; it is required to regulate DNMT3A/B activity.[78,79] Loss of DNMT3L in females prevents establishment of maternal imprints but not methylation of retrotransposons.[78]

Similar to the sperm chromatin, the oocyte chromatin also undergoes compaction, although not to the same extent as during spermatogenesis.[80] Upon compaction the oocyte achieves a transcriptionally quiescent state.[80] Fluorescence microscopy of oocyte sections from 21- to 25-day-old mice showed that oocyte maturation had varying levels of chromatin organization.[81] Specifically, in the beginning of oocyte growth the chromatin is in a decondensed state, termed "NSN", where the nucleolus

is not surrounded by chromatin.[82] As the oocyte matures, the chromatin becomes more compacted and achieves the "SN" state, where the nucleolus is surrounded by chromatin.[82] The molecular mechanisms behind the initiation of chromatin compaction and maintenance are only beginning to be discovered.

One key player in the chromatin organization of the oocyte may be the oocyte-specific linker histone, H1FOO. First described in 2001,[83] its expression is restricted to the developing oocyte.[84] While the molecular role of H1FOO is still being elucidated, preliminary results show that it may play a role in decondensing chromatin in the regions where it is bound.[85] Another protein that may play a role in chromatin condensation is nucleoplasmin 2 (Npm2). The oocytes from transgenic mice deficient for Npm2 are not able to transition from the NSN to the SN stage in oogenesis.[86] However, the $Npm2^{-/-}$ mice are still able to achieve transcriptional quiescence, even in the absence of complete chromatin condensation.[87]

The role of histone modifications and miRNA in the maintenance of proper chromatin structure during meiosis has also been evaluated. Immunohistochemistry using antibodies against acetylated histones H3 and H4 in mouse oocytes reveals that the lysines within H3 and H4 undergo almost complete deacetylation.[88] Treatment with the histone deacetylase inhibitor, trichostatin a (TSA), caused chromatin decondensation in SN oocytes.[87] Over the course of oocyte development some histone modifications remain stable (H3K9me3, H3K4me3), while others are more dynamic, changing throughout oocyte maturation (H4ac, H3R17me, H3R3me).[89] While, miRNA, siRNA, and piRNA have all been localized to the oocyte, their roles remain elusive.[90] miRNA appears to be downregulated with oocyte maturation and its activity suppressed.[91,92]

Postfertilization Epigenetics

When the two parental genomes combine during fertilization, the newly created diploid zygote must achieve totipotency within a very short amount of time. In order to do so, the epigenetic marks inherent in the sperm and egg chromatin that allowed for transcriptionally quiescent states must be reprogrammed to allow for the proper developmental genes to be expressed. The sperm chromatin, which is mostly packaged into protamines, must be reorganized. DNA methylation and histone modification patterns must be newly established. By the time the developing embryo achieves the blastocyst stage, there are two distinct lineages formed. However, in order to reach the blastocyst stage, a great deal of epigenetic reorganization must occur.

Upon fertilization, one of the first things that must occur is the replacement of the paternal protamines with maternal histones available within the cytoplasm of the oocyte. In order to achieve this, maternally derived glutathione aids in breaking the disulfide bonds between proteins.[93] Studies in mice show that by 8 h postfertilization protamines have been removed from the paternal chromatin.[94,95] With removal of protamines the sperm chromatin expands to three times the size as when it was packaged within the sperm nucleus.[48]

After the removal of protamines, the paternal chromatin goes through a round of global demethylation.[96] This global demethylation excludes centromeric heterochromatin, repeat regions, and imprinting centers.[97] It is thought to be an active process, due to the fact that it is not coupled to DNA replication, although the specifics of the process have not been completely elucidated.[98] Studies in the mouse model have revealed that the paternal genome is demethylated within 4 h following IVF.[99] Interestingly, the maternal genome appears to be protected from this active demethylation process. While the maternal genome does undergo demethylation upon fertilization, it is a passive demethylation that occurs through successive cell divisions.[100,101] It is hypothesized that remethylation is achieved, at least in part, through the activity of the oocyte-specific DNMT1o, which remains in the cytoplasm until the eight-cell stage where it translocates to the nucleus.[74,75]

Histone modifications must also be reprogrammed in the developing embryo. However, even at the two-cell stage the parental genomes are still epigenetically unequal.[89,102] In general, as the paternal genome becomes repackaged into nucleosomes, it obtains histone modifications generally associated with active chromatin, while the maternal genome appears more enriched with repressive modifications. For example, after fertilization, the paternal pronucleus is enriched with acetylated histones, while the maternal pronucleus contains less acetylated histones.[103] Sperm chromatin contains histone H4 acetylated at K8 and K12 even before decondensation is complete, suggesting these modifications are contained within the sperm chromatin.[104] As the paternal chromatin is being reestablished, histones acetylated at H4K5, 12, and 16, as well as H3K9, 14, and 18, also appear on the paternal chromatin.[104] These modifications are attributable to the histones in the cytoplasm and therefore are maternally contributed.

The paternal chromatin also lacks many histone methylation marks, although they are found in the maternal chromatin. No mono-, di-, or tri-methylation of histone H3K9 or 27 was detected in the paternal chromatin within 210 min after fertilization using IVF in the mouse.[105] These marks were visualized in the maternal chromatin. H3K4me3, a marker for transcriptionally active chromatin, is also absent from the paternal genome until 8–10 h postfertilization, and becomes indistinguishable from the levels in the maternal genome at approximately 12 h.[106]

Histone variants are also unequally distributed between the two parental genomes. While H3.1 can be found within the maternal genome, the paternal is nearly

devoid of this variant.[105] The opposite is the case with histone H3.3.[105] MacroH2A can be found in the maternal pronucleus but not the paternal.[107] However, the oocyte-specific linker histone H1FOO can be seen associated with both pronuclei. In fact, it is associated with sperm chromatin within 5 min following ICSI in the mouse.[108]

By the time the developing embryo reaches the blastocyst stage, two lineages have been formed: the inner cell mass (ICM) and the trophectoderm (TE). These lineages can be distinguished epigenetically from each other. The ICM has increased DNA and H3K9 methylation levels compared with the TE.[109] In the mouse there is also an asymmetric lineage distribution of H3K27me3 within the promoters of signaling and developmentally regulated genes.[110] It is not known why the TE is spared from the enrichment of repressive marks or how the asymmetry is delineated.[109]

The process of fertilization is unique from an epigenetic standpoint. As we have outlined, both the sperm and egg develop their own epigenetic milieu in order to function properly as gametes. Both undergo specific modifications in order to achieve a compact structure and a quiescent transcriptional state. Yet when fertilization occurs, the epigenetic state that defines each individual gamete is not ideal for a developing embryo. Both genomes undergo extensive remodeling, including global DNA demethylation and then the reestablishment of DNA methylation patterns, establishment of canonical nucleosomes throughout the paternal genome, and establishment of the zygotic histone code. The timing of many of these events has been reported, yet the mechanisms behind how and when remain largely unexplored. However, it is clear that the establishment of a proper epigenetic code in both the gametes and the embryo is essential for fertility and developmental success.

IMPRINTING

In 1984, elegant studies in the developing mouse embryo were published and first described that both parental genomes are not equivalent. Moreover, contributions from both male and female genomes are necessary for proper embryonic development. Using transplantation studies, diploid single cell mouse embryos with either two paternal pronuclei or two maternal pronuclei were created.[111] Neither was able to complete development. Surani et al. performed similar experiments, which yielded the same results; an oocyte with two maternal pronuclei cannot develop.[112] They concluded that parental imprinting, specific for the male and female genomes, is necessary for normal development. In this section we define imprinting and elaborate on the epigenetic mechanisms that maintain parent-of-origin expression. Table 45.2 summarizes the imprinted genes we discuss in this section and their associated diseases.

Mechanisms of Imprinting

Genomic imprinting ultimately results in parent-of-origin-specific, monoallelic expression of a gene. Intuitively, this seems as though it could be deleterious to development. Diploidy allows for two copies of the same gene to be expressed; a mutation in one allele may be rescued by the second fully functioning copy present in the diploid individual. Why eutherian mammals have developed a subset of genes that are regulated by genomic imprinting remains a mystery. One hypothesis, the "parental conflict theory", postulates that imprinting is a parental "tug of war" for resources.[144] In general, with imprinting genes, those that are paternally expressed (and maternally repressed) drive fetal growth, while those that are maternally expressed (and paternally repressed) moderate fetal growth by limiting maternal resources to the fetus.[113,144]

While the total number of imprinted genes is not yet known, there are 100 imprinted genes characterized in mice, and more than 50 of these maintain the imprinted status in humans.[114] Imprinting can be ubiquitous, meaning that the parent-of-origin expression is the same in all tissues. It can also be tissue specific. For example, *Mash2*, *Obph1*, and *Tssc4* are monoallelically expressed

TABLE 45.2 Imprinted Genes and Disease Associations

in the placenta but biallelically in other tissues.[115] *Igf2* is monoallelically expressed in almost all tissues but shows biallelic expression in the choroid plexus and leptomeninges.[116] The *Grb10* gene is paternally expressed in the brain but maternally in other tissues.[115] To date, there is only one gene where imprinting is not localized to the brain or extraembryonic tissues. *Ddc* is imprinted only in the heart.[117] The mechanisms governing the tissue-specific nature of expression are still unknown.

Most imprinted gene clusters are located within 1 MB of each other, however, imprinted genes can also be found as pairs or singletons throughout the genome.[118] Expression of imprinted genes within each cluster is under the control of an imprinting control region (ICR), also known as an imprinting center (IC) or imprinting control element (ICE).[119] DNA methylation appears to be an essential epigenetic mark for maintenance of parent-of-origin expression, although histone modifications have also been shown to play a role.[119] In fact, allele-specific methylation has been described at all known ICRs.[119]

Insulator Model of Imprinting Control

Study of the *H19-Igf2* imprinted genes has led to the most detailed mechanistic understanding of the insulator model of maintaining parent-of-origin monoallelic expression. *H19* is a noncoding RNA, expressed from the maternal allele, and is required to moderate fetal and placental growth.[120] *Igf2* is paternally expressed and is required to promote fetal and placental growth.[121] Both genes use the same enhancers for expression.[122] The differentially methylated region (DMR), which controls expression of these two genes, lies between them and spans approximately 2.4 kb.[123] This DMR serves as the ICR.

In general, there are two types of DMR. Germ line DMRs acquire methylation during gametogenesis, and somatic DMRs acquire methylation after fertilization.[124] The *H19-Igf2* DMR is established in the germ line and is only methylated on the paternal allele.[130] Within the DMR, there are four binding sites for the insulator protein, CTCF.[145] CTCF can only bind the maternal DMR, which is unmethylated, but not to the methylated paternal allele. This inhibits maternal *Igf2* expression through blocking communication between the *Igf2* promoter and the shared *H19-Igf2* enhancer.[145] Mutation of the CTCF binding sites within the ICR results in biallelic expression of Igf2 and no expression of H19, revealing that CTCF binding is necessary for control of biallelic expression.[131,146]

Differential methylation within the ICR of the *H19-Igf2* locus is essential to maintain parent-of-origin expression. However, the contribution of histone modifications cannot be ignored. The histone code within this region has been mapped, and specific modifications are associated with specific alleles and transcriptional states. Within the maternal allele, the *H19* locus is enriched for modifications associated with active chromatin (i.e., H3K4me3), while the paternal allele is enriched with repressive marks (i.e., H3K9me3).[123] However, within the paternally expressed *Igf2* promoter, active chromatin marks pervade, while the same region on the maternal allele is enriched with repressive marks.[147–149] Histone modifications may help maintain the proper chromatin state, which helps to activate or repress the gene in an allele-specific manner.

Noncoding RNA Model of Imprinting Control

While DNA methylation is the most highly studied epigenetic regulatory epigenetic mechanism involved in imprinting, it is becoming apparent that ncRNAs are important for maintenance of monoallelic expression. At least one gene in imprinted clusters is a macro ncRNA.[136] These ncRNAs can either act as either short- or long-range silencers.[150] The short-range ncRNA transcripts partially overlap the one of the regulated genes, while with the long-range ncRNAs there is no overlap. An example of a functional ncRNA is that of the *Airn* gene, which helps to regulate the *Igf2r* imprinting cluster. In the placenta, *Igf2r* is expressed only from the maternal allele, as well as two other genes within the imprinting cluster, *Slc22a3* and *Slc22a2*.[136] *Airn* is an ncRNA within this imprinting cluster and is only expressed from the paternal allele. *Airn* is a short-range ncRNA as the transcript overlaps with the promoter of *Igf2r*. The necessity of *Airn* expression in the maintenance of monoallelic expression was shown in an elegant experiment where only a truncated form of *Airn* could be expressed from the paternal allele.[151] Without the full-length transcript the paternal alleles were expressed, and monoallelic control was lost at this imprinted locus. Expression of the truncated allele exhibited imprinted expression, and the methylation within the *Airn* promoter remained unchanged. While evidence shows that ncRNAs are able to repress genes in *cis*, the mechanism(s) through which they act is under investigation.

Although only about 1% of all genes are imprinted, loss of proper monoallelic expression of these genes is deleterious to the developing embryo. Epigenetic mechanisms are essential in marking and controlling which allele is expressed and which is repressed. While DNA methylation is essential for maintenance of the genomic imprints, the contributions of both histone modifications and ncRNAs are beginning to be explored.

IMPRINTING DISORDERS

More than 30 disorders whose etiology arises from an imprinting disorder have been characterized.[152] Because imprinting disorders involve alterations in proper epigenetic patterning, and these patterns are disrupted

during fetal development, the study of imprinting disorders truly is a study of the fetal epigenetic origins of disease. A disease that is considered to have an epigenetic etiology is unique from one with a strictly genetic cause. For imprinting disorders, it is possible for the individual to have one unaltered/unmutated copy of an implicated allele. However, due to genomic imprinting, the "healthy" gene cannot be expressed and this leads to a phenotype. The expression of this gene is prohibited by an epigenetic mechanism, namely, DNA methylation within the imprinting control region.

In this section we will discuss the most well-characterized imprinting disorders, including PWS, Angelman syndrome (AS), Silver–Russell syndrome (SRS, also called Russell–Silver syndrome), and transient neonatal diabetes mellitus (TNDM1). While Beckwith–Wiedemann syndrome (BWS) is also a highly characterized imprinting disorder, we will discuss the clinical characteristics, genetic and epigenetic changes in the next section on imprinting disorders and ART.

PWS and AS

PWS was first described in 1956, but its genetic origins weren't discovered for 30 years after its first characterization.[153] It is a rare neurodevelopmental disorder, occurring in approximately 1:25,000 live births.[154] PWS patients go through two distinct stages, phenotypically, during development. From birth to approximately 3 years of age, the child is characterized by hypotonia, feeding difficulties, lethargy, and failure to thrive.[153] A switch to an excessive interest in food, coupled with excessive eating, marks transition to the second stage. While the height of the PWS patient will fall behind others in the age range, the weight will far surpass, due to the excessive hyperphagia exhibited by these patients. By school age, the PWS child will show signs of mild intellectual disabilities and social difficulties.[153] Early diagnosis is essential to alleviate some of the more severe phenotypes such as short stature, which can be alleviated with growth hormone supplements. Other phenotypes the PWS child may exhibit include temper tantrums, mood and sleep disturbances, and repetitive and ritualistic behaviors.

AS was originally described in 1965 and occurs in 1:12,000 births.[155] AS patients develop normally up to 6 months of age, but development severely declines shortly thereafter. AS patients display gait ataxia, severe mental retardation, seizures, hyperactivity, sleep disorders, and limited speech.[132,152] They generally display a happy disposition and are characterized by excessive and inappropriate laughter.[54] AS patients also have a characteristic EEG pattern.[57] Autism is described in approximately 40% of Angelman patients,[133,134] perhaps due to the exhibited communication deficits.

The 15q11q13 Region

Deletions in the same chromosomal region (15q11q13) were identified by chromosomal banding to be associated with both AS and PWS.[132] This discovery seemed at odds with the drastically different phenotypes exhibited by patients with the two different syndromes. In 1989, Knoll et al. published that the four AS patients tested in their study carried a deletion in this region inherited from the mother,[135] establishing a parent-of-origin effect that could account for the two syndromes arising from deletions in the same chromosomal location. This conclusion is supported by the fact that maternal uniparental disomy of chromosome 15 (mUPD15), where the offspring carries two copies of chromosome 15 inherited from the mother and none from the father, is found in some PWS patients.[156] On the other hand, some AS patients have pUPD15.[137]

The parent-of-origin effect arises from the fact that the deleted region in the aforementioned cases is part of a large cluster of imprinted genes. While the contribution of these genes to the etiology of PWS is rather complicated, the cause of AS appears to be much more straightforward. Within this imprinted cluster lies an E3 ubiquitin ligase gene, *UBE3A*. *UBE3A* is biallelically expressed in all tissues except for in the brain, where the paternal copy is silenced.[155] The majority of AS cases have been traced to a large (6 MB) deletion within the 15q13q11 region that contains *UBE3A*. However, mutation of the maternal allele of *UBE3A* alone has been found in approximately 15% of AS cases.[138] pUPD15 accounts for approximately 7% of AS cases, and deletions that disrupt imprinting only account for 2–4% of all AS cases.[139,157]

The mechanism of imprinting within the neurons does not involve differential promoter methylation between the maternal and paternal alleles.[139] Instead, repression of the paternal allele is achieved through expression of the antisense RNA, *UBE3A-ATS*, only from the paternal allele and only in neurons.[158] *UBE3A-ATS* directly mediates silencing of the paternal *UBE3A* allele in *cis*.[159] In mice, it is possible to activate the paternal *UBE3A* gene. This can occur through repression of the paternal antisense RNA, through deletion of the imprinting control region.[160] Perhaps future work on inactivating *UBE3A-ATS* will provide a treatment for this complex disease.[159]

While the etiology of PWS is not as well defined as that of AS, current data suggest that specific genes within the 15q13q11 imprinted locus contribute to PWS etiology. Approximately 70% of all PWS patients have a deletion of this chromosomal region on the paternally inherited chromosome, while 25% patients have mUPD15.[132] Studies of patients with microdeletions within this region have helped to further establish the contribution of specific genes within the imprinted cluster involved in the

PWS phenotype. Within this region, *MKRN3*, *MAGEL12*, *NDN*, *C15orf2*, *SNURF-SNURPN*, and the *SNORD116* cluster are all paternally expressed and maternally repressed.[132] A key cluster of genes in PWS appears to be the SNURF-SNURPN locus, which also contains a cluster of small nucleolar RNA (snoRNA) genes.

The SNURF-SNURPN locus encodes one mRNA, which is translated as two independent genes (SNURF and SNRPN).[161] The locus contains 10 exons: exons 1–3 encode SNURF, and 4–10 encode SNRPN. Within the introns of SNRP-SNRPN lie seven snoRNAs whose molecular function is still unknown.[140] Paternal expression of the SNURF-SNRPN locus is maintained through differential methylation within the PWS-ICR, where the maternal allele is methylated and the paternal unmethylated. The promoter region and exon 1 of SNURF-SNURPN overlap with the PWS-ICR.[132] While the snoRNAs within this region do not show differential methylation, it is likely their paternal specific expression is regulated through expression of SNURF-SNURPN.

Many studies have implicated the SNURF-SNURPN genes in PWS. Balanced translocations of this locus, as well as inactivation of the snoRNAs encoded within the locus, have been described in PWS.[57] Microdeletions within the PWS-ICR have also been reported in PWS patients. PWS has also been described in patients who have epimutations within this region without a chromosomal deletion. The patients all have a paternal chromosome that carries the incorrect maternal imprint.[141]

Transient Neonatal Diabetes Mellitus 1

First distinguished from the classical disease in 1962, TNDM1 has an incidence of 1:400,000–500,000 and accounts for about 40–50% of diabetes cases diagnosed at birth.[142,143] Infants with TNDM1 are characterized by severe intrauterine growth restriction (IUGR), hypoglycemia, and low insulin.[142,162] Interestingly, the diabetes resolves itself, on average, at about 3 months of age, and normal height and weight is achieved by 2 years of age.[125] Diabetes returns in approximately 50% of these patients between the ages of 4–23.[163]

TNDM1 is caused by an aberrant expression of the *PLAGL1* and *HYMA1* genes located at 6q24. In fetal tissues, these genes are only expressed from the paternal locus.[164] Expression of these genes is controlled through differential expression of the TDM DMR, where the unexpressed maternal allele is methylated while the paternal is not.[126] While AS and PWS are caused by loss of expression of imprinted genes, TNDM1 is caused by any genetic or epigenetic mutation that leads to overexpression, or two functional copies, of these two genes. TNDM1 has been described in patients with pUPD6, as well as patients who have a duplication of the paternal 6q24 locus.[127,142] Furthermore, loss of methylation of the maternal DMR can lead to expression of the maternal genes and has been described in some patients.[128]

Silver–Russell Syndrome

Also referred to as Russell–Silver syndrome, SRS is a complex imprinting disorder whose genetic and epigenetic etiologies remain poorly understood. The clinical characteristics are varied, but mostly include both intrauterine and postnatal growth restriction, relative macrocephaly, failure to thrive, low BMI, a triangular face with a prominent forehead, and limb and body asymmetry.[165] Children who do not exhibit catch-up growth by two years of age may be recommended for growth hormone supplementation.[166]

While no specific gene locus has been definitively implicated in the etiology of SRS, aberrations within two chromosomes have been reported in SRS patients. Approximately 7–10% of SRS patients have mUPD7.[167] One candidate region within chromosome 7 appears to be 7p11.2-p13, as patients with SRS have duplications of this region.[168] One candidate gene within this region is *GRB10* (growth factor receptor-bound protein 10), which is imprinted and shows complex expression in most tissues.[166] In mice, loss of maternal *Grb10* leads to fetal overgrowth while overexpression leads to growth restriction.[169,170] However, no mutation in *GRB10* in humans has been found to be associated with SRS.[171]

The role of chromosome 11 was discovered when two patients with SRS were reported to have duplications of 11p15.[172] Within this region lie the imprinted genes *IGF2* and *H19*. Mutations, UPD, and aberrant methylation within this region had already been described for BWS. Therefore, studies of methylation status within this region in SRS patients were initiated. Indeed, approximately 38% of SRS cases revealed hypomethylation of ICR1.[166] While this could potentially repress *IGF2* expression, serum levels of SRS patients of *IGF2* are unaltered.[173]

Implications

The role of imprinting in human disease is one that has frustrated scientists for decades. How have we evolved such that we can have a completely healthy copy of a gene, but because of imprinting the gene cannot be expressed and a disease state is inevitable? While many imprinting disorders have a genetic as well as an epigenetic cause, there are patients who only exhibit epimutations associated with their disease. The challenges for the scientist are to determine how to overcome this parent-of-origin effect in order to reestablish expression of the healthy copy of the gene in the diseased individual. The role of *UBE3A* in AS is a great candidate to consider. The AS patient likely has the healthy paternal copy of *UBE3A*

being expressed in all tissues except for the neurons. How can the paternal allele be turned on in the brain in order to alleviate the symptoms? How can we protect proper imprinting to begin with? There are many questions to ask regarding imprinting and human disease, and we have only just begun to consider the answers.

IMPRINTING DISORDERS AND ART

In 2003, three studies emerged with the same conclusion: incidence of BWS is increased in children conceived using ART. The results of these studies stimulated discussion and debate and prompted hundreds of follow-up studies to determine if ART is associated with imprinting disorders and altered DNA methylation patterns. Questions emerged whether the increased incidence was due to the superovulation, the culturing techniques, or perhaps to problems inherent in subfertile couples. Here we summarize the clinical characteristics of BWS, the known causes, and the studies of BWS incidence and ART. We further discuss the studies of other imprinting disorders, such as AS and PWS in children conceived using ART.

Beckwith–Wiedemann Syndrome

BWS is the most common pediatric overgrowth syndrome, characterized by macrosomia, macroglossia, abdominal wall defects, anterior ear lobe creases, and visceromegaly.[174,175] BWS children have a clinically recognized increased risk for tumor development before the age of eight, especially Wilms tumor and hepatoblastoma, but also including neuroblastoma, rhabdomyosarcoma, and adrenocortical carcinoma.[175] The etiology of BWS was first mapped to chromosome 11p15 in 1983,[128] and has since been rigorously characterized concerning imprinted genes and parent-of-origin expression. The changes within this region associated with BWS can be genetic (uniparental disomy and mutations) or epigenetic (loss or gain of methylation at imprinting control regions).[174]

Within chromosome 11p15.5 are two distinct functional domains of imprinting. Within Domain 1 lies two imprinted genes, H19 and IGF2, whose expression is controlled by methylation of an imprinting center, IC1, located between the two genes.[176] IGF2 is a paternally expressed growth factor, while H19 is a maternally expressed noncoding RNA. Expression of these genes is controlled through methylation of IC1 on the paternal allele, while the maternal IC1 is unmethylated.[176] Domain 2 contains five imprinted genes: *KCNQ1*, *KCNQ1OT1*, *CDKN1C*, *SLC22A18*, and *PHLDA2*.[176] Expression of these genes in controlled by IC2, located within intron 10 of *KCNQ1OT1*.[176] Sporadic loss of methylation at IC2 or gain of methylation at IC1 has been reported in BWS patients with and without accompanying genetic changes.[55,177,178]

Incidence of BWS with ART

Three studies published in 2003 implicated the use of ART with an increased incidence of the imprinting disorder BWS.[76,77,179] Because BWS is such a rare disease (0.7–1.2% in the general population),[77,179] and only 1–3% of all births involve ART,[180] concluding an association between BWS and ART is extremely difficult. While these studies have been criticized for their small sample size and lack of proper controls, they have initiated a cascade of studies that seek to determine the increased incidence, if any, of alterations in genomic imprinting and imprinting disorders that may be more likely in children conceived using ART.

The study by Maher et al. focused on the incidence of ART in a cohort of 149 BWS children who had been referred to the BWS research group in Birmingham, UK.[77] Within this group, six children had been conceived by ART, including three from intracytoplasmic sperm injection (ICSI) and three from in vitro fertilization (IVF). This incidence is equal to 4%, which is higher than the incidence found in the general population (0.7–1.2%). Furthermore, two of these cases were assessed and found to have loss of methylation of the maternal allele at the KvDMR1 locus. Very similar results were found in a study published by Gicquel et al.[77] They too studied a cohort of 149 patients with BWS and similarly found that six of the 149 patients were born after ART. All six showed hypomethylation of KvDMR1. A third study published in the same year found that three out of 65 patients in the Washington University BWS registry were conceived using ART.[179] This indicates an incidence of BWS at 4.6% following ART, approximately a sixfold increase over the reported 0.76% in the general population.

While these studies are of interest, the size of the population in all three studies is perhaps too small to make a broad claim that indeed ART is associated with increased BWS incidence. Since these studies have been published, others have followed suit, analyzing larger cohorts of BWS patients and including more rigorous control groups. In 2004, Halliday et al. performed a case control study to determine BWS incidence with ART.[181] In their study design, they started with 37 BWS patients born in Victoria, Australia between 1983 and 2003, which was a prevalence of 1/35,580 of live births. As controls, four randomly selected live-born infants were chosen for each BWS patient, and were born within a month of the case for a total of 148 controls. They found that IVF was the method of conception for four of the BWS patients (10.8%) and only 1 (0.67%) of the controls, with an odds ratio (OR) of 17.8% (95% CI 1.8–432.9), $p = 0.006$. Although this study shows an almost 18-fold greater

chance of BWS through ART, the confidence interval is rather large.

While the foregoing studies begin to make a convincing argument, other studies, using larger cohorts, have shown that ART and BWS are not associated. In 2005, Lidegaard et al. published a study including all live births in Denmark between 1995 and 2001.[182] Within this cohort were 442,349 non-IVF and 6052 IVF children. They found no incidence of BWS in either cohort. Similar results were found in a Swedish study in 2005.[183] Their study included 16,280 children born after IVF in Sweden between 1982 and 2001. They did not find any incidence of BWS in this cohort.

The published studies describing an association, or lack of association, between ART and imprinting disorders are conflicting, to say the least. While many studies show as association, larger-powered studies do not reveal an increased risk for imprinting disorders with ART. Because these disorders are so devastating, and because the number of individuals born using ART is increasing, a more definitive answer on this issue is essential. Likely, a large international study, including data from many centers worldwide, would provide a more concrete answer. Furthermore, it could be determined, knowing the cause of infertility, if the cause of the imprinting disorder was due to the issues that underlie the infertility or from the ART procedures themselves.

Incidence of AS with ART

While many of the first reports of ART and imprinting disorders focused on BWS, other imprinting disorders have also been studied. AS prevalence has been reported to increase with ART. In the general population, AS frequency is approximately 1:12,000 births.[180] However, imprinting defects only account for approximately 4% of AS cases.[184] The first two reports of AS association with ART described three children born after ICSI who had AS.[185,186] Two Dutch studies also demonstrated that AS children were more likely in subfertile couples (TTP > 12 months) with a higher relative risk (6.3%) with ART than in the general population.[184,187] In one study, out of 16 children with AS born to subfertile couples, four of them had sporadic imprinting defects.[184] In a second study, out of 63 children with AS, four had been conceived using ART.[187]

Implications

ART has not been associated with an increased risk for PWS or SRS.[188] However, the current evidence for an association between ART and BWS or AS is concerning. While clinical follow-up studies on BWS and AS patients conceived after ART must continue to determine the etiology behind their disorder, research into whether the ART process plays a role in increasing the incidence of imprinting disorders is essential.

THE DEVELOPMENTAL ORIGINS OF HEALTH AND DISEASE: MATERNAL CONSTRAINTS

Developmental Origins of Health and Disease (DOHaD) is a hypothesis that postulates that adverse experiences in utero can increase the susceptibility of the developing fetus to the adult onset of metabolic disease (Figure 45.4).[189] In 1998 Barker et al. published that blood pressure as an adult was significantly related to birth weight.[2] Many studies followed that confirmed that the in utero experience could influence adult disease. In this section we highlight studies from individuals born during the Dutch famine during World War II, as well as animal models that have studied epigenetic changes in utero with maternal methyl donor supplementation, protein restriction, obesity, and tobacco smoke exposure. These changes are summarized in Table 45.3

Exposure to Famine: The Dutch Hunger Winter of 1944–1945

Studies of individuals born during the Dutch famine give us a unique understanding of the effects of in utero exposure to maternal calorie restriction and starvation on birth weight and adult metabolic diseases. The Dutch famine, or Hunger Winter, occurred during a defined time period from late 1944 to early 1945. During

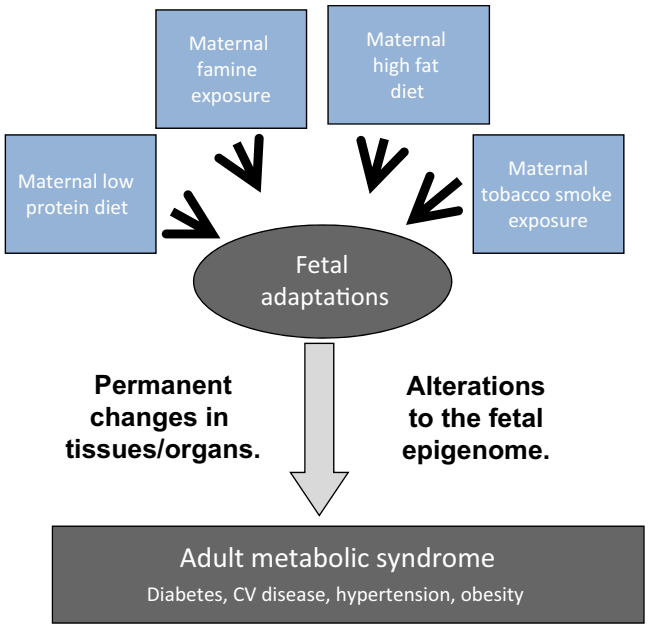

FIGURE 45.4 Maternal constraints: the developmental origins of adult health and disease (DOHaD). Many studies have shown that various maternal constraints are associated with the adult onset of metabolic disease such as exposure to in utero protein restriction, high fat diet, or famine. Epigenetic mechanisms may play a role in maintaining a memory of this in utero exposure until adulthood.

this time, areas of northern and western Holland were subject to starvation due to a Nazi-imposed embargo on food supplies. Because of this, the average citizen had only approximately 500 calories per day, and more than 18,000 people died from starvation.[212] Yet, throughout the famine, meticulous health care records were kept, including information on pregnant women and their newborns. Due to the meticulous records, the gestational period when the fetus was exposed to starvation (periconceptually, early gestation, late gestation) can be established. These individuals who were born during the Hunger Winter have been studied. Researchers have been able to determine phenotypic outcomes associated with in utero exposure to starvation. In many studies, unexposed siblings have served as the controls. In this section, we will summarize studies of the phenotypic outcomes of these individuals, as well as the epigenetic changes that have been recorded.

Besides the meticulous records kept during the famine, another unique aspect of this period is that once the famine ended, the population had an abundance of food. Individuals exposed to starvation in the womb were not born into a world where they would be exposed to starvation for a long period of time. Perhaps a disconnect between the fetal life (starvation) versus postnatal life (abundance) can account for the myriad published metabolic consequences these individuals experienced in adulthood. For example, in 1976 Ravelli et al. demonstrated that individuals exposed to the famine during the first half of gestation had an increased likelihood of developing obesity by age 19 ($p > 0.0005$).[213] Further studies on these individuals revealed a plethora of cardiovascular symptoms. Exposed individuals are more likely to have an atherogenic lipid profile, hypertension, disturbed coagulation, and a significant chance of developing coronary heart disease in adulthood.[190] The effects of the famine may even be transgenerational. In a study of women exposed to famine in the womb, their children showed increased neonatal adiposity compared with mothers who were not exposed in utero.[191]

The results of these studies beg the question: how is the memory of in utero exposure to starvation maintained for decades? Many researchers believe that epigenetics plays a critical role in establishing a molecular memory in the fetus that could be maintained into adulthood. To date, there are only two reports studying DNA methylation in individuals exposed in utero to the Dutch famine.[214,215] Both reports demonstrate a difference in peripheral blood DNA methylation levels at specific loci.

In 2008, Hejimans et al. used a quantitative mass spectroscopy analysis to determine if exposed individuals had differential methylation of the imprinted IGF2 promoter six decades after the famine.[215] Sixty individuals exposed in utero to the famine were enrolled, and their same sex siblings served as controls. Within the exposed individuals, four out of five CpG sites within the IGF2 DMR were hypomethylated compared with their siblings. A similar test of DNA methylation from 62 individuals who were exposed to the famine in only the last 10 weeks of gestation did not reveal a difference in methylation. Timing of exposure is likely important in setting these persistent epigenetic changes in utero. In a follow-up study of the same individuals, the methylation status of 15 genes involved in metabolism and cardiovascular disease was interrogated.[214] In this study, it was reported that methylation of *INSIGF* was decreased, while methylation of *IL10*, *LEP*, *ABCA1*, *GNASAS*, and *MEG3* were increased. These results show that the in utero environment is crucial in establishing DNA methylation of imprinted regions, and that disruptions during this period may actually be associated with life-long changes in the epigenome.

TABLE 45.3 Maternal Constraints and Epigenetic Changes

Maternal Constraint	Epigenetic Change	Model System	References
Famine exposure	Differential DNA methylation in peripheral blood	Human	188,189
Methyl donor enriched diet	Changes in DNA methylation at Agouti promoter	Mouse	190,191
Protein restriction	Fetal liver DNA hypomethylation	Rat	192
Protein restriction	Promoter specific changes in DNA methylation and histone modifications	Rat	193–198
High fat diet	Global and promoter specific hypomethylation in the brain	Mouse	199
High fat diet	Promoter specific DNA methylation changes in bone	Rat	200
High fat diet	Hypermethylation of cell cycle regulator in liver	Rat	201
High fat diet	Changes in levels and promoter specific H3K14ac	Monkey	202–205
Tobacco smoke	Promoter specific changes in DNA methylation and gene expression	Human	206,207
Tobacco smoke	Global DNA hypomethylation in cord blood from smokers	Human	208
Tobacco smoke	Changes in repeat DNA methylation in buccal cells and placenta	Human	209–211

Metastable Epialleles: Evidence for the Fetal Epigenetic Origins of Disease

Studies using the Agouti yellow mouse demonstrate how maternal diet influences epigenetic programming and can influence the adult onset of metabolic disease. These mice contain a "metastable epiallele" that coincides with a distinct phenotypic readout. An epiallele is an allele of a gene that differs from other alleles of the same gene by virtue of its methylation status. Metastable epialleles are epialleles whose DNA methylation pattern can be altered by the environment. The expression of a metastable epiallele is influenced by DNA methylation in the promoter region. Therefore, the epiallele can be differentially expressed in genetically identical individuals, simply based on the methylation status surrounding the gene.[216]

The *Agouti* gene (A^{vy}) in mice codes for a paracrine signaling molecule. In the absence of the gene product, the follicular melanocytes produce a brown pigment; in its presence, they produce a yellow pigment (reviewed in Ref. 217). Expression of agouti is regulated through methylation of nine CpG sites within its promoter; increased methylation silences expression, while decreased methylation promotes transcription. The readout of expression is simply the coat color of the mouse. In a scenario where the promoter is completely methylated, the agouti gene is silenced and the mouse is brown. When the promoter is unmethylated, the gene is expressed and the mouse is yellow. Partial promoter methylation yields a mottled brown/yellow coat color. Besides the change in coat color, an increase in body weight in mice expressing the *Agouti* gene has been observed.

Because agouti gene expression is related to the amount of promoter methylation, this model system is ideal for identifying factors that can alter the fetal epigenome during development, with varying maternal constraints. In 2003, Waterland and Jirtle found that supplementation of the maternal diet with potential methyl donors, including folic acid, B12, choline, and betaine led to changes in percent methylation of the agouti locus and changes in coat color in the offspring, compared with unsupplemented controls.[5] Similar results were reported from the Wolff lab.[7] Experiments where the maternal diet was supplemented with genestein, the major phytoestrogen found in soy, also revealed similar results.[218] Not only did the offspring exposed in utero to maternal genestein supplementation show increased methylation at the Agouti locus and decreased expression but the methylation persisted into adulthood and appeared to protect the offspring from obesity. Using the same mouse model, Waterland et al. performed an elegant experiment to show that methyl donors prevent the transgenerational amplification of obesity.[6] They found that the tendency for Agouti mice toward obesity was worsened as the gene passed through generations of obese mothers. However, supplementation of the maternal diet with methyl donors prevented obesity in the next generation.

Use of the agouti mouse model has provided strong evidence relating a fetal exposure to adult disease. Methylation of the agouti locus is essential for prevention of obesity in the adult mouse. Proper methylation is established in utero and can be altered with supplementation of the maternal diet with the methyl donors typically found in prenatal vitamins such as folic acid. Increased methylation at this locus is associated with the prevention of obesity in the adult mouse. These studies provide a firm foundation elucidating a role for epigenetics in adult disease and the importance of the in utero environment in establishing these epigenetic patterns.

Maternal Protein Restriction

Animal models have been crucial in elucidating the phenotypes of offspring exposed to a maternal low protein (MLP) diet. Much of the MLP diet research has been performed in rat models, using casein as the protein source. Traditionally, the low protein diets will have approximately half the protein found in the control diets. Decades of research have revealed that offspring exposed to MLP in utero will have permanent metabolic changes, including hypertension, decreased body weight, and altered glucose metabolism.[219,220] These rat models of MLP diet exposure have enabled scientists to characterize epigenetic changes associated with specific phenotypes of these offspring such as hypertension and altered glucose metabolism.

The hypertension phenotype in the offspring is a highly characterized outcome of MLP exposure. The offspring have hypertension throughout adulthood.[221] Bertram et al. showed that glucocorticoid receptor expression, an important regulator of blood pressure, is increased at least two-fold in the kidney in fetal, juvenile, and adult offspring.[192] Others have shown that the hypertension in the MLP-exposed offspring can be alleviated with supplementation of the maternal diet with glycine or folic acid.[193,222]

Epigenetic mechanisms may play a role in establishing these adverse phenotypes in utero. A study of global DNA methylation in the rat fetal liver revealed hypermethylation in MLP-exposed fetuses compared with control diet.[194] In rat pups, 6 days after weaning, the MLP-exposed animals had an increased expression of both glucocorticoid receptor (GR) and PPARα.[195] This increase in expression is associated with a decrease in promoter methylation in both genes. The GR promoter is also enriched for histone modifications of active transcription (H3K9ac, H4K9ac) and depleted for repressive marks (H3K9me2, H3K9me3).[196] The changes in

gene expression and DNA methylation are alleviated with supplementation of the MLP diet with folic acid.[195] Similar changes in expression and methylation are seen at the AT_{1b} angiotensin receptor gene.[197] Within the first week of life in rat pups, adrenal gland AT_{1b} expression is increased, while the proximal promoter is undermethylated after exposure to MLP diet.

Epigenetic mechanisms may similarly contribute to the altered glucose homeostasis phenotype also observed in these offspring. In this rat model system of MLP diet exposure, offspring undergo a gradual loss of glucose tolerance and develop symptoms of T2D by 17 months.[198,223] One mechanism behind this loss of tolerance could be an alteration in expression of hepatocyte nuclear factor 4-α (HNF4-α), a gene required for glucose homeostasis. MLP-exposed offspring, at both 3 and 15 months of age, show decreased HNF4-α expression in islet cells compared with controls.[224] This decreased expression is accompanied by an increase in promoter DNA methylation, a depletion of the activating histone modifications (H3ac and H3K4me1) and an enrichment of the repressive H3K9me2. Also, MLP-exposed offspring have an increased expression of CCAAT/enhancer binding protein β (C/EBPβ) in skeletal muscle.[225] C/EBPβ is an important transcription factor driving expression of insulin-responsive genes. The increase in expression is accompanied by an increase in both H3 and H4 acetylation within the promoter.[225]

While these aforementioned studies have demonstrated promoter-specific epigenetic changes with MLP-diet exposure, the most compelling evidence that epigenetics is involved in programming metabolism, and therefore adult disease, comes from studies showing that the effects of MLP exposure are transgenerational. Two separate groups have tested the F2 offspring using a rat model of maternal low protein diet exposure in utero, and both found similar results. In both experiments, the grandmother (F0) is given a low protein diet during gestation, such that the daughters (F1) were exposed in utero to MLP. After weaning, however, all F1 mothers consumed a control diet. In the next generation (F2), who were not exposed to MLP in utero, abnormal glucose metabolism is observed. Martin et al. demonstrated that the F2 generation from the F1-exposed MLP mothers had an increased insulin response at 30 and 120 min after a glucose challenge, compared to control F2 offspring.[226] Zambrano et al. found that the F2-female offspring of F1-MLP-exposed mothers showed evidence of insulin resistance.[227] A third group was able to show that fasting glucose and insulin levels were disrupted in the F3 generation, even though only their grandmothers were exposed in utero to an MLP diet.[228]

The rat model of maternal low protein diet exposure has offered compelling evidence that epigenetic alterations can be altered in fetal life in response to a suboptimal in utero environment. The modifications may be setting a memory of the in utero exposure that can last through adulthood. Because the altered glucose metabolism is seen in both the unexposed F2 and F3 generations, a likely epigenetic mechanism is transmitting this "exposure memory" throughout the germ line. It is unlikely that this transmission involves changes to the genetic code itself.

Maternal Obesity and Dietary Exposure

Although animal models of protein and calorie restriction have been studied for decades, in the era of the current obesity epidemic, animal models of maternal overnutrition have become of extreme importance. Over the past three decades the United States has seen a dramatic rise in the prevalence of obesity. Although it appears that this increase is leveling off, the most recent report from the CDC indicates that 68% of American adults are overweight or obese.[229,230] Obesity increases the risk for a number of health conditions, including metabolic syndrome and nonalcoholic fatty liver disease (NAFLD).[231]

While obesity is associated with adverse health outcomes for the individual, obesity during pregnancy bears unique maternal and fetal risks. The incidence of obesity among pregnant women is estimated between 18.5% and 38.3%.[199,232] These women are more susceptible to preeclampsia and gestational diabetes.[199,232] Newborns of obese and overweight women are more likely to be large for gestational age (LGA) and have a higher birth weight.[231] We are quickly finding many detrimental health consequences to the fetus exposed to a maternal high fat diet (HFD) and obesity in utero. In this section we will highlight studies using animal models of maternal HFD exposure that have shown epigenetic changes in the offspring bone, brain, and liver that correlate with specific morbidities associated with metabolic syndrome.

Is it maternal obesity or the maternal diet that bears primary influence on the offspring? Animal models have shown us that offspring of mothers who eat a high fat diet during gestation will have a preference for a high fat diet compared with unexposed offspring.[233,234] Vucetic et al. analyzed expression of genes in different regions of the brain that are involved in the consumption of palatable foods. They found that expression of the dopamine reuptake transporter, the μ opioid receptor, and preproenkephalin were all altered with HFD exposure in the adult male offspring exposed in utero to a maternal HFD.[200] They also found global and promoter-specific hypomethylation in the brains of these mice. This could serve as an epigenetic mechanism with the potential to reprogram a propensity to obesity in the offspring.

Another study of the deleterious effects of maternal HFD on offspring investigates an epigenetic predisposition to decreased bone mass and increased fracture

risk. Studies have shown that maternal HFD and obesity inhibit fetal skeletal development.[201,235] Chen et al. showed that fetuses of obese rats have inhibited skeletal formation at embryonic day e18.5 compared with controls.[236] The fetal cells involved in osteogenesis showed a decreased expression of HoxA10, a gene implicated both in fetal bone development and adult bone maintenance. Associated with this decreased expression, the authors found increased promoter methylation of the HoxA10 gene. They showed similar results in cell culture. Treating stromal-derived ST2 cells with free fatty acids showed an increased methylation of the Hox10A promoter compared with untreated cells. If the osteogenic cells respond to maternal lipids through methylation of the genes required for fetal skeletal formation, this could provide a mechanistic link between maternal HFD and inhibited skeletal formation.

Many studies have addressed the damage to the fetal liver with maternal high fat diet exposure. In rodents, it is well characterized that HFD exposure results in a high susceptibility to NAFLD in juvenile life and adulthood.[202] Dudley et al. studied the cell cycle in the postnatal rat liver of HFD-exposed offspring and found a significant cell cycle arrest in the G0/G1 phase at postnatal day 2 (P2).[203] In the HFD-exposed liver they found a decreased expression of the cell cycle inhibitor Cdkn1a, associated with promoter hypermethylation. However, the changes in cell cycle arrest, expression, and methylation observed in the P2 animals were not observed at P27.

Work in our laboratory has revealed many epigenetic changes in the nonhuman primate (NHP) fetal liver exposed to a maternal HFD. In this model, we are able to tease out epigenetic changes due to maternal obesity and those from a high fat diet. An NHP model closely mirrors human gestation. The Japanese macaques typically have a singleton, 6-month gestation, in contrast to the 21-day gestation in the mouse, where 8–12 pups per litter is common. In our NHP model, the dams are either on a control or a high fat diet throughout successive gestations. During this time the dams progress from overweight to obese. A subset of these obese dams is then switched to the control diet during breeding and throughout gestation. Because dams in this "diet reversal" cohort remain obese, we are able to determine the molecular effects of HFD versus maternal obesity.

Using this NHP model we have shown that the HFD-exposed fetus, at the beginning of the third trimester, has the pathology of NAFLD.[204] In an effort to determine if there are any epigenetic changes associated with NAFLD in the HFD-exposed fetal liver, we performed western blots on fetal liver lysates using antibodies specific for a myriad of histone modifications. We found that H3K14ac was uniquely enriched in the HFD-exposed fetal liver.[205] This increase in H3K14ac, while associated with HFD exposure, was not found in the diet reversal cohort.[237] In an effort to determine the mechanism behind the increase in K14ac observed in the HFD animals, we analyzed mRNA, protein, and activity levels of the known protein deacetylase SIRT1.[237] We found that all SIRT1 levels tested decreased with HFD exposure, which correlates with the increased K14ac levels. SIRT1 levels in the diet-reversal cohort were unchanged compared with controls.

Because we found an increase in H3K14ac in the fetal liver, we were interested to know which promoters were differentially enriched or depleted for this modification in HFD-exposed animals compared with controls. Using ChIP followed by differential display PCR we identified the *Npas2* gene, an important transcriptional regulator of circadian gene expression in the fetal liver.[205] Further investigation revealed that H3K14ac is enriched in the *Npas2* promoter only in HFD-exposed fetal liver and not in the diet-reversal cohort.[238] We found a similar promoter-specific enrichment of H3K14ac in the promoter of the thyroid hormone receptor beta gene, which drives transcription of thyroid hormone-dependent genes in the HFD-exposed fetal liver.[239] Our work on the NHP fetus shows that H3K14ac is a modification amenable in fetal life to maternal diet in the liver, and it is associated with specific promoters of important regulators of metabolism.

Similar to the results found in the offspring of protein-restricted mothers, some of the phenotypes of in utero HFD exposure can be transmitted transgenerationally. Interestingly, the effects of exposure can be transmitted by both the male and female offspring, as observed in a mouse model system.[240] Transmission of these phenotypes through the paternal germ line suggests an epigenetic mechanism. Dunn et al. found that the offspring of mothers and fathers who had only been exposed to HFD in utero had an increase in body length. These offspring also showed a reduction in sensitivity to insulin 30 min after an insulin tolerance test. Another study showed that obesity occurred earlier and was more severe in the third generation if both the mothers and grandmothers were raised on a HFD.[241] An increased propensity for obesity compared with offspring of control diet animals may suggest epigenetic reprogramming that occurred in utero with HFD exposure.

Maternal Tobacco Smoke Exposure

The epigenetic changes in the fetus associated with maternal tobacco smoke exposure (MTSE) have also recently been investigated. Despite decades of public health warnings, as many as 20% of pregnant women continue to smoke throughout gestation.[242] Since 1957 it has been repeatedly shown that smoking during pregnancy is associated with low birth weight babies and prematurity.[243,244] However, it has been noted that not all infants exposed to tobacco smoke in utero are born small

for gestational age (SGA). The mechanisms behind this differential susceptibility to MTSE are currently being explored. Specific genetic polymorphisms in genes that metabolize the xenobiotic compounds in tobacco smoke have been implicated in IUGR with MTSE.[245–247] Therefore, any epigenetic modification that alters expression of one or more of these genes could similarly contribute to IUGR susceptibility.[206,207] Here we highlight studies of epigenetic alterations associated with MTSE in placenta, cord blood, buccal cells, and peripheral blood.

In 2003, Antilla et al. published that expression of *CYP1A1*, the enzyme that metabolizes the polycyclic aromatic hydrocarbons in tobacco smoke, is highly upregulated in the lungs of smokers.[208] Within the *CYP1A1* promoter lies an essential element crucial for transcription called a xenobiotic response element (XRE). They found in the lungs of smokers that the XRE was hypomethylated compared with nonsmoking controls. We hypothesized that *CYP1A1* expression and promoter methylation would be similarly altered in the placenta from mothers who smoke compared with nonsmoking controls. Indeed, we found that *CYP1A1* expression is upregulated more than four-fold, and the XRE was hypomethylated by 10% compared to the nonsmokers.[209] Furthermore, methylation status only within the XRE correlated with *CYP1A1* expression. Methylation elsewhere within the 1.5 kb proximal promoter did not correlate with expression.

To see if other such genes showed a correlation between expression and methylation in smokers, we tested the DNA methylation and gene expression on a genome-wide scale from 18 smokers and 18 nonsmoker controls.[210] Methylation changed significantly at 1024 CpGs. We found that 438 genes had a significant correlation between methylation and gene expression in placentas from smoking mothers. These genes are enriched for members of the oxidative phosphorylation, mitochondrial dysfunction hypoxia response pathways. All of these mechanisms could potentially provide a mechanistic link between epigenetic changes and IUGR.

To date only one study has been published interrogating epigenetic changes observed in cord blood from smoking mothers. In an effort to determine if DNA methylation changes with MTSE, Guerrero-Preston et al. utilized an ELISA assay that measures global DNA methylation levels.[211] They correlated this data with measurements of cord blood cotinine levels, which is a reliable biomarker of maternal smoking. In this report they found that DNA methylation was highest in the cord blood from nonsmoking mothers and lowest in the heavy smokers. In other words, there was a negative correlation between DNA methylation and cord blood cotinine levels.

Only a few studies have looked at epigenetic changes in children or adults exposed in utero to MTSE. In two studies using buccal cells from kindergarten and first grade students, it was found that DNA methylation of the AluYb8 repeat is decreased, while methylation within the site-specific AXL gene is slightly increased.[248,249] This data corroborates a study in human placentas that showed that AluYb8 repeat DNA methylation is similarly lower in smokers than in nonsmokers.[250] Sat2 repeats show differential methylation in adult woman in peripheral blood granulocytes between those who were and were not exposed in utero to MTSE.[251]

THE DEVELOPMENTAL ORIGINS OF HEALTH AND DISEASE: PATERNAL CONSTRAINTS

For decades, research has focused on phenotypes in the offspring arising from various in utero, constraints such as maternal calorie restriction, low protein diet, or a high fat diet. More recently, however, a few publications have demonstrated that the father can also pass through the paternal germ line the "memory" of the exposure he experienced in utero. In other words, a male subjected to an adverse in utero environment can transmit that in utero experience to his offspring. Although such studies are not as plentiful, these recent studies are provocative and provide compelling evidence that epigenetic changes can be inherited through the germ line. In this section we will discuss Skinner's work on rats showing transmission of a paternal in utero exposure for four generations. We also highlight two separate studies showing paternal transmission of in utero exposure to protein restriction as well as postweaning exposure to an HFD.

Seminal work from Michael Skinner's lab used a rat model of endocrine disruption exposure in pregnancy to show that male offspring had a reduced fertility and that this phenotype was perpetuated for four generations.[252] In their previous experiments they had tested the effects of two known endocrine disruptors on pregnant rats and their offspring. They utilized methoxychlor, a pesticide, and vinclozolin, a fungicide used in the wine industry, which both have antiandrogenic activity. They found that a daily exposure of either chemical from E8–E15 resulted in the male offspring showing increased sperm apoptosis and a decreased sperm count.[253,254] However, daily exposure from E15–E20 did not show the same effect. They wanted to test if the F1 offspring who were exposed in utero to either methoxychlor or vinclozolin could transmit the phenotype of reduced sperm count and motility and increased sperm cell apoptosis.

In their experiment they crossed male progeny from an F0 treated mother with a female from an untreated mother. The male offspring of this cross showed a similar increase in spermatogenic sperm apoptosis, decreased sperm count, and increased motility.[252] A similar cross using female progeny from an F0 treated mother and a

male from an untreated mother did not have the same results. Continued crosses of the male offspring showed that this phenotype was transmitted through the F4 generation. These experiments suggest that epigenetic mechanisms were involved in transmitting the phenotype through the paternal germ line. Because 90% of all males in the F1–4 generations exhibited the phenotype, the frequency is too high to be explained by genetic mutation. Measurement of DNA methylation in epididymal sperm and testis did reveal slight changes in DNA methylation in the male progeny of F0 treated mothers.[252] The researchers concluded that the phenotype was only carried through the paternal lineage.

While we have highlighted many studies of maternal high fat diet exposure, one study has shown that the effects of postweaning paternal chronic consumption of a high fat diet are transmissible to female offspring.[255] Ng et al. showed that male rats chronically consuming a high fat diet showed increased body weight and adiposity and reduced glucose tolerance. The female offspring of these HFD-fed fathers also showed impaired glucose tolerance and insulin secretion but did not have an increased body weight. Transcriptional analysis of the β-cells in these female offspring revealed a significant change in 642 genes. The authors also tested promoter methylation of the gene that showed the highest fold-change in their analysis, *Il13ra2*. They found the increased expression was accompanied by promoter hypomethylation.

A final study that highlights transmission through the paternal germ line uses a mouse model of maternal low protein diet exposure.[256] In this model, male mice exposed in utero to the MLP diet are crossed with unexposed females. The livers of the offspring from this cross were analyzed for changes in gene expression at 3 weeks of age. They found that 1595 genes showed differential expression compared with offspring of unexposed fathers. Analysis of this gene set revealed an increase in expression of genes involved in lipid and cholesterol biosynthesis. Physiological analysis of the offspring livers revealed a two-fold decrease in cholesterol and cholesterol esters in these offspring. Because these changes in gene expression were transmitted through the father, the authors proposed an epigenetic mechanism is likely at play. They used high-throughput sequencing to look at miRNA levels in the offspring liver. While they found modest changes in a few miRNAs, they did not find expression changes in their expected targets. Analysis of approximately 1% of the mouse genome for changes in DNA methylation revealed a slight (20%) but significant change in methylation.

Transmission of phenotypes of environmental exposures by the father is an interesting and provocative discovery. In utero exposure to a low protein diet, or chronic consumption of an HFD, will not alter the underlying DNA sequence of the sperm genome. However, a distinct phenotype can be transmitted through the sperm. How epigenetic markings in the sperm can program the offspring is an important question in the field of the fetal epigenetic origins of disease and is likely a long way from being answered. As we have discussed previously in this chapter, the sperm chromatin is uniquely packaged and compacted, and very few histones remain within the paternal genome. Could the remaining paternal histones transmit such phenotypes to the offspring? Or are there changes in DNA methylation that occur in response to an environmental insult that are retained and somehow protected against the active demethylation event after fertilization? Currently, the study of transmission of environmentally derived phenotypes through the paternal genome is still very young. Many more studies will be required to observe the extent of the paternal transmission before a mechanism can be elucidated.

AREAS OF EMERGING INTEREST

The Microbiome: Important Player in the Fetal Epigenetic Origins of Disease?

The "human microbiome" is comprised of all the microorganisms present in the human body that exist in symbiotic (of benefit to the host) or nonsymbiotic (commensal or pathogenic to the host) relation in a complex ecosystem.[257–259] For several centuries, microbes were viewed primarily as pathogens in a negative context to causation of human diseases. However, recent advances in sequencing technology have enabled scientists to catalog all the organisms (culturable and nonculturable) present in the human body, and we have expanded this work specifically among pregnant women.[260–265] Suffice it to say, we now appreciate that the microbial genome exceeds the human genome by at least 150-fold, and this community genome (or "metagenome") encodes for an antigenically and metabolically vibrant community.

While these impressive efforts to date have cataloged the human microbiome and its carriage patterns, we are only beginning to understand how the microbiome is established and what influences its composition. A few studies have shown that changes in the maternal microbiome may have protective effects on the infant. For example, Blumer et al. exposed pregnant mice to lipopolysaccharide, a component of the gram negative cell wall.[266] The neonates showed enhanced neonatal IFN-γ, but not IL-4 and IL-2 production, which may have implications for lessening the severity of allergies in the offspring. One study in humans has indicated that prenatal use of antibiotics may be associated with allergies in the offspring.[267] It has even been shown using probiotics that colonizing the mother with *Lactobacillus rhamnosus*

strain GG in late pregnancy can similarly colonize the neonatal gut.[268] During pregnancy, the maternal gut microbiome is related to body weight, weight gain, and metabolic biomarkers, and could therefore influence fetal health.[269] Such studies indicate that the maternal microbiome is having an effect both on offspring health and microbiome. In other words, we are now beginning to appreciate how human behavior and exposures shape the maternal microbiome, which in turn is capable of shaping the microbiome in the next generation.

While studies of the maternal microbiome are gaining interest, studies of how the microbiome associates with epigenetic changes are rare. Schaible et al. investigated whether maternal methyl donor (MD) supplementation changes the offspring susceptibility to colitis in mice.[270] They found that indeed, not only did these offspring have an increased susceptibility to colitis, they also had an altered gut mucosal transcriptome as well as changes in DNA methylation. However, at postnatal days 30 and 90 they did not show changes in the gut bacteriome. The role of MD supplementation on changes in DNA methylation, and subsequent colitis susceptibility, will be important to elucidate in future studies. In another study, Kellermayer et al. interrogated the gut microbiomes of WT mice and mice lacking the Toll-like receptor 2 (*Tlr2*$^{-/-}$) gene, a known modulator of gut tissue integrity.[271] Not only did species bacterial abundance differ between the two groups but they also had differential gut mucosal transcription and DNA methylation. Whether the epigenetic changes are associated with the change in gut flora or the genetic mutation of the mouse remains to be determined.

Obviously if the microbiome influences the epigenome or vice versa, there are many factors at play. Both have an important role in regulating fetal health and perhaps increasing the offspring's susceptibility to adult disease. We fully anticipate that in the very near future our understanding of the role of the microbiome–epigenome interactions in shaping reproductive health will have already expanded significantly. We further predict that this will be one of the most influential arenas for high-impact research in the history of developmental biology and reproductive outcomes.

Micronutrient Supplementation

We have highlighted studies of supplementing the maternal diet with methyl donors in animal models. However, many scientists are interested in whether similar changes occur in humans, especially in the context of prenatal vitamins, which typically provide many of the nutrients involved in one-carbon metabolism, including folic acid. Because the few available studies on humans hint that offspring DNA methylation changes are associated with micronutrient supplementation of the mother, many studies are warranted to tease out which doses and timing of supplementation are best.

One study that measured the two DMRs within the *IGF2* gene in umbilical blood found differential methylation between newborns from mothers who started taking prenatal vitamins before pregnancy compared with those who started only after conception.[272] Further studies have shown that methylation of LINE-1 repeat elements in cord blood DNA correlates with homocysteine levels and birth centile.[273,274] A study of micronutrient supplementation in Gambian women, which provided 14 different vitamins and minerals, revealed differential cord blood methylation compared with newborns from women taking a placebo.[275] The changes occurred in genes associated with immune defense, and could reveal an important mechanism through which epigenetics can predispose offspring to either health or disease.

CONCLUSION

There are major questions yet to be resolved regarding the epigenetic contributions to the developmental origins of health and disease. Numerous studies have chronicled changes that occur in the offspring with various in utero constraints. However, longitudinal studies as to how long the modifications last over the life span of the individual are lacking. If epigenetic modifications serve as a molecular memory of an in utero experience, it is important to know how long they persist throughout development and aging of the individual. Secondly, the question of how these epigenetic changes can be correlated with the phenotype observed in adulthood is unknown.

In humans, adult phenotypes likely have many converging etiologies, and determining the contribution of the in utero experience is difficult. However, animal models have their limitations as well. Being able to translate our observations from the mouse, rat, and monkey models to humans is also difficult. We are currently unable to determine if epigenetic changes that occur in utero are a consequence or cause of later-in-life phenotypes.

In the future, studies that follow epigenetic changes in individuals over the course of their lifetime, spanning several decades, will be essential to determine how persistent these epigenetic changes are. For example, DNA methylation changes have been reported in cord blood from newborns, buccal cells from children, and blood cells from adults after in utero exposure to maternal tobacco smoke. Whether these modifications are stable or change over the life span of the individual is unknown. However, this knowledge would aid in understanding the persistence of the changes in DNA methylation, and would further our understanding of such changes as a molecular memory of the in utero experience.

In the decades since Waddington initially coined the now common term epigenetic, our advances in reproductive biology and development have led us to discover the molecular epigenomic mechanisms that drive much of human adaptation, evolution, and developmental plasticity. The field has advanced from one of primarily phenomenology and observational descriptions to its current state of broad application to human health and disease. We anticipate that the "current" state of the science as described herein will similarly likely be historically relegated in a matter of a few short years as the fields of epigenomics, metagenomics, and comparative genomics rapidly merge to reveal the incredible grandiose beauty inherent to evolution—as observed one generation at a time. It will now be incumbent upon all of us who serve as reproductive biologists and clinician scientists to join in dynamic conversation with our social science, nutritional science, and behavioral science colleagues. Together we can expand this dialog to our public officials, community health workers, and policy makers to work ardently within our communities to push forward positive changes in diet and lifestyle modification across all strata and across the globe to be agents of change for better health and less disease burden in the years and generations to come. We speculate that we have only begun to see a fraction of the developmental landscape that is affected by the rapidly changing world in which we live, and have yet to fully appreciate the impact of environmental exposures on our metagenome and epigenome. We have the utmost confidence that with such dialog we will see a greater responsibility for the health of our population be assumed by those with the likely greatest ability to enable change.

CHAPTER

46

Lactation and its Hormonal Control

Steven M. Anderson, Paul S. MacLean, James L. McManaman, Margaret C. Neville

University of Colorado Denver, Anschutz Medical Campus, Aurora, CO, USA

INTRODUCTION

Breastfeeding offers significant advantages to both infants and their mothers as elegantly reviewed in a recent article by Mohammed and Haymond.[1] However, breast milk production is often compromised in those mothers whose children might benefit most by breastfeeding according to the recommendations of the American Academy for Pediatrics, the Centers for Disease Control and the World Health Organization. These organizations all recommend exclusive breastfeeding for the first six months of infant life with supplementation with appropriate complementary foods up to one year of age.[2] Breast milk has significant benefits for at-risk populations such as preterm infants and those born to mothers with diabetes, metabolic syndrome, and obesity,[2,3] as well as for mothers with gestational diabetes mellitus.[4] Breastfeeding is critical in developing nations where clean water and resources to purchase formula are in short supply. We are beginning to understand that nonnutritive components of breast milk offer significant benefits to both the infant and the mothers that exceed the nutritional components present in this complex fluid.

The nutritional status of the mother prior to conception and during pregnancy has profound effects upon mammary gland development and function, as well as neonatal development. While infants born to nutritionally deprived mothers have long been a focus of public health policy, it is clear that at-risk infants also include preterm infants, and those born to mothers with diabetes, metabolic syndrome, and obesity. Given the importance of lactation to human health, it is increasingly important that we understand mammary gland development and the physiology of lactation in a manner that can guide public health policy. In this chapter we will examine lactation physiology from a variety of perspectives, with an initial focus on the understanding of molecular mechanisms gained by in-depth analysis of experimental models and protein interactions. We will proceed to metabolic interactions that lead to the increased flux of substrate to the mammary gland for milk synthesis and end with a summary of milk ejection mechanisms. We will also describe recent approaches to lactation research in humans, emphasizing some of the unique components of human milk and some new technologies that are beginning to provide molecular insight into human lactation.

Much of the early physiological research in lactation was carried out in dairy animals. Sometime in the 1950s, Jim Linzell, working at the Agricultural Research Council of the Institute of Animal Physiology at Babraham, Cambridge, UK, began to examine the blood flow in the mammary gland of the goat. Along with a young researcher, Malcolm Peaker, he soon began to combine blood flow measurements with new techniques that allowed metabolic reactions to be traced with radioactive isotopes in the animal. These experiments, summarized in *Physiological Reviews* in 1971,[5] provided insights into the mechanisms of milk secretion that had been undreamed of even a decade earlier. Around the same time, a world away in Berkeley, California, another researcher, Dorothy Pitelka, was applying her skills with the new miracle of microscopy, the electron microscope, to an examination of the morphology of the mammary gland at the minutest level.[6] Pitelka used her skills with transmission and freeze fracture electron microscopy to publish a series of papers that essentially defined cell–cell contacts in the mammary gland. She then went on to establish tissue culture models that would allow study of the regulation of these contacts and other aspects of the molecular control of the synthesis of milk proteins even to the present.[7] One of the exciting moments in the field was when Linzell and Pitelka both presented their work at a Gordon Conference in 1973, where each discovered that the other was working on complementary aspects of

Knobil and Neill's Physiology of Reproduction, Fourth Edition
http://dx.doi.org/10.1016/B978-0-12-397175-3.00046-6

tight junction regulation in the mammary gland, providing a framework for the work on tight junction regulation in the mammary gland that continues today. Many other researchers, too numerous to mention in this introduction, have contributed to our current understanding of the physiology of lactation, and some of their work will be described later in this chapter.

We are once again at a strategic junction in our understanding of the biology of milk secretion. During the decades leading up to the 1970s, biochemists identified and characterized the numerous enzymes that underlie the ability of the mammary gland to make milk. The application of molecular techniques during the 1980s allowed the cloning of genes for proteins known to be present in milk or to participate in synthesis and secretion of milk as well as identification of the promoter elements that regulate expression of these genes. The 1990s brought the identification of signal transduction pathways that control expression of specific genes and the differentiation of the mammary gland. The use of genetically modified mice confirmed the importance of these signaling molecules and pathways in regulating developmental processes during puberty, pregnancy, lactation, and involution, providing a better understanding of mammary gland development at the molecular level. In the last decade gene expression profiling, comparative genomics, and analysis of single nucleotide polymorphisms have produced a more complex picture of lactation that includes an appreciation of cross species differences and variation. The use of metabolomics is allowing a new appreciation of mammary physiology in a whole body context. Finally, the ability to localize specific molecules within the mammary cell using immunohistochemistry is greatly expanding our knowledge of the mechanisms of milk secretion. Our goal in this chapter is to make available a scaffold composed of past and current knowledge of the mammary gland providing a foundation for future advances that utilize biochemical, molecular, cell biological, nutritional, and genetic approaches in an integrated manner and advance our understanding of lactation and its importance to neonatal development.

DEVELOPMENTAL ASPECTS OF MILK SECRETION

Methods for Studying Mammary Gland Development and Function

Histological Methods

Examination of the primary structure of the mammary gland has long been the first approach to analysis of developmental alterations that affect glandular function. In fact, characterization of glandular function without examining the morphology of the gland for changes that underlie changes of function is likely to lead in erroneous directions. The first standard approach is preparation of whole mounts of the mammary gland allowing determination of whether ductal elongation, alveolar budding, and alveolar expansion have taken place (Figure 46.1). To do this, the whole mammary gland is excised, fixed, stained with either carmine alum or hematoxylin, and clarified to remove excess stain in such a way that the ductal tree can be appreciated (for review of methods see Ref. 10). Under low power it is possible to discern many aspects of mammary gland development particularly during puberty and early pregnancy before the florid development of late pregnancy and lactation make it difficult to discern individual ducts and alveolar units.

Conventional examination of thin tissue sections that have been stained with hematoxylin and eosin remains highly informative as the fine details of terminal end buds (TEB) and secretory alveoli are readily evident. While lipid droplets are readily identifiable in sections stained in this manner, greater detail is revealed when a combination of stains is used to identify various structures. For example, the use of anti-adipophilin antibody to outline cytoplasmic lipid droplets (CLDs), DAPI (4′, 6-siamidino-2-phenylindole) to stain nuclei, and fluorescent tagged-wheat germ agglutinin that binds to the luminal surface of secretory alveoli has allowed investigators to demonstrate that the size and position of CLDs changes during the transition from pregnancy to lactation[11] (see following). The combined use of antibodies to specific proteins with cytological markers for the nucleus, mitochondria, or other organelles will continue to provide in-depth understanding of cellular and signaling events in mammary gland development and lactation.

Transplantation Methods

The fact that the majority of mammary gland development occurs postnatally offers the unique opportunity to use transplantation to study the development of mammary epithelia containing targeted mutations.[12,13] In this method the mammary fat pad of a three-week-old prepubertal mouse is cleared by removal of the region of the gland proximal to the nipple, leaving a fat pad devoid of precursor cells capable of developing into the ductal tree (Figure 46.2). In the majority of studies a section of mammary gland from another mouse is placed into the cleared fat pad to develop in this new environment. Development is assessed at varying times following transplantation by whole mount analysis using contralateral glands on the same mouse as a control. Numerous variations on this basic technique have been developed over the years, including transplantation of tissue into non-cleared glands, transplantation of partially purified mammary "stem cells", and transplantation of "marked" cells expressing different fluorescent proteins or other

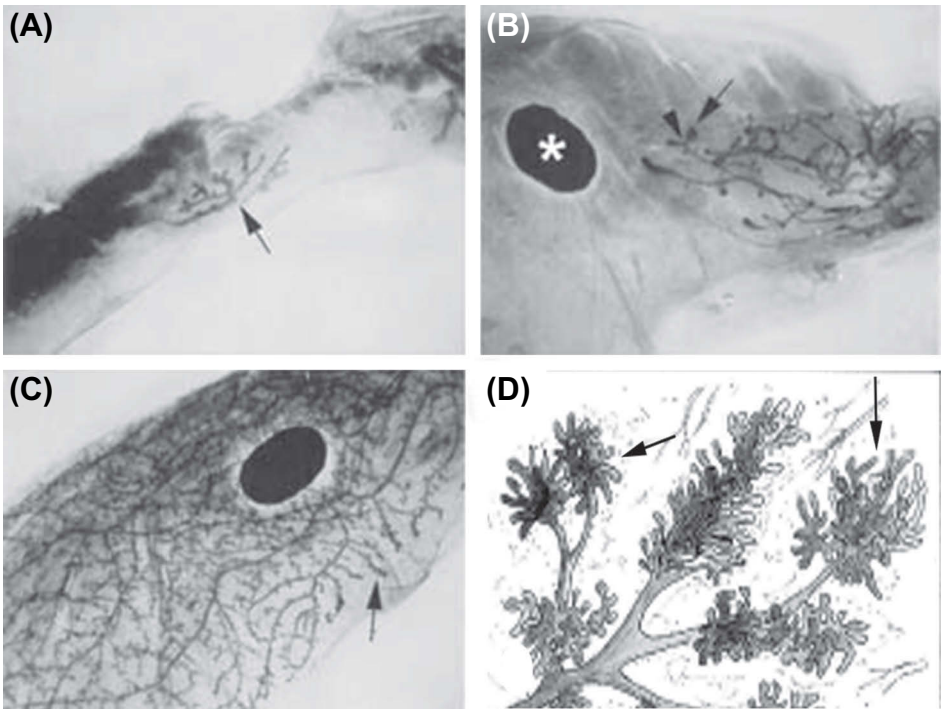

FIGURE 46.1 Whole mounts of mammary glands from virgin mice and humans. detectable markers such as β-galactosidase. Transplantation studies have been critical in the identification of cell autonomous features, and in determining the role of the surrounding stromal environment in mammary gland development.

Methods to Assess Lactation Competency

Since the primary purpose of lactation is to support the growth of neonates, neonatal growth remains the best indication of lactation competency in most experimental species, although milk production can easily be assessed in dairy animals. Comments here are directed toward rodent experiments. Although it is simple to measure the weight of the litter and track its increase on a daily basis, several considerations should be given to this process so that meaningful data are obtained. First, it is important to standardize all litters to the same number of offspring so that each dam experiences an equivalent demand for milk; in the mouse, many investigators have standardized litters to eight pups, although for some lower producing strains six pups are more relevant.[15] Second, it is important to utilize pups without a developmental defect, often achieved by cross-fostering litters from a normal dam. When pups are well fed, the milk-filled stomach is readily apparent. Pups are either weighed individually or as a group, and the weights plotted over time. Numerous genetically modified mice display lactation defects when pup growth is used to access lactation competency; these include transgenic dams overexpressing constitutively activated AKT1,[16] *Akt1* null mice,[17] thyroid hormone responsive protein (THRSP or SPOT14) null mice,[18] and mice lacking tissue-specific expression of SREBP cleavage-activating protein (SCAP),[19] among many others.

Another approach is the "weigh-suckle-weigh" method in which pups are withdrawn from the dam for a defined period of time, such as 4 h, the pups weighed immediately before being returned to the dam, and then weighed again after 1–2 h of suckling. This method allows analysis over a defined period of time, sometimes in response to a specific treatment or intervention (for example, treatment with bromocriptine to disrupt prolactin (PRL) secretion[20]). Yet another approach is to weigh the excised mammary glands; however, results of this approach are likely to be influenced by the amount of time since suckling has occurred.[15]

In addition to analysis of pup growth, there is much to be learned by analysis of milk or milk curd itself.[15] Milk can be obtained from a lactating mouse with use of a suction device and oxytocin (OT).[21] The amount of

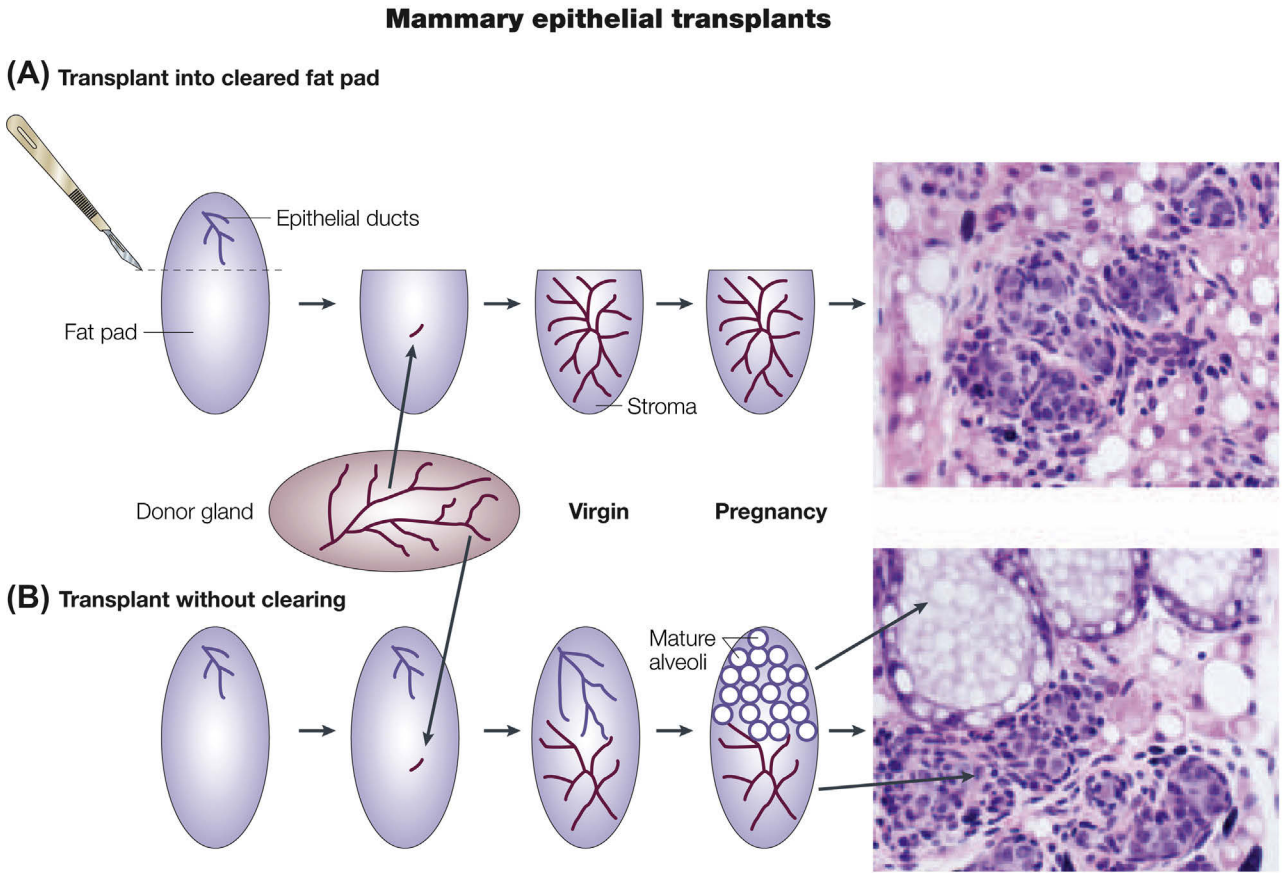

FIGURE 46.2 Use of mammary gland transplantation to assess developmental potential. This figure is reproduced in color in the color plate section. (A) The area containing the ductal anlage (purple) in a 3-week-old mouse is surgically removed to generate a "cleared fat pad" into which donor tissue (dark pink) is transplanted. The development of the transplanted tissue is monitored at intervals posttransplant by either whole mount or standard histological analysis. (B) An alternative approach involves direct transplantation into a non-cleared mammary gland. Transplanted cells are frequently marked with either immune-fluorescent markers, genetic markers, or infected with viruses expressing detectable markers. *Source: Used by permission from Macmillan Publishing Company; Ref. 14.*

protein present in the milk and the protein species present can be readily determined by gel electrophoresis. The milk lipid content can be determined on a volume basis using whole milk. Analysis of the milk clot from the stomach of pups after nursing is also possible, although effects of digestive enzymes make precise findings less reliable, or on dry weight basis using milk clot analysis. Furthermore, gas chromatography–mass spectroscopy can be used to determine the precise fatty acids present in the milk and their relative or exact concentrations.[19,22] New technologies are allowing precise determination of increasingly important components of milk, such as oligosaccharides, growth factors, cytokines, and glycosylated proteins.[23,24]

Methods for Studying Human Lactation

Studies of the physiology of lactation in humans have the advantage of direct clinical relevance. Further, milk is available in quantities that allow precise quantitation of nutrients and other molecules. They are made more difficult by the complex methods needed to accurately quantitate milk volume transfer to the infant and the near impossibility of obtaining samples of mammary tissue in a systematic fashion at various stages of mammary development. Our understanding of the histology of the human breast has come mostly from autopsy studies[25] and from samples of normal tissue taken in association with breast cancer diagnostic procedures. However, breast milk is available at all stages of lactation and offers considerable insight into both the complex composition of this fluid and its changes with time postpartum. Recently, insight into molecular mechanisms has been obtained from analysis of milk fat globule (MFG) membranes; these contain significant amounts of mammary cell cytoplasm, allowing assessment of mRNA expression.[26] In addition, the process of secretory activation takes place after birth rather than prepartum as in most species, allowing the molecular underpinnings of this process to be studied by careful analysis of milk components.

Breast milk production can be assessed in three ways: (1) In mothers who are pumping their breasts to obtain

milk for a preterm or ill infant, the volume of milk pumped is easy to measure, most accurately by weighing the milk container before and after pumping. This technique allowed researchers to determine that retained placental fragments can inhibit secretory activation in women, most likely by their secretion of P4.[27] (2) Willing mothers can apply a version of the weigh-suckle-weigh technique to assess quantitative transfer of milk to the infant. If this procedure is carried out on a 24 h basis, the daily production of milk can be assessed as was done in a landmark study of secretory activation in the Neville laboratory.[28,29] (3) Finally, the rate of appearance of deuterated water in the saliva or urine of the infant after defined dosage of the mother provides an accurate measure of milk transfer once milk volume has stabilized.[30] While the doses of deuterium necessary are not harmful,[31] it is often difficult to obtain permission to use the technique in mothers who have an aversion to taking an "isotope" (albeit a stable one) while breastfeeding.

The concentration of macronutrients in human milk has been known for many decades.[32] However, recent advances in mass spectroscopic techniques have allowed a remarkable refinement both in the analysis of low abundance proteins and their structures, e.g., glycosylation and phosphorylation, as well as a detailed understanding of the structures of the numerous oligosaccharides present in milk. The importance of these compounds to intestinal microbiome development in the infant is just now being revealed.[33,34]

Analysis of mRNA associated with the MFG is being carried out in a number of species. Most importantly this technique is available for human milk and has been used effectively in the Haymond laboratory at Baylor College of Medicine (Texas) to examine the transcriptome of the human mammary gland during lactation[26] and the gene expression correlates of the onset of lactose synthesis during secretory activation.[35] Application of new technology such as RNA-Seq[36] and advanced bioinformatics technology[37] in situations where lactation is likely to be compromised such as obesity is an exciting prospect for advances in our understanding of human lactation.

Hormonal Control of Anatomical Development

Endocrine and Paracrine Regulation of Ductal Development

The mammary gland is unique since, unlike most secretory organs, the capacity for milk secretion develops in the adult in concert with other reproductive events and is directed by reproductive hormones.[38] The mammary anlagen and the adipose fat pad into which the gland will develop are specified during embryonic development, however, further growth and differentiation must await the hormones of puberty and pregnancy.[39–42] The molecular basis of the developmental process has been best described in the rodent, where the ductal development that occurs during early puberty has been extensively studied using both genetically modified mice and transplantation approaches. Although hormone ablation studies demonstrated a role for estradiol-17β (E2), P4, and PRL in ductal and alveolar development in the 1950s, recent studies have provided better definition of this process and indicate that insulin-like growth factor-1 (IGF-I), growth hormone (GH), and amphiregulin are also important. At birth the gland contains a rudimentary ductal tree that is attached to the teat (Figure 46.1(A)). During puberty the ducts elongate until they reach the margins of the fat pad (Figure 46.1(C)). Elongation of the ducts occurs through proliferation of mammary epithelial cells (MECs) present in bulb-like structures at the ends of the ducts, which are referred to as TEB and disappear by the end of puberty (Figure 46.1(B)). Ductal branching also occurs during puberty resulting in a structure composed of regularly spaced ducts that never cross each other. Spacing between ducts appears to be the result of growth inhibitory effects of transforming growth factor-β (TGFβ).[43] Cross-transplantation experiments by Naylor and Ormandy showed that strain specific patterns of ductal branching in the mouse are a function of the mammary stroma rather than the epithelium,[44] and the extent of branching also varies between different strains of mice. Side branches develop under the influence of P4 during the luteal phase of the estrous cycle. In the rat the side branches are generally more complex and tend to be variable.[45] In the human the lobular units that are derived from the side branches are complex in character. In this species the so-called terminal duct lobular unit (TDLU) consists of a straight extralobular duct that branches into several intralobular ducts terminating in acinar complexes (Figure 46.1(D)).[9,46] In most dairy species, the ductal structure does not reach the margin of the fat pad until the hormones of pregnancy stimulate both ductal elongation and branching.[47]

Estrogens are known to act through two variants of the nuclear estrogen receptor, ERα and ERβ, which are both expressed in the mammary gland.[48] Mice in which expression of ERβ has been eliminated still show normal ductal elongation during puberty.[49] Initial studies demonstrating that ductal elongation was diminished in ERα knockout mice were complicated by the presence of a residual truncated ERα in these mice.[50,51] More recently, elegant studies by Cathrin Brisken and her colleagues have clearly demonstrated a role for ERα in elongation.[52] ERα null MECs transplanted into the cleared fat pad of three-week-old normal mice showed no ductal outgrowth. However, when ERα null MECs were co-transplanted with wild-type MECs, they were able to form ducts, suggesting the presence of a paracrine signaling pathway dependent upon ERα.[52] Further studies

identified amphiregulin as the paracrine growth factor and thereby implicated the epidermal growth factor receptor (EGFR), the only known receptor for amphiregulin, as a critical signaling molecule for ductal elongation.[53] EGFR is expressed in both MECs and the stromal cell compartment, however, only stromal expression of EGFR is required for ductal elongation,[52,54] suggesting the presence of a second paracrine signaling network regulating ductal elongation.

Increased production of circulating GH is coincident with the onset of puberty; formation of TEBs and ductal elongation have clearly been shown to require both GH and its primary transcriptional target IGF-I.[55,56] IGF-I, IGF-II, the IGF-I receptor (IGFIR), and IGF-binding proteins are all expressed in the murine mammary gland throughout puberty.[57] IGF-I is expressed in the mammary gland stroma throughout postnatal development and in the TEBs during puberty.[58] Loss of greater than 50% of IGF-I expression from MECs resulted in a decrease in both ductal complexity and the cyclins A2 and B1, which are important for S and G2 phase progression.[59] The role of circulating versus locally produced IGF-I in ductal elongation has been debated at length; recent studies by Cannata et al. demonstrate that elevated circulating IGF-I can stimulate development resulting in a more complex ductal network.[60] These data suggest roles for both circulating and locally produced IGF-I in pubertal development. However, it is clear that at least a portion of ductal elongation requires local production of IGF-I, which cannot be completely replaced by circulating IGF-I.[61]

In contrast to IGF-I, expression of IGF-II is induced by PRL and not GH.[62,63] During puberty IGF-II is coexpressed with IGF-I, however postpuberty and during early pregnancy IGF-II expression is restricted to ductal and alveolar epithelial cells in a nonuniform pattern reflecting that of the receptors for progesterone (PR) and PRL (PRLR).[64] The differential regulation of IGF-I and IGF-II suggests that they may each have unique roles in mammary gland development. MECs lacking PRLR transplanted into a wild-type mammary fat pad showed normal ductal elongation,[65] suggesting that neither PRL nor IGF-II is necessary for this process.

For a more complete description of these morphological changes the reader is referred to a number of excellent reviews[8,9,45,46] and an excellent online tutorial at http://mammary.nih.gov.

Mammary Development in Pregnancy

The hormones of pregnancy are critical in producing a mammary gland that is capable of producing milk. Although ductal elongation is normal in mice that lack PR, alveolar differentiation does not occur in PR knockout mice, or in wild-type fat pads transplanted with MECs lacking PR.[65,66] Deletion of PR from the stromal compartment does not alter alveolar differentiation during pregnancy. Two different isoforms of PR are produced from different promoters present in the same gene, and analysis of genetically modified mice lacking specific PR isoforms has revealed that only PR-B is required for alveolar development during pregnancy.[67,68]

In addition to P4, PRL is required for lactogenic differentiation during pregnancy. Genetically modified mice lacking either PRL or PRLR have been generated, and ductal elongation is normal in these mice.[69,70] However, analysis of lactogenic differentiation is complicated by the diminished fertility. Alveologenesis and differentiation of PRLR null MECs transplanted into wild-type mammary fat pads is completely blocked.[71] Consistent with a critical role for PRL and its receptor in lactogenic differentiation, MECs lacking either JAK2 or STAT5, the signaling molecules downstream of PRLR are also unable to undergo lactogenic differentiation,[72,73] further demonstrating the critical nature of the PRL pathway in pregnancy-induced mammary gland differentiation.

Understanding the role of IGFs in mammary gland development is confounded by the complex pattern of expression of both IGF-I and IGF-II during pregnancy; however, a role for IGF-I is suggested in recent studies by Sun et al.,[74] who examined lactogenic differentiation in genetically modified mice expressing a dominant-negative form of IGFIR in the mammary epithelium. Expression of this receptor delayed alveolar differentiation, luminal expansion, decreased epithelial cell proliferation, lipid droplet formation, activation of signaling molecules downstream of the IGFIR, and expression of milk protein genes.[74] Despite these dramatic changes, pup growth was not altered, suggesting that either the mammary gland is able to compensate for the observed defects, that complete loss of IGFIR is required, or that the insulin receptor (IR) takes over signaling through these pathways during lactation.[75,76]

In addition to IGFs, there is also increasing evidence that insulin plays an important role in mammary gland development and function in both pregnancy and lactation. The potential importance of insulin and its receptor in mammary gland development and lactation are at variance with previous thoughts that lactation would be insulated from the actions of insulin since insulin levels vary dramatically with food intake.[77] Berlato and Doppler analyzed the expression of both IGFIR and IR during lactation and observed that the levels of the IGFIR decreased at both the mRNA and protein levels following parturition, with an approximately 80% decrease in the amount of mRNA.[76] In contrast, the expression of total IR remained constant at both the mRNA and protein levels.[76] IR exists as the product of two different splice variants, referred to as IR-A and IR-B, which differ in the presence (IR-B) or absence (IR-A) of exon

11, which encodes 12 amino acids that are located at the C-terminus of the extracellular subunit of the receptor.[78,79] The major difference between IR-A and IR-B is that IR-A has a 10-fold higher affinity for IGF-II, making it a second physiological receptor for IGF-II.[78] Analysis of the expression pattern of IR-A and IR-B during pregnancy and lactation revealed that while the mRNA levels of IR-A remain the same over this developmental time course, the amount of IR-B mRNA increases three- to fourfold following parturition.[76] When the sixfold decrease in the amount of IGFIR mRNA that occurs following parturition is also taken into account,[76] one must conclude that there is a dramatic increase in insulin signaling during lactation.

The importance of insulin signaling in mammary gland development and lactation is indicated by recent analysis of mice bearing a floxed IR. Excision of the IR gene from MECs using Cre recombinase expressed specifically in these cells resulted in the formation of mammary glands that lack at least 50% of secretory alveoli by day 14 of pregnancy, and in a 75% decrease in pup growth over the first 10 days of lactation.[80] Despite this dramatic decrease in pup growth, the majority of pups do survive. A comparison of the genetically modified mice expressing the dominant-negative form of IGFIR and mice lacking expression of IR in the mammary epithelium clearly provides evidence that while IGF-I may be important for alveolar development during pregnancy, it is not the entire story in either pregnancy or lactation. These observations suggest that conditions that impair insulin signaling, such as obesity and diabetes, may have dramatic effects upon lactation.

Functional Differentiation

Functional differentiation of the gland can be divided into three phases that have been most thoroughly studied in the mouse: (1) the *proliferative* phase of early pregnancy, (2) *secretory differentiation* starting in mid-pregnancy, during which the gland becomes competent to secrete milk, and (3) *secretory activation* around parturition when the secretion of milk commences.

The Proliferative Phase

This phase starts immediately after conception, reaching a peak about day 5 of pregnancy, when an astonishing 25% of the mammary alveolar cells are labeled with ^{3}H-thymidine 1 h after injection in the mouse (Figure 46.3(A)).[81,82] Cell proliferation tapers off gradually through the remainder of pregnancy until MECs reach quiescence just prior to parturition. During this period the content of mRNA for epithelial markers cytokeratin 19 and claudin 7 increases nearly three orders of magnitude (Figure 46.3(B)),[83] indicating a remarkable expansion of the alveolar compartment. Whether these markers reflect cell number, cell size, or a denser cytoplasm is not currently clear. Three paracrine factors—Rank ligand (RANKL), WNT 4, and amphiregulin—show an expression pattern that parallels proliferative activity (Figure 46.3(C)); expression of RankL is regulated by PR[68] while expression of amphiregulin is induced by IGF-II.[62,63] In the mouse a single, coordinated round of cell division takes place immediately after parturition (Figure 46.3(D)),[82] possibly resulting in the high proportion of binucleate cells present in the lactating gland[85]; it is currently unknown what growth factors stimulate this round of cell division as the three paracrine factors elevated during early pregnancy are not expressed at this time. It is also not clear whether the proliferative activity in early lactation is specific to the mouse or occurs in other species as well.

As mentioned before, studies using genetically modified mice have indicated that P4[86,87] and PRL[88] are the major hormones that promote side branching and the formation of alveoli.[39] It is surprising to note that the receptors for PR are expressed in only a subset of cells in the mammary epithelium[64,89–92] (Figure 46.4). Indirect evidence indicates that this is also the case for the PRLR. Analysis of normal human mammary epithelium has shown that 98% of the proliferating cells are negative for estrogen receptor (ER) and PR,[90] and, significantly, the absence of PR in proliferating cells has also been observed in the mammary epithelium of mice, rats, and cows.[94–96] The disparate localization of proliferating cells and PR^{+} epithelial cells could be explained by the rapid downregulation of steroid receptors following ligand binding; this hypothesis is supported by observations that ERα is rapidly degraded by the proteasome,[97] and that ERα is also rapidly lost in MECs following entry into the cell cycle.[98]

The generally accepted view is that PR is not expressed in proliferating cells and that P4 action induces expression of paracrine growth factors that stimulate proliferation of PR^{-} epithelial cells. Thus, PR has been shown to induce expression of RANKL[68] and WNT-4,[99] while PRL induces expression of IGF-II.[62,63] WNTs are a family of signaling molecules similar to the *Drosophila* protein wingless and the mammalian INT. Overexpression of WNT-4 stimulates ductal branching and formation of alveoli following transplantation into cleared mammary fat pads in a manner that resembles development observed in pregnant mice.[100] Further studies have demonstrated that expression of WNT-4 is dependent upon activation of PR by P4, and that WNT-4 functions in a paracrine manner to induce ductal branching and alveologenesis during pregnancy.[99] It is not clear whether WNT-4 acts directly upon PR-negative MECs, or on other cells in the surrounding microenvironment.

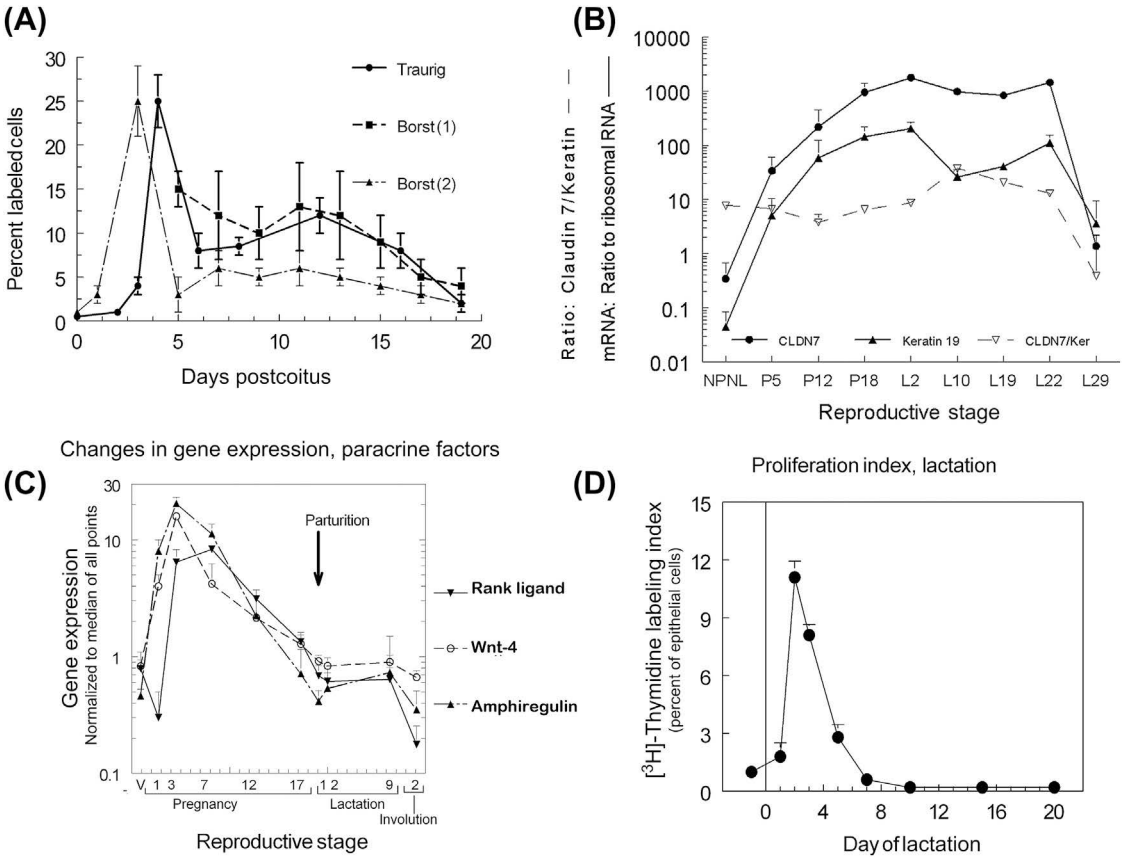

FIGURE 46.3 Proliferative activity during pregnancy and lactation in the mouse. (A) Proliferation through pregnancy as measured by 1 h incorporation of ^{3}H-thymidine in vivo. (B) Expression of mRNA for keratin 19 and claudin 7, epithelial cell markers determined by real time RT-PCR. Dashed line is the ratio of claudin 7/keratin 19. These changes are indicative of the proportion of epithelial cells in the gland as pregnancy progresses. (C) Changes in expression of mRNA of the paracrine factors Rank ligand (RANKL), Wnt-4, and Amphiregulin over pregnancy and lactation. (D) One hour ^{3}H-thymidine labeling index during lactation. The synchronized round of DNA synthesis probably results in the production of the binucleate cells that are numerous in the mammary gland of the lactating mouse. *Source: (A) Data replotted from Refs 81,82; and Borst DW, Mahoney WB. Mouse mammary gland DNA synthesis during pregnancy.* J Exp Zool *1982;**22**:245–50. (B) Reproduced from Ref. 83. (C) Unpublished data from Ref. 84. (D) Data replotted from Ref. 82.*

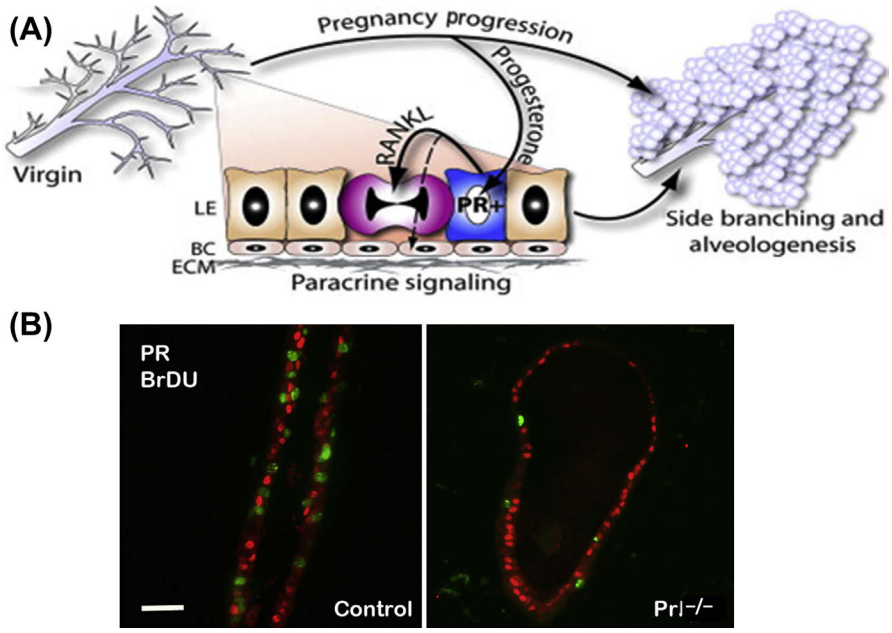

FIGURE 46.4 Role of paracrine signaling in alveologenesis. This figure is reproduced in color in the color plate section. (A) As pregnancy progresses side branches develop at discreet intervals along the ducts; cells in these side branches proliferate to form alveoli. The progesterone receptor (PR) is expressed in a subset of alveolar cells that are stimulated by increasing P4 from the ovaries to secrete RANKL. This paracrine factor acts on neighboring cells to promote proliferation. (B) Expression of PR and proliferating cells after 2 days of treatment with E2 and P4 in wild-type (control) and PRL-null mice. Proliferating cells (BrDU labeled, green) and PR positive cells (red) are generally not coincident. Note that the number of proliferating cells is reduced in the absence of PRL. Scale bar, 50 μm. *Source: (A) Used by permission from Ref. 93. (B) Original figure from Ref. 64.*

To observe the effects of overexpression of RANKL in MECs, Fernandez-Valdivia et al.[101] constructed transgenic mice in which expression of RANKL was driven by the mouse mammary tumor virus (MMTV) promoter, resulting in RANKL expression in the pubertal mammary gland when RANKL is not normally expressed. Transgenic mice expressing RANKL exhibited more TEBs, ductal side branching, and alveolar buds reminiscent of an early pregnant mammary gland, and there was a dramatic increase in the number of proliferating cells in both ductal and alveolar structures.[101] The florid proliferation and development observed in the RANKL transgenic mice is consistent with the attenuated alveologenesis and lactation defect observed in the RANKL knockout mice.[102] Expression of RANKL in MECs in vivo can be induced by treatment with either P4 or PRL.[62,67] Induction of RANKL is restricted to PR^+ cells, which reside in close proximity to PR^- cells that express cyclin D1 and proliferate in response to P4.[68] Further details regarding both WNT-4 and RANKL can be found in excellent recent reviews by Rajaram and Brisken[103] and Fernandez-Valdivia and Lydon.[93] Future research is needed to reveal the cells targeted by WNT-4, the signaling pathway(s) activated by WNT-4, and the role of these ligands in maintaining mammary stem cells in the normal gland. How amphiregulin, whose expression pattern in early pregnancy parallels that of WNT-4 and RANKL (Figure 46.3(C)), fits into this picture is not yet clear.

Another interpretation comes from experiments in the Haslam laboratory where the mammary gland from early pregnant mice showed a decrease in expression of PR-A, while the expression of PR-B remained constant in alveolar epithelial cells. Further, and in contrast to the virgin gland, expression of PR-B co-localized with cells that label with 5-bromo-2′-deoxyuridine (BrDU) indicating that these cells are proliferating.[104,105] These authors concluded that P4 interacting with PR receptor directly stimulated proliferation of alveolar cells during pregnancy.

Secretory Differentiation

Secretory differentiation, previously referred to as lactogenesis I,[106] begins about mid-pregnancy and is signaled by changes that depend on the species and the experimental paradigm used for their study. For example, Akers[47] showed that α-lactalbumin increased in mid-pregnancy in the fluid extracted at this time from the bovine mammary gland; a similar phenomenon is also observed in the mouse. McManaman and colleagues[16,107] have documented the accumulation of lipid droplets in the mammary alveolar cells of the mouse starting around day 8–10 of pregnancy (Figure 46.5(A)). Mellenberger and Bauman[108] showed a biphasic increase in the enzymes of lipid synthesis in the rabbit mammary gland, and Hartmann and colleagues[109] showed that lactose appeared in the plasma and urine in the women at mid-pregnancy. Gene expression profiling of whole murine mammary glands during pregnancy and lactation has revealed that expression of milk protein genes increases about fivefold during pregnancy and then increases a second time at parturition (Figure 46.5(B)).[84] Similar data are obtained when the expression of these genes is examined in preparations of adipocyte-depleted MECs (Rudolph and Anderson, unpublished data). Analysis of genes involved in de novo synthesis of fatty acids and β-oxidation of fatty acids reveals that the latter decrease over the course of pregnancy, while expression of genes involved in fatty acid biosynthesis increases sharply at parturition. Expression analysis of adipose-depleted MECs reveals that the increase in fatty acid biosynthetic genes is specific to the epithelium during pregnancy.[19] There is also a decrease in the proportion of adipose tissue observed in the mammary gland by microscopic examination, reflected by a proportionate decrease in expression of adipocyte-specific mRNAs. However, this decrease may reflect expansion of epithelial cells rather than loss of adipocytes (Figure 46.5(A)).[84] There is also a decrease in collagens expressed in the mammary gland as pregnancy progresses; it is not clear whether this change represents stromal remodeling or simply dilution of stromal components by the expanding epithelium. During late pregnancy the gland begins to produce small amounts of secretion product. This product can escape the gland through the junctional complexes between the alveolar cells, which are highly permeable during pregnancy.[110,111] Copious milk secretion in all species that have been examined is inhibited by the high concentrations of circulating P4 produced by the ovaries or placenta, depending on species, at this time.

Hormonal Regulation of Secretory Differentiation

PRL, P4, and the lactogenic product of the placenta, placental lactogen (PL), have all been implicated in the regulation of secretory differentiation.[112] There are clearly species differences in the roles of these hormones, particularly PRL and PL, and even though genetically modified mice have allowed a good understanding of the role of PRL, the role of PL remains unclear. GH is lactogenic in many species,[113] but its role in differentiation has been controversial because it is not clear whether the growth hormone receptor (GHR) is expressed in stromal cells or epithelial cells.[114] Lactation occurs although it is not normal in the $GHR^{-/-}$ mouse.[115] Furthermore, definition of the precise role of GH is complicated by its ability to induce expression of IGF-I, which has been shown to have direct effects upon secretory differentiation (see previous discussion).

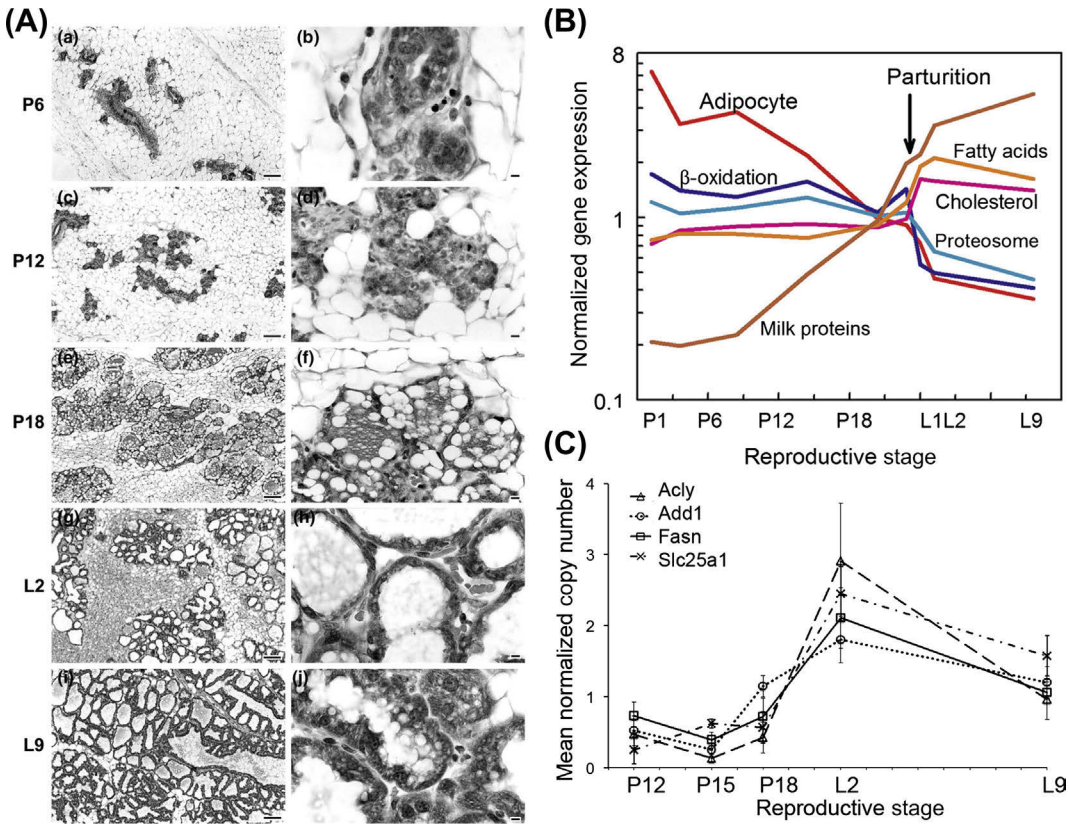

FIGURE 46.5 Changes in the differentiated activity of the mammary gland in pregnancy and lactation. Part B of this figure is reproduced in color in the color plate section. (A) Morphology of secretory development in the mouse. Shown are histological sections of the mammary gland of FVB mice through pregnancy and lactation. Mammary glands were isolated on the days indicated, fixed, sectioned, and stained with hematoxylin and Eosin. Scale bars, 100 μm in (a, c, e, g, and i) and 10 μm in (b, d, f, h, and j). Note the intracellular lipid droplets in late pregnancy (panel (f)), the expansion of the lumens at the onset of lactation (panels (f) and (h)), and the diminution of adipocytes as lactation progresses (compare panel L2 and L9). (B) Changes in gene expression of different categories of genes in the mouse mammary gland from microarray studies. Expression of adipocyte-specific genes and collagens (not shown) decreases six- to eightfold during pregnancy and another twofold at parturition, whereas the genes for fatty acid degradation and many components of the proteosome are level during pregnancy and decrease about twofold at parturition. Milk protein genes, on average, increase about fivefold during pregnancy and another threefold around parturition, whereas the genes for fatty acid and cholesterol synthetic enzymes increase about twofold just after parturition. Normalized data for each class were averaged to produce the lines on this graph. (C) Time course of expression of genes important for de novo lipogenesis. Note that the major increase in expression occurs during secretory activation. *Source: (A, B) From Ref. 11. (C) Original data from Rudolph MC. University of Colorado, Denver.*

PROLACTIN

PRL remains high throughout human pregnancy, and women with low PRL levels during pregnancy have difficulty in lactating,[116] suggesting that PRL is involved in secretory differentiation in humans.[117] The role of PRL in secretory differentiation has been more extensively studied in rodents, and although PRL is secreted in a pulsatile fashion early in pregnancy (Figure 46.6(A)), PRL itself is not necessary in mid-pregnancy in rodents and may even be deleterious by inducing premature secretory activation. Circulating PRL returns to high levels just prior to parturition[119] (Figure 46.6(B)). Furthermore, expression of the PRLR changes during pregnancy, and the long form, which activates downstream signaling pathways, is downregulated in pregnancy and increases markedly at parturition[118] (Figure 46.6(D)). Finally, if a constitutively active PRL receptor is expressed under the control of the β-lactoglobulin promoter, alveolar development is increased in late pregnancy, but the animals fail to lactate.[120] PRLR and the downstream signaling molecules JAK2 and STAT5 are required for secretory differentiation since mice lacking PRLR, JAK2, or STAT5 lack expression of milk protein genes.[69,72,73,121,122] PRLR, like PR, is expressed in only a subset of epithelial cells in early pregnancy,[64,123] and it is not yet clear whether these cells are coincident or not.

In the human serum, PRL and PL levels rise starting in early pregnancy reaching the very high levels of about 100 ng/ml (compared to ~10 ng/ml in the nonpregnant woman) and 2000 ng/ml (nonexistant in the nonpregnant animal), respectively, by the twentieth week of gestation; increases in PRL levels directly correspond to increases in lactose excreted into urine,[124,125] implying that PRL regulates activation of lactose synthesis.

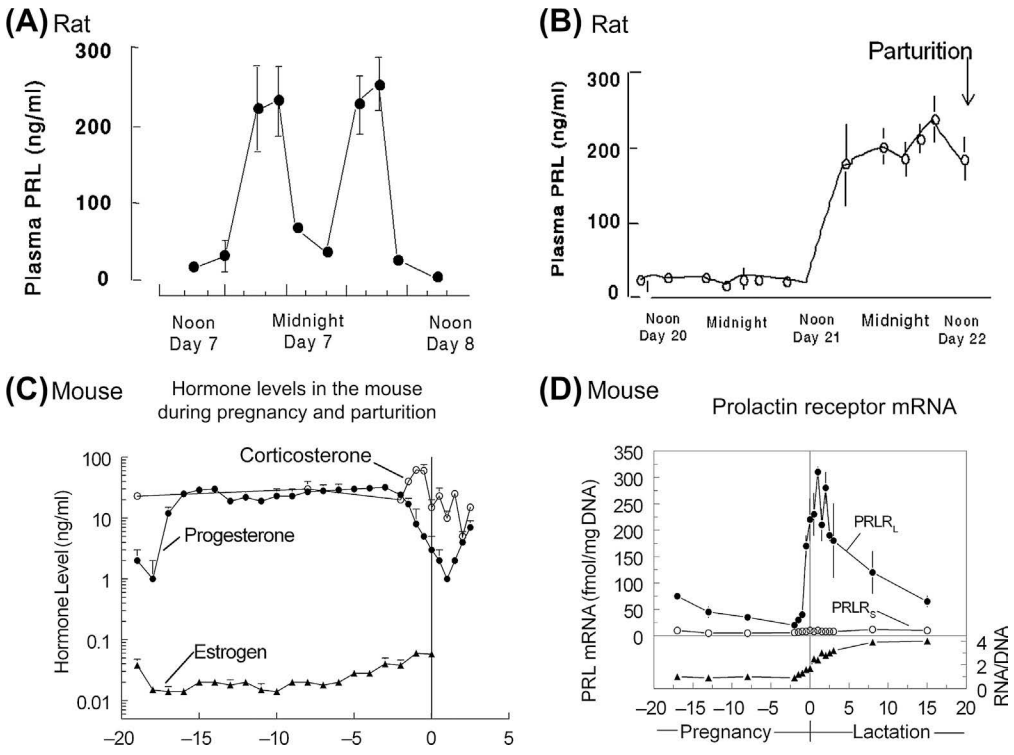

FIGURE 46.6 Hormone profiles during pregnancy in rats and mice. (A) Pulsatile secretion of PRL during early pregnancy in the rat. At 8 days postcoitus, this pulsatile activity ceases. (B) Return of PRL secretion 24h prior to parturition in the rat. (C) Steroid hormone profiles in the mouse during pregnancy. Corticosterone remains approximately constant with a slight elevation at parturition, possibly due to stress. P4 rises early in pregnancy and falls one day prior to parturition. Estradiol rises about threefold over the course of pregnancy. (D) Expression of mRNA for the long (PRLL) and short (PRLS) forms of the prolactin receptor during the transition from pregnancy to lactation. Note the increase in the ratio of total RNA to DNA at the onset of lactation. *Source: (A, B) Modified from Ref. 118. (C, D) Data replotted from Mizoguchi Y, et al. Corticosterone is required for the prolactin receptor gene expression in the late pregnant mouse mammary gland.* Mol Cell Endocrinol *1997;**132**:177–83.*

PLACENTAL LACTOGEN

PL is present at high levels only during secretory differentiation.[126–129] The hormone has evolved at least twice, in rodents and ruminants from the PRL gene and in primates from the GH gene.[112,130,131] Women with deletions in the GH/PL gene complex and undetectable PL concentrations in plasma have been reported to have quite normal lactations,[132,133] suggesting that PRL is the hormone responsible for secretory differentiation in humans. Several rodent PLs have been fully characterized (mouse, rat, hamster) and their patterns of secretion in pregnancy measured. The twice-daily surges of pituitary PRL in rats are replaced in mid-pregnancy by, first, a surge in PL I and then by PL II, which continue to increase until term. There is currently no evidence for a specific PL receptor, and PL is thought to act through either the GHR, the PRLR, or both.[134]

PROGESTERONE

P4 increases early in pregnancy (Figure 46.6(C)) secreted by the ovaries. As discussed previously, there is good evidence that it drives proliferation during early pregnancy; however, it is not clear whether it plays a role in secretory differentiation during mid- to late pregnancy. In most species ovarian secretion of P4 continues through pregnancy. However, in women ovarian P4 is replaced by placental P4 after the first trimester. There is incontrovertible evidence that it does inhibit secretory activation in late pregnancy[135,136] and prevents premature lactation in all species that have been studied. P4 withdrawal triggers both secretion and tight junction closure. Thus these processes are triggered in the mammary epithelium of late pregnant mice by injection of the PR antagonist RU486; PRL and glucocorticoids are required.[136] This observation, which has been repeated in many species, indicates that P4 is able to suppress secretory activation through the small number of P4 receptors present in late pregnancy, although it is not clear whether an unidentified paracrine factor could be involved in a manner similar to that responsible for alveolar proliferation in early pregnancy or whether myoepithelial cells could be involved.

Secretory Activation

Secretory activation is the onset of copious milk secretion; it is sometimes referred to as lactogenesis II or the initiation of lactation.[106] As described before, this process is set in motion by the fall of P4 around parturition in all species that have been studied[135,137–142]; while in mice the fall in P4 occurs at parturition, in humans P4 levels fall two orders of magnitude over the first four days postpartum, resulting in the production of approximately 500 ml/day of milk by day 5.[143] In both the mouse and human, PRL levels are high at parturition. In the mouse the fall in P4 is accompanied by profound changes in the expression and metabolic activities of many classes of molecules including milk proteins and the enzymes of lipid and cholesterol synthesis (Figure 46.5(B)). The expression of milk protein genes is largely regulated by PRL via the PRLR/JAK2/STAT5 signaling pathway due

to the presence of specific promoters that bind STAT5,[14] however, the regulation of fatty acid biosynthesis is less well defined.

Among potential regulators of fatty acid biosynthesis are PRL, sterol-response element binding protein (SREBP), AKT1, and SPOT14 (also known as THRSP). Experimental evidence supports roles for both SREBP and PRL in regulating enzymes involved in fatty acid and cholesterol biosynthesis[19,20] (Figure 46.7). Analysis of gene expression profiles in adipose-depleted MECs from lactating mice that were treated with bromocriptine for 8 h to block PRL-dependent signaling demonstrated a two- to fourfold decrease in the expression of genes involved in glycolysis and the pentose shunt, a three- to sixfold decrease of genes encoding enzymes involved in de novo fatty acid biosynthesis, and a two- to twentyfold decrease in the expression of genes involved in triacylglycerol synthesis.[20] When SCAP was deleted from MECs, SREBP function was lost and pup weight gain decreased from day four of lactation on. Expression of fatty acid synthase (FASN), the mitochondrial citrate transporter SLC25A1, and stearoyl-CoA-desaturase (SCD2) were all decreased in MECs from lactating mice lacking SCAP, however, the levels of other enzymes involved in de novo fatty acid biosynthesis were unchanged.[19] These findings indicate that PRL has a more significant role in upregulating the expression of enzymes involved in de novo fatty acid biosynthesis at secretory activation than SREBP, which regulates this process in the liver and adipose tissue. However, both molecules do contribute to the regulation of these genes (Figure 46.7). It is very likely that other levels of control remain to be discovered as de novo fatty acid biosynthetic enzymes are likely to be regulated at both the

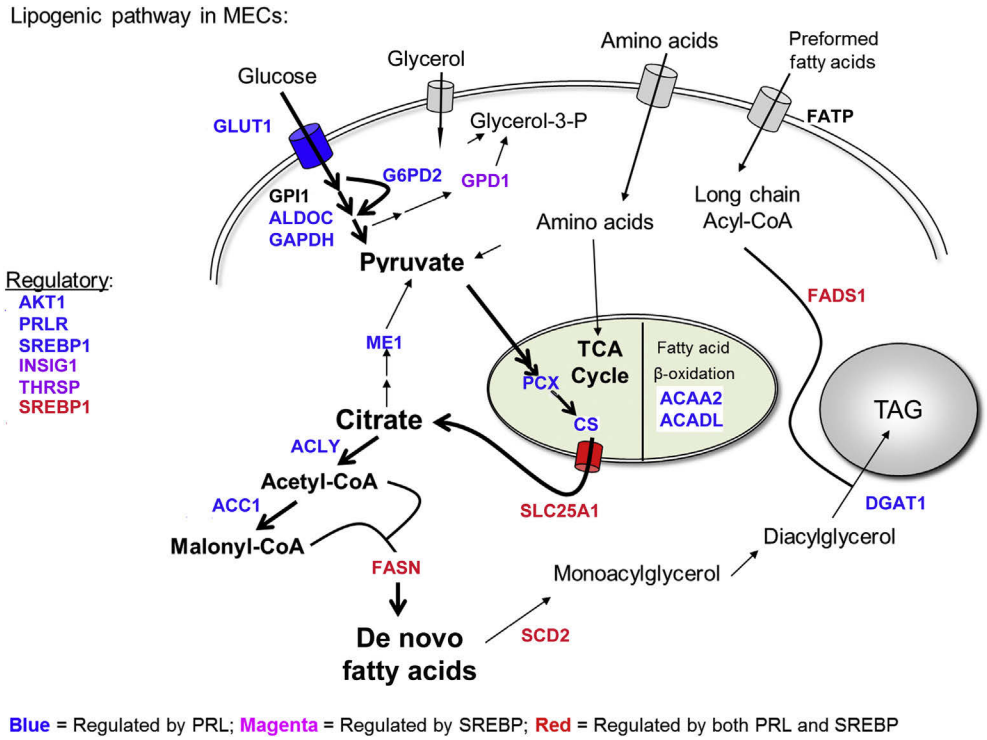

FIGURE 46.7 Lipid synthesis pathways in mammary epithelial cells during lactation. This figure is reproduced in color in the color plate section. Substrates for lipid synthesis enter the cells via the glucose transporter (GLUT1), a glycerol transporter, as amino acids, or as preformed fatty acids via a fatty acid transport protein (FATP). Glycolysis leads to the production of both glycerol-3-phosphate and pyruvate from glucose. The genes for several enzymes in this pathway, fructose bis-phosphate aldolase (ALDOC) and glycerol-3-phosphate dehydrogenase (GAPDH), as well as glycose-6-phosphate dehydrogenase (G6PD2 in the mammary gland) are all upregulated by prolactin along with mitochondrial genes for pyruvate carboxylase (PCX) and citrate synthase (CS). Glycerol-3-phosphate is formed from dihydroxyacetone phosphate, a product of glycolysis, by glycerol-3-phosphate dehydrogenase (GPD1) to be used as a backbone for triacylglyceride (TAG) synthesis. GPD1 is regulated by SREBP. Amino acids are transformed into pyruvate and other substrates that enter the mitochondria to be transformed into citrate, which is exported via the tricarboxylic acid transporter, SLC25A1. Citrate is the major substrate for de novo synthesis of fatty acids in species other than ruminants, which utilize acetate for this purpose. Citrate is transformed into acetyl-CoA by ATP citrate lyase (ACLY), then to malonyl CoA by acetyl-CoA carboxylase (ACC1), and finally to saturated fatty acids with 8–16 carbons (C:8–C:16) by fatty acid synthase (FASN). Cytosolic malic enzyme (ME1) and the enzymes of the pentose phosphate shunt both provide the necessary reducing molecule NADPH that is required for activity of FASN. C:16 fatty acids can be desaturated by stearoyl-CoA desaturase (SCD2) prior to being esterified into monoacylglycerol, then diacylglycerol, and finally into triacylglycerols, with subsequent integration of the fatty acids derived from preformed sources. The final step in the TAG synthesis pathway is catalyzed by diglyceride acyltransferase (DGAT1). The TAG coalesce into lipid droplets. Both prolactin and SREBP have been shown to regulate the genes for FASN, SLC25A1, SCD2, and FADS1. *Source: Diagram derived from data in Refs 19,20.*

posttranscriptional and posttranslational level by diet and other factors.

Lactose is the main osmotic agent present in milk, and the levels of lactose are a major determinant of the amount of water drawn into milk in most species. The synthesis of lactose in the mammary gland requires two proteins present in the Golgi compartment, galactosyltransferase and α-lactalbumin; these combine to produce an enzyme capable of producing lactose at physiological concentrations of glucose.[144] It should be noted, however, that milk from fur seals, sea lions, and walruses does not contain lactose apparently because of a mutation in their α-lactalbumin gene.[145] It has also been suggested that the presence of this mutated form of α-lactalbumin may allow the mammary glands of these species to maintain lactation even in the presence of long interruptions that occur during foraging.[145] Synthesis of lactose has been examined in rodents, dairy cows, and humans,[134,144,146–150] and it is clear that P4 inhibits high level synthesis of lactose during pregnancy. Thus robust expression of the requisite enzymes and high level synthesis/secretion occurs around parturition, the timing depending on the timing of the fall in P4.

Lactation

The continuous production of milk is known as lactation; in earlier literature it was referred to as galactopoiesis. As noted before, lactation is set into motion by a decrease in serum levels of P4 and either a rise in PRL levels (rodents) or maintained high PRL levels (humans). In rodents and dairy animals the decrease in P4 occurs the day before parturition, also setting parturition in motion. In humans, where most P4 is made by the placenta, this decrease takes place over four days after removal of the placenta. Levels of PRL rise at parturition in rodents (Figure 46.6(B)), coincident with a rise in the PRL receptor (Figure 46.6(D)). Further rises in humans and dairy animals after parturition are dependent on stimulation by suckling.[124,151,152] Once lactation is initiated, it is sustained by two different hormones, PRL and OT.[151] During lactation, PRL secretion is stimulated by suckling or milking; in seasonal animals the plasma concentration of PRL is influenced by the day length,[153] the time since feeding/eating, and the time postpartum (reviewed in Ref. 154). Treatment of women,[155] rats,[156] and mice[20] with bromocriptine, a dopamine analog that suppresses PRL release from the pituitary, blocks lactation. In addition to being required for expression of milk protein genes, studies with bromocriptine demonstrate that PRL is required for expression of genes involved in glucose metabolism and de novo synthesis of fatty acids. Furthermore, loss of PRL results in apoptosis of MECs, indicating that it activates survival pathways. Circulating levels of PRL generally decrease as lactation proceeds[96,157] despite continued high production of milk, providing evidence that PRL does not control day-to-day milk volume production.

As described in further detail in the sections Conclusion Milk Ejection, OT is critical during lactation as it stimulates the contraction of myoepithelial cells resulting in the ejection of milk from the alveolus into the ducts. If this function is impeded in any way, involution ensues.

Lactation consists of two phases in placental mammals, a colostral phase during which the secretion product contains large concentrations of immunoglobulins and other protective substances[158] and a mature secretion phase during which large quantities of milk are produced. Colostrum is critical in species such as dairy animals, which do not transport immunoglobulins across the placenta. In these species colostrum contains particularly large quantities of immunoglobulins, which are transported across the intestinal epithelium, providing immunoprotection to the young, which suffices until maturation of their own immune systems.[158] It has been suggested that the delay in the production of mature milk in humans is beneficial in exposing the infant to the immune-protective components of colostrum,[159] which is, however, produced in very small quantities. Mature milk provides all the nutrients required by the offspring of the particular species for growth during a period of time that varies from 7 days in the guinea pig to 4 to 6 months in the human. Some adjustments in milk composition occur during this process.[28] For example, in humans the concentrations of protein, Na^+, K^+, Cl^-, and Ca^{++} decline significantly between 3 weeks and 6 months postpartum, whereas lipid, lactose, and glucose increase.[28] In general these changes are small, usually not more than 20%.

When both the concentration of milk constituents and milk volume were monitored in 12 very cooperative women, a dramatic illustration of the changes in the activity of the gland over the period of secretory activation was obtained (Figure 46.8).[29,160,161] The increase in milk volume, which takes place primarily between days 2 and 4 postpartum in women and earlier in many other species,[29,160–162] is brought about by the coordinated increase in the activity of pathways for ion (citrate, $PO_4^=$, K^+, Mg^{++}, Ca^{++}, Na^+ and Cl^+) secretion and for lipid, lactose, and protein synthesis and secretion. A number of other changes take place prior to this coordinated increase in milk secretion. As detailed in the section on cell–cell interactions, although present between alveolar cells throughout pregnancy, tight junctions are highly permeable, closing only at the onset of lactation, leading to a decrease in the Na^+ and Cl^- flux from the interstitial space into the lumen as a well as a decrease in lactose flux out into the interstitium; the result is a rapid increase in lactose concentration and fall in milk Na^+ and Cl^-.

One of the remarkable aspects of lactation is that milk production can expand to meet increased demands, and

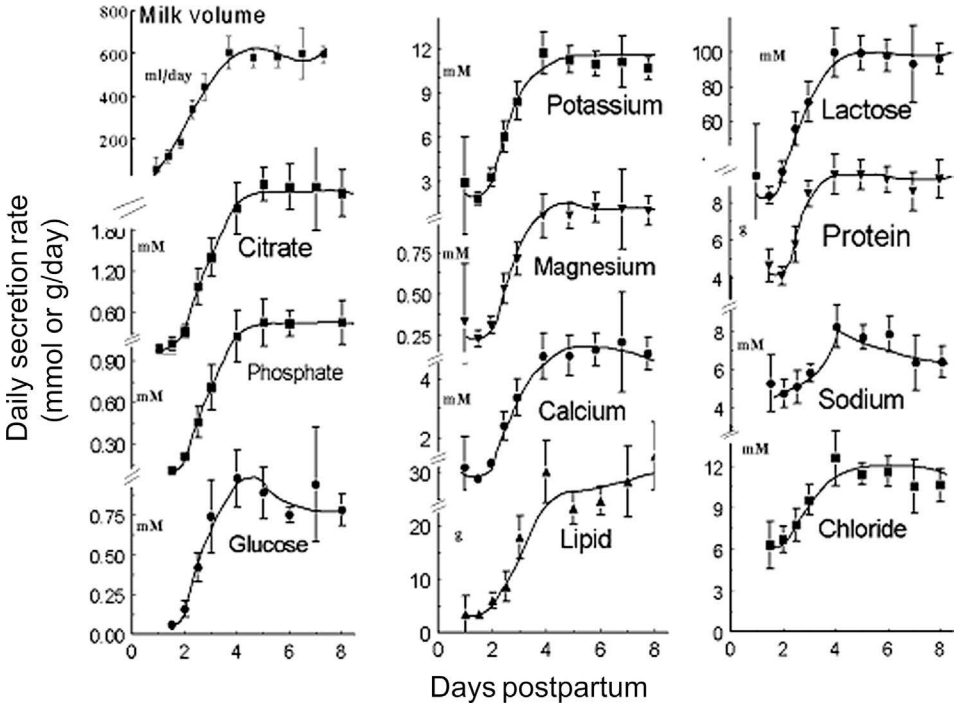

FIGURE 46.8 Milk volume secretion and the rate of secretion of several milk components during the first week postpartum in women. Twelve subjects weighed their infants before and after every feed for the first week postpartum and mid-feed milk samples were taken twice a day from each breast. *Source: Reproduced by permission from Ref. 160.*

can cease when milk is no longer needed. The precise feedback mechanisms that control the dynamics of lactation have been the topic of great speculation for a long time, specifically around the topic of what are the sensors for milk stasis that lead to loss of milk secretion. The long hypothesized "feedback inhibitor of lactation"[163] has never been purified or proven to exist, however, in recent years attention has focused on the possibility that serotonin may play this role. While searching for PRL-induced transcripts, Matsuda et al. identified the enzyme tryptophan hydroxylase (TPH) as a target for PRL that was induced during pregnancy and lactation.[164] TPH is the rate-limiting enzyme in the synthesis of serotonin (5-hydroxytryptamine, 5-HT), a neurotransmitter regulating mood and cognition. Expression of TPH was induced by PRL in a time- and concentration-dependent manner, and its expression was highest in mammary glands whose teats were sealed producing milk stasis. Further studies showed that treatment of mammary tissue slices or MECs with 5-HT suppressed expression of milk protein genes and induced histology similar to that of involuting mammary glands.[164] Further study demonstrated that 5-HT regulated tight junctions and milk secretion,[165] suggesting that accumulation of 5-HT in the interstitial fluid surrounding secretory alveoli during milk stasis could lead both to cessation of milk secretion and apoptosis of epithelial cells. Treatment of bovine MECs and lactating cows with the selective 5-HT uptake inhibitors (SSRI) such as fluoxetine increased plasma lactose and increased the ratio of Na^+/K^+ in the milk, decreased expression of milk protein genes, and decreased milk volume secretion in lactating cows.[166] These studies were confirmed in mice; further, Tph1 (tryptophan hydroxylase 1) null mice were resistant to these effects.[167] SSRIs are a highly prescribed class of drugs that are commonly used to treat depression, and therefore it should be of little surprise that pregnant women taking SSRIs were found to be more likely to experience delayed secretory activation.[167] It has been long appreciated that there is a delay in the onset of lactation in obese women, and recent studies have suggested that a high fat (HF) diet significantly increases the expression of TPH1 and the mammary receptor for 5-HT (HTR7).[168] These findings produce tantalizing evidence that the serotonin pathway may contribute to the effects of diet and obesity upon lactation.

For a relatively complete description of milk composition in various species, see works by Jenness[169,170] and Jensen.[171] In marsupials, in which the young are born at an extremely immature stage and develop within an abdominal pouch, the changes in milk composition during lactation are much more extreme.[172] A new area of investigation is how the composition of milk from primates may change with the gender of the infant, as well as psychological/emotional factors,[173–176] raising fascinating questions in evolutionary biology.

Involution

After weaning, most of the secretory cells as well as their stromal environment undergo a process of remodeling, and the mammary gland returns to a state similar

to that of the virgin through a process referred to as involution.[177,178] This process is complex, highly regulated, and occurs in two distinct phases: the first phase is reversible and protease independent, while the second phase is not reversible, depends on expression of proteases, and involves considerable remodeling of connective tissue.[179] The use of genetically modified mice and global gene expression profiling over the last decade has greatly advanced our understanding of the changes that occur during the first six days of involution. The vast majority of these studies have used a model of forced involution in which the pups are removed from the lactating dam on day ten of lactation. Although this model is artificial when compared to normal weaning, which is more gradual, it does allow for a very reproducible series of events, which have been well characterized at the cellular and molecular levels. An alternative approach involves sealing of teats on one or more glands to induce milk stasis and involution in the affected gland. This less utilized approach has the advantage that functional and nonfunctional glands can be compared in the same animal with the maintenance of the hormonal environment of lactation.

The original definition of the two phases described the time, approximately 48 h after pup removal, at which the process becomes irreversible: if pups are returned to the dam within 48 h, lactation resumes.[179] In the human this period is about three days. Interestingly, there are species such as fur seals in which lactation can be interrupted by at least 3 weeks when the mothers feed offshore before returning to nurse.[180] A more functional definition might divide the 6-day involution interval into the period, usually 3 days in the rodent, during which alveolar volume is markedly decreased by removal of both milk and epithelium,[181] and a second phase starting after 3 days that involves stromal remodeling. Teat-sealing studies in the mouse clearly demonstrated that the first phase is regulated by local factors within the individual gland and not by circulating hormones.[179,182]

During the first day after pup removal the luminal spaces fill with milk (Figure 46.9); by 24 h shed, apoptotic cells appear within this expanded luminal space. It has been suggested that MECs die of an apoptotic process since activation of executioner caspases (caspase 3 and 8) and fragmentation of DNA typically associated with this process are readily detected.[184–187] However, the shed "apoptotic" cells do not have the classical appearance of apoptotic cells in other organs in that they are swollen, frequently have two hypercondensed regions of chromatin, and lack the membrane blebbing classically associated with apoptotic cells.[188] Monks et al.,[181] in an elegant study that for the first time took into account the volume of the gland, found that the peak of apoptosis occurs between 2.5 and 3 days following pup withdrawal and that almost all of the apoptotic cells as well as the milk are cleared in this interval. In this study MECs were thought to be responsible for the removal of apoptotic bodies because they did not detect markers of macrophages in the mammary gland during the first 3 days following pup withdrawal.[181] These authors

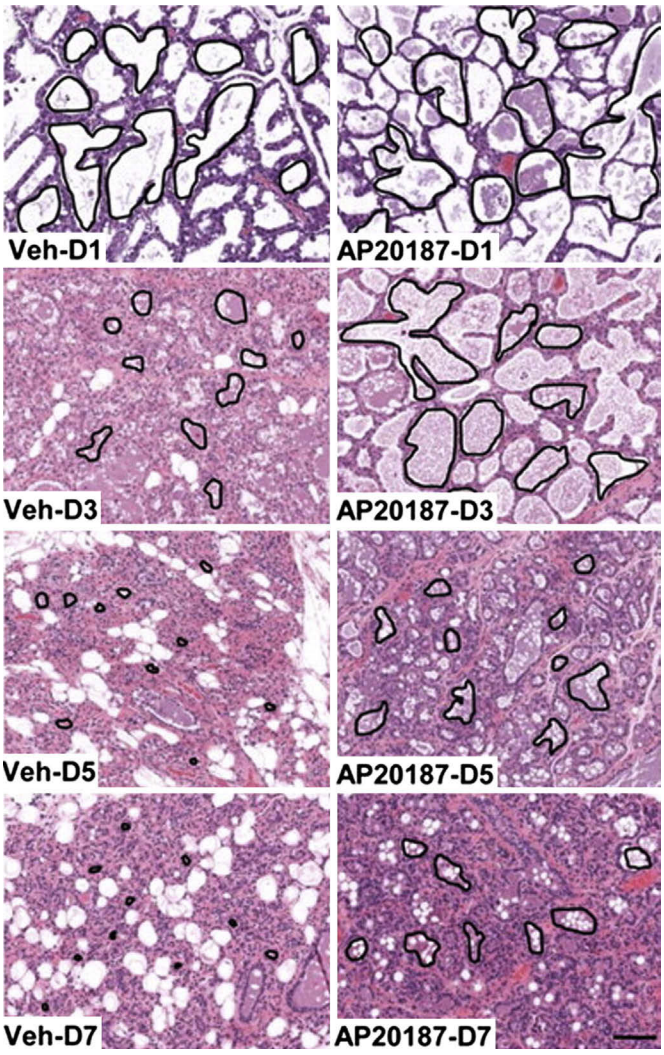

FIGURE 46.9 The role of macrophages in mouse mammary gland involution; histological analysis. This figure is reproduced in color in the color plate section. Glands from Mafia mice were analyzed on days 1, 3, 5, and 7 after pup removal from a 10-day lactating mouse suckling five to six pups. Three days prior to pup withdrawal experimental dams were given a dose of AP20187, which depletes macrophages in this strain. Left-hand images, vehicle only (macrophages present); right-hand images, AP20187 (macrophages depleted). In both control and experimental mice marked luminal expansion is evident 1 day after removal of pups (some lumens outlined in black for illustration). In vehicle-only mice a marked decrease in lumen size by day three is observed as milk is resorbed. Very small lumens remain on day 7, however significant numbers of lipid filled adipocytes are evident between the alveoli starting on day three and increasing to day 7. These changes occur much more slowly in the glands of AP20197-treated mice, providing evidence that macrophages are required for several aspects of normal involution. *Source: Reproduced by permission from Ref. 183; link at Development:* dev.biologists.org.

proposed that clearance of shed (apoptotic) epithelial cells during the first 3 days after pup removal is accomplished by the remaining resident MECs by a process they refer to as efferocytosis from the Greek for "to take to the grave" or "to bury". Their elegant images depict apoptotic cells clearly being engulfed by epithelial cells in the monolayer.

However, in a subsequent study O'Brien et al.[183] clearly showed involvement of M2 macrophages in several aspects of involution, including clearance of apoptotic epithelial cells during the first 3 days following pup withdrawal. Further, in the absence of M2 macrophages involution was dramatically delayed and the rate of milk clearance was drastically reduced (Figure 46.9). Macrophages bearing markers of M2 development were clearly present and stained with anti-F4/80 antibodies in normal mice. When mice sensitive to a treatment that depletes macrophages were used, all aspects of involution were drastically slowed, and milk was not cleared from the luminal space 3 days after pup withdrawal. The sum of the evidence leads to the conclusion that both MECs and macrophages are involved in clearance of milk and shed cells.

An alternative hypothesis was put forth by Watson and her colleagues who suggested that a nonapoptotic form of programmed cell death was activated during involution; they proposed that lysosome-mediated cell death occurs during involution.[189] This process would occur independently of caspases 3, 6, and 7; however, it requires STAT3, which upregulates the expression of cathepsin B and L. Cathepsins B and L are dramatically activated during the first 3 days of involution corresponding to the first phase of apoptosis. Current evidence suggests that activation of STAT3 alone may not be sufficient to induce programmed cell death during involution since loss of M2-differentiated macrophages prevented this type of cell death even in the face of tyrosine-phosphorylated, activated STAT3.[183] Perhaps both activated STAT3 and M2 macrophages are necessary for involution to proceed, but neither alone is sufficient to support this process. It also remains possible that other processes are involved in this cell death, including autophagy, which appears to be involved in cell death in three-dimensional culture models of the mammary epithelium.[190,191]

Numerous molecules have been implicated in the apoptotic process. Some investigators have suggested that the relative balance between pro- and anti-apoptotic members of the BCL2 family of proteins is important in regulating apoptosis and involution.[192–195] Consistent with this hypothesis, overexpression of *Bcl2* delays involution,[193] as does overexpression of an activated form of AKT1, which is capable of phosphorylating and inactivating pro-apoptotic BCL2 proteins.[196] The relation of anti-apoptotic BCL2 family members to the formation of apoptotic mammary cells is currently unclear.

Milk stasis appears to be the major trigger for involution,[182] possibly involving increased mechanical stretch of alveolar epithelial cells due to expansion of the luminal space.[197] Two different groups have used global gene expression profiling to independently identify a group of genes whose expression changes during the first 12 h following pup withdrawal.[198,199] Both groups noted increased expression of genes encoding death receptors, and their ligands, proteins associated with the acute phase response, and most notably the transcription factor STAT3 and its targets.[198,199] Death receptor ligands included leukemia-inducing factor (LIF), tumor necrosis factor, tumor necrosis-like weak inducer of apoptosis, Fas Ligand, and TGFβ.[198,199] LIF activates STAT3, which in turns enhances expression of pro-death molecules; consistent with a critical role for STAT3 is the observation that cell death is delayed in STAT3-deficient mice and that the first phase of involution is extended for at least 6 days in the forced involution model in these mice.[200–202] Other critical changes include decreased expression of both AKT1 and insulin-regulated substrate-1,[196,203,204] which would eliminate the ability of AKT1 to suppress apoptosis. In addition to STAT3, the nuclear factor kappa B-signaling pathway is also likely to be an important component of the immediate signaling response to pup withdrawal.[205,206] It has also been suggested that decreased expression of the plasma membrane Ca^{++}ATPase 2, which is important in transport of Ca^{++} into milk,[207] results in an increase in intracellular Ca^{++} thereby stimulating apoptosis within the cell by a direct mechanism.[208]

Another important regulator of involution that has received extensive study is TGFβ. Although all three isoforms of TGFβ are expressed during pregnancy, expression of all three is downregulated at parturition, and only low levels of TGFβ3 are detected in alveolar cells during lactation.[209–212] Expression of TGFβ3 increases dramatically during milk stasis and involution.[198,199,211,213] Studies with transplanted MECs from TGFβ3 null mice support a paracrine role for this growth factor in mammary involution.[211] Expression of TGFβ from the whey acidic protein (WAP) promoter, which turns on in late pregnancy, inhibited alveolar development,[214] and it appeared that the stem cell pool available for alveolar morphogenesis was reduced.[215] Moses and others found that targeting a dominant-negative TGFβ Type II receptor (MMTV-DNTGRII) to the mammary gland inhibited TGFβ signaling and resulted in alveolar hyperplasia and premature secretory activation in pregnancy, followed by lactation failure.[216–218] This result is expected if TGFβ is inhibiting both alveolar proliferation and secretory activation. Expression of a constitutively active subunit of the Type I receptor leads to apoptosis in pregnancy and decreased proliferation in a transgenic mouse model.[219] More recently, in studies in which TGFβ type

II receptor was deleted from the mammary epithelium using Cre recombinase driven by the WAP promoter, the first phase of involution occurred normally, but TGFβ appeared to be required for commitment to the second phase of involution.[220] MECs lacking TGFβ-RII continued to express markers typical of a cell from a lactating mouse even 7 to 10 days after induction of involution.[220] These data all suggest a critical role for TGFβ in suppression of ductal and alveolar proliferation, suppression of PRL-induced gene programs, and programmed cell death of MECs particularly during the second phase of involution.

In contrast to the first phase of involution, commitment to the second phase of involution is dependent upon factors such as TGFβ as described earlier, and can be halted by treatment with glucocorticoid[179]; it has been speculated that glucocorticoid may act through maintenance of tight junctions.[221] The activation of matrix metalloproteases (MMPs) is critical in the remodeling of the tissue that occurs in the second phase, and although MMPs are expressed during the first phase of involution, their activation is held in check by tissue inhibitors of metalloproteases (TIMPs).[222,223] Substrates for MMPs include collagen IV, chemokine, and E-cadherin, and loss of these proteins causes detachment of epithelial cells and death by anoikis (detachment-induced cell death). The importance of MMP activation in the second phase is demonstrated by the observation that involution proceeds more rapidly in TIMP-3-deficient mice.[224] Recently it has been shown that MFG epidermal growth factor 8 (MFGE8) is essential for the second phase of involution as it binds to phosphatidylserine on the plasma membrane of apoptotic cells and enhances their phagocytosis.[225] Gene expression profiling studies by Stein et al.[199] suggest that the increase in pro-inflammatory signals during phase 1 of involution is important in the infiltration of inflammatory cells during the second phase,[199] but these signals could actually be important in attracting macrophages to the gland in the first phase.

Further details of the two phases of involution are available in numerous excellent reviews.[226–228] Future research should show how all these somewhat disparate pathways work together and also provide further understanding of the aspects of the microenvironment of the involuting mammary gland that promote mammary tumorigenesis.

CELL–CELL INTERACTIONS IN THE MAMMARY EPITHELIUM

Epithelial cells are joined to their neighbors by four types of junctional complex.[6] Starting from the apical pole of the cell these are: (1) the tight junctions (*zonula occludens*), which regulate passage of molecules through the paracellular pathway; (2) the adherens junctions (*zonula adherens*), thought to provide structural stability to the epithelium as a whole; (3) desmosomes (*macula adherens*), specialized for cell-to-cell structural adhesion; and (4) gap junctions made up of hexamers of connexin proteins that permit passage of molecules between cells. We will summarize the role of these junctions in turn as they apply to alveolar development and lactation.

Mammary Tight Junctions and Their Regulation

Production of milk of a defined composition requires that the milk space be firmly isolated from the fluids of the interstitial space, such that milk composition is entirely determined by the secretory activity of the mammary epithelial cell. By injecting a marked compound that could not cross cell membranes into the milk space and determining its appearance in the blood stream, Linzell and Peaker[229,230] showed in the 1970s that this isolation is complete in the lactating goat. Specifically they measured the transfer of injected [^{14}C]-sucrose from the lumen into the blood stream and could detect no transfer of the tracer during lactation. When a similar tracer was injected into the blood, it did not appear in the milk. Further, potential differences of −20 to −35 mV were found between the blood and the milk in lactating goats[231] and mice.[232] All these findings provide very strong evidence that the paracellular pathway of the mammary epithelium is highly impermeable during lactation.

The same is not true of the mammary epithelium during pregnancy. [^{14}C]-sucrose has consistently been observed to move from the blood stream into the milk at this stage of development,[136,229,230] and no electrical potential difference can be measured between electrodes in the blood stream and milk space. Moreover, transfer of macromolecules labeled with fluorescent tracers across the epithelium, either from the lumen to the interstitial space or in the opposite direction,[136,233] has been observed. These experiments, illustrated in Figure 46.10, show that during pregnancy molecules as large as albumin and IgA permeate the junctional complexes[111]; such molecules do not pass through the paracellular pathway in the lactating gland. When such large plasma proteins are present in milk, they must be transferred across the epithelium of the lactating gland by transcytosis as described in the section Transcytosis (Pathway III). Taken together these findings from isotope tracer, blood-milk potential, and fluorescent tracer experiments indicate that the mammary tight junctions, particularly in the alveoli, are leaky during pregnancy and close around parturition to form a tight barrier that prevents paracellular movement of molecules across the mammary epithelium.

This transition has a profound effect on the composition of the mammary secretion. During pregnancy, the

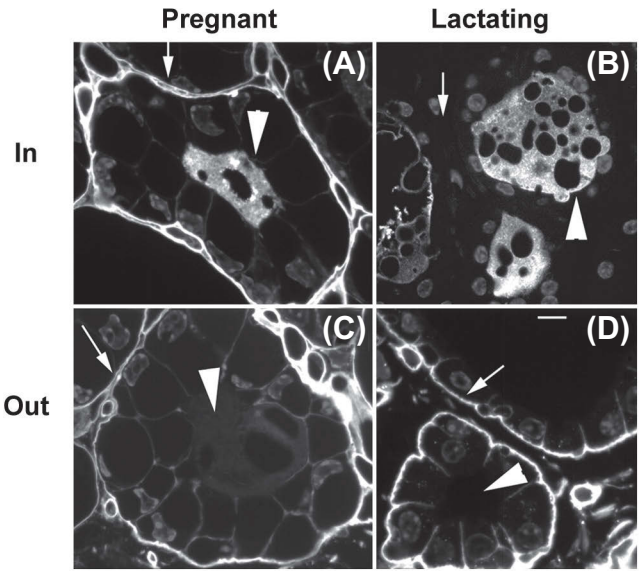

FIGURE 46.10 Paracellular permeability to FITC-albumin during pregnancy and lactation. (A, C) Pregnant mice. (B, D) Lactating mice. (A, B) FITC-albumin was injected intraductally (designated "In") and fixed within 5 min. The excised glands were embedded, sectioned, and visualized with the fluorescent microscope. During pregnancy, tracer can be seen in both lumen (arrowhead) and interstitial space (arrows); in lactation it is confined to the lumen. (C, D) The in situ gland was incubated with tracer for 1 h to expose the basolateral surface of the alveoli (designated "Out") and visualized as in (A) and (B). In pregnancy, tracer can be seen throughout the interstitial space and in the lumen; during lactation tracer is confined to the interstitial space extending just up to the tight junctions. Magnification bar (D) is 10 μm and applies to all panels. *Source: Reproduced from Ref. 136.*

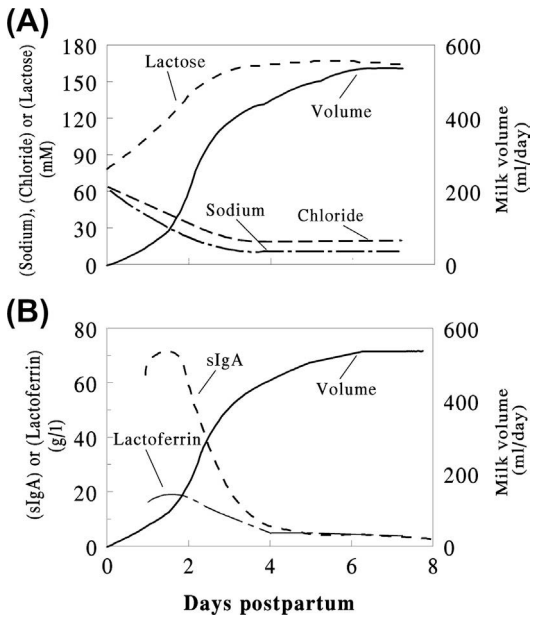

FIGURE 46.11 Changes in human milk composition during the colostrum-forming stage. (A) Na^+ and Cl^- concentrations fall rapidly and lactose increases as the tight junctions between the epithelial cells close. Note that these changes are well underway prior to the increase in milk volume secretion beginning on day 2. (B) Secretory IgA (sIgA) and lactoferrin are found at very high concentrations in the mammary secretion during the first three days postpartum, the period when colostrum formation is at its peak. *Source: Reproduced with permission from Ref. 160.*

milk has high Na^+ and Cl^- and low K^+ as the result of ions moving through the paracellular space down their electrochemical gradients. The low Na^+ and Cl^- and high K^+ of true milk is produced by the activity of ion pumps in the basolateral and apical membranes of the cells. The transition between the two states is well illustrated for human milk in Figure 46.11. Thus Na^+ and Cl^- fall and lactose rises (Figure 46.11(A)) as the tight junctions close prior to the increase in milk volume illustrated in both panels of Figure 46.11. Freeze fracture studies carried out by Pitelka[6] showed that the tight junction strands in the gland during pregnancy are highly disordered, suggesting that molecules permeate between the strands. In lactation the strands are highly ordered and show no breaks that might allow passage of large or small molecules.

Role of Claudins, Occludin and Tricellulin in Mammary Tight Junctions

Although claudins in low resistance epithelia permit the passage of monovalent ions,[234,235] the high transepithelial potential maintained in the lactating mammary gland despite substantial transcellular permeability to these ions suggests that the complement of claudins prevents paracellular movement of both large and small molecules. Our unpublished studies show a large increase in claudin 8 gene expression at parturition in the mouse mammary gland from both microarray and real time PCR analysis (Rudolph MC and Neville MC, unpublished). This claudin does not permit ion flux between lumen and interstitial space in other epithelia. Recently claudin 3 was localized to the apical junctions in the lactating mammary gland,[236] and the authors suggested that it is responsible for the low permeability of the mammary epithelium.

It is worth mentioning that claudins are also present in large numbers of small vesicles that appear never to interact with junctional complexes in the cell. Claudin 7 has been carefully studied in this regard,[83] but claudins 3 and 4 are also found in such vesicles in both normal and tumorous mammary cells in locations that suggest they are not merely serving as reservoirs for tight junction proteins (Baumgartner Wilson, personal communication). The function of these very common nonjunctional claudins is currently unknown, but they may play a role in interactions with the extracellular matrix.[237] Occludin is also present at mammary tight junctions and is considered to play a role in epithelial permeability; recent studies also implicate occludin as a signaling molecule that helps initiate apoptosis when tight junction integrity is compromised.[238]

The structure of the tight junctions at positions where three cells come together in the formation of the epithelial sheet appears to differ from that of the bicellular junctional complexes. Here a novel tetraspanin protein, tricellulin, is concentrated at the vertically oriented TJ strands of tricellular contacts. RNA interference studies of tricellulin depletion suggest that this protein is necessary for complete sealing of the epithelial barrier.[239] Recently another protein has been identified as a component of the tricellular junction, the lipolysis-stimulated lipoprotein receptor. This immunoglobulin receptor-like protein was actually found to recruit tricellulin to tricellular junction and again appeared necessary for full tight junction sealing.[240] In the liver it is involved in lipoprotein metabolism. Whether it serves this function in the mammary gland remains for future research.

Hormone Dependence of the Change in Tight Junction Permeability between Pregnancy and Lactation

When mice were ovariectomized on day 17 of pregnancy, the subsequent decrease in circulating P4 set the transition between pregnancy and lactation in motion, and the sucrose permeability of the epithelium progressively decreased over the 20 h subsequent to ovariectomy[136]; the effect could be delayed by injection of P4 at intervals. Injection of a P4 antagonist, RU486, produced the same effect as ovariectomy. These experiments firmly establish that P4 withdrawal is the trigger for tight junction closure. A series of endocrine ablation experiments showed that both PRL and glucocorticoid are necessary for mammary tight junction closure[241]; these molecules also alter tight junction permeability in tissue culture models.[242] These are the hormones that promote secretory activation in the mammary gland, providing evidence that tight junction closure is closely linked to secretory activation. Although insulin also promotes milk secretion in mice,[75,76] its role in tight junction closure is unknown.

Epithelial Permeability during Mastitis and Involution

The direct passage of interstitial molecules such as Na^+ and Cl^- across the mammary epithelium during pregnancy leads to the higher concentration of these ions in colostrum and the appearance of milk components such as lactose and α-lactalbumin in the blood stream as illustrated by the schematic in Figure 46.12. As discussed earlier, such changes in milk composition have been fully documented during the onset of lactation but have also been used as an indicator of tight junction status under conditions where direct tracer measurement of the permeability of the mammary epithelium is not possible such as during involution[243–245] and with infections such as mastitis.[246,247] Stelwagen and colleagues showed that increased milk components such as lactose and α-lactalbumin were found in the blood stream if goats and cows were left unmilked for 18 h.[245,248] The authors interpreted these results as showing an effect of milk stasis on tight junction permeability. However, in none of these studies were tracers injected into the gland or blood stream to distinguish between opening of tight junctions and aberrant basally directed exocytosis in the stretched mammary epithelium. Thus it is not clear whether the changes in ion concentrations in the milk result from a return of the tight junction strands to the disordered condition of pregnancy, a loss of integrity of the epithelium as epithelial cells are lost by apoptosis, or

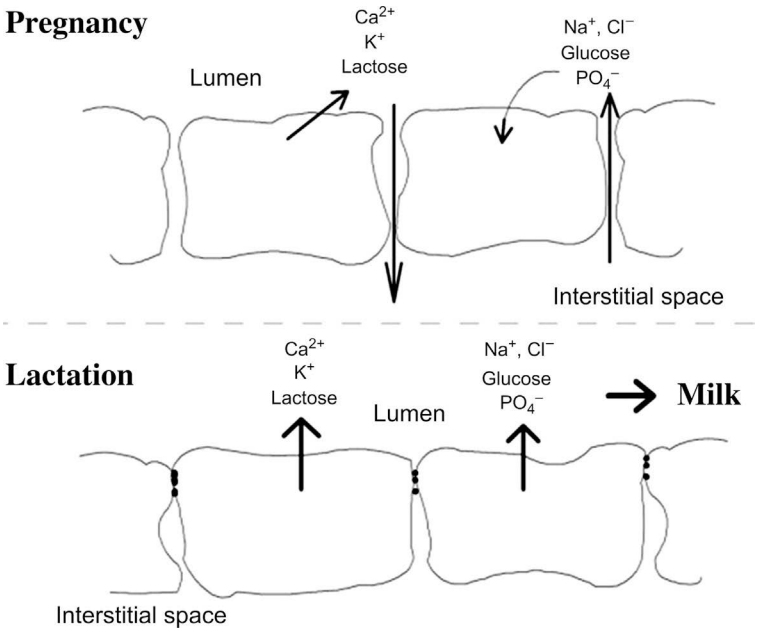

FIGURE 46.12 The paracellular pathway is open in pregnancy and closed in lactation. The schematic illustrates the net flux of several small molecules during pregnancy when the junctional complexes are very leaky and in lactation when they are tightly closed. As shown in Figure 46.10 large molecules such as albumin and α-lactalbumin are able to pass through the junctions during pregnancy. *Source: From Neville MC. Lactogenesis in women: evidence for a cascade of cellular events. In: Jensen RG, editor.* Handbook of composition of milks. *1st ed. San Diego: Academic Press; 1995. p. 87–98. Used with permission from Elsevier.*

activation of purinergic receptors in the mammary epithelium by mechanical or other disruptive stimulation.

Interestingly, it has been shown that cultured MECs release ATP, UTP, and UDP when stressed; these nucleotides interact with purinergic receptors to bring about an increase in cell Ca^{++} and activate Ca^{++}-sensitive apical Cl^- transporters[249] as well as alter Na^+ and K^+ transport.[250] It is possible that closure of junctions at the initiation of lactation is an irreversible process and that changes in both directional secretion of ions and milk components across the mammary epithelium may be responsible for alterations both in milk composition and the appearance of milk components in the blood when the gland is stressed by milk stasis or infection. The matter clearly requires additional investigation.

Regulation of Tight Junction Formation

Biochemically, tight junctions are complex structures, with claudins, occludin, and the junctional adhesion complex interacting across the intercellular space to form a tight apical band that restricts permeability through this space.[251] Intracellularly these molecules interact with scaffolding molecules immediately below the membrane called ZO-1, ZO-2, and ZO-3, which in turn interact with actin as well as members of the polarity-regulating complex PAR6/PAR3/aPKC.[252] A variety of regulatory molecules including PKCzeta[253] and the molecular complex CRUMBS3/PALS1/PATJ[252] have been shown to interact with the PAR complex and alter tight junction permeability.[254] A complete listing of tight junction proteins with their functional context is available,[255] with the suggestion that many of them may have a regulatory function in mammary development. Recently it has been shown that cytoplasmic polyadenylation element binding protein is necessary for claudin 3 and ZO-1 localization to both MECs in the mouse and in cell culture models of mammary acini.[256] Horseman and his group have implicated serotonergic signaling in tight junction integrity,[165] and work by Fischer et al. implicates the RHO pathway as well.[242] Occludin, a component of the tight junction, also plays a role in initiating apoptosis of MECs when tight junctions are perturbed.[238] At this writing a comprehensive picture of the interactions of all these signaling pathways in establishing and maintaining tight junction integrity in the lactating mammary gland is not yet available.

Adherens Junctions in the Mammary Epithelium

Adherens junctions encircle epithelial cells, usually basal to the tight junctions, and provide both cell–cell adhesion and linkage to the cytoskeleton through a group of molecules, the catenins. A transmembrane molecule, E-cadherin that interacts with the catenins, forms a Ca^{++}-dependent bridge from one cell to its neighbor, stabilizing cell–cell interactions. Disruption of these linkages by infusion of EGTA intraductally into the lactating mammary gland both decreases milk production and leads to apoptosis of MECs.[257] E-cadherin is essential for the self-organization of epithelial monolayers in culture models of the mammary epithelium[258] and was found to be necessary for establishment of the lactating phenotype in a Cre/loxP model directed to the mammary epithelium.[259] One of the catenin molecules, β-catenin, acts not only to stabilize the adherens junction but it is also a transcription factor, acting through the TCF/LEF pathway to regulate transcription and tumorigenesis by mechanisms well reviewed by Carraway and colleagues.[260]

Beta-catenin also functions as a transcriptional regulator in the WNT-signaling pathway[261]; its normal function was found to be essential for lobular-alveolar development.[261] Overexpression of the cytoplasmic domain of E-cadherin promoted precocious mammary development in mice but interfered with development of polarity in the fully differentiated gland.[262] Because loss of cadherin is considered to be a hallmark of the epithelial-to-mesenchymal transition that occurs during tumorigenesis,[263] much of the work on mammary adherens junctions is part of the breast cancer literature, which will not be reviewed here.

Desmosomes

Desmosomes are localized spot adhesions on the lateral sides of cells that use desmoglein and desmocolin to bind across the intercellular space possibly to prevent shearing forces from disrupting the epithelial monolayer. These structures have been found to be essential for branching morphogenesis of the mammary gland[264] and for formation of acinar cultures from purified MECs.[265] However, Pitelka and her colleagues showed almost 40 years ago that as the alveoli become secretory the desmosomes disappear,[6] likely to allow the profound shape changes in the epithelial cells as the lumens expand and contract with the accumulation and ejection of milk.

Gap Junctions in the Mammary Epithelium

Direct cell-to-cell signaling is mediated in part by the passage of molecules with molecular weights less than 1000 kDa through gap junctions. These junctions are formed from six connexin molecules that aggregate to form a hemichannel or connexon in each cell; when these hemichannels in the opposing membranes of two cells are aligned, they form a channel with a

pore that allows intercellular passage of signaling molecules, metabolites, vitamins, and other substances up to 1.5 kDa,[266] but not macromolecules. Freeze fracture studies showed that gap junctions between epithelial cells in the mammary gland are composed of an aggregate of many connexons.[267] Studies using lucifer yellow dye showed extensive coupling between cells of the lactating mammary alveolus as well as suggested dye transfer between alveolar and myoepithelial cells.[232]

Four connexins have been shown to be expressed in rodent mammary glands.[268] The mRNAs for connexin 26 (*Cx26*) and connexin 32 (*Cx32*) are expressed at all stages of mammary development[268,269] but are markedly upregulated in pregnancy (*Cx26*[269–271]) and lactation (*Cx26* and *Cx32*[271,272]). The corresponding proteins are found in the junctional plaques where they form both homomeric and heteromeric channels.[273] Connexin 30 (CX30) was expressed after day 15 of pregnancy and peaked at the onset of lactation, disappearing thereafter.[268,273] Gusterson and his colleagues speculate that the heteromeric CX26/CX30 channels specify cell–cell communication at late pregnancy and are replaced by heteromeric CX26/CX32 channels with differing specificity during lactation.[273] Connexin 43 (CX43) is the only isoform that has been positively identified in the myoepithelium.[274] It switches to a hypophosphorylated form during lactation, a change that may by specified by a loss of WNT-5A signaling.[275] Serra and her colleagues found that overexpression of WNT-5A in the mammary epithelium altered CX43 phosphorylation and led to impaired lactation with no change in any other junctional complex proteins. Based on this and other evidence, the authors suggested that CX43 promotes communication between myoepithelial cells essential for milk ejection.[275]

Talhouk and his colleagues have presented convincing evidence that gap junction formation is essential to the differentiation of MECs.[268] Although part of this effect may be coordination of epithelial cell activities between members of the epithelial layer including both basal and luminal cells, there is considerable evidence that gap junction proteins interact with regulatory proteins more generally thought to be associated with the tight and adherens junctions. As shown in Figure 46.13, the proteins for which there is current evidence are α-catenin, β-catenin, and ZO-2.[266] The authors propose that as they form, maturing gap junctions recruit β-catenin away from the nucleus, promoting a switch from proliferation to differentiation. Since gap junctions are lost in breast cancer cells, it is also possible that functional gap junctions help prevent transformation of MECs into tumor precursors.[266] This is a story worth following into the future.

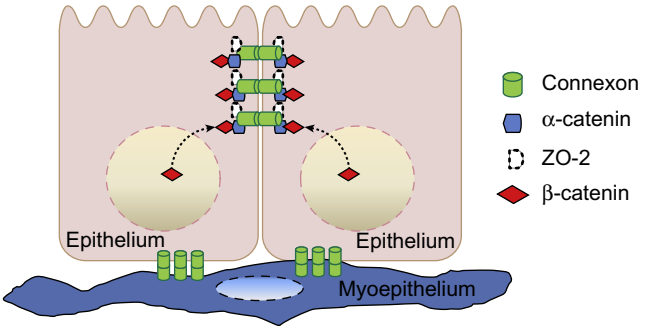

FIGURE 46.13 Gap junction localization in the differentiated mammary epithelium. Connexons interact as shown across the interstitial space between luminal epithelial cells as well as between luminal cells and myoepithelial cells. Luminal cell connexons also interact with signaling molecules α-catenin, β-catenin, and ZO2. As differentiation progresses, β-catenin may be recruited away from the nucleus to diminish the stimuli for proliferation. *Source: Reproduced with permission from Ref. 266.*

MILK COMPOSITION AND ITS REGULATION

Milk is qualitatively and quantitatively complex, containing proteins (mostly caseins), lipids (triglycerides), sugars (including oligosaccharides), vitamins, minerals, and growth factors, in addition to water.[169–171,276] The relative amounts of these substances vary significantly among species,[169,171] and the composition of milk can be influenced by the stage of lactation[28] and the mother's nutritional status.[277,278] Such variability implies that the mechanisms responsible for synthesis and/or secretion of milk substances are genetically determined and physiologically regulated. In this section we begin by summarizing the major milk components followed by a discussion of the major pathways for secretion of milk components and their regulation.

Major Milk Components

Genome-wide comparisons of mammalian taxa, including humans,[279] have led to greater understanding of how milk secretion evolved in mammals. These data suggest that the mechanisms of milk secretion developed over 160 million years ago and are highly conserved. Nevertheless, significant interspecies variability in genes encoding milk proteins as well as proteins involved in milk protein production have been detected. Such findings suggest that species variation in milk composition is likely to reflect differences in gene copy number and/or transcriptional or posttranscriptional mechanisms rather than major gene sequence differences.

Proteins

The protein content of human milk, initially about 3% (wt/vol), decreases to about 1.5% by the second week of lactation.[28] Caseins, which represent about 80% of total milk proteins,[280] form insoluble micelles containing high concentrations of calcium and phosphate. Other milk proteins are found in the soluble (whey) fraction, or are associated with the membrane that surrounds fat globules. A total of 285 distinct gene products have been identified in human milk; by comparing proteome data sets from human and bovine milk, a core of 106 conserved proteins has been identified.[280] Gene ontology analysis suggests that core mammary cell proteins fall into four general functional categories: cell proliferation, lipid metabolism, nutrient transport, and immune function.[280] Proteins enter milk through four distinct pathways as discussed in the section Milk Secretion Pathways, below.

Lactose and Oligosaccharides

Human milk is enriched in lactose (a disaccharide unique to milk) and oligosaccharides, relative to milk from most other species.[279,281,282] Total oligosaccharide concentration in human milk is higher in the colostral phase of lactation compared to that of mature milk. More than 200 different free oligosaccharides have been identified in human milk,[283] suggesting the presence of diverse mechanisms for oligosaccharide biosynthesis within human MECs. Analysis of oligosaccharides in the milk of other primates further suggests that primate milk oligosaccharides are generally more complex, and exhibit greater diversity, than those found in nonprimate milk.[284]

Lipids

Lipids in milk are primarily triglycerides (>98%),[285] which due to their high energy content provide the majority of the calories required for neonatal growth in most species.[286] Milk lipids also serve as a primary source of essential fatty acids needed for neonatal membrane synthesis, as substrates for synthesis of eicosanoids and other bioactive lipid signaling molecules, and they provide a mechanism for transfer of fat-soluble vitamins to infants.[276] The lipid content of milk is variable, with content differing among species and influenced by lactation stage.[287] In humans, the amount of lipid in mature milk is greater than that in colostrum, and it is positively affected by the degree of breast emptying.[288] It is thought that the total lipid content of milk is not significantly affected by diet for adequately nourished mothers.[77] However, more recent evidence from laboratory animals indicating that diet may influence milk consumption, and that maternal obesity may reduce milk lipid levels,[278] raises questions about possible negative influences of maternal overnutrition on human milk lipid content and offspring obesity risk.

Milk Secretion Pathways

Five general pathways are responsible for secreting the majority of milk products (Figure 46.14). Proteins, oligosaccharides, and some small molecules synthesized by MECs, as well as water are secreted by exocytosis (pathway I). Lipids, lipid-associated proteins, and membrane proteins are secreted by a unique membrane-envelopment process (pathway II). Externally derived macromolecular substances, including albumin, immunoglobulins, growth factors, cytokines, lipoproteins, and micronutrients enter milk by two pathways: transcytosis

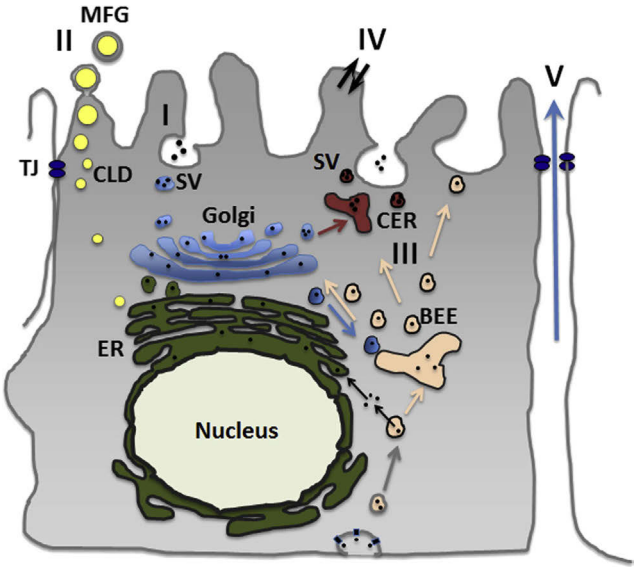

FIGURE 46.14 Cellular pathways for the secretion of milk. Five distinct pathways are responsible for the secretion of milk components. Major milk proteins, such as casein, and oligosaccharides, lactose, and water are packaged for secretion by exocytosis of secretory vesicles (pathway I) by processes originating in the Golgi complex. Lipids are synthesized and packaged into cytoplasmic lipid droplets (CLD) by enzymes in the endoplasmic reticulum. CLD are transported to the apical plasma membrane, where they are secreted by an apocrine process (pathway II) forming membrane-enveloped structures called milk fat globules (MFG). Immunoglobulins, and other macromolecules from the maternal circulation, are transported into milk by the transcytosis pathway (pathway III). In this pathway, substances taken up by either clathrin-dependent or clathrin-independent endocytosis at the basal plasma membrane initially enter into a basolateral early endosome (BEE) compartment where they are sorted to the trans-Golgi network for packaging into the secretory vesicles or to a common endosome recycling compartment (CER) for further sorting to apical or basolateral membranes. Direct movement of monovalent ions, water, and glucose across the apical and basal membranes of the cell occurs via membrane transporters (pathway IV). A paracellular pathway between epithelial cells, open during pregnancy, allows flux of plasma components into milk (pathway V). Tight junctions (TJ) close at the onset of lactation. *Source: From Monks J, Manaman JL. Secretion and fluid transport mechanisms in the mammary gland. In: Zibadi S, Watson RR, Preedy VR, editors.* Handbook of dietary and nutritional aspects of human breast milk. *Wageningen Academic Publishers, in press. Used with permission of J.L. McManaman.*

(pathway III), which involves elements of endocytic recycling and exocytotic pathways; and paracellular transport between cells (pathway V) prior to tight junction closure. Ions and small molecules, such as glucose and amino acids, are transported into milk by specific membrane transport pathways (pathway IV). Each of these pathways is affected by the functional state of the mammary gland, and is directly or indirectly regulated by actions of hormones and growth factors. Information exists about the general features of these pathways, however, few details are available about their mechanisms, or how their activities are regulated. The properties and regulation of pathway V are discussed in the section Cell–Cell Interactions in the Mammary Epithelium.

Exocytotosis (Pathway I)

During the secretory activation phase of mammary development, there is significant expansion of the rough endoplasmic reticulum and the Golgi complex, the organelles responsible for synthesis and packaging of proteins, lactose, and oligosaccharides into secretory vesicles for secretion into milk.[289–291] In species where it has been studied, the Golgi complex accounts for between 5% and 15%, and the rough endoplasmic reticulum accounts for approximately 25%, of the total volume of milk secreting cells at mid-lactation.[292] In addition to protein and oligosaccharide cargo, the Golgi complex packages nutrients, such as lactose and citrate, into secretory vesicles. The basic mechanisms by which secretory vesicle cargo is released during exocytosis were established over 40 years ago in studies of the pancreas.[293] The same mechanisms are thought to apply to essentially all exocrine cells, including those that secrete milk.

The Golgi complex is composed of seven cisternae that are classified as cis-, medial-, or trans-compartments based on their structural and functional characteristics.[294] Newly synthesized proteins are transported from the endoplasmic reticulum to the Golgi in vesicles that dock at the cis-compartment, where they are incorporated into new cisternae. The protein cargo remains within the cisternal lumen of the Golgi as cisternae progress to trans-portions of the complex.[295] Here they are sorted into transport vesicles and exit the Golgi complex. High-resolution 3D-electron micrograph tomography, in combination with rapid freezing procedures that stop cellular processes without disrupting cellular structural integrity,[296–299] has demonstrated that the trans-Golgi compartment is structurally and functionally distinct from other compartments. Vesicles destined for the endosomes or lysosomes are derived exclusively from the trans-most cisternae,[294,298] whereas vesicles destined for the apical and basolateral regions of the plasma membrane are derived from preceding cisternae.[294] Tomographic 3D reconstructions of Golgi in actively secreting cells in tissue culture[296,300] also demonstrate that direct tubule connections can form between cisternae. Such connections may facilitate cargo transfer between individual cisternal elements of the Golgi and promote secretory vesicle formation. Similar structural changes, if they occur among Golgi cisternae in milk-secreting cells, provide a mechanism by which the rate of secretion adapts to changing lactational demands of nursing young.

Exocytotic secretion requires fusion of secretory vesicle membranes with the plasma membrane to achieve cargo release. Fusion occurs at specialized sites on the plasma membrane called porosomes[301] and depends on the formation of a fusion complex between *N*-ethylmaleimide (NEM)-sensitive fusion protein (NSF), soluble NSF-attachment proteins (SNAPs), and specific soluble NSF-attachment protein receptors (SNAREs) that are found on vesicle membranes and the plasma membrane.[302] Interactions among these proteins lead to fusion of vesicles with the plasma membrane, resulting in the release of the vesicle contents into the luminal space by an ATP-dependent process.[303] This general mechanism of exocytosis appears to be conserved among cell types,[304] and striking similarities exist in protein composition of the machinery that mediates regulated- and constitutive-exocytotic processes.[304] Members of the fusion complex are expressed in mammary glands of lactating mice,[305] and proteomic analysis of isolated Golgi from MECs has demonstrated that lactation leads to the upregulation of exocytotic machinery and vesicle trafficking proteins.[306] Localization studies have implicated SNAP-23, Syntaxin-2, and VAMP (vesicle associated membrane protein)-8 as possible mediators of casein secretion. However, the specific functional importance of these proteins to milk secretion processes has not been validated by gain or loss of function studies.

PROTEINS

Proteins are secreted by both constitutive and regulated pathways. The primary function of the constitutive pathway is the delivery of new membrane proteins, however in some cases it functions to deliver proteins for secretion.[307] Conversely, the regulated pathway specifically targets proteins to the plasma membrane for secretion in response to physiological signals. This pathway is the primary mechanism by which proteins are secreted in the pancreas, salivary, and adrenal glands. Elements of regulated secretory pathway have been identified by proteomic analysis of Golgi preparations from lactating rat mammary glands,[306] and evidence of regulated secretion of casein has been detected in isolated milk secreting cells.[308] However, this mechanism appears to account for only a small percentage of total casein secretion.

LACTOSE AND OLIGOSACCHARIDES

Lactose is synthesized within the Golgi complex by the transfer of galactose from UDP-galactose to glucose

in a reaction that is catalyzed by a complex between β-4-galactosyltransferase-1 and alpha-lactalbumin.[309] Biochemical studies showing that lactose is enriched in preparations of casein-containing secretory vesicles from mammary glands of lactating rats suggest that it may be secreted along with milk proteins.[310] Milk oligosaccharides are synthesized by addition of glycosyl groups, including *N*-acetylglucosamine, fucose, and *N*-acetylneuraminic acid to the galactose residue of lactose. This basic mechanism accounts for the synthesis of both linear and branched-chain oligosaccharides.[311] Relatively few details are known about the regulation of milk oligosaccharide synthesis, what determines oligosaccharide structural diversity, or how oligosaccharides are packaged into secretory vesicles for secretion during lactation. The various glycosyltransferase reactions responsible for generating specific oligosaccharide structures localize to different Golgi compartments,[312,313] suggesting the existence of specific mechanisms for detecting and regulating oligosaccharide abundance, as well as for transporting oligosaccharides within the Golgi to achieve specific structural characteristics. Specific domains within the C-terminal regions of glycosyltransferases control their localization within Golgi cisternae,[314] however, the mechanisms controlling glycosyltransferase targeting to a particular Golgi compartment have not been identified.

CALCIUM, PHOSPHATE AND CITRATE

Milk is rich in calcium, $PO_4^=$, and citrate, which exist in a variety of chemical forms including free ions, as Ca^{++} $PO_4^=$ or Ca^{++}citrate complexes, or bound to casein for Ca^{++} and $PO_4^=$ ions. Citrate is synthesized de novo by MECs, whereas milk Ca^{++} and $PO_4^=$ are derived from the maternal circulation. Biochemical, physiological, and kinetic evidence indicates that all three molecules are secreted into milk by exocytosis of Golgi-derived secretory vesicles.[315] Golgi membranes contain Ca^{++} pumps and citrate transporter activities that presumably mediate the transport of these substances into Golgi-derived vesicles.[316] Although it is likely that $PO_4^=$ enters the Golgi system by transport, in some species Golgi $PO_4^=$ may also originate by UDP hydrolysis during lactose synthesis. Although some of the Ca^{++} in milk must be transported from the exocytotic pathway, clear evidence for a powerful apical membrane transporter, PCMA2, that transports the majority of Ca^{++} in rodent and bovine milk, has been obtained from several laboratories.[207,317,318]

Lipid Secretion (Pathway II)

The mechanism of milk lipid secretion is distinct from the exocytic pathway used to secrete proteins, sugars, and water into milk and from exocytic pathways used by hepatocytes or enterocytes to secrete lipids into the circulatory system.[319] Milk lipids originate from CLD,[320–322] which are secreted into milk as membrane-bilayer coated structures, known as MFG, through an apocrine mechanism.[322,323] Proteomic analyses,[324] which documented that the overall protein composition of CLD isolated from milk secreting cells is similar to that of the secreted MLG, suggest that CLD are secreted into milk in toto, without significant modification of their compositions. Such studies also demonstrated that the protein signature of CLD isolated from milk-secreting cells is distinct from that of CLD isolated from hepatocytes, which are not secreted, suggesting that protein composition of mammary CLD may be specialized for transport and secretion. The reason why milk-secreting cells have evolved a specialized mechanism(s) of lipid secretion that bypasses the endoplasmic reticulum and Golgi packaging machinery used in the secretion of other substances is unclear. However, the presence of a "direct lipid secretion" pathway may provide means of delivering large amounts of lipid to neonates during critical growth periods.[319] In addition, the membrane surrounding MFG protects milk lipids from emulsification and may possess additional biological functions.[325–327]

Based on ultrastructural evidence showing CLD contacting and being surrounded by the apical plasma membrane,[320] it has been proposed that CLD are secreted by a "membrane envelopment" mechanism.[322] Although most evidence favors this mechanism,[322,328] an alternative mechanism involving interactions between secretory vesicles, CLD, and the plasma membrane has been proposed.[329] In support of this alternative pathway, the SNARE protein SNAP-23, which has been implicated in the secretion of casein vesicles, has also been detected on CLD by immunofluorescence microscopy.[305] The possibility that CLD may be secreted by more than one mechanism is further suggested by observations that lipid-containing structures with a diverse range of sizes and lipid compositions have been detected in milk.[330]

Details about the mechanisms by which CLD form contacts with the apical plasma are limited. However, CLD are known to accumulate near the apical plasma during lactation,[289] and ultrastructural analyses have shown that they are separated from the plasma membrane by a 10–20-nm-thick layer of electron dense material.[290] Material of similar appearance has been shown to separate the surface of the lipid droplet from the surrounding membrane in secreted MFG.[290,331] Proteomic analyses of human, bovine, caprine, and mouse MFG membranes have shown that they are uniquely enriched in three proteins: the apical plasma membrane protein butyrophilin (BTN); the cytoplasmic enzyme, xanthine oxidoreductase (XOR); and the CLD-associated protein, adipophilin (ADPH/ADRP/perilipin 2).[332] Biochemical and immunocytochemical analyses indicate that these proteins exist as a stable complex in MFG,[333] and loss of function studies suggest that each protein contributes to normal milk lipid secretion.[334–337]

How BTN, XOR, and ADPH interact to mediate lipid secretion is not well understood at the molecular level, but interactions between these proteins have been documented and critical functional domains are beginning to be identified. ADPH on the CLD surface is proposed to form a complex with BTN and XOR that allows CLD to dock at the apical plasma membrane.[332] This mechanism is supported by experiments showing that ADPH exists as a complex with BTN and XOR on MFG membranes and co-localizes with these proteins on the apical plasma membrane at sites of CLD secretion.[107] Binding studies have further shown that XOR binds tightly to a cytoplasmically oriented domain, B30.2, of mouse BTN.[338,339] The C-terminal region of ADPH, which forms a four-helix bundle structure,[337] has also been implicated in CLD secretion by experiments in which mutant ADPH lacking the four-helix bundle domain was shown to disrupt CLD secretion in lactating mice.[337] Four-helix bundle motifs bind to phospholipid membranes and have been implicated in the induction of membrane curvature[340,341] and the recruitment of other proteins to the curvature site.[341] It is an intriguing possibility that interactions between the C-terminal four-helix bundle domain of ADPH and the apical plasma membrane of milk-secreting cells may initiate changes that lead to BTN and XOR recruitment to CLD contact sites and ultimately to the envelopment and secretion of CLD.[342]

Transcytosis (Pathway III)

Transcytosis provides a pathway for proteins and other macromolecules from the maternal circulation to be transported into milk. Substances transported by this pathway are taken up either by clathrin-dependent or clathrin-independent endocytosis at the basal plasma membrane of milk secreting cells and enter into a basolateral early endosome (BEE) compartment. Substances within this compartment are sorted into a rapid recycling pathway, to late endosomes/lysosomes, to the trans-Golgi network, or to a common endosome recycling (CER) compartment.[343,344] There is further sorting of substances within the CER to the apical membrane or back to the basolateral membrane.[344] Thus, transcytosis involves a series of complex sorting events that may or may not intersect with the exocytotic pathway used for secreting endogenously synthesized proteins, lactose, and oligosaccharides. The extent to which the exocytotic and transcytosis pathways intersect in the secretion of milk substances derived by endocytosis is unknown. However the demonstration that concanavalin A-ferritin complexes taken by endocytosis were found in secretory vesicles containing casein[345] provides experimental evidence of endocytic and exocytotic pathway intersection in the milk secreting cells of lactating animals.

IMMUNOGLOBULINS

Of the substances transported into milk by transcytosis, immunoglobulin A transport (IgA) is the best understood. Immunoglobulin A exists as a dimer (dIgA) and is by far the predominant immunoglobulin class in human milk.[346] At the onset of lactation, plasma cells home to the mammary gland where they lodge in the interstitial spaces, producing much of the IgA secreted into milk. Dimeric IgA synthesized by plasma cells or elsewhere in the body binds to polymeric immunoglobulin receptors (pIgR) on the basolateral surface of milk-secreting cells.[347] The entire IgA–pIgR complex is internalized by clathrin-dependent endocytosis and transferred to the apical membrane. In other cell types, dIgA–pIgR transcytosis has been shown to involve the BEE and CER compartments and an apical recycling endosome compartment.[348] Fusion of endocytic vesicles with the apical plasma membrane delivers the dIgA–pIgR complex to the apical plasma membrane, where the receptor undergoes proteolytic cleavage at arginine 585 to release dIgA bound to a portion of the pIgR extracellular domain called secretory component.[347] The mechanism of fusion of dIgA–pIgR vesicles with the plasma membrane in kidney cells involves *N*-ethylmaleimide sensitive factor (NSF) and components of the SNARE machinery.[350,351] Presumably a similar mechanism operates in milk-secreting cells, but the process has not been studied. Transgenic pIgR expression in mouse mammary glands demonstrated that pIgR levels limit dIgA transport into milk.[351] Dimerization of pIgR, induced by dIgA binding, stimulates the transcytosis of the complex in cultured immune cells,[352] possibly by activating PKC/PI3 kinase signaling pathways.[344] It is unknown if similar processes regulate dIgA transfer into milk.

SERUM ALBUMIN

In addition to transporting dIgA, elements of the dIgA–pIgR pathway also appear to be responsible for transcytosis of serum albumin into milk.[233] Fluorescently labeled serum albumin is found in close proximity to dIgA on the basolateral membrane of milk-secreting cells of lactating mice, and it co-localizes with dIgA in endosomal vesicles within these cells.[233] However, the identity of the vesicular compartment containing dIgA and serum albumin was not defined, and it remains unclear if dIgA and serum albumin undergo co-transcytosis at each step of the pathway. Nevertheless, co-localization analyses of serum albumin and casein demonstrated that the albumin transcytosis pathway does not intersect with the post-Golgi compartment mediating milk protein secretion.[233] Receptor mediated uptake has been implicated in the transport of albumin across various epithelial barriers. The presence of approximately 30 times more serum albumin than dIgA in mouse milk suggests the existence of mechanisms for concentrating albumin, or the presence of albumin receptors, for

transport into milk that differ from those for dIgA. In contrast to mice, where the serum albumin concentration in milk is approximately equal to that in serum,[233] the serum albumin concentration in human milk is significantly lower than that in serum.[353] Thus there appear to be species differences in aspects of serum albumin transcytosis into milk.

TRACE ELEMENTS

Transport of trace elements, such as iron, copper, and zinc, combines elements of transcytotic and exocytic pathways. Distinct mechanisms exist for trace element uptake into milk-secreting cells. Like IgA and albumin, iron is internalized by a receptor-mediated endocytotic process. Iron bound to transferrin (TFN) binds to the transferrin receptor (TFNR) on the basolateral surface of the mammary gland. The TFN–TFNR complex is internalized by clathrin-dependent endocytosis and transported into the BEE of the mammary epithelium, where the acidic environment releases iron from TFN. It is thought that released "free" iron is transported out of endocytic vesicles into the cytoplasm by the divalent metal ion transporter identified in hepatic cells and placental tissue,[354,355] but direct evidence that this process occurs in milk-secreting cells is lacking. In the cytoplasm, iron complexes with iron-binding proteins, such as ferritin, or it is transported into the secretory machinery by ferroportin where it complexes with transferrin or lactoferrin and is packaged into secretory vesicles carrying milk proteins.[356] While significant amounts of iron are transported into rodent milk to meet the nutritional demands of the growing offspring, human milk iron is very low as the full-term infant stores enough iron from the breakdown of fetal hemoglobin to meet infant demand for four to six months postnatally.[357]

Copper is transferred from the circulatory system into milk-secreting cells by basolateral located transporters. Three copper transporters have been identified in the mammary gland: Copper transporter 1 (CTR1), ATPase7A (ATP7A), and ATPase7B (ATP7B). CTR1, an essential regulator of copper import in most tissues,[358] including the mammary gland,[359] is found at the plasma membrane and forms a multimeric complex having a central copper channel with high affinity for copper.[358] ATP7A and B are polytopic transmembrane cation-transporting P-type ATPases that are closely related to each other.[360] Both proteins are found in the secretory pathway and function in the transfer of copper to copper-binding proteins or copper-dependent enzymes in this compartment.[361] Copper complexed to ceruloplasmin or metalothionine is packaged into secretory vesicles and secreted by the exocytotic pathway. Mutations in ATP7A and B are responsible for copper excretion defects observed in livers of Menke and Wilson disease patients. In each case, the defects are associated with impaired trafficking of these proteins from the Golgi to secretory vesicles.[362] ATP7A and 7B have been implicated in the secretion of copper into milk.[356] However, only impaired ATP7B function has been shown to influence milk copper levels in mice.[363] Transgenic studies in fact suggest that ATP7A mediates copper secretion from the basolateral membrane of the mouse.[364] Although ATP7A and 7B are expressed in human MECs,[364,365] their roles in milk copper secretion are not fully established. Milk copper levels are reported to be lower in patients with Wilson's disease,[366] however Wilson's disease does not appear to interfere with lactation.[367] Whether ATP7A is able to compensate for ATP7B dysfunction in the milk copper secretion in Wilson's disease patients is unknown. However, ATP7B has been shown to rescue copper accumulation defects observed in cells derived from mice with defective ATP7A,[360] thus overlap in the functions ATP7A and B may account for the limited effect of ATP7B loss on mammary gland function and milk copper levels.

The organization of the zinc secretory system is broadly similar to the copper secretory system in that specific transporters mediate zinc uptake from the maternal circulation and its subsequent transport from the cytoplasm into the secretory system. Twenty-four different zinc transporters (ZnT) have been identified in mammals; they fall into two categories, 10 ZnT and 14 zinc import proteins (ZIP).[368] ZnT family members transport zinc from the cytoplasm across the plasma membrane or into the secretory or endosomal pathways.[369] ZIP family members mediate transfer of zinc into the cytoplasm from the circulation or intracellular compartments.[370] ZnT family members are known to be critical regulators of zinc transport into milk of humans and rodents. In humans, a missense mutation in ZnT2 has been identified that is associated with low milk zinc levels,[371] and in mice a spontaneous ZnT4 mutation appears to be responsible for decreased milk zinc levels associated with the lethal milk phenotype. Specific roles for ZIP family members in zinc secretion into milk have not been described.

Membrane Transport (Pathway IV)

Na^+, K^+, and Cl^- ions are the most prevalent minerals in most milks, comprising about 10% of the osmolality of human milk, 25% of the osmolality of bovine milk, and about 65% of the osmolality of rabbit milk,[372] with lactose making up most of the rest. Because the total concentrations of Na^+ and K^+ in milk are equivalent whether determined by ion selective electrodes or flame photometry,[373,374] these ions are considered to be free, e.g., not complexed with other molecules. The same assumption is usually made for Cl^-.[375] The important questions are: What are the concentrations of these ions within the various compartments of the mammary tissue? What are the mechanisms by which the

TABLE 46.1 Monovalent Ion Concentrations in the Guinea Pig Mammary Gland

		Cell, mEq/L		Milk, mEq/L	
Component	**Interstitial, mEq/L**	**Guinea Pig; Ruminant**	**Mouse**	**Guinea Pig; Ruminant**	**Mouse**
Sodium (Na^+)	150	41.7	47	8	27

Chloride (Cl^-)	116	66.5		12	N/A

Data from Ref. 5.

concentration gradients between interstitial fluid, cell, and milk are maintained in the lactating epithelium? The first question was answered at least for goats and guinea pigs in a 1971 publication by Linzell and Peaker.[5] Table 46.1 shows the concentrations of Na^+, K^+, and Cl^- in the interstitial space, the cell water, and the milk. Similar results were reported for goats, cows, and sheep.[5] Before dealing with potential mechanisms for monovalent ion transport, it is useful to reiterate the basic principles proposed by Linzell and Peaker in 1971:[5]

1. All mammary membranes are freely permeable to water so that the concentrations of osmolytes essentially determine the volume of milk.
2. The ducts have the same ionic permeability properties as the alveolar cells, and milk composition is unchanged as it passes through the mammary ducts.
3. The ionic concentration in the cytoplasm is maintained by pumps and exchangers present on the basolateral membranes of the cells.
4. The apical membrane is permeable to Na^+, K^+, and Cl^-.
5. Na^+ and K^+ are at electrochemical equilibrium across the apical membrane, whereas the concentration of Cl^- in the milk is lower than predicted by passive distribution.

These concepts have not changed since Linzell and Peaker first proposed them[5]; they apply during full lactation when the paracellular pathway is closed.

WATER PERMEABILITY OF MAMMARY TISSUES

The major evidence for the free permeability of the mammary membranes, both epithelial and endothelial, to water is that milk is iso-osmotic with plasma under any circumstances in which it has been measured.[376,377] An interesting example is that during Ramadan, when women fast, their blood becomes slightly hypertonic and their milk follows suit.[378] Water channels called aquaporins are thought to be responsible for the water permeability of cell membranes. Aquaporin 1 (AQP1) was clearly shown to be present in myoepithelial cells in the bovine mammary gland as well as the capillary endothelium.[379] Aquaporin 3 (AQP3) was found on the basolateral membranes of secretory epithelial and ductal cells in the rodent mammary gland[380] and more selectively in the bovine gland.[379] Aquaporin 5 (AQP5) was present on the apical membranes of the mammary ducts of virgin animals[381] and possibly intracellularly during lactation. Aquaporin 7(AQP7), a water and glycerol channel, has been shown to be expressed in the murine mammary gland at lactation (Ramanathan and Neville, unpublished) but its localization is unknown. It can be assumed that these channels are at least partly responsible for water permeation across mammary membranes, but final answers are not yet in.

ROLE OF THE DUCTAL EPITHELIUM IN THE CONCENTRATION OF IONS IN MILK

Although the concentration of many secretions such as saliva is altered as the fluid passes through the ducts, the mammary gland appears to be an exception. The best evidence is that the concentration of ions is the same in milk obtained early in milking, which presumably has lingered in the ducts, as in milk obtained at the end of milking as long as high levels of OT are not used to obtain milk letdown.[382]

BASOLATERAL MEMBRANE TRANSPORTERS

There is abundant evidence for a number of pumps and exchangers in the basolateral membrane. The functional and immunohistochemical evidence for a ouabain-sensitive Na/KATPase in the basolateral membranes of the lactating mammary alveolar cells was first reported in the early 1970s[229,383] and has since been obtained in many laboratories (reviewed in Ref. 376); it is widely accepted that the Na^+ and K^+ levels in the mammary cell are mostly maintained by this enzyme. However, Na^+ levels in the cell (43 mM in the guinea pig, for example, 26 mM in the mouse[384]) are higher than in many other cells. The mechanism is not clear, but many Na^+-dependent exchangers are thought to be present on the basolateral membrane,[376] which could account for excess entry of this ion into the cell (Figure 46.15). Evidence for an amiloride-sensitive Na^+/H^+ exchanger as well as a DIDS-sensitive Na/HCO_3^- cotransporter were obtained in the 31EG4 cell line,[385] a nontransformed mouse mammary cell line derived

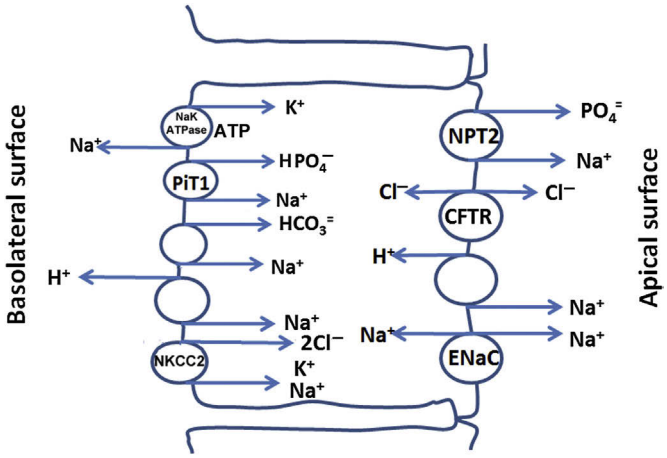

FIGURE 46.15 Transporters and channels in the basal and apical membranes of the mammary alveolar cell. This figure shows the membrane transporters for monovalent ions for which there is evidence from studies in the lactating mammary gland and tissue culture models. PiT-1 is the product of the Slc20a1 gene; the $Na^+/PO_4^=$ transporter Npt2, also known as NaPi-IIb, is the product of the Slc34a2b gene; the $Na^+K^+2Cl^-$ transporter NKCC2 is the product of the Slc12a2 gene; CFTR is the cystic fibrosis Cl transporter encoded by *Cftr* in the mouse: and ENaC is the nonvoltage sensitive amiloride sensitive Na^+ channel encoded by the murine Scnn1b gene. While Na^+ hydrogen exchangers have been proposed for both membranes, their molecular identity is not yet clear.

from the IM-2 cell line.[386] Shennan and colleagues[387] obtained physiologic evidence for electroneutral $Na^+/K^+/2Cl^-$ exchange in mammary explants inhibitable by furosemide. Clear immunohistochemical evidence supports the presence of this transporter at the basolateral membrane.[122,381,388] Levels were highest in the ducts of the virgin gland, but the protein was detected throughout pregnancy and lactation generally localized to basolateral membranes. Mice with a null mutation of this transporter showed no obvious defects in mammary morphology during lactation; however, the pups failed to thrive.[388] What could not be determined from the experiments was whether the lactation failure was due to a defect endogenous to the mammary gland or some other deficiency, since the mice have defects in a number of tissues.

APICAL MEMBRANE TRANSPORT

Apical membrane transport has also been characterized in a number of laboratories. The earliest experimental evidence was obtained in goats in 1974. Linzell and Peaker found that NaCl and KCl solutions infused up the teat were absorbed into the blood stream, whereas isotonic sucrose solutions infused in the same way drew ions into the milk space.[230] In addition, measurement of the effect of changes in the Na^+, K^+, and Cl^- concentration in the milk space of the goat mammary gland on the transepithelial potential difference provided evidence for the presence of a nonselective cation channel and a Cl^- channel in the apical membrane.[389] Additional evidence for K^+ and Cl^- channels comes from studies of ion transport across membrane vesicles isolated from MFG membranes.[390,391] In the guinea pig (Table 46.1), rat, and rabbit the ratio of the concentrations of Na^+ and K^+ in milk and mammary gland was approximately equal at 3, and both were at approximately electrochemical equilibrium across the apical membrane, suggesting that they are passively distributed.[372] This was also the case in the mouse where careful measurements of the transepithelial and basolateral potential in vivo, gave a transepithelial potential of −35 mV and a basolateral potential of −49 mV. By subtraction the apical potential should be in the range of −14 mV, not too different from the equilibrium potentials of Na^+ and K^+ across the apical membrane of −26 and −15 mV, respectively.[232,384]

The Cl^- concentration is much higher in the cell than in the milk of all species where it has been measured,[372] and the ion is obviously out of electrochemical equilibrium. The mechanism by which milk Cl^- is maintained at a low level is not clear, but experiments in tissue culture models are beginning to show how Cl^- transporters may function. The cell line, 31EG4, mentioned before, is a reasonably satisfactory model as it forms a tight monolayer when grown on a Transwell support. The resistance of this monolayer is substantially increased by glucocorticoid in a manner reminiscent of the in vivo mammary gland.[392] 31EG4 cells were found to possess both the amiloride sensitive epithelial Na^+ channel (ENaC) and the cystic fibrosis transmembrane conductance regulator (CFTR), a Cl^- channel that is stimulated by cyclic AMP and inhibited by diphenylamine-2-carboxylate.[392] Both were localized to the apical border of 31EG4 cells by immunostaining, a location that was confirmed by electrophysiological experiments. CFTR was also identified in sections of human mammary gland at the apical border of the epithelium.[392] This transporter could be responsible for Cl^- movement between the milk and the cell in the lactating mammary gland: however, because it is a passive channel, it cannot account for the movement of Cl^- down its electrochemical gradient from the lumen into the cell. A further difficulty with an important role for CFTR in the ionic composition of milk is that women with cystic fibrosis, a disease with defective CFTR, have no difficulty with lactation.[393] While considerable physiologic evidence indicates the presence of a K^+ channel in the apical membrane,[376] the molecular identity of this channel remains unknown, unless it is the Ca^{++}-activated $K_{Ca}3.1$channel described following. There appears to be a good deal to be learned about the molecular nature of the channels in the apical membrane of the mammary epithelium.

PHOSPHATE TRANSPORT IN THE MAMMARY GLAND

Na^+ $PO_4^=$ cotransport in the mammary gland of the lactating rat was identified physiologically in 1996[394] when it was thought to mediate basal transport of both ions into the mammary cell in vivo. It is hypothesized that this transport is mediated by a Type III neutral Na^+ HPO_4^- transporter known as *PIT* encoded by Slc20 genes.[395] *Slc20a1* is upregulated at lactation in the mouse (Ramanathan and Neville, unpublished), suggesting that PIT-1 is the basal Na^+ HPO_4^- carrier in the mammary epithelium. A specific Na^+ $PO_4^=$ transporter (NPT2B or NaPi-IIB; gene name *Slc34a2*) was shown to be highly expressed at the apical membrane of the lactating mammary gland in the mouse[381] and goat[396] and can be either electrogenic, transporting Na^+ $PO_4^=$, or electroneutral, transporting Na^+ HPO_4^-.[395] These findings suggest that Na^+ and $PO_4^=$ are transported across the basolateral membrane into the cell by PIT-1 and across the apical membrane to the milk by NPT2B. However, detailed proof of this hypothesis is lacking.

A POTENTIAL ROLE FOR PURINERGIC RECEPTORS IN REGULATION OF MAMMARY GLAND ION TRANSPORT

Mammary tumor cells were found to secrete the nucleotides UTP and ADP after mechanical stimulation; these compounds in turn increased intracellular Ca^{++} in the tumor cells.[397] The receptor responsible for these nucleotide effects was found to be the metabotropic P2 purinergic receptor, P2Y. Blaug and colleagues[249] using 31EG4 cells showed that ATP and UTP stimulated apical Cl^- movement by acting on P2Y to increase Ca^{2+} release from the endoplasmic reticulum. Studies of purinergic receptor activation in primary human mammary epithelial cell cultures produced evidence for $K_{Ca}3.1$channels. K^+ intermediate/small conductance Ca^{++}-activated channel, subfamily N, member 4, also known as KCNN4, is a human gene encoding the $K_{Ca}3.1$ protein, which is responsive to P2Y receptors in the basolateral membrane of these MECs. Increased cellular Ca^{++} also activates ENaC in the basal membrane to alter Na^+ transport.[250] The physiological meaning of these findings is not entirely clear, but they indicate that Na^+ and K^+ secretion into milk is subject to a higher level of regulation than previously thought.

In conclusion, the major outlines of monovalent transport into milk have not changed since they were first proposed in 1971 by Linzell and Peaker.[5] However, considerably more molecular information about the mechanism of transport across the basolateral membrane is available. Many questions remain about the molecular mechanisms of apical transport.

MEETING THE ENERGY REQUIREMENTS OF LACTATION

The energy demands of lactation are significant and require a major shift in energy homeostasis. Some animals can meet this energy demand wholly by mobilizing endogenous energy stores.[398] Such animals (some bears, seals, baleen whales) usually have a large body size and the storage capacity that allows them to remain fasted throughout lactation. For most animals, however, the energy consumed in the diet is needed to support the demands of this expensive process. One adaptation of maternal physiology is the growth and increased absorptive surface area of the alimentary tract to extract the available nutrients from dietary intake.[399,400] This adaptation, in isolation, however, would be insufficient. To meet these demands, multiple signals converge to increase maternal caloric intake, minimize the energy requirements in nonessential tissues, and direct nutrients that will be used for milk production to the mammary gland.

Exogenous Nutrients

Much of the research on the role of exogenous nutrients in providing substrate for milk synthesis has been carried out in rodents, animals with large litters that require an enormous increase in energy transfer to support their high rate of growth. While the general adaptive mechanisms to meet these demands are thought to be present in most lactating animals, including humans, there are certainly species-specific adaptations. Here we will deal mainly with the extensive information available from studies in rodents as well as earlier studies in dairy animals.

Increasing Energy Intake

Two primary hormonal signals are thought to be involved in promoting hyperphagia during lactation: (1) PRL release associated with suckling; and (2) a decline in the adiposity-associated hormone, leptin (Figure 46.16).

Suckling can stimulate energy intake in the absence of milk production,[401–403] even when peripheral signals of negative energy imbalance are not present.[404] Suckling is a major stimulus to PRL secretion,[405] and PRL is thought to promote feeding in order to meet the high energy demands of lactation. PRL induces hyperphagia in nonlactating dams in a dose-dependent manner[406–408] and rescues the inhibitory effects of bromocriptine on the appetite of galactophore-cut dams (dams who are still being suckled but not producing milk).[409] This effect on appetite is thought to involve key areas of the hypothalamus that regulate energy balance. Both PRL and suckling can increase the expression of orexigenic (e.g., appetite promoting) neuropeptide Y in the dorsomedial hypothalamus.[410,411] In addition, these areas of the brain

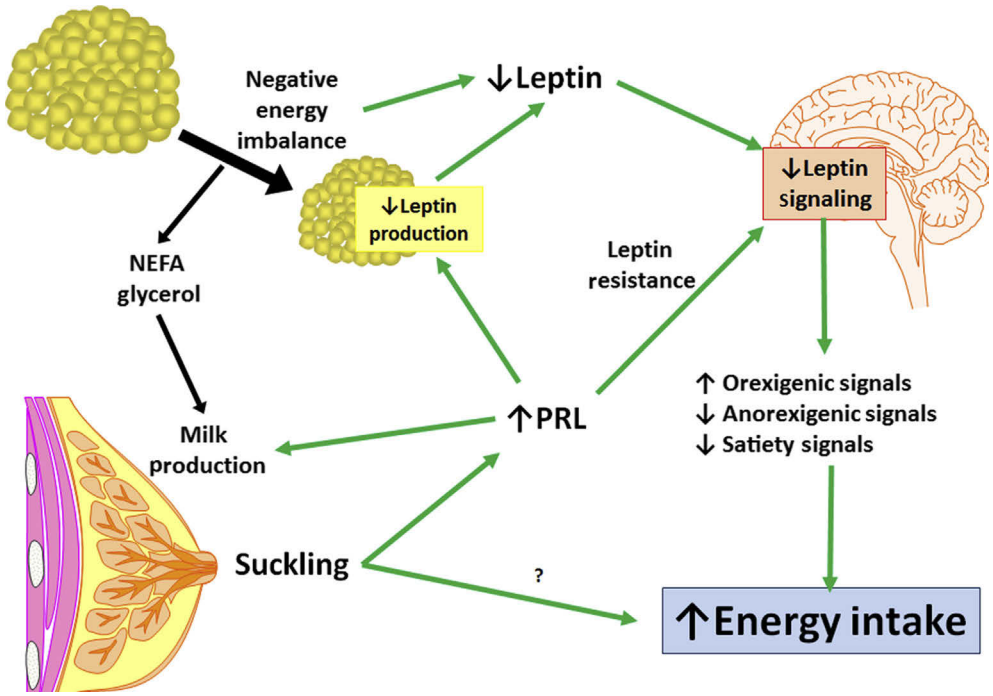

FIGURE 46.16 The regulation of energy intake during lactation. PRL secretion reduces the sensitivity of the brain to leptin. Suppressed leptin levels and central leptin resistance converge to promote feeding. Other signals from the suckling response may also contribute to this interplay between the mammary gland, adipose tissue, and the brain. The neural pathway linking suckling to energy intake is currently unclear as indicated by "?". The increased energy intake helps meet the energetic demands of lactation. PRL = prolactin; NEFA = nonesterified fatty acids.

become resistant to the anorexigenic (anti-appetite promoting) actions of leptin. PL signals through the PRL receptor and promotes hypothalamic leptin resistance by mid-pregnancy in the rat.[412,413] Central leptin resistance is maintained throughout lactation,[414] likely by PRL,[415] and appears to be essential for the maintenance of hyperphagia.[416–419]

Leptin signaling during lactation is also suppressed by decreased levels of the hormone.[403,420] Circulating levels become less responsive to meals and more responsive to maternal energy balance, while displaying a diminished diurnal fluctuation throughout the day.[403,420] The decline in leptin levels may result from the depletion of maternal adipose stores during lactation, as endogenous lipid stores are trafficked to the mammary gland.[403,404,418] Alternatively, PRL may directly inhibit the secretion of leptin.[421] Regardless of the mechanism, with a brain that is resistant to leptin, and leptin levels falling, the inhibition of orexigenic signals is diminished and the stimulation of anorexigenic signals is minimized, both of which result in increased appetite.[422]

Adaptations in Expended Energy

Lactation is an expensive process, particularly in rodents who increase their metabolic requirements up to threefold to nourish a rapidly growing litter of pups. This increased requirement is founded not only on the energetic value of the milk constituents but also in the maternal energy expended to produce and secrete the milk. In women, the efficiency of milk production is predicted to be between 80% and 95%,[423] suggesting that during lactation basal metabolic rate should increase anywhere from 5% to 20% due to the energy cost of milk production.[424,425] Butte et al. elegantly showed in women that there is a direct correlation between milk production and total energy expenditure, consistent with the idea that metabolic rate is affected by the costs of milk production.[426] However, this effect on metabolic rate has not been observed in all studies, suggesting that the energetic efficiency of milk production may *vary* substantially between individuals or that peripheral tissues become more metabolically efficient to compensate for the increased energetic demand of milk production.

The efficiency of milk production is inherently linked to the type of macronutrient used to make milk lipid (Figure 46.17). Thus, it is energetically more expensive to produce milk lipid from carbohydrate or protein because as much as 25% of the energy must be expended to convert them to a free fatty acid precursor. On the other hand the energetic cost of producing milk lipid with preformed fatty acids derived from the diet or from endogenous stores is substantially less (<1–2%). For this reason the composition of the diet and the availability of preformed precursors can have a significant effect on the energetic requirements of milk production.

In addition, evidence suggests that the body can adapt in other ways to conserve energy for milk production (Figure 46.17). Three of the proposed adaptations are: (1) decreased physical activity[427–429]; (2) suppressed anabolic activity of adipose and muscle[430–432]; and (3) reduced nonshivering thermogenesis by brown adipose tissue (BAT).[427,433–437] With respect to BAT, falling leptin levels may coordinately explain the inhibition of BAT and the suppression of nonshivering thermogenesis during lactation.[404,427,438]

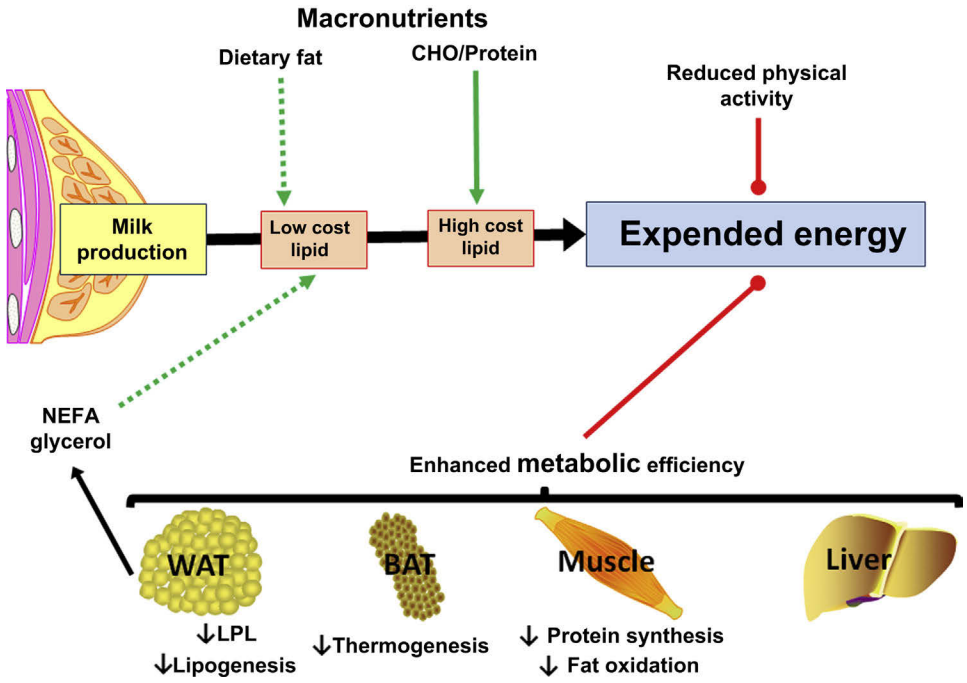

FIGURE 46.17 **The regulation of energy expenditure during lactation.** Milk production is energetically expensive. This cost includes not only the energy found in the milk constituents but also the energy that must be expended to produce and secrete the final product. Preformed fatty acids from the diet (exogenous) or mobilized from adipose tissues (endogenous) require relatively little expended energy to produce milk lipid. If milk lipid is made from CHO or amino acid precursors, these substrates must be converted to fatty acids via de novo lipogenesis, increasing the amount of energy needed to produce milk lipid. To conserve energy during lactation and maintain thermoneutrality, peripheral tissues become more metabolically efficient and physical activity declines. WAT = white adipose tissue; BAT = brown adipose tissue; NEFA = nonesterified fatty acids; LPL = lipoprotein lipase.

Dietary Fat versus De novo Derived Lipid: Effects on Milk Lipid Content

The positive energy imbalance resulting from the combined effects of hyperphagia and enhanced metabolic efficiency can provide the extra energy needed for milk production. The extra energy makes its way to the mammary gland in the form of carbohydrate, lipid, or protein, and may be trafficked through other tissues prior to being utilized by the mammary gland for milk production (Figure 46.18).

Breakdown products from hydrolysis of dietary lipids are taken up by the intestinal cells, re-esterified into triglycerides (TAG), and released in a lipoprotein called a chylomicron. Chylomicra are released into the lymphatic circulatory system and eventually enter the portal vein from which they are distributed through the blood stream to be utilized by lipoprotein lipase (LPL) containing tissues for oxidation or storage or synthesis by MECs into milk TAG. If there is very little fat in the diet, a larger portion of the lipid component of the milk must be produced from the available carbohydrate and/or protein, via a process called de novo lipogenesis. If this process occurs in the mammary gland, the fatty acids synthesized are limited to 8- to 16-chain saturated fatty acids, while in the liver and adipose tissues fatty acids of 16 carbons and longer are produced (Figure 46.18). Increased dietary fat has been shown to downregulate de novo lipogenesis in the mammary gland[439–445] and in turn reduce the proportion of medium chain fatty acids in the milk fat. As such, milk TAG composition reflects dietary fat composition.[446]

Endogenous Nutrients

In addition to the positive energy imbalance, endogenous nutrients are mobilized and directed to the mammary gland to meet the demands for lactation. PRL and β-adrenergic stimulation from the sympathetic nervous system provide critical signals for this shift in fuel trafficking. However, these signals have tissue-specific effects in the periphery. Fat stores in adipose tissue and liver (made via de novo lipogenesis or transported to these tissues from dietary sources[446]) are mobilized during lactation to provide milk fat substrates and energy for milk production.

Adipose Tissues: The Primary Source of Endogenous Energy

During pregnancy, ingested energy gradually accumulates in white adipose tissues (WAT) in preparation for lactation, stored as TAG in lipid droplets. During

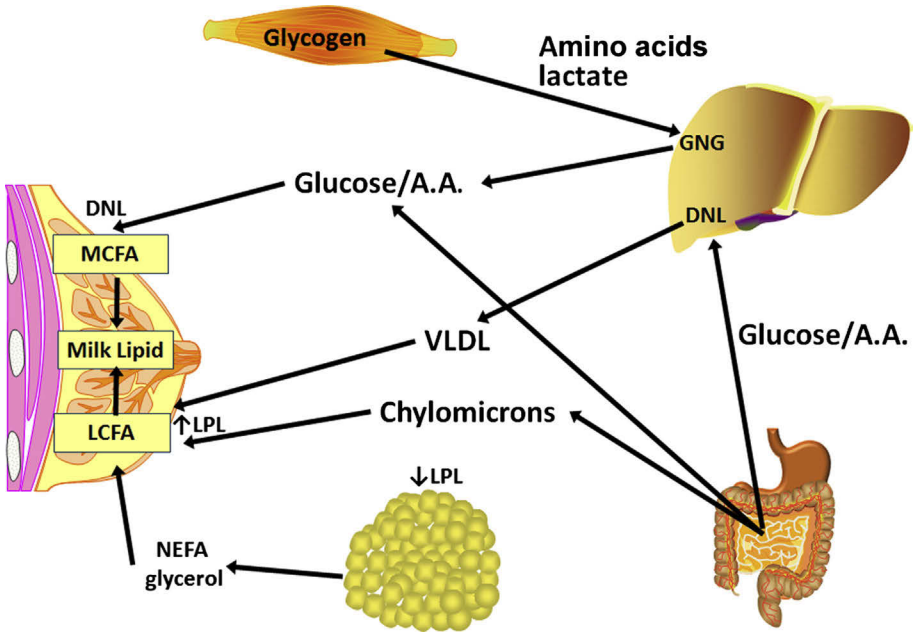

FIGURE 46.18 Exogenous and endogenous nutrients affect the composition of milk lipid. Dietary fats primarily enter circulation through the lymphatic system as triacylglycerol in chylomicrons, while the liver releases stored lipid in the form of VLDL. The differential expression of LPL in the mammary gland and adipose tissues leads to the trafficking of these neutral lipids toward milk production. Adipose tissue lipid is mobilized and trafficked to the mammary gland in the form of NEFAs. Glucose and amino acids, mobilized from endogenous stores or absorbed from the diet, are directed to the mammary gland as precursors for milk carbohydrate and protein. When in excess, the mammary gland and liver convert these precursors to fatty acids via de novo lipogenesis. The product in the mammary gland is primarily MCFA, while in the liver it is long-chain fatty acids (LCFA) and subsequently triacylglycerol. The types of fats that end up in milk lipid are a function of dietary fat (usually LCFA), the amount that is mobilized from endogenous stores (usually LCFA), and the location of DNL (MCFA, mammary gland; LCFA, liver). LPL = lipoprotein lipase; NEFA = nonesterified fatty acid; VLDL = very low density lipoprotein; DNL = de novo lipogenesis; A.A. = amino acid; MCFA = medium chain fatty acid; LCFA = long chain fatty acid.

lactation, this stored energy is then mobilized to provide fatty acid substrates for energy production and milk lipid synthesis.[77,431,446] Lipolytic enzymes, such as hormone-sensitive lipase and adipose triglyceride lipase, hydrolyze the lipid droplets to release the stored TAG. The released fatty acids and mono-acylglycerol are transported out of the cells into the blood. They bind to albumin and are circulated throughout the body.

This shift of WAT from an anabolic state during pregnancy to a catabolic state during lactation is in part due to the reversal of the low sympathetic tone that develops in this tissue during pregnancy. Shortly after parturition, the sympathetic tone in adipose tissues increases. The concentration of norepinephrine in WAT increases, stimulating β-adrenergic receptors on adipocytes, which become more responsive to the activation of lipolysis by cyclic AMP.[430,447–450] At the same time, insulin suppression of lipolysis in WAT and its ability to promote lipogenesis becomes impaired.[451,452] Under normal postprandial conditions or hyperphagia, elevated insulin will activate lipogenic pathways and inhibit lipolysis,[453] resulting in a net deposition of energy in WAT.[454,455] During lactation, impaired insulin sensitivity resulting from decreased expression[456,457] and responsiveness of IR[452,458,459] in WAT blunts the uptake and deposition of energy and diverts ingested energy to the mammary gland.[432,456,460] Evidence from both humans[461] and animals suggests that the PRL secreted after secretory activation may have direct effects on adipose tissues that suppress adiponectin secretion and impair insulin suppression of lipolysis.

In addition to mobilizing the stored lipid, the impairment in insulin signaling decreases the deposition of ingested carbohydrate and protein[430,449,462,463] so that these nutrients can be directed to the mammary gland. Glucose uptake and oxidation decline,[432,451,464,465] making the available glucose carbons for the production of milk.

Liver: An Alternate Source for Carbohydrate, Lipid, and Protein

During lactation, the liver serves as both a way station for endogenous nutrients and a metabolite interconverter to meet the nutrient needs of the mammary gland. Under postprandial conditions, excess nutrients accumulate in the liver and are stored until endogenous sources become less available. Unlike adipose tissues, hepatic lipid is released into the circulation in the form of very low density lipoproteins (VLDL). As such, this lipid becomes available to the mammary gland in much the same form as dietary fat (but via VLDL).

In addition to providing lipid, the liver converts metabolic intermediates into glucose in order to help to provide a regular supply of carbohydrate to the mammary gland. Skeletal muscle provides the precursors in the form of lactate[466] and amino acids[465] to support hepatic gluconeogenesis,[447,467] which increases during lactation.[424] Increased gluconeogenesis has been explained as a consequence of liver hypertrophy, a lower insulin-to-glucagon ratio in the portal vein, and intermittent hypoglycemia.[468] Hepatic glycogen also becomes a source for hepatic glucose production.[469] In humans, glycogenolysis may become the primary pathway for hepatic glucose production under fasting conditions.[470] However, there is evidence that the relative contributions of glycogenolysis and gluconeogenesis vary with species and metabolic state. Regardless, the end result serves to divert glucose to the mammary gland to meet the immense demands of milk production.

Improved Metabolic Control

Despite the fact that studies in animal models suggest that the insulin resistance of peripheral tissues helps to direct nutrients to the mammary gland, studies in humans indicate that this extension of pregnancy-associated insulin resistance resolves as lactation proceeds.[471] This improvement in metabolic control may lead to levels of insulin sensitivity that surpass that of nonlactating controls.[472] The mechanism of this improvement is not well understood, but it likely reflects the depletion of endogenous energy stores.

Trafficking Exogenous and Endogenous Nutrients to the Mammary Gland

Controlled in large part by the rate of milk secretion, active blood flow to the mammary gland increases the delivery of glucose, amino acids, fatty acids, and lipoproteins.[446,473,474] PRL also inhibits the expression of LPL in WAT,[475–477] while increasing LPL expression in mammary gland tissue.[477] This tissue-specific effect of PRL traffics triglyceride carried by chylomicra and VLDL away from WAT and to the mammary gland.

Glucose is the major substrate for synthesis of lactose and glycerol in the mammary gland during lactation. Glucose uptake in the mammary gland significantly increases during lactation, and although blood glucose may be somewhat elevated from lactation-induced hyperphagia, glucose uptake in the mammary gland is elevated independent of dietary supply.[465,478]

In rodents the proportion of long-chain fatty acids in milk is high during early lactation reflecting the mobilization of fat stores.[432] The increased availability of substrate for milk fat synthesis decreases the need for the mammary gland to produce its own lipid via de novo lipogenesis.[446] Endogenous fatty acids from WAT contribute 10–20% of the lipid used for milk fat production,[446] and mice mobilize up to 70% of their adipose reserves during lactation.[432] However, most of these endogenous stores are used up during the first several days of lactation.

Evidence for Impaired Lactation in Maternal Diet-Induced Obesity

Animal Models of High Fat Feeding and Maternal Diet-Induced Obesity

Rodent models of diet-induced obesity have historically been the most common models used to study the effects of obesity on pregnancy and lactation. Typically, obesity is induced by feeding a HF diet using either a cafeteria-style diet where rodent chow is supplemented with high calorie human snacks[439,443,479–481] or a semipurified diet using lard or vegetable oil as the primary fat source.[445,482,483] There are benefits and downfalls of both HF-feeding paradigms. Cafeteria-style diets are more representative of the human condition; however, the specific source of calories is not as well controlled as with semipurified HF diets. Additionally, when a rodent is left to choose its own food there is the potential for deficiencies in essential nutrients, which can have adverse effects on lactation independent of HF feeding.[484,485] Finally, it is important to consider the composition of the fatty acids used to induce obesity, as different types of fat substantially affect milk composition.[22,480,486]

Further, the conclusions that can be drawn from studies with diet-induced obesity models are confounded by the problem that HF diets themselves may have effects on lactation separate from effects of obesity. Typically, short-term exposures to HF diets are employed in lean animals to dissect these two effectors.[445,487–489] This approach is particularly useful in examining how HF feeding affects the various stages of mammary gland development. Separating the effects of chronic HF feeding from obesity is more challenging. To achieve this objective, some researchers have switched HF-fed, obese animals to a low fat diet during pregnancy, lactation, or both.[490] Such an approach, however, reflects an acute dietary change, rather than dissecting chronic HF feeding from the effects of obesity.

Diet-Induced Obesity Impairs Mammary Gland Development and Function

Obesity in dairy cows has long been known to impair milk production,[491] and rodent studies show similar effects.[443,492] When an HF diet was employed for 16 days prior to puberty in the mouse, one group found that the branching frequency and the width of mammary ducts were reduced along with the presence of abnormal myoepithelial cells in virgin mice.[492] In another study, lobuloalveolar development of the mammary gland was impaired when HF feeding was begun after puberty.[443] Morphologically, these authors reported abnormal side

branching and alveolar development by day 14 of pregnancy. In addition they showed a significant difference in mammary gland weight due to the increased size of the fat pad. Decreased pup weight, depressed milk synthesis genes, and the retention of large CLDs in the epithelium by day one of lactation suggested an inherent impairment in milk synthesis.[443] Together, these studies support the concept that diet-induced obesity can interfere with mammary gland function at different stages of development, but they fail to differentiate the effects of chronic HF feeding and obesity.

Unlike its effects on mammary gland development, the impact of HF feeding and obesity on milk production and composition has been relatively well characterized in rodents. The overall consensus is that diet-induced obesity impairs milk production early in lactation.[443,490,493] Observations of delayed pup growth and sometimes even death[479] within the first few days after parturition were an indication of decreased milk production and/or secretion. Additionally, milk composition is altered by HF feeding and obesity.[22,488] As mentioned previously, milk lipid composition is reflective of dietary lipids. However, it has also been shown that HF feeding can increase milk lipid content[480,490,493] as well as decrease milk protein.[443,480] However, in one study HF feeding during lactation actually led to decreased milk fat production.[445] Additionally, feeding conjugated linoleic acid or transfatty acids during lactation has resulted in suppressed milk fat production.[22,486,494] Therefore, the type of dietary fat may prove to be a determining factor in how milk composition is affected.

The effects of high-fat feeding and obesity during lactation on neonatal growth have also been inconsistent[441,443,444,495,496] with some studies reporting impaired neonatal growth linked to lactation defects[443,444] and others reporting increased neonatal growth correlating with an obese phenotype.[495,496] These inconsistencies suggest that the impact of HF feeding and obesity may vary with the stage of mammary development.

Evidence for Impaired Lactation in Humans with Diet-Induced Obesity

There is clear data indicating an increased risk for a failure of breastfeeding in obese women (BMI≥30).[497–500] Based on findings that obese white and Hispanic women are more prone to fail in initiating breastfeeding than normal weight women,[501,502] it has been proposed that obesity delays secretory activation[503,504] possibly by blunting PRL release in response to suckling.[505] Obesity is also associated with a shorter duration of breastfeeding.[497,506–509] Taken together, these studies indicate that obesity is an important risk factor for dysfunctional lactation. However, the biological basis for this increased risk has not been elucidated, and because of the current epidemic of obesity, it is an important area for further research.

MILK EJECTION

Secreted milk is stored in the alveoli and, to a limited extent, in the udder of ruminants. Milk ejection, necessary for milk delivery to the suckling, is effected by the contraction of myoepithelial cells whose processes form a basket-like network around the alveoli (Figure 46.19). Stimulation of nerve terminals in the nipple or teat produces impulses in spinal afferent nerves that reach the magnocellular neurons in the supraoptic (SON) and paraventricular (PVN) nuclei of the hypothalamus. The axons of these neurons run through the pituitary stalk terminating in the posterior pituitary[510] and releasing the nonapeptide, OT, when stimulated. Released OT is carried through the circulation to the lactating mammary gland where it interacts with specific receptors on myoepithelial cells, initiating a coordinated contraction that expels milk from the alveoli into the ducts and subareolar sinuses or udder. Milk ejection is essential for lactation, as shown by the observation that mice genetically deficient in OT have a severe lactation deficit.[511,512] Although milk ejection was the first recognized action of OT, the hormone and its receptors are found in many organs including the brain, where its release is regulated by a wide variety of peptides and hormones.[513] Methods are becoming increasingly available for assessing the effects of targeted mutations on this process. A particularly useful video illustrating techniques for

assessing mammary development from whole mounts of tissue as well as an ex vivo technique for assessing myoepithelial contraction has recently been published.[514]

The Letdown Reflex

Figure 46.20 shows neurophysiological correlates of OT release in rats, humans, and cows. These processes are the subject of an excellent review by Armstrong.[516] The rat nurses her litter for about 30 min each hour. Letdown is delayed for at least 15 min after the attachment of the pups.[510,516] Thereafter, increases in mammary pressure corresponding to OT-induced milk ejection can be measured every 5–12 min (Figure 46.20(A) and (B)). In cows a more sustained release of OT has been measured (Figure 46.20(D)). In women, Cobo and colleagues[517] showed that ejection can be measured as a rise in pressure sensed with a small catheter placed in a mammary duct or noted subjectively by the mother as a "tingling sensation" in the breast prior to or shortly after the start of suckling. When milk was continuously pumped from the breast, these contractions lasted about 1 min and occurred with a frequency of 4–10 contractions per 10 minutes. When measured from blood samples drawn at 2 min intervals, the pulses of OT in the blood stream correspond to these contractile episodes. Unlike OT release in the rat, in women OT release begins prior to suckling in response to the cry of the infant or the mother preparing for the feed[518] (Figure 46.6(C)), indicating a psychological input to the magnocellular OT neurons.

The Neuroendocrinology of OT Synthesis and Release

OT holds the distinction of being the first naturally occurring peptide hormone to be synthesized,[519] a feat for which Vincent du Vigneaud received the Nobel Prize in Chemistry in 1955. OT release involves exocytosis of secretory granules stored in the posterior pituitary following a burst of impulses carried from the OT neurons in the SON or PVN.[510] Immunostaining techniques were used to show that OT is synthesized mainly in magnocellular neurons in these nuclei of the hypothalamus, separate from the vasopressin-synthesizing neurons.[520] Pulse chase experiments showed that OT is synthesized as part of a 30 kDa prohormone in the hypothalamus.[521] After cleavage to smaller subunits, the prohormone is packaged into secretory granules and transported down the axonal

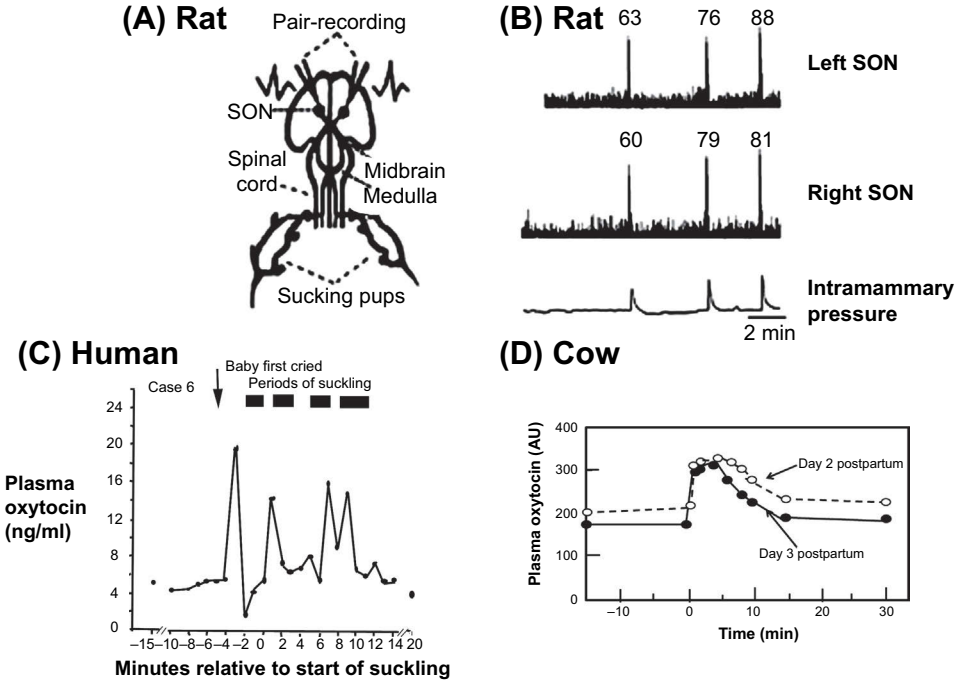

FIGURE 46.20 Oxytocin (OT) secretion. (A, B) Recordings from OT-releasing neurons in the anesthetized rat made simultaneously with recordings of intramammary pressure. Bursts of neuronal activity with firing rates indicated by the numbers above each peak are spaced at 5–12 min intervals. Neurons from both sides of the brain fire simultaneously leading to a pulse of OT release from nerve terminals in the posterior pituitary and a rise in the plasma OT level, followed shortly by a rise in intramammary pressure. (C) OT release in the woman during suckling. Plasma OT rises when the woman first hears the infant cry. Pulses of OT continue during suckling intervals. (D) OT release in the cow showing the prolonged pulse of OT in the plasma during milking on days 2 and 3 postpartum. *Source: (A, B) Used with permission from Wang YF, Negoro H, Higuchi T. Lesions of hypothalamic mammillary body desynchronise milk-ejection bursts of rat bilateral supraoptic OT neurones.* J Neuroendocrinol *2013;**25**(1):67–75. (C) Used by permission from Ref. 515. processes of the SON and PVN neurons to the posterior pituitary. There it is further cleaved to OT and its binding protein, a 10 kDa neurophysin. The complex between OT and neurophysin is stable at pH 5.5, but dissociates at pH 7.4, freeing OT as the complex is released to plasma.[510,522]

The neurophysiology of OT release is complex and subject to regulation by steroid hormones and many other agents.[515,523] Critical to the appropriate release of OT during lactation is conditioning of the OT neurons during pregnancy.[523] OT release requires an increase in cytoplasmic Ca^{++}, both in magnocellular neurons and in nerve terminals; however, the Ca^{++} homeostatic mechanisms differ at the two locations with involvement of the endoplasmic reticulum in the dendrites, but not in the axonal terminals.[524] OT release is modulated by many agents including the sex steroids P4 and E2 as well as norepinephrine[515,523]; the mechanisms involved remain the object of intense study by neurophysiologists.[524,525] Of importance for lactation, endogenous opioid peptide systems inhibit release of OT at the magnocellular neurons in the hypothalamus and at their neurosecretory terminals in the posterior pituitary. Opioids likely also have an inhibitory effect on the cell bodies of afferent input cells that stimulate magnocellular neuron activity.[526]

Myoepithelial Cell Contraction

The processes of the myoepithelial cells lie within the basement membrane of the mammary alveolus and along the interlobular ducts. Autoradiographic studies showed that OT binding sites are similarly localized[527] and that there is 10-fold increase in the concentration of OT receptors in the rat mammary gland during pregnancy. The gradual increase in mammary OT receptor concentration contrasted sharply with the sudden increase in these receptors in the uterus on the day of parturition. The contractile response depends on interaction of smooth muscle alpha-actin (ACTA2) with myosin, and it has been found that lack of ACTA2 expression in null mice leads to severely impaired pup growth.[528] However, it appears that other pathways are involved in relaxation following this contractile response. Raymond et al.[529] found that conditional deletion of a laminin receptor, α3β1 integrin, from myoepithelial cells also led to low rates of milk ejection with impaired phosphorylation of focal adhesion kinase, an altered balance of elements of the Rac/Rho pathway and sustained phosphorylation of myosin light chain. These authors found that the lack of relaxation after OT-induced contraction in vitro could be rescued with constitutively active Rac or treatment with an inhibitor of myosin light chain kinase (MLCK). The authors suggest that α3β1 integrin stimulates Rac signaling that in turn inhibits MLCK activity, bringing about completion of the contraction relaxation cycle associated with milk letdown.

OT also appears to stimulate the growth of myoepithelial cells both in vitro and in vivo. When administered with E2 and P4 via implantable pellets into a virgin mouse mammary gland, it also enhanced myoepithelial differentiation of the cap cells surrounding the terminal end bud.[530] The potential role of OT in stimulating myoepithelial cell proliferation has recently been reviewed.[531]

The OT Receptor

The OT receptor is one of a family of nonapeptide hormone receptors that belong to the seven membrane spaning Rhodopsin-like Class I G-protein coupled receptors.[532] The human OT receptor has 389 amino acids and a core molecular mass of ~40–45 kDa that can be increased by glycosylation. The OT receptor gene has been cloned from a number of species[533,534] and a number of regulatory elements identified in the promoter including a palindromic estrogen response element and a half-steroid response element[534] that may be responsible for the E2-induced stimulation of OT receptor mRNA. In an elegant study, Olins and Bremel[535] found that OT stimulated the influx of extracellular Ca^{++} ions leading to phosphorylation of the myosin light chain in rat mammary myoepithelial cells. Influx of extracellular Ca^{++} ions regulated the duration of the response. There is also evidence that intracellular Ca^{++} stores are involved. Because the OT receptor is found in many locations, both in the brain and in organs such as the myometrium, heart, and peripheral nervous system, it is considered as a prime candidate for pharmacotherapeutic interventions.[536]

Cholesterol is an essential allosteric modulator of OT receptor function as is Mg^{2+},[533] although whether either plays a role in modulation of the activity of this receptor in the mammary gland is unknown. P4 has little effect on mRNA expression but exerts a powerful inhibitory action on receptor activity at a nongenomic level.[537] Whether this effect is mediated by interaction of P4 directly with the OT receptor as reported by Grazzini et al.[538] or by in some way altering the essential interaction of cholesterol with the receptor[539] remains to be elucidated. An interesting question is whether this interaction of cholesterol with the OT receptor plays a role in the elusive mechanism by which secretory activity is downregulated by P4 in late pregnancy.

OT and Maternal Behavior

OT has been implicated in a host of physiological and pathological functions such as stress management, maternal behavior, appetite, and social recognition. In the late 1970s, Pederson and Prange and others noted that intraventricular administration of

OT induced maternal behavior in virgin rats.[540] This observation led to extensive studies of the role of OT in maternal behavior (summarized in Chapter 51 and in Ref. 533). It has been found that OT neurons release the hormone not only from their axons but also from their dendrites in the hypothalamus where it acts on OT receptors that are widely distributed in the brain to decrease anxiety and appetite and facilitate social recognition.[541] It seems likely that these mechanisms are involved in the positive response to nursing observed by many mothers; in rats NMR images showed increased activity associated with OT in regions of the brain associated with mother–pup bonding.[542] The extensive literature relating OT and mood is beyond the scope of this chapter; a number of recent review articles are available for the interested reader.[536,541,543]

CONCLUSION

We are at a strategic junction in research on mammary development and function. Starting from a clear understanding of the systems physiology and biochemistry of milk secretion developed in the 1970s, in the succeeding decades the stages of mammary development as they coordinate with reproductive maturation have been well defined. We know the structures of the genes, mRNAs, and proteins that are involved in both development and the synthesis and secretion of milk components. More recently new technologies have allowed a finer structural definition of the minor components of milk, and we are on the cusp of understanding the role of oligosaccharides, cytokines, and glycosylated proteins in infant development. We have visualized the cell biology of the mammary cell at the level of both the light and electron microscope and now can marry structure and function using advanced immunocytochemical techniques to understand where proteins are located in the cell and how that localization varies with developmental stage and functional activity. Although the role of nutrition in milk secretion has occupied dairy scientists for decades, with the now clear effects of obesity on lactational competence in women, the whole body flux of nutrients and the dietary and hormonal regulation of these processes are coming to prominence. PRL and OT are no longer just hormones that promote milk synthesis and ejection, respectively; it is now clear that they have actions in the central nervous system that regulate nutrient intake as well as maternal-infant bonding. Our next steps are to delve more deeply into the protein–protein interactions that mediate both regulation of mammary development and milk secretion and to come to an improved understanding of how the nutrient and emotional demands of lactation fit into systemic metabolism.

A few of the many interesting questions that we must address in the next decades are:

1. Molecular regulation of mammary development
   - **a.** Ductal development: What regulates the temporal and special pattern of expression of the receptors for the hormones, particularly estrogens, and growth factors that regulate development? Is this pattern of expression established within the mammary stem cell compartment, and does it respond to environmental factors?
   - **b.** Alveolar proliferation and differentiation in pregnancy: While we know that changes in circulating P4, PRL, and PL drive these processes, what are the molecular pathways that lie between the receptors for these hormones and the genes whose expression is changed?
   - **c.** What are the roles of microRNAs, gap junction proteins, insulin, and other factors in secretory differentiation in pregnancy?
   - **d.** Could the inhibitory effects of P4 on milk secretion in late pregnancy be mediated by P4 interaction with the OT receptor in myoepithelial cells?
   - **e.** What are the membrane channels that mediate transfer of monovalent ions at both the apical and basolateral membrane? How do they change with development and what are the mechanisms by which they are regulated?
2. Involution
   - **a.** How do the many signaling molecules that have been shown to affect involution interact at the molecular level?
   - **b.** What is it that macrophages do to facilitate the involution process?
   - **c.** Do the tight junctions play a role in the increased Na^+ and Cl^- in milk during involution and mastitis, or does increased stress on the alveolar cells set in motion purinergic pathways that alter secretion and transport in alveolar cells? Could ATP and UTP be the elusive "feedback inhibitors of lactation" that have been shown to be present in both ruminant and human milk?[544,545]
   - **d.** In addition to macrophages, are there other immune cells and factors that interact with the involution process?
3. Nutrition, metabolism, and mammary development
   - **a.** Are SREBP and STAT5 the only transcription factors that drive alveolar development in pregnancy, and how is this process modulated by diet, obesity, or malnutrition?

   b. What is it that macrophages do to facilitate the involution process?
   c. What are the mechanisms by which nutrients are directed toward the lactating mammary gland for milk synthesis?
   d. How are the activities of organs such as the liver, digestive tract, and heart stimulated in lactating animals? Are hormones involved? If so, which ones, and by what mechanisms?
   e. What are the mechanisms that regulate appetite so that food intake is upregulated to meet the demands of lactation?
4. Systemic factors regulating milk secretion and ejection in lactation
   a. How do obesity and food intake interact with mammary gland development and milk secretion to alter lactation?
   b. Can we utilize the mRNA from the MFG to analyze the molecular basis of effects of obesity, emotional state, immune disorders, etc., on lactation in women?
   c. What are the mechanisms by which infant gender and maternal emotional states alter milk secretion and composition?
5. Interactions between the immune system and mammary development and function
   a. What are the details of the interaction of dIgA with its receptor and the cleavage event that releases secretory IgA into the milk?
   b. More recent evidence indicates that immune cells such as macrophages and eosinophils are necessary for both ductal development[546] and involution.[183] What other immune interactions promote or impede mammary development, particularly during pregnancy?
   c. Are there specific immune reactions that link maternal diseases, obesity, and metabolic disorders to lactation?
6. The maternal and infant microbiome
   a. What are the critical nonnutrient components that support normal neonatal development, and how do they interact with the infant gut and immune system?
   b. What components of milk foster development of the infant microbiome, and how is their secretion into breast milk regulated?
   c. If microbes from the mother are actually transferred to the infant through the milk, how do they get across the mammary epithelium? Is the process selective?
7. Lactation and breast cancer
   a. How does breast-feeding before the age of 30 suppress breast cancer risk?
   b. What are the mechanisms by which pregnancy promotes breast cancer risk?

Acknowledgments

The work of all four authors has been supported by Program Project NIH PO1-HD38129, and many students and fellows joined in the work described in this chapter. We would particularly like to acknowledge the work of Michael Rudolph and Elizabeth Wellberg in Steve Anderson's laboratory; Jessica Wahlig, a joint student of Paul MacLean and Jim McManaman; Jennifer Monks, most recently an instructor in Jim McManaman's laboratory; Tanya Russell, a graduate student in Jim McManaman's laboratory; and Palaniappan Ramanathan, Neal Beeman, and Heide Baumgartner-Wilson in Margaret Neville's laboratory.

CHAPTER

47

Sexual Differentiation of Brain and Behavior

INTRODUCTION

The vast majority of vertebrates come in two sexes: male and female. Because at most half of the individuals (i.e., females) in a sexually reproducing species ever give birth, this severely reduces their reproductive potential, something that has been referred to as "the cost of producing males".[1] The textbook explanation for why sexual reproduction is so ubiquitous, despite this large cost, is that sexual reproduction allows for genetic variability, which can be an advantage in a highly variable world. There is, however, surprisingly little direct evidence to support this theory, and there is some evidence to the contrary.[2] Another, not mutually exclusive theory proposes that sexual reproduction provides a mechanism for minimizing the number of mutations within a population, most of which will be neutral or mildly deleterious.[3] Yet another theory states that the rapid evolution afforded by sexual reproduction allows a population to outrun pathogens, or outcompete other organisms, thereby holding on to a niche that it already occupies.[4] This "Red Queen Hypothesis" is named after a character in Lewis Carroll's *Through the Looking Glass* who has to run as fast as she can just to stay put. Remarkably, none of these three leading theories have as yet been accepted as fully satisfactory explanations for the existence and pervasiveness of sexual reproduction among eukaryotes.[5] As Margulis and her colleagues gently mocked some years ago, "Sexual reproduction is still a waste of time and energy".[6]

In contrast to our fuzzy understanding of why, exactly, sex evolved, its biological consequences are often clear. To put it briefly: *where there is sex, there are sex differences*. In practically all cases where reproduction involves males and females, organisms can be easily distinguished based on male- and female-typical anatomical, physiological, and behavioral characteristics, which we will refer to as masculine and feminine traits in this review. For example, to reproduce, males typically generate an abundance of small germ cells (sperm), whereas females make many fewer, large cells (ova). Males and females also typically display different behavioral strategies, the ultimate explanation of which is to maximize the chances that their germ cells will fuse with those of the opposite sex to produce viable offspring. In addition to differences in morphology, males typically show one set of reproductive behaviors, whereas females show another. Such differences have presumably been selected for whenever they enhanced the chances of successful mating. Depending on the species, males and females may also show differences in behaviors and cognitive functions that are not directly related to reproduction; such traits may indirectly contribute to the reproductive potential of the organism or may simply be pleiotropic consequences (essentially, side effects) of the sexual differentiation of reproductive processes.

Sex differences in behavior have inspired researchers to look for underlying causes in the brain. Not all of this research has withstood the test of time. In the nineteenth century, for example, men's brains were reported to be heavier and more symmetric than those of women, differences that were presumed to reflect differences in intellect.[7,8] Even though recently sex differences in gross structure of the human brain that cannot be explained just by differences in body weight have been confirmed,[9–12] this line of research did not get much traction, probably at least in part because of the dubious interpretations. Two lines of animal research rekindled interest in sex

Knobil and Neill's Physiology of Reproduction, Fourth Edition
http://dx.doi.org/10.1016/B978-0-12-397175-3.00047-8

differences in the brain in the second half of the twentieth century, one physiological and the other behavioral. The first started with a classical experiment by Harris and Jacobsohn done in the early 1950s, aimed at clarifying why females generate surges in gonadotrophic hormones (associated with ovulation), whereas males exhibit more tonic release.[13] They showed that female rats with male pituitary transplants placed under their hypothalamus still exhibited ovarian cycles.[13] This important demonstration disproved the idea that pituitaries or gonads were driving the sex difference in gonadotropic hormone release and pointed instead to sex differences in the brain, specifically the hypothalamus. A couple of years later, Barraclough et al. showed that neonatal injections of testosterone led to infertility in female rats.[14,15] After demonstrating that the anterior preoptic area of the hypothalamus drives cyclicity in gonadotropic hormone release, they suggested that "the anterior preoptic area is undifferentiated at birth with regard to its subsequent control of gonadotropin secretion", and that, in the absence of androgen, the anterior preoptic area differentiates to sustain cyclicity (as in females), whereas in the presence of androgen it "becomes refractory to both intrinsic and extrinsic activation, and the more tonic type of male gonadotropin secretion is observed."[16] Although this paper related to the function rather than structure of the brain, it suggested a fertile region to look for sex differences in brain structure.

Many previous reviews have catalogued sex differences in the mammalian brain,[17–26] and we will not attempt to repeat that here. Instead, we will focus on mechanisms for generating neural sex differences, and will highlight new areas of investigation in this field. We also will consider, in some depth, the function of neural sex differences. Although some sex differences in the nervous system can be related to differences in physiology and behavior, we find that in most cases the extent to which neural structure relates to function remains unclear.

A BRIEF HISTORY AND DEFINITION OF TERMS

Sex differences in physiology and behavior were recognized long before scientific attempts were made to study the causes and consequences of such differences. One of the first studies, often cited as a foundation of modern research in the differentiation of the brain and behavior, built on something farmers had known for centuries: that castrating a male chick early in life produces a capon, an animal lacking many of the masculine traits of the normal, gonadally intact rooster. In 1849, Berthold showed that if a castrated male chick was given a testis transplant, it developed the typical male, rooster-like phenotype.[27] Not only did those animals look like intact roosters, but they crowed and postured like roosters as well, instead of showing the "feighaft" (timid) behavior common to capons. This result led to the important insight that substances produced by the testes caused the behavioral differences between roosters and capons. Where these substances (which we now know are gonadal hormones) acted to change behavior was not really addressed, however, for another 100 years.

The idea that sex differences in gonadal hormone levels early in life cause lasting sex differences in behavior was first clearly stated by Phoenix et al., who found that injecting pregnant guinea pigs with testosterone permanently masculinized the sexual behavior of their female offspring.[28] Even though these authors only speculated that neural tissue (i.e., the brain) itself was sexually differentiated, their hypothesis—that during development, steroid hormones have permanent or, as they labeled it, "organizational" effects, as opposed to the transient, or "activational", effects that occur later in life—remains a fundamental principle of sexual differentiation of brain and behavior (as discussed in this chapter). Over the last 50-plus years, the "organizational hypothesis", as this idea was soon dubbed, has guided numerous researchers in their study of behavioral and neural sex differences, and their causes and consequences (Figures 47.1 and 47.2). The fact that the organizational hypothesis was developed to account for sex differences in behavior may be why, even today, a search in PubMed for papers with "sex differences" in the title turns up an inordinate number of studies in those disciplines related to behavior: neuroscience, psychology, and psychiatry.

Use of the terms "organizational" and "activational" to distinguish between permanent and transient effects of gonadal steroids, respectively, has had enormous heuristic value, and the organizational hypothesis was justifiably honored with a special issue in *Hormones and Behavior*,[29] and an editorial in *Endocrinology*[30] on the occasion of its 50th birthday in 2009. Nonetheless, we would like to argue that it may be time for a change. The term "programming" is currently used in most other fields of biology to describe lasting effects of endogenous as well as exogenous factors on biological functions, including factors involved in sexual differentiation of gonadal tissue (see, e.g., Ref. 31). As there are no reasons to assume that differentiating effects of gonadal hormones on brain function differ in principle from other programming effects, holding on to the term "organizational" may become a hindrance to communicating with scientists in other fields and in uncovering general principles that underlie long-lasting effects of gonadal hormones on the development of the brain and behavior. Likewise, as the term "activational" is usually used only in the context of the "organizational hypothesis", we will emphasize the more widely understood term "acute effects" throughout this review.

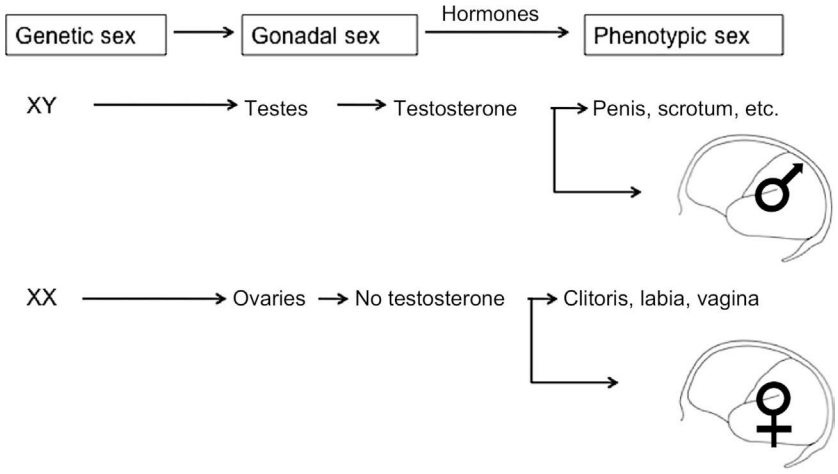

FIGURE 47.1 The organizational hypothesis, originally proposed by Phoenix and collegues and subsequently amended by many others, emphasizes the role of testosterone in sexual differentiation of the body and brain. In genetically male mammals (XY), the undifferentiated gonads develop into testes, which then secrete testosterone. This testosterone acts as an androgen or after conversion to an estrogen to masculinize the body and brain. In genetic females (XX), the undifferentiated gonads develop as ovaries; testosterone is not produced, and the female phenotype results. Such "organizational" or "programming" effects of testosterone can account for many of the known sex differences in the neurobiology and behavior of mammals. *Source: Original artwork by S. Marc Breedlove.*

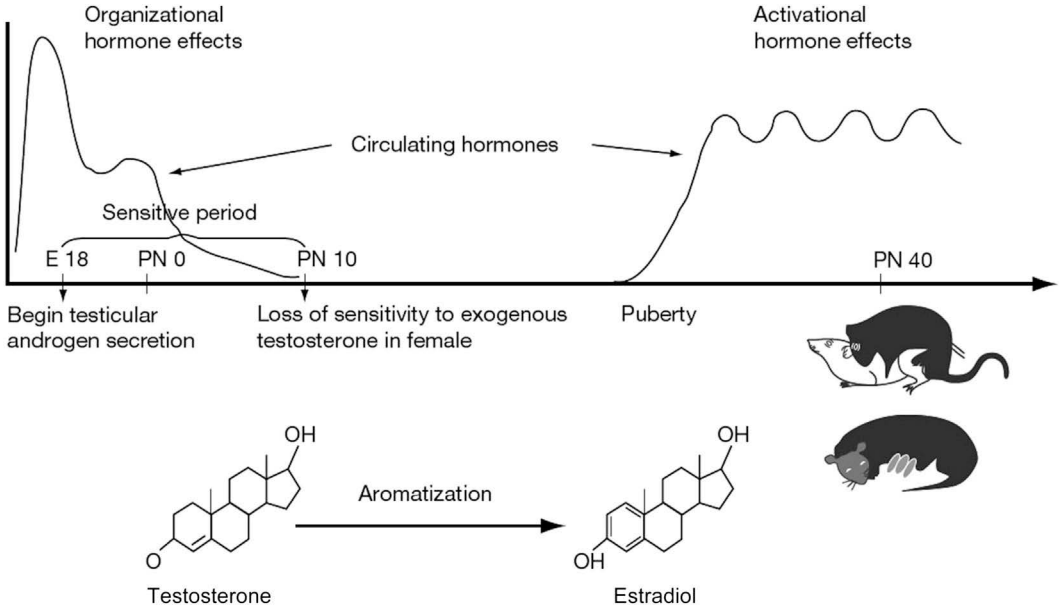

FIGURE 47.2 The organizational–activational hypothesis of steroid hormone action as it applies to laboratory rats, a species intensively studied in the sexual differentiation field. A perinatal sensitive period is operationally defined as the onset of gonadal steroid synthesis in males, beginning prenatally around embryonic day (E) 18, followed by a second surge on the day of birth (postnatal day (PN) 0) and the loss of sensitivity of females to exogenous steroid administration, which is usually around PN10. During the sensitive period, steroids are said to have organizational or programming effects because they are largely permanent. The organized, or programmed, neural substrate is then acted upon by adult, circulating steroid hormones and may cause the expression of sexually dimorphic behaviors, such as sexual behavior, or may coordinate behavior so that it is similar in both sexes, such as parenting behavior. Alternatively, the acute, or activational, effects of steroids in adults may be entirely independent of organizational–programming effects and may induce temporary sex differences. Testosterone can be converted to one of several estrogenic hormones via a process known as aromatization. Many of the effects of testosterone on the brain and behavior of rodents are secondary to its aromatization to estradiol, especially in rodents. *Source: Adapted with the permission of Elsevier from Ref. 24.*

This chapter will focus especially on the process by which male and female brains become different, first by identifying the roles of gonadal hormones, sex chromosomes, and environmental factors in brain differentiation. Next, we discuss the molecular and cellular targets of these factors, as well as the role of context in the expression of sex differences. Although much of the evidence in the foregoing sections focuses on animal models, we follow with a section on sexual differentiation of the brain and behavior as it applies to humans and conclude by presenting some emerging concepts and future directions in the field.

AGENTS OF SEXUAL DIFFERENTIATION

Perhaps the most important strategy that has been brought to bear on the question of how sex differences in behavior arise has been drawing upon lessons learned about how sex differences in body structure arise.

This strategy was made explicit in the aforementioned groundbreaking paper by Phoenix et al.[28] and has been fruitfully followed since. Taking cues from sexual differentiation of the periphery not only offers testable hypotheses but also helps constrain the number of possibilities that one might consider, or at least suggests which possibilities are more likely to pay off. As we'll see, as of this date, the approach has been very successful. Many sex differences in behavior, in nonhuman animal models at least, have been successfully manipulated by altering one or another factor that has been shown to underlie differentiation of the body. This success itself suggests that natural selection has hit upon a limited number of mechanisms to accomplish sexual differentiation, of either the body or the brain. Thus, when one chances upon any sex difference in behavior, one can systematically test each of the factors shown to underlie sexual differentiation of the periphery to see whether that same factor underlies sexual differentiation of the behavior in question.[32]

We can categorize the factors that have been found to affect the development of sex differences in the body into three classes.

Sex Chromosomes

Some sex differences result from differences in the inheritance of genes, specifically chromosomes that are found exclusively in one sex. Among vertebrates, this mechanism is especially important in mammals, in which only males inherit a Y chromosome and are therefore heterogametic, and birds, in which females are the heterogametic sex.[33] In these species, sex chromosomes trigger a molecular cascade that ultimately determines whether the embryonic gonad, which initially is undifferentiated or "bipotential", will develop as an ovary or a testis.[34] In mammals, the *sex-determining region of the Y chromosome* (*Sry*) gene, in cooperation with several other downstream genes, induces the indifferent gonad to develop as a testis.[35,36] In the absence of *Sry*, as in most XX individuals, the indifferent gonad will develop as an ovary.

We will see that some sex differences in behavior also appear to develop under the direct influence of genes on the sex chromosomes, including possibly *Sry* itself (see the section The Role of Sex Chromosomes). Note that in other vertebrates, including many reptile and fish species, there are no sex-specific chromosomes or genes. Instead, environmental factors, such as the temperature at which the egg is incubated, regulates the expression of genes that trigger development of either an ovary or a testis.[37,38] The gonads then arrange for individuals of the two sexes to be exposed to different levels of steroid hormones, which accounts for many secondary sex characteristics.

Gonadal Hormones

Regardless of how the fate of the bipotential gonads is determined, much of the sexual differentiation of the body is directed by hormonal secretions from the gonads. Paraphrasing Jost's classic formulation, genetic sex determines gonadal sex and gonadal sex in turn determines phenotypic sex (see Figure 47.1).[39] Genetic sex affects gonadal development via differential gene expression, but gonadal sex affects phenotypic development via hormone release. Of course, any hormone that affects the development of an organ, including the brain, is likely to do so by directly or indirectly regulating gene expression in that target organ, so we may think of the gonads as using hormones as intermediaries in regulating gene expression in other tissues.

In mammals, several testicular secretions are crucial for development of a male phenotype. Anti-Müllerian hormone (AMH; also called Müllerian-inhibiting hormone), is secreted by Sertoli cells and, as the name implies, suppresses development of the precursors of the female duct system, the Müllerian ducts, thereby averting development of the oviducts, uterus, and inner vagina.[40] It is the earliest product known to be secreted by the fetal testis; in mice, this occurs from embryonic day E12.5 until about 1 week postnatally.[41,42] In females, AMH is expressed by granulosa cells in the ovary, but only from postnatal day 6 onward.[41] Other, often overlooked testicular products play a role as well. For example, insulin-like factor 3 (INSL3) triggers the shortening of the gubernaculum, a ligament that at one end connects to tissue that will become the scrotal wall and at the other end connects to the testis. Shortening of the gubernaculum pulls the testis through the inguinal canal into what will become the scrotal cavity. Thus, mice with a mutation in either INSL3 or its receptor develop cryptorchidism.[43,44] Although AMH and INSL3 have traditionally been thought to play roles only in sexual development of the periphery, several recent studies suggest a role for AMH in sexual differentiation of the brain and behavior in both mice and humans (Figure 47.3).[45–47]

The main testicular products directing masculine development form a class of steroid hormones known as androgens, including the principal testicular secretion, testosterone (Figure 47.2). Androgens are responsible for "virilizing" Wolffian duct structures, precursors of the male duct system, and for shaping the external genitalia into a masculine form. They are also responsible for almost all male secondary sexual characteristics.

Nearly all work on sexual differentiation of the brain and behavior has focused upon the notion that testosterone or its metabolites are responsible for masculinizing males and, to a truly remarkable extent, this has turned out to be the case. In the accounts that follow, it will almost always be the action of testosterone, acting

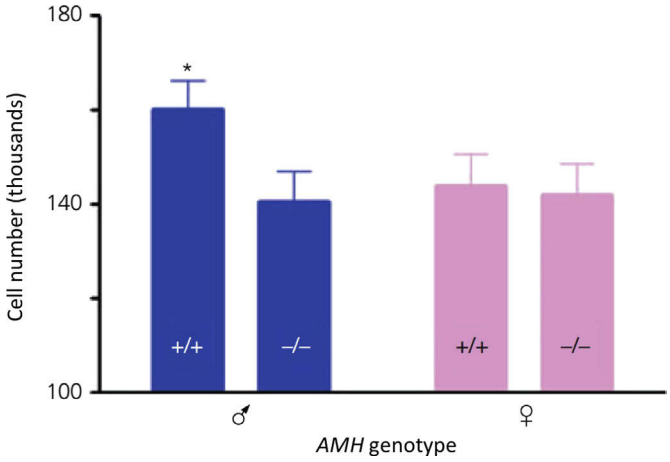

FIGURE 47.3 Anti-Müllerian hormone (AMH) influences some sex differences in the brain. This figure illustrates the number of Purkinje cells in the cerebellum in wild-type and AMH-knockout male and female mice. There is a male bias in the number of Purkinje cells in wild-type mice that is eliminated in the AMH knockouts, indicating that this particular sex difference depends on AMH. These findings suggest that testosterone is not the only gonadal hormone that is important for sexual differentiation of the brain. Significantly different compared to female and *AMH−/−* male mice. *Source: Adapted with the permission of John Wiley and Sons from Ref. 45.*

upon androgen receptors (ARs), (following conversion to estrogen) estrogen receptors (ERs), or both ARs and ERs, that shapes the developing brain into a masculine configuration and masculinizes behavior. Indeed, this outcome is so pervasive that exceptions to the rule will command some additional consideration in this chapter (see the section The Role of Sex Chromosomes).

Environmental Factors

The category of environmental factors is not only broad but also, for all practical purposes, infinite. But in terms of the sort of factors that might play a role in sexual differentiation of the nervous system, the list of those that have actually been examined by scientists is not quite so long. In fact, those other factors can be roughly divided into (1) environmental factors that mimic or interfere with hormonal signaling systems (e.g., endocrine disruptors), and (2) social influences.

There are some studies of nonhuman species demonstrating that social influences affect sexual differentiation of behavior, and even a few that demonstrate social influences on nervous system structure or function.[48–50] What makes these few studies especially noteworthy is the possibility that they may relate to social influences on the sexual differentiation of brain and behavior in our own species. As the gender roles of humans differ considerably across cultures and have changed appreciably across history, it is obvious that society exerts powerful influences on sex differences in human behavior.

This social influence on gendered behavior in humans appears to begin at birth. In a series of studies that are sometimes referred to as "Baby X" experiments, adults are handed a newborn infant, whose sex is clearly communicated, and then observed to see how they interact with the child. On average, adults of either sex spend more time looking into the baby's face and talking to the baby if they believe that the child is a girl than a boy. They are also more likely to bring a doll into play with the child if they believe it is a girl.[51] Conversely, they interact more physically, moving the child around through the air, if they believe the child is a boy than a girl.[52] These differences in adult behavior are not cued by the infant's preferences, because the genuine sex of the baby has no discernable effect on the adults' behaviors.[52] It is impossible to rule out the possibility that differences in how adults interact with babies, based on what they perceive as the child's proper gender, play a role in the later unfolding of sex differences in verbal ability (favoring females) and rough-and-tumble play (favoring males), among others.

Nevertheless, we will see evidence that hormones play a role in sexual differentiation of some human behaviors. Evaluating that evidence requires us to consider whether social influences may have in fact played a role. For example, as boys engage in more rough-and-tumble play than do girls, then the question is whether that sex difference comes about via the same mechanisms that direct sexual differentiation of the body, or via social interactions with other humans who encourage physical activity more often in boys than in girls, and encourage verbal social interactions more often in girls than in boys. Perhaps not surprisingly, both biological and social factors play a role and in some cases may reinforce each other.[53,54]

THE ROLE OF SEX CHROMOSOMES

The role of gonadal hormones in sexual differentiation was known long before the genetic basis of sex was firmly established. As mentioned in this chapter, the work of Berthold in the nineteenth century, and Jost and others in the first half of the twentieth century, highlighted the crucial role of the testes in masculinization. It was not until 1959 (interestingly, the same year as the groundbreaking work by Phoenix, Goy, Gerall, and Young, also mentioned here) that the Y chromosome was established to be testis determining in mammals,[55,56] and it would take an additional 30+ years before the testis-determining gene, *Sry*, was identified.[35] This may help to explain why, until quite recently, the prevailing view has been that although the sex chromosomes determine which gonad develops, it is hormones from the gonad that do the rest of the work as far as sexual differentiation

is concerned. It is now clear that this idea is in need of revision as evidence for direct, gonad-independent effects of sex chromosomes has accumulated. On the basis of this new evidence, it may be time for a revised, unified view of sexual differentiation that recognizes the primacy of genetic factors and is, as one author has put it, less "gonad-centric" (Figure 47.4).[58]

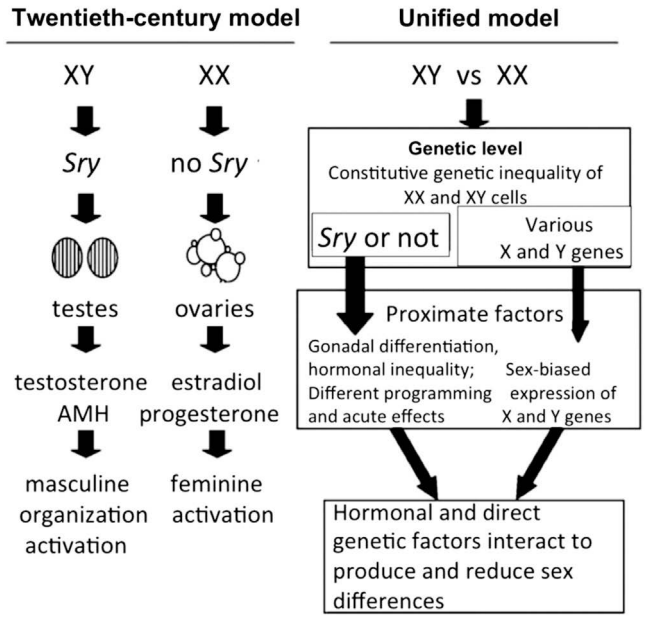

FIGURE 47.4 Contrast between the predominant twentieth-century model to explain sex differences in the phenotype of tissues, with a revised, unified model. In the twentieth-century model, the sexual differentiation of the gonads is ascribed to the male-specific effect of the Y-linked gene *Sry*. Once the gonads have differentiated, they secrete different sex steroid hormones. As described in Figures 47.1 and 47.2, these act on diverse tissues (e.g., the genital tracts and brain) in the fetal and neonatal male to cause masculine patterns of development resulting in permanently sexually differentiated substrates. Later in life, ovarian and testicular hormones act differentially on those substrates to create further sex differences in phenotype. In contrast, the unified model recognizes that *Sry* and other (to be identified) X and Y genes occupy the same primary logical level because they are all unequally encoded by the sex chromosomes in males and females. Some X and Y genes act in a sex-specific manner, on the gonads and other tissues, to cause sex differences in XX and XY cells. *Sry* plays a dominant role by setting up the lifelong sex difference in secretion of gonadal hormones, which have organizational–programming and activational–acute effects on the brain and other tissues. Because of the independent sex differences in sex chromosome genes and in hormonal secretions, the various sex-specific factors interact in one of several ways. Their effects are synergistic (as, e.g., when Y factors and testicular testosterone both push the male's tissues to function differently than in females), or they counteract each other to reduce sex differences (e.g., when the female-specific process of X inactivation shuts down one X chromosome in each female cell to counteract the female bias in X gene expression that would otherwise occur). With minor modification, the schema shown here can apply equally to birds or other groups that have a constitutive sexual imbalance of sex chromosome genes, by substituting species-appropriate sex determining gene(s) for *Sry*. *Source: Reproduced with permission of Elsevier from Ref. 57.*

Sex chromosome complement is the only thing that differs between XX and XY zygotes. As described here, one very important consequence of this genetic difference is the specification of testis development by the Y chromosome gene, *Sry*. And, indeed, a host of sex differences follow as a result of testis formation and exposure to the hormones produced by the testes. However, some sex differences are independent of the gonads. It has long been known, for example, that in tammar wallabies, differentiation of the scrotum versus pouch is controlled by the number of X chromosomes and not by gonadal hormones.[59] There is also more recent evidence that gene expression in very early XX and XY embryos differs prior to the time of gonad differentiation. For example, nearly one-third of the actively expressed genes in the bovine embryo may be expressed differently in males and females as early as the blastocyst stage,[60] that is, well before the formation of ovaries or testes.

Another approach to examining gonad-independent effects on sexual differentiation has been the use of animals in which no testes or ovaries form. In mice lacking the gene for steroidogenic factor 1 (SF1), for example, the undifferentiated gonads initially form, but then regress at an early stage.[61] Female duct structures and external genitalia are present in XY SF1-knockout animals, indicating that, indeed, there has been little or no exposure to testosterone or AMH.[61] These mice therefore provide an opportunity to examine the development of XX and XY animals in the absence of hormones produced by their own gonads. A caveat to this model is that the adrenals also do not form (animals are kept alive by glucocorticoid replacement at birth and later adrenal transplants), and there is a disruption in the development of at least one brain region, the ventromedial nucleus of the hypothalamus,[62] which is independent of the effect of the SF1 gene knockout on peripheral tissues.[63] Abnormalities in the brain and behavior of SF1 knockouts therefore could be due to a number of causes. Nonetheless, since SF1 gene deletion prevents the formation of the gonads, adrenals, and VMH in both XX and XY mice, any sex differences remaining in SF1-knockout mice likely reflect sex chromosome complement.

As predicted by the traditional view of gonadal steroid-dependent sexual differentiation, many sex differences in the body, brain, and behavior are eliminated in SF1-knockout mice. For example, size of the sexually dimorphic nucleus of the preoptic area (SDN-POA) is normally larger in males than in females of several species (Table 47.1), due to the actions of testicular steroids acting early in development. The SDN-POA is completely female-like in SF1 knockouts, regardless of whether they are XX or XY,[153] confirming an essential role for the gonads in the differentiation of this brain region. There are exceptions, however. Male wild-type mice have more of the enzyme neuronal nitric oxide

TABLE 47.1 Examples of Several Well-Studied Sex Differences in the Rat Brain and Their Underlying Causes

Neural Area	Nature of the Sex Difference in Rats	Likely Cause(s) of the Sex Difference	Other Species Examined
Preoptic area of the hypothalamus (POA)	Males have more dendritic spines on neurons, more complex morphology of astrocytes; and more activated microglia than do females.[64–66]	Testosterone acts perinatally after conversion to an estrogen to program all three differences. Estradiol induces prostaglandin-E_2 synthesis to alter dendritic spines and microglia.[64–66]	n/a
Sexually dimorphic nucleus of the preoptic area (SDN-POA)	Males have larger volume and larger neurons and more neurons than females in this densely staining subregion of the POA.[67]	Testosterone acts perinatally after conversion to an estrogen to prevent cell death in males.[68–74]	Homologous cell group also larger in male mice, gerbils, guinea pigs, ferrets, hyenas, sheep, monkeys, and humans.[75–85]
Spinal nucleus of the bulbocavernosus (SNB)	SNB motoneurons are larger and more numerous in males than females. These motoneurons reside in the spinal cord and innervate striated muscles of the phallus.[86]	Testosterone acts via androgen receptors to prevent the death of SNB cells perinatally. The hormone likely acts at the target muscles, with SNB cells rescued indirectly.[87–94]	Similar sex difference in most other mammals studied to date, including mice, gerbils, dogs, hyenas, monkeys, and humans.[95–99]
Anteroventral periventricular nucleus (AVPV)	Females have larger volume and more neurons than males in this hypothalamic nucleus located near the rostral extreme of the third ventricle.[100]	Testosterone acts perinatally after conversion to an estrogen to increase cell death in males.[73,101–104]	Similar sex difference in mice.[105,106]
Bed nucleus of the stria terminalis, principal nucleus (BNSTp)	Males have larger volume and more neurons than females in this relatively large forebrain structure.[107,108]	Testosterone acts perinatally after conversion to an estrogen and via estrogen receptor α to prevent cell death in males. Androgen receptors also play a role in masculinization of BNSTp volume.[74,78,107,109–112]	Homologous cell group also larger in males in guinea pigs, mice, and humans.[78,105,113]
Medial amygdala, posterodorsal division (MePD)	Males have larger volume, and more neurons and astrocytes, as well as larger neurons and astrocytes, than females. These sex differences are hemisphere dependent.[108,114,115]	Dependent on both androgens and estrogens acting in adulthood; testosterone increases MePD volume in adult males.[115–117]	Similar sex difference in mice.
Vasopressin expression	Males have more vasopressin-expressing neurons in the bed nucleus of the stria terminalis and medial amygdala, and denser projections to target regions, than do females.[118–121]	Testosterone acts perinatally via both androgen and estrogen receptors to increase the number of vasopressin neurons. Also a direct effect of the Y chromosome on vasopressin cell number. Gonadal hormones influence the decision to make vasopressin, rather than by altering cell death, and are required in adulthood for maintenance of vasopressin expression.[121–132]	Similar sex difference in most other vertebrates studied to date, including frogs, lizards, birds, and mammals; too numerous to list here but reviewed elsewhere.[133,134]
Kisspeptin expression	Females have many more cells expressing the peptide kisspeptin in the AVPV than do males.[135]	Testosterone acts perinatally after conversion to an estrogen; cell death does not seem to be involved in establishing the sex difference. Gonadal steroids also regulate expression in adulthood.[135–137]	Similar sex difference in humans and animals as diverse as mice and fish, but no sex difference in lizards.[138–142]
Estrogen receptor	Females have more estrogen binding (or, in later studies, more estrogen receptor alpha protein or mRNA) in the POA than do males.[143–146]	Dependent on programming and acute effects of gonadal steroids; testicular steroids downregulate receptor expression in males.[144,147,148]	Similar sex difference seen in mice and voles.[149–152]

synthase in the anteroventral periventricular nucleus (AVPV) than females, and this sex difference persists in SF1-knockout mice.[153] The existence of a sex difference in the knockouts (i.e., in the absence of gonads) suggests a contribution of sex chromosomes to the development of this neural trait.

For some traits, a sex difference seen in wild-type mice is reduced but not eliminated in SF1 knockouts, suggesting that both gonadal steroids and sex chromosomes may contribute to the dimorphism. For example, when gonadectomized in adulthood and treated with estradiol followed by progesterone, wild-type female mice show much more female sexual behavior than do similarly treated wild-type males.[154] Although this female sex behavior is reduced in both XX and XY SF1-knockout mice, a sex difference nonetheless persists: XX SF1 knockouts exhibit higher lordosis quotients and receive more intromissions during testing than do XY knockouts (Figure 47.5).[155] Again, a contribution of sex chromosome genes, independent of their effects on the gonads, is suggested but not directly proven by this finding. Additional results using this model have recently been reviewed.[156]

A second and very effective mouse model used to directly test for the effects of sex chromosomes on sexual differentiation is the so-called Four Core Genotypes (FCG) model.[157] In this model, the *Sry* gene is deleted from the Y chromosome (designated Y-, or Y-minus) and inserted on an autosome. Whether an animal is XX or XY, if it inherits the autosomal *Sry* gene, testes will form and testicular hormones will be produced. By crossing wild-type XX females with XY-mice with a transgenic copy of *Sry* on an autosome (XY^- *Sry*, which are for all intents and purposes "males"), four types of offspring are obtained: XX (wild-type female), XX *Sry* (essentially, chromosomal females with testes), XY^- (essentially, chromosomal males with ovaries), and XY^- *Sry*.[157] Using this model, evidence has steadily accumulated for direct effects of sex chromosomes on the brain and behavior.

For example, midbrain neurons harvested from XY^- embryos show greater expression of tyrosine hydroxylase, the rate-limiting enzyme for dopamine biosynthesis, than do neurons harvested from XX embryos, regardless of gonadal sex.[158] The sex difference in vasopressin innervation of the lateral septum (see Table 47.1) is also in part dependent on sex chromosome complement, because animals with a Y chromosome (XY^- *Sry* and XY^-) have more vasopressin than XX mice, regardless of which gonads are present (Figure 47.6(A)).[122,157] Evidence has also been reported for direct, gonad-independent effects of sex chromosomes on aggressive and parenting behavior,[122] responses to noxious stimuli,[159] social and investigatory behaviors,[160,161] and habit formation.[162,163]

One caveat to the FCG model is that one can never be completely sure that XX *Sry* and XY^- *Sry* groups (XX and XY males) are exposed to exactly the same gonadal hormone levels perinatally. The testes of XX males are smaller than those of XY^- males and are infertile, for example, because genes on the Y chromosome other than *Sry* are required for spermatogenesis. It is possible

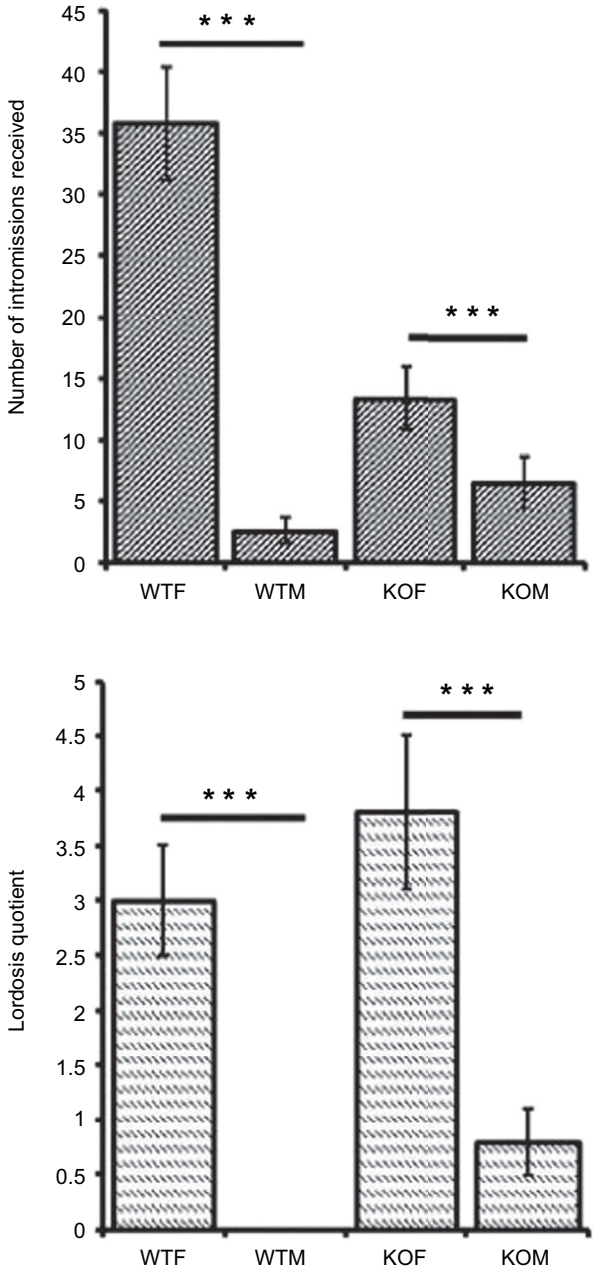

FIGURE 47.5 A sex difference in female sexual behavior persists in SF1-knockout mice. Wild-type female (WT F) and wild-type male (WT M) mice were compared to female and male SF1-knockout mice, which develop in the absence of gonads. Wild-type animals were gonadectomized at weaning, and all animals received estradiol and progesterone to stimulate sexual behavior. The top figure shows average lordosis quotient (a measure of receptivity), and the bottom shows intromissions received from the males over seven sexual behavior tests. Females show more feminine sexual behavior than do males, regardless of whether they are wild-type or SF1 knockouts. *Source: Adapted with permission of Elsevier from Ref. 155.*

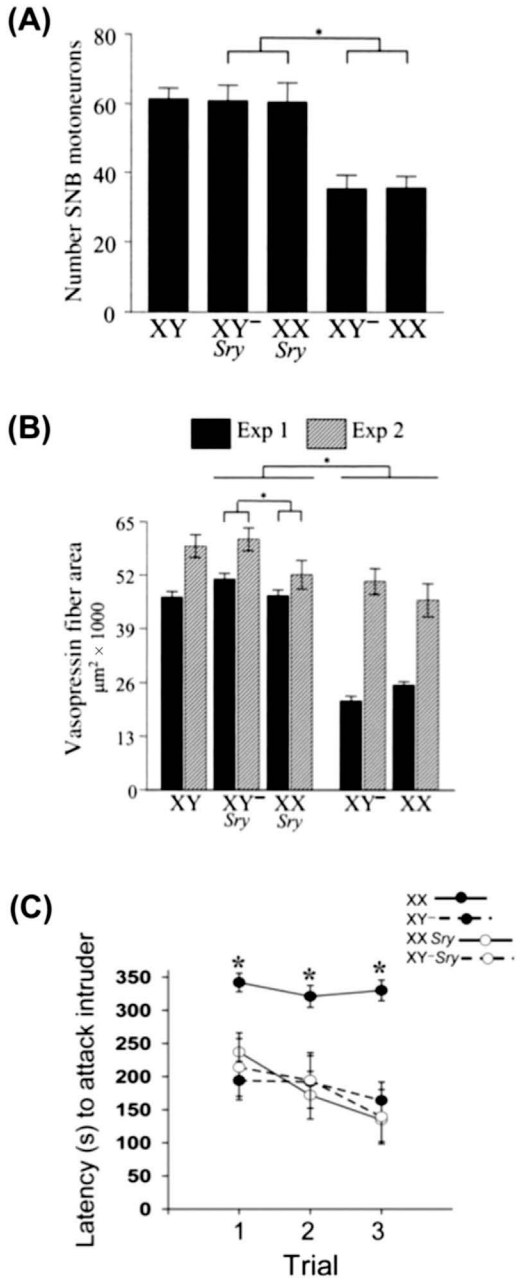

FIGURE 47.6 Four core genotype mice, in which genetic and gonadal sex are inherited independently, can be used to test for the effects of sex chromosome complement on sex differences in neuroanatomy, neurochemistry, and behavior. (A) The number of motoneurons in the spinal nucleus of the bulbocavernosus (SNB) was greater in gonadal male mice (XY⁻ *Sry* and XX *Sry*) than in gonadal females (XY⁻ and XX), with no effect of the sex chromosomes on this measure. (B) In contrast, there was a small but consistent effect of sex chromosomes on the density of vasopressin immunoreactive fibers in the lateral septum. As expected, gonadal males (XY⁻ *Sry* and XX *Sry*) had a higher density than did females (XY⁻ and XX), but in addition XY⁻ *Sry* males had a higher density than XX *Sry* males, showing an effect of sex chromosome complement. The same pattern of results was seen across two experimental replications (black bars and hatched bars). (C) Aggression latencies in resident–intruder tests over three consecutive days. All mice were adults, gonadectomized, and treated with a testosterone-filled implant. XX females were significantly slower to display aggression than all other groups. *Source: Adapted with the permission of the Society for Neuroscience from Ref. 127 (A and B), and Ref. 122 (C).*

that there are also subtle differences in hormone secretion by XX and XY testes. However, this worry is lessened by the observation that a number of traits known to be sensitive to circulating gonadal steroids are virtually identical in XX and XY males (e.g., the number of motoneurons in the spinal nucleus of the bulbocavernosus (SNB); Figure 47.6(B)).[157]

There are also some apparent inconsistencies between findings using the FCG and SF1-knockout models. For example, a resident-intruder paradigm has been used to examine whether there is a direct effect of sex chromosome complement on territorial aggressive behavior using both models. In both studies, all animals were tested in adulthood in the absence of gonads and with testosterone treatment. In the FCG study, XX mice were less aggressive than all other groups (XX *Sry*, XY⁻ *Sry*, or XY⁻) (Figure 47.6(C)).[122] This result suggests that either developmental exposure to testes (i.e., in those groups with the *Sry* transgene) or a Y chromosome in the absence of testes (XY⁻) is sufficient to confer a high level of aggression. However, using a similar behavioral test in the SF1 model, only wild-type males showed high levels of aggression.[164] XY mice that developed in the absence of gonads were no more aggressive than XX mice. An explanation may be found in the ways that the test was conducted in the two different laboratories (see the section Sexual Differentiation in Different Contexts) or differences in the endocrine "history" of the animals: SF1-knockout mice are exposed to steroids from the mother or from wild-type uterine neighbors, but not to secretions from their own gonads, whereas FCG mice are exposed to secretions from their own testes or ovaries in addition to maternal and littermate sources. A similar explanation may underlie the finding of a direct chromosome effect on vasopressin innervation of the septum in the FCG model,[122,157] but not in the SF1-knockout model.[156]

The gene or genes responsible for sex chromosome effects on behavior or neuroanatomy are not known. The most obvious candidates are Y chromosome genes, which are present only in males, or X chromosome genes, which may be present in different doses in males and females (Figure 47.7). All cells in female mammals possess two X chromosomes, while male cells possess only one. Early in development, one X chromosome is randomly inactivated in each female cell, more or less equalizing gene dosage.[165] However, X chromosome inactivation may not be complete and some genes on the X escape inactivation altogether.[166] These X-escapees could cause sex differences in gene expression and, hence, function. Some Y chromosome genes and X-escapees are in fact expressed in the brain.[167] For example, *Sry* itself is expressed in the brains of mice and humans.[168] Moreover, knockdown of *Sry* in dopaminergic midbrain neurons results in a decrease in expression of tyrosine hydroxylase (the rate-limiting enzyme in dopamine production) and impaired motor function, but only in males.[169] Recent evidence

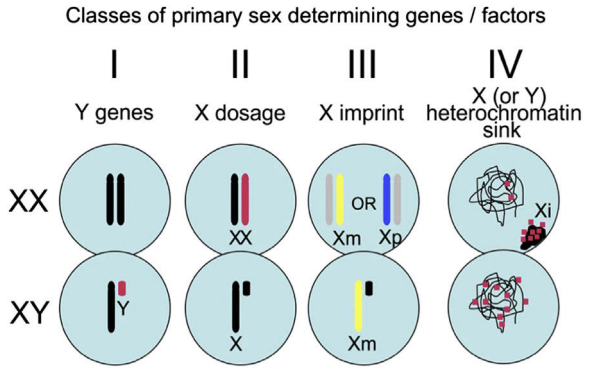

FIGURE 47.7 Four ways that sex chromosomes could affect gene expression. This figure is reproduced in color in the color plate section. Four possible classes of primary sex-determining factors are recognized. Class I comprises Y genes that have a male-specific effect on one or more tissues. Class II is X genes that are expressed at a higher level in females than males by virtue of the 2:1 ratio in the number of X chromosomes. Class III is X genes that receive a parental imprint. The X chromosome receiving a maternal imprint (Xm, yellow) is active in half of XX cells and all of XY cells, whereas the X chromosome receiving a paternal imprint (Xp, blue) is active in half of XX cells and no XY cells. Class IV comprises proposed regions of the sex chromosome heterochromatin (the heterochromatic inactive X (Xi) is illustrated here) that act as sex-specific sinks for factors (red dots) that regulate the amount of euchromatin–heterochromatin at interphase and therefore affect gene expression throughout the genome. To date, specific members of only Class I have been identified (*Sry* and spermatogenesis genes). Although evidence indicates that the number of X chromosomes leads to some sex differences in phenotype, the specific genes or chromosome regions that explain these X effects have not been identified. Class IV is particularly speculative at present because it is based on a limited number of studies. Future studies are likely to expand the importance of Classes II–IV. *Source: Adapted with permission of Elsevier from Ref. 58.*

suggests that *Sry* similarly regulates tyrosine hydroxylase expression in dopaminergic neurons of humans.[170] Note that differences in *Sry* would not explain the direct effects of the sex chromosomes in the FCG model because *Sry* is present (or absent) in both comparisons (XY^- versus XX, and XY^- *Sry* versus XX *Sry*).

In addition to X and Y gene dosage, there are at least two other ways in which sex chromosome complement causes male and female cells to differ (Figure 47.7). One is a difference in parental imprints (essentially, epigenetic marks that affect gene expression). Only females receive an X chromosome from their fathers, so only females have a paternally imprinted X. In addition, recent evidence suggests that the X chromosome could act as a heterochromatin "sink". The inactivation of one entire X chromosome in each cell of XX mammals presumably requires a significant amount of epigenetic machinery to maintain. This large area of heterochromatin may also interact with other parts of the genome, an idea that receives direct support from observations in fruit flies[171] and may also explain some sex differences in gene expression in mammals.[58,172]

It is also important to keep in mind that expression of X or Y genes underlying gonad-independent effects on the brain and behavior could be peripheral (i.e., outside of the brain). In this scenario, signals from the periphery stemming from a sex difference in X or Y genes then change gene expression in the brain. Recent work has demonstrated sex differences in gene expression in, for example, the liver, adipose tissue, and muscle,[173] some of which is independent of the gonads.[174] Although rarely considered, this type of indirect effect of sex chromosome genes on the brain would, in fact, be analogous to the very familiar actions of Y chromosome on the brain via its role in directing differentiation of the developing gonads (see the section What Will the Future Bring? for additional consideration of this idea).

EFFECTS OF GONADAL HORMONES: CELLULAR AND MOLECULAR MECHANISMS

In principle, sexual differentiation of any neural trait must involve one (or a combination) of four basic cellular mechanisms: cell birth, cell migration, cell death, and the differentiation of neuronal phenotype. It is often difficult to identify which of these mechanisms contributes to a sex difference of interest. For example, assume that in a certain brain region, males have more neurons than do females that express neurotransmitter "x". If this sex difference persists even after adult hormone levels are made equivalent, but can be reversed by developmental manipulation of gonadal steroids, we would say that this difference is programmed by gonadal steroids. This difference, however, could have arisen because steroid hormones caused more neurons destined for the region in question to be born in males (i.e., a hormonal effect on neurogenesis), or because steroids affected the movement and aggregation of cells, such that more cells overall came to be associated with the brain region of interest in males. The difference also could have arisen because fewer cells died in males (an effect on cell death), or because gonadal steroids caused existing cells to express neurotransmitter "x" (i.e., a hormonal effect on neurochemical differentiation). Of these four mechanisms of sexual differentiation, evidence is best for cell death, followed closely by phenotypic differentiation. The extent to which differential cell birth or migration contributes to known neural sex differences is less clear.

Neurogenesis

Neurogenesis often can be ruled out as a factor, because for some neural sex differences, all cells are born before the gonads differentiate. For example, motoneurons that populate the SNB undergo their final mitosis

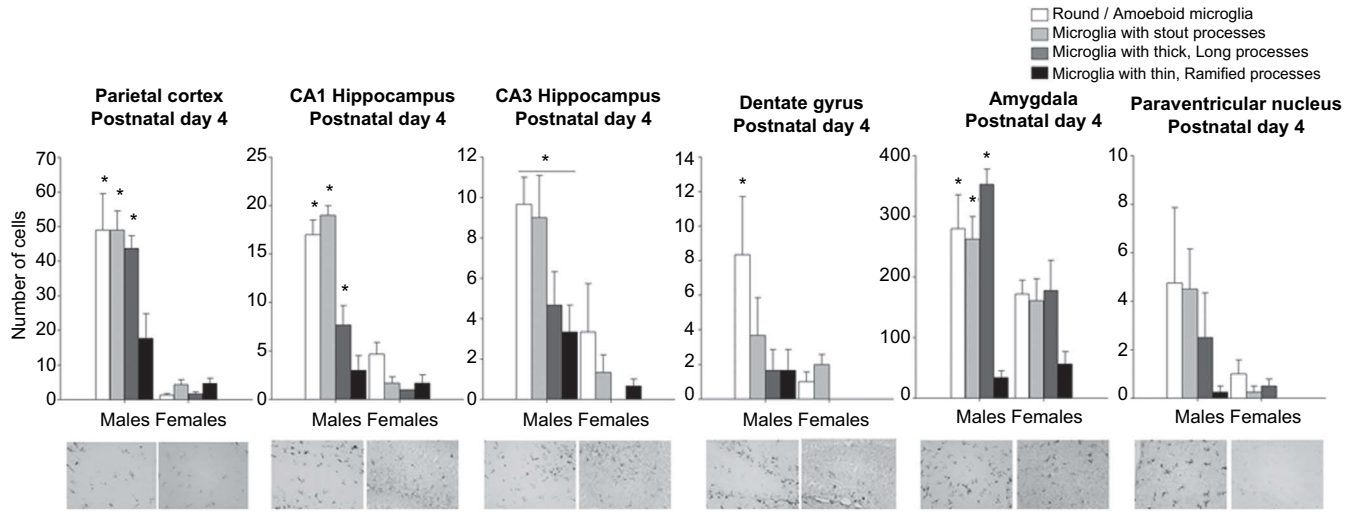

FIGURE 47.8 The morphology and number of microglia are affected by sex in the postnatal day 4 rat brain. Microglia were identified using immunohistochemistry for ionized calcium binding adapter molecule 1 (Iba1). All brain regions displayed more amoeboid microglia and microglia with stout processes than microglia with thicker or thinner processes at this age. Within the parietal cortex, the CA1 and CA3 regions of the hippocampus, the dentate gyrus, and the amygdala, there was a significant interaction of sex and microglial morphology (within-subjects ANOVA, $p < 0.05$; $n = 4$ rats/group). Males had more amoeboid microglia, microglia with stout processes, and microglia within thick, long processes than females within the parietal cortex, CA1 hippocampus, and amygdala. Within the CA3 of the hippocampus, males had significantly more microglia in all morphological categories than females; and within the dentate gyrus of the hippocampus, males had significantly more amoeboid microglia than females. No effects of sex on glial morphology or number were detected within the paraventricular nucleus. Data represent the mean ± SEM of all Iba1+ cells in each morphological category across all sections analyzed. *Source: Reprinted with permission of John Wiley and Sons from Ref. 182.*

by the 14th day of gestation in rats,[175] several days before testosterone will be produced by the testes. In other cases, however, gonadal steroid production and cell birth overlap. This is true for the SDN-POA, for example.[68,176] Using tritiated thymidine or bromodeoxyuridine to label dividing cells and examining the number of cells labeled after very short survival times (to rule out effects due to death or migration), neurogenesis has been eliminated as important for the initial differentiation of the SDN-POA.[177] Interestingly, neurogenesis could still contribute to the maintenance of this sex difference.[178] In brain regions where neuron production continues throughout life, hormones could create sex differences in cell number by controlling this cell production. For example, estradiol increases neurogenesis in the dentate gyrus of female rats.[179] However, this does not result in differences in total cell number in this area, presumably because increases in cell death are offset by increases in cell birth. At present, no sex difference has been convincingly linked to the hormonal control of neurogenesis, although this may be a possibility in the developing CA1 region of the hippocampus.[180,181]

Although this section is titled "Neurogenesis", at least half of the cells in any given brain region are glial cells, and sex differences in glial cell number have been described (Figure 47.8).[114,182–185] Thus, the hormonal control of gliogenesis may also be an important mechanism for sexual differentiation, and this is clearly an area deserving more attention. Because glial cells are born throughout life, hormonal effects on gliogenesis could in theory happen at any time, including the pubertal period. For example, the number of astrocytes in the rat medial amygdala is equal in the two sexes prepubertally, thereafter increasing much more in males than females. The greater increase in males is hormonally driven, because genetic males with defective androgen receptors show a more modest, female-typical increase in astrocytes by adulthood.[116] Sex differences in the number of microglia are also seen in several brain regions during early postnatal life,[182] although whether this is due to differences in the genesis of microglial cells or to some other mechanism (e.g., migration) is not yet known.

Cell Migration

Like neurogenesis, cell migration can be excluded as an important factor for many of the well-known sex differences in the brains of mice and rats (e.g., in the POA, AVPV, and principal nucleus of the bed nucleus of the stria terminalis (BNSTp)), as most cells in these regions have migrated to their respective location prior to the perinatal sex difference in testosterone synthesis.[186–188] However, in some brain regions, cells are added throughout perinatal development,[109,186] and even for cells that are already in place before testosterone levels surge in males, gonadal steroids may cause subtle changes in cell position within a general brain region. For example, adult male and female rats have similar numbers of ERβ-expressing cells in the AVPV, but these cells are more medially located in females.[189] This sex difference

in the position of cells, however, is not necessarily due to sex differences in migration. For example, if testosterone increases the survival of cells in the lateral but not the medial AVPV, then males will wind up with more laterally positioned cells.

To address the question of whether cell migration plays a role in sexual differentiation, Stuart Tobet et al. followed the migration of tagged cells in organotypic cultures of the POA–anterior hypothalamus (AH) of embryonic mice. They noted that males showed significantly more medial-to-lateral migration than did females,[190] which matched well with a transient sex difference in the location of phenotypically identified cells in the POA–AH two days later.[191] Moreover, they showed that this migration was affected by estradiol, but not by the androgen dihydrotestosterone, which cannot be converted to an estrogen,[192] and that GABA receptor antagonists influenced cell migration as well.[193] This latter observation suggests that sex differences in neural activity could influence cell positioning.

Although the functional significance of sex differences in cell migration is not clear, one could imagine that the positioning of cells might affect afferent input, cell-to-cell communication on a local scale, or exposure to diffusible signals. For example, the closer proximity of ERβ-expressing cells in the AVPV to the ventricle in females could increase access to chemosignals in the cerebrospinal fluid.

Cell Death

Development of the nervous system is characterized by a period of developmental cell death, or apoptosis, during which about half of the neurons initially produced are thought to die,[194] and gonadal steroids can modulate this cell death. Of all the cellular mechanisms considered as factors in sexual differentiation of the brain, differential rates of developmental cell death are currently the best established. Nonetheless, only in a handful of cases is the evidence rather complete.[177] These include some of the most "famous" sex differences, including the SNB, SDN-POA, BNSTp, and AVPV in rats.[68,69,87,101] Cell death may also play a role in sexual differentiation of the rat visual cortex,[195] the gerbil preoptic area,[196] at least one birdsong nucleus,[197] and frog laryngeal motoneurons.[198] In each of these cases, sex differences in cell numbers in adulthood are correlated with sex differences in the number of dying cells at some point in development. For example, adult males have more SNB motoneurons than do females, and females have more pyknotic cells in the SNB region around birth.[87] Early postnatally, females also have more pyknotic cells than do males in the BNSTp,[69,109] which correlates with greater BNSTp cell number in adult males. In both cases, developmental testosterone treatments that eliminate the sex difference in size and cell number of these nuclei in adulthood also eliminate the sex difference in apoptosis during development,[69,87] supporting the conclusion that differential cell death is the mechanism underlying sexual differentiation in these cases.

Counting pyknotic or TUNEL-positive cells to determine the rate of cell death has its limitations because such cells provide merely "snapshots" of dying cells at a particular stage of apoptosis. For example, the rat locus coeruleus shows more neurons in adult females than in males, which corresponds with greater rates of cell death in males at birth,[199] suggesting that differential rates of cell death cause this difference. However, a more fine-grained developmental study of the changes in cell number suggests that the adult sex difference may actually result from the addition of cells in the female locus coeruleus after puberty.[200] A similarly complex situation applies to the greater number of cells in the visual cortex of males versus females.[201]

Recently, mice "mutation for cell death" genes have been used to get beyond correlational studies and to test more directly the contribution of differential cell death to sexual differentiation of the brain. The period of developmental neuronal cell death occurs perinatally in mice, and cell death falls to very low levels in most brain regions after the first week of life.[202] In mice carrying a deletion in *Bax*, a pro-death gene of the Bcl2 family, this neuronal cell death is virtually eliminated.[202,203] In these mice, the number of cells in the SNB, AVPV, and BNSTp is significantly increased,[88,105] and, more importantly, sex differences in the total cell number in each of these regions are completely eliminated (Figure 47.9). Thus, a functional *Bax* gene is required for sexually dimorphic cell death in the mouse forebrain and spinal cord.

Besides allowing us to identify genes necessary for sexually dimorphic cell death, cell death mutants also allow us to estimate more precisely the contribution of cell death to a given neural sex difference. Although not all neural regions require Bax protein for cell death, for many regions Bax is essential for this process.[202,203] If this is true for the SNB, AVPV, and BNSTp as well, then the difference in neuron number between Bax−/− and Bax+/+ mice represents the total number of neurons lost to cell death, integrated over the entire developmental cell death period. In the AVPV, BNSTp, and SNB, the cell number is equivalent in male and female Bax−/− mice,[88,105] suggesting that cell death alone can account for the sex difference in the overall cell number in these regions in wild-type animals. If the numbers were different, other mechanisms in addition to cell death would have to be considered. In the same vein, studying Bax−/− mice allows us to identify sex differences not dependent on Bax, and demonstrates that the control of cell number may vary not only from region to region, but also among

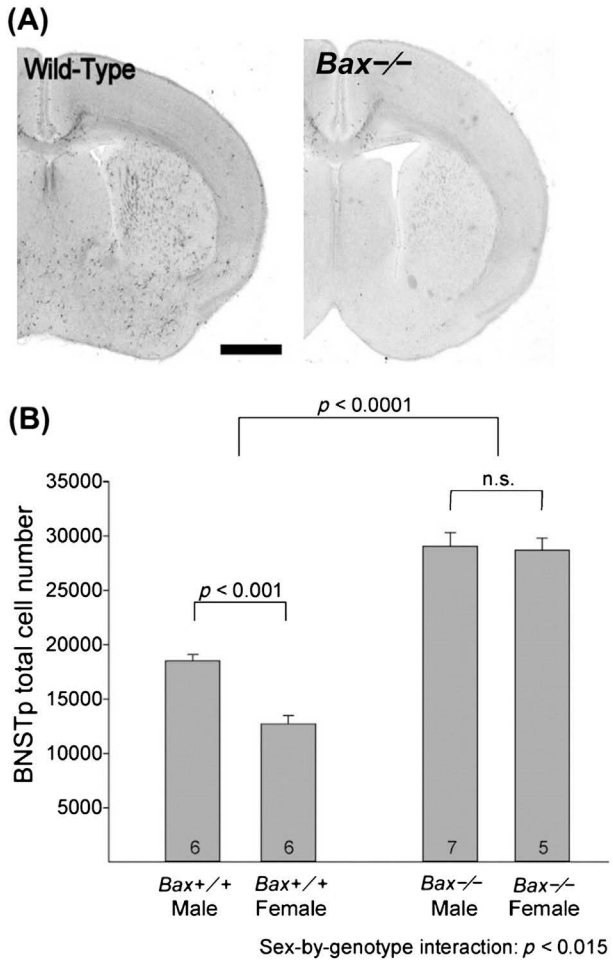

FIGURE 47.9 The effect of preventing developmental cell death on a sex difference in the principle nucleus of the bed nucleus of the stria terminalis (BNSTp). (A) Cell death throughout the developing mouse brain is dependent on the pro-death gene, *Bax*. Dying cells (black dots), labeled by immunohistochemistry for activated caspase 3, are much more numerous in newborn wild-type mice (*Bax*+/+) than in Bax-knockout mice (*Bax*−/−). (B) In adulthood, cell number in the BNSTp was greater in wild-type males than in females. Deletion of the *Bax* gene increased cell number overall and eliminated the sex difference, suggesting this sex difference depends on developmental cell death. The number of animals per group is indicated at the base of each bar. n.s.: not significant. *Source: Reprinted with permission of Wiley from Ref. 202 (A), and reprinted with the permission of the National Academy of Sciences of the USA from Ref. 105 (B).*

subtypes of cells within a single region (Refs 105,106,123; and discussed further in this chapter).

A central question is how gonadal steroids such as testosterone regulate cell death. Many studies have linked the steroid hormone-regulated death of peripheral tissues and cancer cells to changes in the ratio of pro-life and pro-death Bcl2 family members. Steroid hormones also regulate the expression of Bcl2 family members in neural tissue.[177] This regulation may be direct in some cases, since the Bcl2 and BclxL genes contain putative estrogen response elements.[204,205] Because research on steroid effects on Bcl2 family members has been primarily geared toward understanding the neuroprotective effects of estrogens in injury models, we do not know much about the hormonal control of Bcl2 family proteins during development. Interestingly, however, testosterone as well as estradiol regulates Bcl2 and Bax expression in the SDN-POA of newborn rats.[206,207] Thus, the mechanisms by which estradiol regulates cell survival in adult peripheral tissues may also apply to sexual differentiation of the brain.

An interesting new line of research suggests that sexual differentiation of specific brain areas and behaviors uses components of signal transduction pathways that are common to inflammatory processes.[208–210] Some of these components may be involved in cell death as well. For example, using microarrays, Krishnan et al. demonstrated that genes involved in the tumor necrosis factor α (TNFα)-TNF receptor 2 (TNFR2)-NF kappa B cell survival pathway are expressed at higher levels in the female AVPV than in the male AVPV on postnatal day 2.[102] The sex differences illustrated here in the number of microglia in various brain regions of the postnatal rat may provide another example, as these are the resident immune cells of the brain. The rat preoptic area provides a case in point. At postnatal day 2, males have twice the number of activated microglia as females, and microglial inhibition at that time prevented sex differences in dendritic spine density and adult masculine sexual behavior (Figure 47.8).[66] Immune–nervous system interactions may also help to explain the sexually dimorphic effects that infections during development have on brain development.[211]

Differentiation of Neural Morphology and Neurochemistry

Newly generated neurons that have migrated and survived the cell death period differentiate into myriad forms that differ in size, shape, dendritic and axonal ramification, the number and location of synapses, the palette of neurotransmitters expressed, and the types of receptors that adorn their membranes or reside intracellularly. Each of these features may affect the function of neuronal circuits and can be altered by gonadal steroids. Rather than exhaustively reviewing the literature here, we present a number of salient examples of sex differences in, or gonadal steroid hormone regulation of, morphological (axon outgrowth, dendritic branching, and synaptogenesis) and neurochemical differentiation.

Axon Outgrowth

A number of sex differences in axonal projections from one brain region to another have been described. It is not so easy to determine, however, whether these are due to sex differences in axonal outgrowth per se or to some other process (e.g., a sex difference in neurogenesis or cell

death that alters the number of cells contributing to the projection). Projections to and from the AVPV provide examples where this issue has been addressed. Unlike most of the sexually dimorphic regions studied to date, the AVPV is larger and more cell dense in *female* rats and mice than in males (see Table 47.1). Anterograde labeling experiments indicate that neurons in the AVPV provide direct inputs to gonadotropin-releasing hormone (GnRH)-containing neurons in the preoptic region[212] (see also Chapter 11). Many of the neurons projecting to GnRH cells are kisspeptin-expressing cells that are much more numerous in females,[213,214] and this sexually dimorphic input may explain why male rodents have relatively tonic luteinizing hormone (LH) release, while females exhibit cyclical LH surges. Similarly, descending projections from the AVPV to dopaminergic neurons in the arcuate nucleus are more abundant in female rats than in males.[215] Although these are bonafide examples of sex differences in axonal projections, it is not currently known whether these sex differences are due to differences in axon outgrowth or to an alternative mechanism.

Somewhat more direct evidence comes from considering the projection from the BNST to the AVPV, which is about 10 times denser in male rats than in females. Developmental studies suggest that a massive projection from the BNST to the AVPV is established between postnatal days 9 and 10 in males, but never forms in females.[216] This is apparently due to hormone action at the target tissue (in this case, AVPV), as determined by mix-and-match co-culture experiments (Figure 47.10). When explants of the BNST and AVPV taken from neonatal male or female rats were co-cultured in the same dish, robust outgrowth from the BNST to the AVPV formed only if the AVPV came from a male or a testosterone-treated female.[217] AVPV explants from females did not support outgrowth from either male or female BNST explants. This result suggests that either an unknown diffusible factor from the AVPV of females repels BNST axons, or a factor from the AVPV of males (or testosterone-treated females) attracts BNST axons.

Hormone effects on axon outgrowth no doubt occur in other brain regions as well and may not always involve hormone action at the target site. For example, estradiol increased axon elongation of rat embryonic hypothalamic neurons grown in culture,[218] which suggests a direct effects of steroids on the cells growing axons, unless the target cells were also present in the culture. Speert et al.[219] recently provided a potential molecular explanation for the hormonal regulation of axonal outgrowth. They found that the hypothalamus of neonatal female rats has higher levels of focal adhesion kinase (FAK) and paxillin, two molecules associated with cell adhesion and axon growth, than that of males. These sex differences were reversed by treating female neonates with estradiol or by administering an aromatase inhibitor to the males, indicating that they are due to the perinatal gonadal hormone milieu. Because FAK and paxillin are involved in axon outgrowth, sex differences in these molecules, or others like them, could underlie regional sex differences in outgrowth.

Dendritic Growth and Branching

The earliest work pertaining to the hormonal control of dendritic growth came from in vitro studies by Toran-Allerand, who showed that estradiol greatly increased the neurite outgrowth from organotypic explant cultures of the newborn mouse hypothalamus and preoptic area.[220] The term "neurite" was used in the initial studies because any given outgrowth from an explant could be an axon or dendrite (or, for that matter, a glial protrusion[221]). Based on Golgi staining of cultured neurons, however, at least some of the effect is due to estrogen action on dendrites.[222] Immunocytochemical markers can specifically label dendrites in explant studies, or, alternatively, dendritic identity can be inferred based on cell morphology in cultures of dissociated neurons.

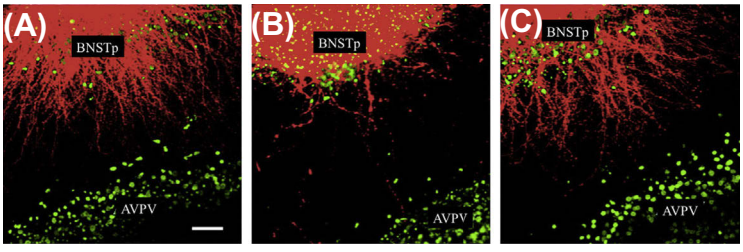

FIGURE 47.10 Target-dependent induction of neurite outgrowth in co-cultures of the principal nucleus of the bed nucleus of the stria terminalis (BNSTp) and anteroventral periventricular nucleus (AVPV). This figure is reproduced in color in the color plate section. Confocal images of BNSTp-AVPV co-cultures show DiI labeling of neuritis (pseudo-colored red) that extend from the BSTp toward the AVPV. The BSTp explant was derived from a male rat on postnatal day 5 (PN5) and co-cultured with an AVPV explant (pseudo-colored green) derived from a PN9 (A) male, (B) female, or (C) androgenized female. A marked difference in the density of neurites between the co-cultures explants was observed, with many more neuritis seen when the AVPV explant was derived from a male (A) versus a female (B) rat. Treatment of neonatal female rats with testosterone during the first 9 days of life in vivo masculinized (i.e., increased) neurite outgrowth from BSTp explants (C), suggesting that the target-dependent formation of neuritis extending from the BSTp to AVPV is determined by exposure to sex steroid hormones during the neonatal period. Scale bar: 15 μm. *Source: Adapted with the permission from Ref. 217.*

Using these approaches, estradiol increased dendritic branching in cultures of embryonic rat medial amygdala.[223] Effects of estradiol are not always stimulatory, however: estradiol inhibited neurite growth of serotonergic neurons of embryonic rats in culture.[224]

Unfortunately, studying dendritic outgrowth in the actual brain turns out to be quite challenging, and evidence for sex differences in dendritic trees has been sparse. Some of the earliest evidence for an effect of gonadal steroids on dendrites came from studies on songbirds. Dendritic extent is much greater in male canaries, which sing, than in females, which don't sing, within the song control nucleus known as RA. De Voogd and Nottebohm found that testosterone treatment of female canaries in adulthood increased dendritic lengths to male-like levels.[225] Similar effects can be seen in mammals: castration of adult male rats reduced the dendritic extent of motoneurons in the SNB (see Table 47.1) by 50%, and this could be prevented by treating castrates with testosterone.[226] Shrinkage of SNB dendrites was also seen in male white-footed mice exposed to short, winter-like day lengths,[227] suggesting that hormonally mediated growth and retraction of SNB dendrites may be normal features in seasonally breeding rodents. Gonadal hormones also control the initial outgrowth of SNB dendrites during postnatal development; in this case, however, both estrogens and androgens are implicated.[228]

The SNB may also be the only neural region in which the site of hormone action for effect on dendritic trees has been examined. Interestingly, testosterone seems to act not on the SNB motoneurons themselves, but at the target muscles to control SNB motoneuron dendritic extent in adulthood.[229] Similarly, in development, the effect of estrogens on SNB dendrites appears to be mediated by hormone action at the target muscles. Administering estrogens at the target muscle supports the dendritic growth of developing SNB motoneurons, and blocking ERs at the muscles results in stunted dendritic trees.[230]

Few studies have directly examined sex differences or effects of gonadal hormones on dendritic trees in the mammalian brain, which is likely related to the fact that the techniques required can be capricious and are very time consuming. Motoneurons such as SNB cells can be labeled relatively easily by injecting retrogradely transported tracers into their target muscles, but much more tedious Golgi impregnation studies or direct dye filling are generally required in the brain. Based on Golgi staining, sex differences in dendritic trees were first described in the preoptic area of hamsters.[231] Also using the Golgi technique, dendrites in the adult ventromedial nucleus of the hypothalamus (VMN) were found to be longer in male rats than females,[232] a somewhat surprising result since the VMN is a major site for the hormonal control of female copulatory behavior. On the other hand, the regional volume of the VMN is greater in male rats than in females, a sex difference that is dependent upon functional androgen receptors.[233] and there is good evidence that this nucleus plays a role in aggressive behavior in mice.[234] Estradiol and progesterone have opposing effects on dendrite length in the VMN in females,[235] and, in fact, dendritic length in the VMN can change from day to day over the course of the estrous cycle.[236] This suggests rapid, hormone-dependent plasticity in the circuitry underlying female sexual behavior.

Most other evidence pertaining to sex differences and hormonal effects on dendrites has focused on dendritic spines, protuberances on dendrites that are often the sites of excitatory synapses, or by quantifying synapses themselves.[64,231,237–243] In the arcuate nucleus of the hypothalamus, for example, females have a two- to threefold higher density of axodendritic spine synapses than males, while males have more axosomatic synapses than do females. This sex difference is reversed in males castrated as neonates or females treated with testosterone at birth.[239] Because axosomatic synapses are generally inhibitory while axodendritic spine synapses are excitatory, a sex difference in the relative number of somatic versus spine synapses is likely to affect neuronal excitability.

In a few cases, researchers have made headway in identifying the mechanisms underlying the sexual differentiation of dendritic spines. For example, male rats have a much greater density of dendritic spines in the POA than do females.[64] The induction of spines in the POA of males is established in the first few days of postnatal life, is due to estradiol, and appears to be permanent (Figure 47.11).[208] The molecular mechanism involves an estrogen-dependent increase in the enzyme cyclooxygenase-2 (COX-2) and its product, prostaglandin E2. Increased prostaglandin E2 in the neonatal POA is then responsible for increased spine formation in males.[244] The molecular basis of hormone effects on dendritic spines is regionally specific, however. In the VMN, for example, the neurons in male rats have longer dendrites with more excitatory dendritic spine synapses than in females.[244] In this case, estradiol acts not via prostaglandins, but by increasing glutamate release from presynaptic neurons. This glutamate acts via ionotrophic glutamate receptors on the postsynaptic cell to induce spine formation.[243]

Although the foregoing examples suggest a programming effect of hormones early in life, in some cases dendrites (and/or their spines) remain sensitive to changes in gonadal steroids in adulthood. In addition to the effects of gonadal steroids on dendritic trees in adult songbirds and the SNB, mentioned in this chapter, dendrites and dendritic spines may be influenced by circulating levels of steroids in the peripubertal (e.g., Ref. 240) or adult mammalian brain (e.g., Refs 245,246). Dendritic spine density can also change quite rapidly, for example from day to day over the estrous cycle.[236,247]

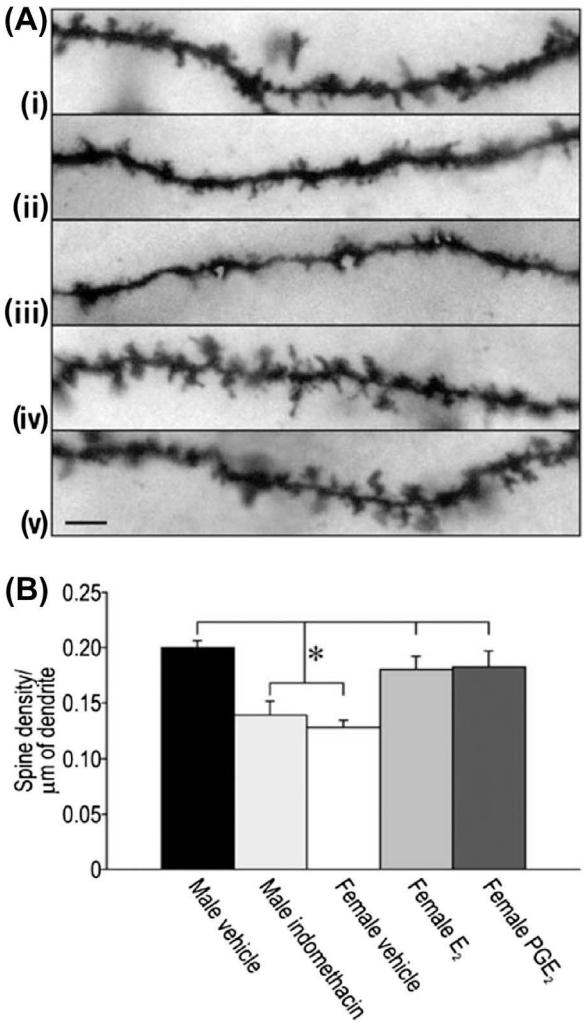

FIGURE 47.11 Estradiol and prostaglandin E_2 (PGE_2) increase dendritic spine density in the developing preoptic area (POA) of the rat. Neurochemical Phenotype

Neurochemical phenotype in its broadest sense refers to all of the chemicals stably expressed in a given neuron. For illustrative purposes, we restrict our discussion here to the expression of neurotransmitters, which show numerous sex differences.[248–250] Given any sex difference in neurotransmitter expression in a brain region, two fundamentally different sets of processes could be involved: processes that determine the absolute number of cells capable of expressing a specific transmitter (i.e., birth, death, or migration of cells) or processes that act on preexisting cells to direct their transmitter expression. It can be surprisingly difficult to disentangle these two possibilities, in part because gonadal hormones often trigger sexual differentiation before the neurons of interest assume their final phenotype.

A case in point is the sexually dimorphic vasopressin innervation of the brain (Table 47.1). This innervation shows one of the most consistently found neural sex differences among vertebrates,[133] with males having more vasopressin neurons than females in the BNST and medial amygdala, and denser projections from these areas, across many mammalian species (Figure 47.12).[133] Nonmammalian vertebrates show similar sex differences in homologous vasotocin projections.[133,134,252] This sex difference has been well studied in rats, where exposure to gonadal steroids during perinatal life determines the number of vasopressin cells found in adults.[124,125] In theory, hormones might influence cell birth, migration, cell death, or cellular differentiation to alter the number of vasopressinergic cells. Differential cell birth and migration are very unlikely to contribute in this case, because vasopressin cells are born on embryonic days 12 and 13,[188,253] prior to differentiation of the gonads and at least a week before gonadal hormones trigger their sexual differentiation. This leaves differential cell death or phenotypic differentiation as the two most likely causes.

Early work provided some circumstantial evidence favoring the differentiation of phenotype. Essentially all vasopressin cells in the BNST co-express the neuropeptide galanin, but not all galanin cells co-express vasopressin.[254] Because the total number of galanin cells does not differ between males and females,[255] it was hypothesized that, during development, higher levels of testosterone act on existing galaninergic cells to increase the percentage that will co-express vasopressin.[254] This hypothesis is difficult to test directly. Although gonadal steroids determine vasopressin cell number soon after birth, the vast majority of presumptive vasopressin neurons do not begin expressing the peptide until several days (in males) to weeks (in females) later.[256] Thus, one cannot identify the cells of interest during the time the sex difference in their number is determined.

Instead, efforts turned to assessing whether cell death could be eliminated as a factor contributing to the sex difference. To do this, vasopressin cell number was examined in the BNST of mice overexpressing the pro-survival protein, Bcl2, or mice lacking the pro-death protein, Bax. Both Bcl2 overexpressors and Bax knockout mice have greatly reduced neuronal cell death, so if cell death is required for the sex difference in vasopressin cell number, it should be eliminated in these animals. These mutations did indeed increase the total number of cells that produce vasopressin in both sexes. Critically, however, the sex difference in cell number remains intact.[123] That is, cell death determines the number of cells with

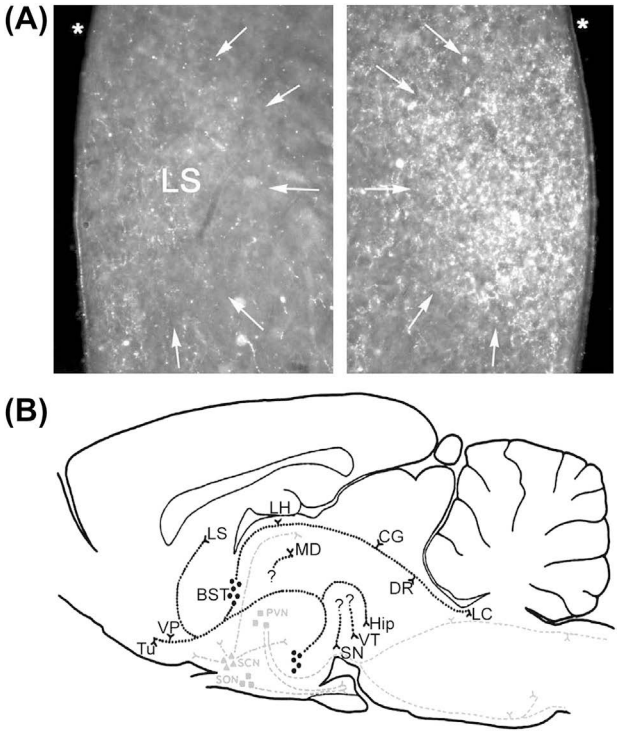

FIGURE 47.12 (A) AVP-immunoreactive fibers (arrows) in the lateral septum (LS) of an intact female (left) and male rat (right). *: Lateral ventricle. (B) Schematic diagram depicting sites of vasopressin synthesis in the rat brain. A limited number of cell groups produce vasopressin (dark circles and gray squares and triangles). The paraventricular nucleus (PVN) and supraoptic nucleus (SON) contain mangnocellular vasopressin neurons that project into the posterior pituitary gland via the median eminence. These cells release vasopressin into the bloodstream to control peripheral tissues. In addition, the suprachiasmatic nucleus (SCN), BNST, and medial amygdala (MeA) contain parvocellular vasopressin cells that project centrally. Vasopressin released from these sites controls circadian rhythms, social behaviors, and other functions. The BNST and MeA projections are sexually dimorphic, with more cell bodies and denser projections in males. Other abbreviations: VP: ventral pallidum; Tu: olfactory tubercle; LH: lateral habenular nucleus; CG: midbrain central gray; DR: dorsal raphe nucleus; LC: locus coeruleus; Hip: ventral hippocampus (Hip). Question marks indicate projections to the mediodorsal nucleus of the thalamus (MD), ventral tegmental area (VT), and substantia nigra (SN), all of which disappear after castration but not after lesioning the BNST. Relatively steroid-insensitive projections (gray lines) originate in the SCN (triangles), PVN (squares), and supraoptic nucleus (SON: squares). *Source: Reprinted with permission from Elsevier from Ref. 251.*

the potential to become vasopressinergic, but does not direct the sex difference. By elimination, this leaves sexual differentiation of cellular phenotype as the only remaining plausible mechanism for sexual differentiation of vasopressin expression.

Numerous other neurotransmitters and neuropeptides (e.g., dopamine, neurotensin, substance P, and enkephalin) show sex differences in cell number (reviewed in Ref. 248), and for none of these has the cellular mechanism of sexual differentiation been established. The search for these mechanisms may be amenable to the same strategies described for vasopressin. If, however, one successfully eliminates cell birth, migration, and death as possible mechanisms, that is, in some respects, only a modest first step. One then faces the task of identifying the molecular mechanism contributing to the phenotype of differentiating neurons.

How might hormones direct the phenotypic differentiation of a neuron? The most likely answer is epigenetics, the same mechanism responsible for the differentiation of cell type throughout the body of a developing embryo. In the case of the sex difference in vasopressin cell number, this might involve, for example, the placement of long-lasting epigenetic marks on the promoter region of the vasopressin gene that ensure expression of the gene in males, or inhibit it in females. Recently, Forbes-Lorman et al. used small interfering RNAs (siRNAs) to transiently reduce expression of the DNA methyl binding protein, methyl CpG binding protein 2 (MeCP2), in the amygdala of male and female rats during neonatal life. A transient reduction in MeCP2 eliminated the sex difference in vasopressin expression in the medial amygdala and BNST of rats.[257] This is consistent with a critical role for DNA methylation in sexual differentiation of the vasopressin system, although it does not address whether the change in DNA methylation is on the vasopressin gene itself or on some other gene that then influences vasopressin expression.

Role of Epigenetic Factors

As we have seen, the effects of gonadal steroid hormones can be permanent or long-lasting and are often characterized by a delay. As mentioned in this chapter, testosterone levels present neonatally determine the number of vasopressin neurons that project to the lateral septum, but the expression of vasopressin by those neurons does not begin until days (in males) to weeks (in females) later.[118,125,256] Presumably, there is a cellular "memory" for the testosterone exposure that gets revealed when the cell reaches a certain developmental stage. Similarly, estrogenic metabolites of testosterone administered on the day of birth reduce cell death in the BNSTp, but that cell death does not occur until nearly a week later,[69,109,202] and effects of neonatal testosterone on AVPV volume are not apparent until long after the hormone is cleared from circulation.[258] Some effects of perinatal steroids may not be observed until adulthood. The basis for such cellular memory has been mysterious until recently, but an explanation may be found in the rapidly exploding field of neuroepigenetics.

Although the definition of epigenetics is not widely agreed on and is still evolving, we use it here to refer to alterations in chromatin that result in relatively long-lasting changes in gene expression without any change in the sequence of nucleotides. Within the

nucleus of every cell, DNA wraps around a complex of histone proteins to form nucleosomes. These nucleosomes are further packaged and condensed to different degrees. In general, loose packaging makes DNA more accessible to the transcriptional machinery and is associated with increased gene expression. More compact, heterochromatic states are associated with reduced gene expression. Epigenetic marks such as DNA methylation and the modification of histone tails determine the degree of packing, and therefore gene expression.[259]

Several observations suggest an important role for epigenetics in sexual differentiation. The first is simply circumstantial evidence based on how steroid hormone receptors work. Steroid receptors, including ARs and ERs, are known to recruit co-activators that increase gene expression and/or co-repressors that decrease expression. These co-factors themselves often have histone-modifying activity.[260–262] An important mechanism by which gonadal steroid hormones activate gene expression may therefore involve the opening up of chromatin structure following the binding of a receptor–co-activator complex. Based on this observation alone, one might wonder whether all effects of steroid hormones are "epigenetic" (i.e., require chromatin modifications). More directly related to the topic of this chapter, blocking these steroid receptor co-factors can prevent the effects of testosterone on morphological and behavioral sexual differentiation.[263,264] Although research into the role of epigenetics in sexual differentiation is still in its infancy, this has become an active line of research in the last few years. To date, a role for both histone acetylation and DNA methylation has been found.

Histone Modifications

The histone proteins have N-terminal "tails" that protrude from the nucleosome and can be posttranslationally modified in a variety of ways. The acetylation of histone tails is the best understood of the histone modifications. Histone acetyltransferases add acetyl groups to lysine residues of histone tails, which opens the chromatin structure, increases access for transcription factors, and enhances transcriptional activity. Histone deacetylases (HDACs), on the other hand, remove acetyl groups from histone tails, and this is generally associated with reduced gene transcription.[265,266] A sex difference in histone acetylation in the cortex and hippocampus of perinatal mice has been described.[267] This sex difference could be reversed by treating females with testosterone, so it correlates with sexual differentiation of the brain.

To more directly test whether modifications in histone acetylation were important in sexual differentiation, Murray et al. treated mice with an HDAC inhibitor during the critical neonatal period.[268] As noted in Table 47.1, the BNSTp is normally larger in volume and cell number in male than in female mice.[105] Neonatal HDAC treatment prevented masculinization of BNSTp cell number in both males and testosterone-treated females, while having no effect on cell number in control females (Figure 47.13).[268] Treatment of newborn mice with an HDAC inhibitor also had no effect on cell number in two non-sexually dimorphic brain regions in this study, suggesting that blockade of histone deacetylation did not have a generalized effect on cell number, but specifically prevented the masculinizing actions of testosterone.

More recently, Matsuda et al. used a similar approach to ask whether the masculinization of male sexual behavior in rats requires alterations in histone

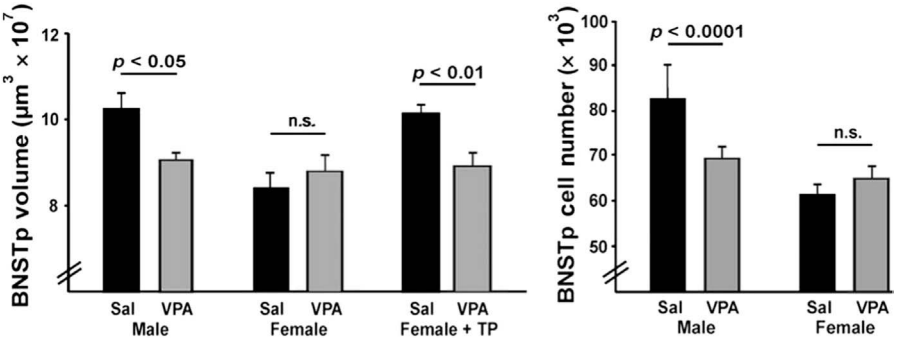

FIGURE 47.13 Treatment of neonatal mice with a histone deacetylase inhibitor prevents masculinization of the principal nucleus of the bed nucleus of the stria terminalis (BNSTp). Valproic acid (VPA), a histone deacetylase inhibitor, or saline (Sal) was given to male, female, or androgenized female mice (female + testosterone propionate) on postnatal days 1 and 2. All animals were sacrificed on postnatal day 21, and volume and cell number of the BNSTp were examined. As expected, saline-treated males and androgenized females had larger volume (left) and cell number (right) of the BNSTp than did control females (compare black bars). Treatment with VPA reduced the volume and cell number of the BNSTp in both males and testosterone-propionate-treated females but did not affect these measures in control females. These findings suggest that histone acetylation plays a role in sexual differentiation of the BNSTp. n.s.: not significant. *Source: Reprinted with the permission of the Endocrine Society from Ref. 268.*

acetylation.[269] When an HDAC inhibitor was infused into the cerebral ventricles of newborn male rats, these animals showed impairments in some aspects of male sexual behavior in adulthood. Similar behavioral effects were seen when antisense oligonucleotides to specific HDACs were infused neonatally. This latter observation is important because it strengthens the conclusion that the effects of the HDAC inhibitor were via its actions on histone acetylation, and not the result of some nonspecific action. The findings of Murray[268] and Matsuda et al.[269] are consistent in suggesting that masculinization of some aspects of neuroanatomy and behavior normally requires testosterone-dependent reductions in histone acetylation. Because reductions in histone acetylation are associated with reduced gene expression, this may mean that some gene or genes need to be turned off in males for masculinization, an interesting twist on the historical view that masculinization is an "active" event. Specific gene targets underlying the effects of the HDAC inhibitors in the studies by Murray[268] and Matsuda et al.[269] are not known. In the case of the BNSTp, since the sex difference normally arises via reduced apoptosis in males, cell death genes are predicted targets. Matsuda et al. observed dynamic, age-related changes and sex differences in histone acetylation in the ERα and aromatase genes in perinatal rats.[269] The challenge for the future is to test whether changes in histone modifications associated with specific genes are causally related to behavioral and neuroanatomical outcomes.

DNA Methylation

Changes in histone acetylation and DNA methylation often go hand in hand, with decreases in acetylation leading to increases in methylation, and vice versa. Methyl groups are added to cytosine residues on DNA, and this generally represses gene expression. A family of DNA methyl transferases (DNMTs) is responsible for placing methyl marks, and a recent study found that female rats express more DNMT3a mRNA and protein than males in the amygdala on postnatal day 1.[270] This was not seen in two other brain regions and was reversed by treating females with either an estrogen or androgen, suggesting that the sex difference in DNMT3a expression was due to gonadal steroids.

The methylation of gene promoter sites often recruits methyl binding proteins and co-repressors, which in turn cause the condensation of chromatin and decreased gene expression. In the hypothalamus and amygdala, neonatal female rats express more of the methyl binding protein, MeCP2, and nuclear receptor co-repressor (nCOR) than do males.[271,272] Taken together, several players in DNA methylation are upregulated in a hormone-dependent fashion in the female amygdala during the critical neonatal period.

In the preoptic area, however, the opposite pattern was seen: DNA methylation in the promoter region of the ERα gene was greater in neonatal males than in females.[273] This correlates with lower levels of ERα expression in the preoptic area of developing males.[143,274] Interestingly, simulated maternal grooming of females (stroking the rat pups with a paintbrush) increased ERα promoter methylation and decreased ERα expression to levels equivalent to those in control males.[273] Male rats normally receive more anogenital licking from the mother,[275] and this increases masculinization of several anatomical or behavioral traits. Thus, the findings of Kurian et al.[273] suggest molecular mechanisms whereby variations in maternal care can affect sexual differentiation of a gene that plays a crucial role in sexual differentiation of the brain.

Schwarz et al.[276] examined the DNA methylation status of promoter regions of the ERα, ERβ, and progesterone receptor genes in male and female rats throughout development. They found several sex differences that were age- and brain region-specific, suggesting dynamic regulation of methyl marks. Indeed, in at least two cases described so far (vasopressin and ERα), the gene may shuttle between methylation states, depending on testosterone status in adulthood (Figure 47.14).[276,277] Several labs are now taking a broader look at the role of DNA methylation in sexual differentiation. For example, Ghahremani et al. recently reported preliminary findings on a whole-genome survey to identify genes that are differentially methylated in sexually dimorphic regions of the mouse brain. Interestingly, the majority of the differentially methylated genes have increased methylation in males (or testosterone-treated females) compared with

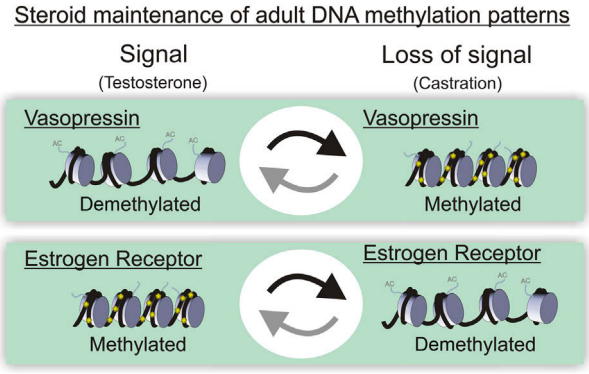

FIGURE 47.14 DNA methylation patterns within the adult brain may be more plastic than originally thought. While some DNA methylation patterns are stable, others have been shown to cycle between methylated and demethylated states. Within the adult male rat brain, testosterone regulates DNA methylation patterns of both the vasopressin and ER gene promoter regions. Loss of testosterone results in increased methylation of the vasopressin promoter and demethylation of the ER promoter. *Source: Adapted with permission from Elsevier from Auger and Auger (2013).*

females,[278] consistent with masculinization being associated with a turning off of genes, as suggested by the histone acetylation studies also mentioned here. Nugent and McCarthy[279] are taking a different approach by looking at changes in gene expression in the preoptic area of newborn male and female rats treated with a DNA methyltransferase inhibitor; any differences are presumably genes whose expression is normally regulated by DNA methylation. Although still preliminary, large-scale studies like these are likely to broaden our understanding of the contribution of DNA methylation to the differentiation of male and female brains.

See Chapter 52 for further discussion of epigenetics in reproduction.

CRITICAL PERIODS

Already in the 1959 landmark paper of Phoenix, Goy, Gerall, and Young,[28] the concept of critical periods in sexual differentiation was made explicit. Treating female guinea pigs with testosterone prenatally changed their behavioral response to hormones in adulthood, but that same effect was not seen in females treated with testosterone postnatally. These results suggested a critical window for the effects of testosterone on sexual differentiation of copulatory behavior.

Similarly, in one of the earliest reports of a sex difference in brain structure, the size of the SDN-POA, which is larger in male rats than in females (Table 47.1), was unaltered by gonadectomy or other hormone manipulations in adulthood but was reduced in males that were castrated as neonates.[67] A follow-up study was designed to determine exactly when testosterone acts to differentiate SDN-POA volume: injections of testosterone were given on single days between late gestation and early postnatal life, and adult size of the SDN-POA was measured in the resulting female offspring. A single testosterone injection on any day between embryonic day 18 and postnatal day 5, but not before or after, increased SDN-POA volume of females,[280,281] thus delineating a sensitive window for effects of exogenous steroids on SDN-POA development. One interesting wrinkle, however, is that the timing of the critical period for administering exogenous testosterone in females may not be the same as that for removing the endogenous androgens of males.[282]

The organizational–activational hypothesis of Phoenix et al.[28] went further than simply demonstrating the existence of critical periods by suggesting that effects of gonadal steroids are permanent (the organizational or programming effects of hormones) and that later in life they are transient (or activational). It is now clear that there is not a neat dichotomy between the early effects of steroids and those happening later in life.[283] Hormones acting long after the perinatal period can have lasting effects, for example, and there is no evidence for fundamentally different modes of hormone action in neonates versus adults. As far as we know, testosterone and its estrogenic metabolites bind the same receptors throughout ontogeny and trigger similar intracellular events. So, to the extent that steroids exert seemingly dichotomous action on behavior depending on whether they are present perinatally or in adulthood, it is likely due to differences in the developmental state of the tissues they act upon.

In some cases, the cellular basis for the existence of a critical period seems clear. As reviewed here, several sex differences in the nervous system depend on differential cell death in males and females, and in rodents the bulk of this cell death takes place perinatally.[177,202,284] Hormones clearly cannot bring dead cells back to life, so it is not surprising that the programming effects of steroids on cell number are time limited. Similarly, the migration of most newly born neurons to their final position in the rat brain is complete perinatally,[186,285,286] so hormones would presumably have to act pre- or early postnatally to significantly influence this process. For example, treating rats with dihydrotestosterone appears to halt the secondary migration of SNB motoneurons to a dorsomedial position in the ventral horn, but only if given prenatally, before the migration is complete.[287]

To the extent that neurogenesis and gliogenesis continue beyond perinatal development, however, the hormonal modulation of these processes could also occur later. It is now clear that in some parts of the brain, neurons are generated throughout life. To the extent that hormonal state can influence the generation or survival of these new cells, the "critical period" for hormone effects on cell number would remain open.[178,179,288,289]

Other sex differences depend on processes that are very active in development, but that nonetheless continue throughout life; the hormonal regulation of dendritic trees and dendritic spines in adulthood, discussed in this chapter, are examples. In at least one case, however, a critical period for hormone effects on dendritic growth has been described. Estradiol increases the dendritic extent of SNB motoneurons in male rats if given during the early postnatal period, but not if administered after the first few weeks of life.[290] The basis for this critical period may be the transient expression of ERs by the target muscles, which are the site of hormone action for estrogen effects on SNB dendrites.[290]

For more subtle sex differences, such as those defined not by cell number or morphology, but by gene expression, the basis of a critical period for hormone action may be less obvious. For example, early exposure to gonadal steroids can have a programming effect on the expression of steroid receptors that is not seen with later hormone manipulations.[144,291] Epigenetic marks that

determine gene expression levels are likely to play a role here. Although DNA methylation and histone modifications can be quite plastic, in some cases histone marks are very long lasting. Ghahramani et al. have recently demonstrated, for example, the presence of sex differences in DNA methylation that are due to early effects of gonadal steroids that remain evident even when circulating hormone levels are equalized in adulthood.[278]

Perhaps inspired by Phoenix et al.'s original dichotomy of "organizational" versus "activational" effects of gonadal steroids, for many years virtually all studies in the field of sex differences examined effects of gonadal steroids either during the perinatal period or in adulthood. The range of ages in between was rarely considered. More recently, however, it has become clear that manipulating hormone levels at puberty (well after the traditional "critical period" for sexual differentiation) can have lasting consequences on the brain and behavior, and consequences that are different from those seen when hormone manipulations are delayed until adulthood. In fact, as more investigators in the field have begun to recognize the importance of puberty for sexual differentiation, some have begun to refer to puberty as a "second critical period". This may be misleading, however. For example, when male hamsters are deprived of testosterone exposure during puberty, the ability to activate male sexual behavior is decreased in adulthood.[292] This indicates that pubertal exposure to gonadal steroids is required to fully organize the brain in the male direction. However, testosterone exposure is even more effective in enhancing later reproduction if it occurs somewhat earlier, that is, prior to normal puberty (Figure 47.15).[294] Thus, puberty may not be a period of renewed sensitivity, or a "second" critical period, but instead the end of a single, gradually waning sensitive period that starts perinatally.[294] In this view, puberty gains its importance not because of special hormonal responsiveness but because it coincides with a marked increase in circulating gonadal steroids over prepubertal levels.

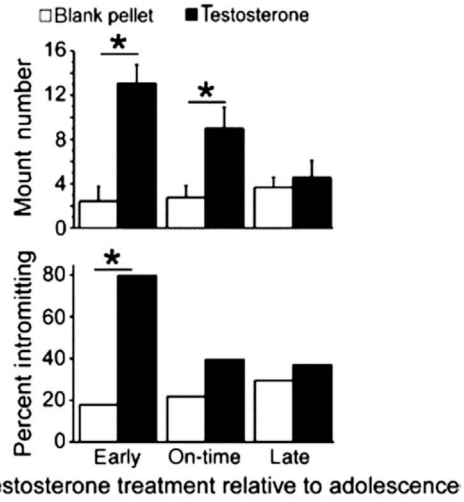

FIGURE 47.15 Effects of periadolescent testosterone exposure on adult reproductive behaviors. Testosterone treatments were designed to simulate early, on-time, and late pubertal development, and all behavior testing occurred in adulthood. Only pre- and mid-adolescent testosterone treatments increased mounts in response to testosterone in adulthood (top graph). Adult intromissive behavior was increased only by preadolescent testosterone treatments (bottom graph). These data suggest that early, preadolescent testosterone treatments may be even more effective than on-time treatments in enhancing behavioral responsiveness to testosterone in adulthood. *: Significant difference ($P<0.05$) between groups. *Source: Adapted with permission from Elsevier from Ref. 293.*

SEXUAL DIFFERENTIATION IN DIFFERENT CONTEXTS

Our understanding of the mechanisms underlying sexual differentiation of behavior rests heavily on research in laboratory rats and guinea pigs, which show clear differences in male and female sexual behavior. Mice were viewed as less useful for studying sexual differentiation in the pre-molecular biology era because behavioral sex differences in that species are less consistent. For example, some investigators find that when female mice are treated with testosterone or estradiol, they mount receptive females at similar or even higher rates than do males, suggesting that male sexual behavior is not sexually differentiated.[295,296] Other studies report that, as in rats, male mice show more masculine sexual behavior than females.[126,297]

Strain differences as well as testing conditions may explain such discrepancies. For example, following sleep deprivation, males show a stronger rebound of rapid-eye-movement sleep than females, but the size of the difference depends on whether the animals are stressed.[298] Context may also play a role in sex differences in reproductive behaviors. In one study, female rats showed a daily rhythm in estradiol's ability to stimulate lordosis behavior. As males did not show such a rhythm, the size of the sex difference in lordosis behavior changed markedly across the 24 h cycle.[299]

The conditions under which animals grow up also contribute to variability in sex differences. For example, most male prairie voles will respond paternally even when exposed to pups that they have not sired; virgin females, on the other hand, typically avoid or attack pups.[300] If females are raised to adulthood in the presence of their parents, however, they respond maternally to pups.[301] Much more subtle changes in developmental history can make a big difference: in one study, prairie voles showed sex differences in partner preference formation, or not, depending on whether they were transported by hand or in a plastic cup during routine cage changing.[302]

Studies on stress and the immune system may provide insight into the molecular processes leading to these different outcomes. In many cases, exposure to stressors during gestation and early postnatal life affects males and females differently. For example, prenatal stress typically affects males more than females.[211,303] This may create sex differences in functions and behaviors that are absent in unstressed individuals, or it may alter (usually diminish) the size of existing sex differences (Figure 47.16).[304]

One of the earliest reports of an effect of stress on sexual differentiation showed that pre- but not postnatal stress reduced male copulatory behavior and increased female-like sexual behavior in intact male rats.[305] Other groups have found similar, although not always identical, results (e.g., Refs 306,307). For example, Dahlöf et al. found that prenatal stress increased feminization, but did not affect masculinization of rat sexual behavior.[306] Physical stressors may also affect sexual differentiation: hypoxia during the last week of pregnancy reduced male rat sexual behavior, but did not affect female sexual behavior.[308]

Stress has also been mentioned as a factor in human homosexuality. Based on reports of a higher number of homosexual men born in Europe during, and shortly before and after, World War II compared to other times, and on questionnaire reports of homo- and heterosexual men about stressful events that their mothers may have been subjected to during pregnancy, some suggested that maternal stress increases the incidence of homosexuality.[309,310] Other studies, however, do not find such a link. For example, there was no significant association between homosexuality or gender identity and exposure to starvation in utero during the Dutch famine in World War II.[311] Differences in study design and quite possibly the nature of the stressors may explain differences in results. Other studies that assessed stress proneness of mothers and mothers' self-report of stress during pregnancy did not find an association between prenatal stress and homosexuality, although in one study prenatal stress predicted increased effeminate behavior among boys.[312] Another study did not find a link between prenatal stress and gender role behavior, but did find that smoking and alcohol use during pregnancy, physical stressors in their own right, were probably a factor.[313] Factors influencing human sexual orientation are discussed in greater detail in the section The Role of Hormones and Other Biological Factors in Sexual Differentiation of Human Behavior.

In addition to reproductive behaviors, exposure to stressors may also affect other sexually dimorphic behaviors. For example, prenatal stress reduces play behavior in male but not female rats.[314] Learning deficits and reductions in hippocampal neurogenesis, long-term potentiation, and dendritic spine density in the prefrontal cortex are more readily seen in prenatally stressed

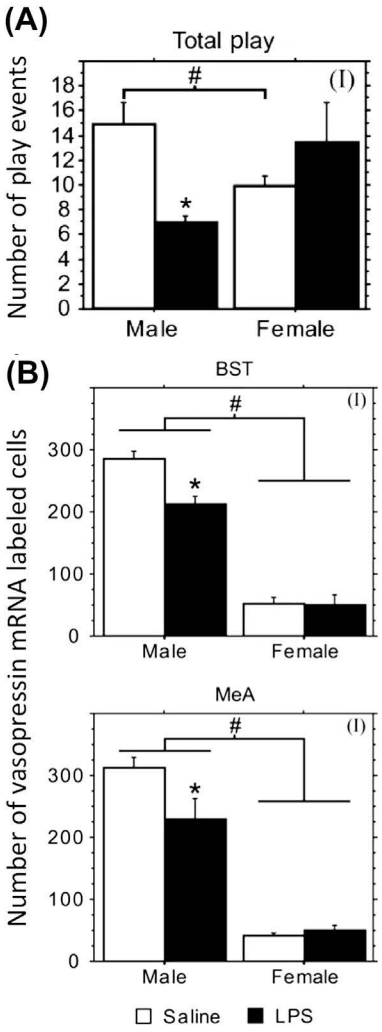

FIGURE 47.16 Effects of a prenatal immune challenge on the sexual differentiation of juvenile play behavior and vasopressin innervation of the brain. Pregnant rats were treated with the bacterial endotoxin lipopolysaccaride (LPS) on gestational day 15, and offspring were tested for juvenile play behavior between postnatal days 26 and 40. (A) The mean ± SEM number of total play events displayed in a 10-min testing period with sexually dimorphic control juveniles, with males playing more than females (white bars). Treatment with LPS reduced play in males, thereby eliminating the sex difference in play in those animals exposed to a prenatal immune challenge (black bars). (B) Following play testing, brains were collected, and the number of cells expressing vasopressin in the bed nucleus of the stria terminalis (BST) and medial amygdala (MeA) was determined by in situ hybridization. There was a sex difference in vasopressin cell number in control animals (white bars). Prenatal LPS challenge decreased vasopressin cell number only in males (black bars). *Source: Reprinted with permission of BioMed Central from Ref. 304.*

males, while anxiety, depression, and increased response of the hypothalamic–pituitary–adrenal axis to stress are more prevalent in females. In addition, after exposure to a social stressor during juvenile life (repeated exposure to an older, aggressive animal), anxiety and depression were increased much more in female rats than in males, suggesting that the sensitivity of the developing brain to

stress hormones may differ in the two sexes.[315] For more extensive reviews on the effects of pre- and postnatal stress on sexual differentiation, see Refs 209,303,316–318.

Context also plays a role in sex differences in human behavior. One of the most consistent cognitive sex differences is found in the Mental Rotations Test. In this famous test, subjects mentally rotate a block figure to match it with a congruent object in a line-up of similarly shaped but not identical objects. Males outperform females on this task in a wide range of studies, and a metaanalysis concludes that females exposed to elevated androgens prenatally perform better, on average, than control females on this task.[319] But, interestingly, a much smaller male advantage is seen if, instead of interconnected cubes, the figures take on a human shape (Figure 47.17).[320] Similarly, the male advantage in certain math tests is eliminated or reduced if female subjects are told in advance that females do as well as males or better on these tests, but sex differences are exacerbated if females are told the reverse (reviewed by Spelke[322]). In all of these cases, context, whether defined as the conditions during the test or those leading up to the test, clearly determines the performance outcome. To what extent these different behavioral outcomes are reflected in context-dependent structure or function of the brain is not known.

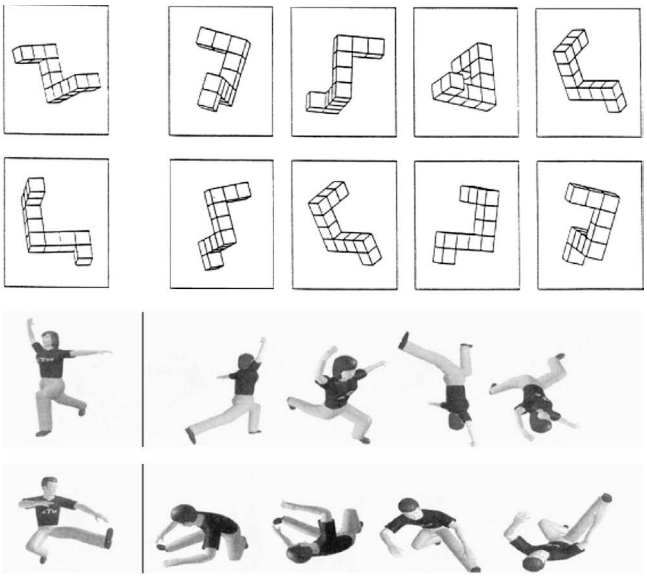

FIGURE 47.17 Size of the sex difference in the mental rotations task depends on the figures used. Top panels: samples of block figures used in the standard mental rotations task. Men generally perform better than women when these stimuli are used in the test. Bottom panels: examples of the human figures used in the modified task by Alexander and Evardone. The male advantage was reduced in this context, particularly if the figures depicted were female. *Source: Adapted with permission from Elsevier from Refs 320,321.*

THE RELATIONSHIP BETWEEN STRUCTURE AND FUNCTION

Although the authors of the classic Phoenix et al. 1959 paper suspected that during development, testosterone permanently changed the neural circuits that drive sexual behavior, they expected these changes to be "subtle" and manifested "in function rather than in visible structure."[28] Subtle changes were indeed found soon thereafter. In 1966, Pfaff showed that neonatal castration permanently changed the size of nucleoli in hypothalamic cells.[323] Four years later, McEwen et al. showed that neonatal steroid treatment altered testosterone and estradiol uptake in rat brains, which probably reflected changes in steroid receptor binding.[324,325] The following year, Raisman and Field used electron microscopy to reveal that males have more synapses of nonstrial origin on dendritic shafts and fewer on dendritic spines in the preoptic area than do females.[326] Although we still don't know the functional implications of these synaptic differences, this was the first demonstration of a morphological sex difference. Moreover, like sexual behavior, it could be reversed by neonatal manipulations of gonadal hormone levels.[237]

It soon became apparent, however, that sex differences were present in gross morphology of the brain as well. The first such difference was found in the size of song control nuclei in the brain of canaries and zebra finches, which are larger in males than in females.[327] A big surprise was Gorski and his colleagues' discovery of the SDN-POA (Table 47.1) 2 years later,[67] considering that its dimorphism is obvious to the naked eye in an area that had been looked at for decades. These early findings opened the floodgates. A PubMed search performed during the writing of this chapter yielded nearly 4000 hits for the entry "sexual differentiation OR sex differences" *and* "brain". Sex differences have been found almost everywhere in the brain, and many of these have been detailed in more than 100 scholarly reviews, some of which we cited in the beginning of this chapter. Finding sex differences clearly is not a problem.

A much more difficult problem has been identifying the *functional significance* of sex differences in brain structure. For example, the medial POA (mPOA) has been linked to male copulatory behavior, so when sex differences were found in this region they were reasonably supposed to be related to sex differences in this behavior. Similarly, sex differences in the ventromedial nucleus of the hypothalamus were presumed to underlie sex differences in female sexual behavior, and sex differences in the AVPV to underlie sex differences in the regulation of gonadotropic hormones, as these areas are most prominently associated with these respective functions.[215,328,329] Sex differences that were found in brain areas that have not been traditionally related to reproductive functions and behaviors have in some cases also been linked to sex differences in functions associated

with these structures. Sex differences in the cortex or corpus callosum, for example, have been attributed to sex differences in cognitive abilities, once again relying upon the notion that sex differences in structure beget sex differences in function.

However, sexually dimorphic areas have also been implicated in functions that show no clear sex differences, or that show differences that are not consistent with the differences in structure, suggesting that the relationship between sex differences in structure and function is not so simple. The mPOA and its role in male coital behavior provide a good illustration. Because the mPOA is required for male copulatory behavior in most vertebrates, when the SDN-POA was discovered, it was first speculated that the sex difference in neuroanatomy might explain the difference in coital behavior. However, lesions limited to the SDN-POA, a small subset of the whole mPOA, had little if any effect on male copulatory behavior in adult rats,[330–332] suggesting that the SDN-POA is dispensable for this behavior.

There are also discrepancies between the effects of perinatal hormone manipulations on size of the SDN-POA and the masculinization of sexual behavior in rats. For example, treating perinatal males with an aromatase inhibitor decreased the size of the SDN-POA in adulthood, but had little effect on masculine copulatory behavior.[333,334] Treating females with testosterone during late prenatal life increased the size of the SDN-POA without a concomitant increase in the likelihood that they would show male sexual behavior when given appropriate activating hormones in adulthood.[335] Finally, treatment of male or androgenized female pups with antisense oligonucleotides to steroid receptor coactivator 1 (to interfere with hormone action) decreased the size of the SDN-POA with no effect on male sexual behavior.[264]

In ferrets, similar inconsistencies are found in sex differences in male copulatory behavior and POA anatomy. Male ferrets have a nucleus in the dorsal POA (the "male nucleus", or MN), which females lack, and this difference is programmed prenatally by testosterone.[336] However, lesions restricted to the MN have only a minor effect on male coital performance.[337] Moreover, treatment of female ferrets with testosterone postnatally (after the MN normally forms) masculinizes sexual behavior without inducing an MN,[336] demonstrating that the MN is not required for masculine copulatory behavior.

Although size of the MN in ferrets, and homologous sexually dimorphic structures in other mammals, can clearly be dissociated from male copulatory performance, these structures nonetheless may play a role in a sexual behavior that is distinct from coital behavior, namely, partner preference. Unlike controls, male ferrets with lesions of the MN prefer male over female conspecifics[338,339] and male over female body odors.[340] Similarly, SDN-POA lesions disrupt sexual partner preference in rats,[341] and natural variation in male versus female preference in sheep correlates with the size of a sexually dimorphic nucleus in the mPOA, the "ovine SDN" (oSDN). About 8% of rams prefer mounting male rather than female sheep, and in these male-oriented rams, the oSDN is half the size of the oSDN in female-oriented rams.[75,342] This difference cannot be ascribed to adult testosterone levels,[343] but may be related to differences in prenatal levels as prenatal exposure to testosterone masculinizes the oSDN in females.[344] In humans, the third interstitial nucleus of the anterior hypothalamus (INAH3), which lies in an area homologous to the mPOA in rats, is larger in heterosexual males than in heterosexual females.[76] One study reported that the volume of INAH3 of homosexual males was smaller than that of heterosexual males.[345] Another found a trend in the same direction.[346] Thus, at present, our best guess about the functional significance of the sex difference in size of the SDN-POA and homologous nuclei is that they relate to sexual partner preference, although admittedly most of the evidence is correlational, and we still do not know how having extra cells in that area affects the attraction to one sex over the other.

Part of the difficulty of assigning a specific function to any given neural sex difference is that most brain regions are involved in numerous functions. In addition to its role in male sexual behavior, for example, the mPOA is critically involved in osmoregulation, thermoregulation, sleep, and parental behavior, to name a few. Some but not all of these other functions also show obvious sex differences; had the SDN-POA been discovered by investigators in the sleep or osmoregulation fields, the hypotheses initially proposed and behaviors examined after SDN-POA lesions may have been very different.

Another difficulty is that many sex differences in the brain may not cause sex differences at all. In fact, they may do just the opposite; they may prevent undesirable sex differences in gene expression, morphology, or function.[347] To take a familiar example, although X chromosome inactivation is exceedingly sexually dimorphic, as it takes places in every female cell and only in female cells, it serves to make gene expression of males and females more alike. That is, a very marked sex difference is there to play a compensatory role. Similarly, some sex differences in the brain may allow the brains of males and females to function similarly despite the very different hormonal conditions they experience in adulthood. At the neural network level, most things that the brain must do (e.g., thermoregulation) must be done by both sexes. A sex difference in one node of the network (i.e., a node that is larger or more active in one sex) may have to be offset by sex differences in other nodes. When viewing any sex difference in the brain, two obligatory possibilities should therefore be considered: the sex difference may be there to prevent or to cause a sex difference in behavior or another overt function of the brain.[32,348] (Figure 47.18).

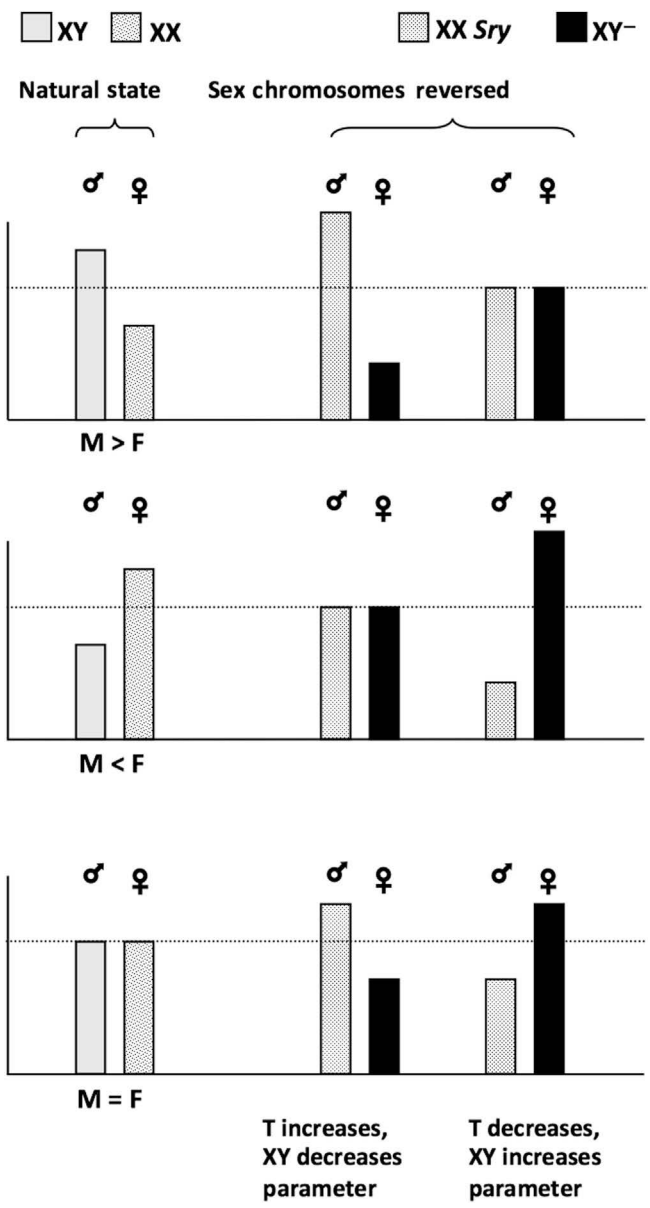

FIGURE 47.18 Gonadal steroid hormones and sex chromosomes may antagonize each others' effects or may synergize with each other in determining sex differences. The figure shows the results of a hypothetical comparison of a trait that differs between males and females, or not, in animals with normal sex chromosomes (XX in female and XY in males) or with a reversed sex chromosome complement (as in XX *Sry* males or XY⁻ female mice of the four core genotypes). The *bars on the left* (natural state) show three possible scenarios in which the parameter is larger in males than in females (M > F), is larger in females than in males (M < F), or does not differ in males and females with normal sex chromosomes (M = F). The *bars to the right* show how these parameters could differ in mice with reversed sex chromosomal complement if testosterone and the XY genotype antagonize each other's action. Under those circumstances, such antagonism may either enhance or eliminate normally occurring sex differences depending on the direction of the antagonism (either testosterone or the XY complement masculinizes the parameter). Likewise, such antagonism may induce differences in traits where they did not exist before. The male and female signs indicate gonadal sex. *Source: Reprinted with the permission of the Endocrine Society from Ref. 349.*

THE ROLE OF HORMONES AND OTHER BIOLOGICAL FACTORS IN SEXUAL DIFFERENTIATION OF HUMAN BEHAVIOR

Studies make it clear that most sex differences in the brain and behavior of animals can be attributed to one of a limited number of factors that may be considered "biological": direct effects of sex chromosomes, or the influence of hormones, principally androgens such as testosterone, or their metabolites. The extent to which these factors account for sex differences in behavior in nonhumans is really quite striking. For the most part, investigators are able to make the brains and behaviors of nonhuman subjects as masculine or feminine as they like, simply by controlling whether and when the individuals are exposed to steroid hormones. So to what extent do these same factors account for sex differences in human behavior?

Certainly there are sex differences in human behavior, but we humans have a long, protracted period of maturation, during which we incorporate tremendous amounts of information, virtually all in a social context, as we begin life utterly dependent on the nurturing of others, who are themselves acting within the confines of a rich cultural milieu. Because every human culture encountered so far promotes subtle, and sometimes not so subtle, sex differences in behavior, we cannot tell whether men and women behave differently because of the sorts of fetal hormonal mechanisms that are at work in animals, or because as boys and girls they were carefully taught, explicitly and implicitly, to behave differently. In other words, most human sex differences in behavior are equally compatible with either alternative.

As we consider various sex differences in human behavior, the question of whether, or to what extent, the differences are due to hormonal or other factors, and the alternative hypothesis of socially inculcated sex differences, will always be with us. Instead, we must rely upon correlational studies that can suggest, rather than demonstrate, whether biological factors have been at work. In addition, even when we find evidence that hormones exert an influence on behavior such that two groups of people differ, on average, in either the behavior they display or the evidence of past hormone exposure, we cannot identify any particular individual in which we can confidently say, "X hormone caused this person to show greater Y behavior".

Cognitive Function

We discussed in this chapter the sex difference in the Mental Rotations Test, which has been suggested to reflect an evolutionary history of men foraging widely for game while women stayed close to home to nurture

children. If this were indeed an evolved adaptation, one might expect the sex difference to be caused by males receiving greater fetal exposure to androgens, which notion is supported by reports that women with congenital adrenal hyperplasia (CAH), who are exposed to higher levels of fetal androgen than control women, also outperform those women on the Mental Rotations Test.[319] However, we also noted that a much smaller male advantage is seen if the figures represent humans rather than three-dimensional abstract shapes.[320]

Closely related to the sex difference in the Mental Rotations Test, at least among some theorists, is the sex difference in math performance. For many years, the average score on the mathematics portion of achievement tests such as the SAT was higher in boys than in girls. Some researchers suggested that this sex difference is independent of cultural or environmental influences. For example, in 1983, a publication in a high-profile journal, *Science*, purported to show that environmental influences were not responsible for the sex difference in SAT scores because it was also present among junior high school students who had not yet had a chance to choose elective courses in math.[350] Despite the naïve assumption that the only influence society might have on sex differences in cognitive function was through public school elective courses (ignoring, e.g., the "Baby X" experiments discussed here, suggesting social influences well before junior high school), this finding was widely reported in the national media as "proof" that sex differences in math ability are "biological", not "social".

The intervening years have not been kind to this hypothesis. First to chip away at this idea, as we mentioned here, was the discovery of stereotype threat, whereby members of a group widely considered to be inferior in some ability will display a decrement in performance on a test if they are reminded of this stereotype. In several studies, the supposed sex difference in math ability, especially at solving more difficult problems, disappears entirely if the subjects are told beforehand that there is no sex difference in performance. The sex difference disappears, not because the males' performance is affected, but because the girls' performance improves.[322] A second problem with the hypothesis that sex differences in math ability are "biological" is the fact that the sex difference in SAT math scores has been steadily dwindling over the past generation, so that it is in peril of disappearing entirely.[351] As we are aware of no change in "biological" influences on sexual differentiation of humans in that time period, the dwindling sex difference in math ability may be due to improved opportunities for women in academia and the workplace over that period. Supporting this notion is the finding that, among Western nations, those with the most gender-neutral cultures display the smallest sex differences in math performance. Indeed, in Iceland, which has a very gender-neutral society, girls now perform better than boys on tests of mathematical reasoning, on average.[352,353] Finally, if, instead of mathematical reasoning ability, we consider computational skill (basically, getting the correct answer when performing arithmetic), there has long been a female advantage.[351] To our knowledge, no one has asked whether male inferiority at this task is due to a detrimental influence of prenatal androgen. Thus, at this time it is difficult to support the idea that androgens, acting in either development or adulthood, have any effect on mathematical reasoning in humans.

There is another sex difference in human cognitive function that is much less discussed, which is the female advantage in most verbal tests. There has been less study of the causes for this sex difference, perhaps because it was smaller than the sex difference in math ability (although that may no longer be true). Because chromosomal males with androgen-insensitivity syndrome (AIS) display a female-typical ability in verbal tests, this sex difference might result from androgenic interference with verbal ability, but it could as readily be due to social influences, since XY individuals with complete AIS are typically raised as girls (see further discussion of this syndrome in this chapter). At the least, the verbal fluency of XY individuals with AIS, who also score in the female-typical range on spatial reasoning,[354] indicates that there is no effect of the Y chromosome on these cognitive differences. Interestingly, the same Icelandic study reporting that the sex difference in math ability disappeared when education became more gender-neutral also noticed that the sex difference in verbal ability increased.[352] This suggests that differential education of boys and girls may actually have served to reduce the size of this sex difference.

In short, most sex differences in higher order cognitive functions are small and getting smaller. This fact alone suggests that if these differences are affected at all by sex differences in androgen exposure, it is a small effect that would be difficult to study. However, we have yet to consider those domains that display much, much larger sex differences in human behavior: aggression, sexual attitudes, and sexual orientation. Let's consider these in turn.

Aggression

Examination of arrest records makes it clear that men are more aggressive than women, as men are over seven times more likely than women to be arrested for murder or manslaughter, and over four times more likely to be arrested for violent crime (Table 47.2). Are men more aggressive because of biological predispositions or because of cultural expectations?

TABLE 47.2 Sex Ratios in Criminal Offenses in the United States of America

Offense Charged	Male 2011	Female 2011	Sex Ratio
Total	5,910,637	2,083,579	2.8
Murder and nonnegligent manslaughter	5951	801	7.4
Forcible rape	11,934	135	88.4
Robbery	59,410	8381	7.1
Aggravated assault	200,755	58,010	3.5
Burglary	162,496	31,497	5.2
Larceny-theft	472,669	367,518	1.3
Motor vehicle theft	33,426	7450	4.5
Arson	6125	1260	4.9
Violent crime	278,050	67,327	4.1
Property crime	674,716	407,725	1.7
Other assaults	584,784	223,455	2.6
Forgery counterfeiting	28,542	17,001	1.7
Fraud	66,262	45,797	1.4
Embezzlement	5510	5565	1.0
Stolen property; buying, receiving, possessing	49,509	12,371	4.0
Vandalism	128,600	30,079	4.3
Weapons; carrying, possessing, etc.	87,682	7741	11.3
Prostitution and commercialized vice	10,439	24,497	0.4
Sex offenses (except forcible rape and prostitution)	42,872	3326	12.9
Drug abuse violations	761,050	193,114	3.9
Gambling	2238	453	4.9
Offenses against the family and children	49,408	18,183	2.7
Driving under the influence	579,176	186,459	3.1
Liquor laws	230,304	97,178	2.4
Drunkenness	303,138	66,955	4.5
Disorderly conduct	263,529	103,646	2.5
Vagrancy	14,406	3294	4.4
All other offenses (except traffic)	1,714,102	554,112	3.1
Suspicion	713	219	3.3
Curfew and loitering law violations	36,320	15,301	2.4

2011 estimated population 203,216,356.

In animal models, there is a clear influence of androgens on aggression, as castration in adulthood reduces aggressive behavior in males of many species, including rats, mice, roosters, dogs, and monkeys. In each species, exogenous testosterone treatment of castrates is sufficient to restore aggression.[355] It has been more difficult to determine whether circulating levels of androgen play a role in the greater aggressive tendencies of men compared to women. James M. Dabbs surveyed large samples of men, looking for correlates of circulating testosterone and various behaviors, occupations, and marital status, among other things. He reported that teenage delinquents and men convicted of crime had higher levels of testosterone, on average, than age-matched controls.

What's more, among men in prison, those convicted of sex or violent offenses had higher levels of testosterone than those convicted of property crimes or drug abuse,[356] as might be expected if androgens in adulthood "activate" aggression. However, Dabbs suggested that testosterone was not directly related to aggression per se, but was more closely related to dominance, since men who win chess tournaments, and spectators at sporting events whose favored team wins, also have higher levels of testosterone.[357] From that perspective, aggression might be more likely to occur among men seeking dominance over other men.

There are little or no data to address whether exposure to androgens early in life programs (or "organizes") aggression in men. Since direct measures of in utero androgen exposure are rarely obtained, available evidence rests on indirect indices. One such measure is digit ratios, which refer to the length of the second finger (index finger) divided by the length of the fourth (ring) finger. This ratio is sexually dimorphic and linked to prenatal testosterone, as discussed in detail in the section Correlates of Prenatal Androgen. Digit ratios suggest that men with indications of greater prenatal androgen exposure self-report more aggressive behavior[358] or, more specifically, aggressive *dominance* behavior.[359] Closely related to adult aggressive behavior are "externalizing behavior problems" in children. Boys with such behavior problems also have average digit ratios indicating greater prenatal androgen exposure than other boys.[360] One way in which greater prenatal androgen might increase the chance of externalizing behavior of boys, which is primarily reported in the classroom, might be by increasing attention deficit-hyperactivity disorder (ADHD). Indeed, digit ratios also indicate that boys with ADHD diagnoses were exposed to greater prenatal androgen than other boys.[361] A fascinating aspect of all of these reports of relationships between digit ratios and aggression or behaviors that might reasonably be expected to favor aggression is that they are seen only in males. None of the cited reports found a relationship between digit ratios and these behaviors in females, which suggests that a certain threshold of prenatal androgen exposure might be required before any effects on aggression-related behaviors would result.

A single functional magnetic resonance imaging study of females with CAH, which results in higher levels of prenatal androgen than in control females, supports that idea. When shown faces displaying negative emotions, adolescent girls with CAH showed a greater response in the amygdala than control girls,[362] a difference that makes them more masculine in this regard. As the amygdala has been associated with the experience of fear, it is possible that prenatal androgen above a certain threshold promotes a more fearful reaction to the negative emotions of others, which might lead to a greater propensity to reactive or impulsive aggression.

Sexual Attitudes

Perhaps the largest sex difference in any psychological trait in humans, certainly larger than the differences in math or verbal abilities, and perhaps larger than the sex difference in aggression, is the sex difference in attitudes about sexual behavior. Across societies, men report a greater interest than women in uncommitted sex, sometimes referred to as sociosexuality.[363] For evolutionary biologists, this sex difference in sexual attitudes fits well with sex differences in sexual behavior in almost all mammals, which has been explained as a result of sex differences in reproductive strategies between individuals making millions of tiny, inexpensive gametes (sperm) and those making relatively few, large, expensive gametes (ova). In mammals, reproducing via ova requires even more resources in order to nurture the offspring through an extended, internal gestation followed by neonatal lactation.

Still, given the pervasive attention of human culture to sexual behavior, the sex difference in interest in casual sex could in theory be due to socially inculcated values. On the other hand, there is evidence that circulating levels of testosterone in men correlate with interest in casual sex,[364] so that the sex difference in this attitude could theoretically be a result of the sex difference in circulating androgens in adulthood. These results also suggest that androgenic augmentation of interest in casual sex, if present, may be unrelated to any programming effect of steroids. Correlating circulating testosterone with sexual behavior in men is complicated by the well-established finding that men in stable sexual relationships have, on average, lower levels of circulating androgen than single men.[357] By definition, almost all of the married men in these samples had been, earlier, part of the population of single men, suggesting that the establishment of a regular sexual outlet reduces androgen secretion.

These two seemingly disparate findings—that testosterone boosts interest in sex, while having sex reduces testosterone—can be reconciled as a case of negative feedback. If androgen both boosted libido and was boosted by sexual behavior, that would lead to a positive-feedback system where androgens would be progressively driven higher and higher. Given the costs of circulating androgen, which inhibits the immune system and increases risky aggressive behavior, thereby increasing the risk of injury, such a positive-feedback system would be maladaptive. If so, then any analysis of a relationship between androgen and interest in casual sex would need to control for the amount of sexual activity and/or the presence of a regular sexual partner. One recent study using such an analysis found that, once the

influence of sexual activity reducing testosterone levels was controlled for, circulating levels of testosterone in men could account for over 20% of the variance in residual sociosexuality.[365] Interestingly, there was no correlation between testosterone and interest in casual sex among women, suggesting that either levels of androgen in women fall below some threshold to activate interest in casual sex, or that exposure to male-typical levels of androgen in utero is required for adult testosterone to activate these attitudes. Of course, it is also possible that cultural norms encouraging interest in casual sex for men, and discouraging it for women, mask any effects of circulating testosterone in women.

Sexual Orientation

Nowhere is the difficulty of explaining human sex differences in behavior more obvious than in the question of sexual orientation. The vast majority of men are gynephilic (sexually attracted to women), and the vast majority of women are androphilic (sexually attracted to men). Like other sex differences in behavior, this sex difference in sexual attraction is equally compatible with either hypothesis: society teaches boys and girls to develop sexual yearnings for the opposite sex, or the fetal androgens that make boys in utero also program their brains to be attracted to women later in life. But, of course, not all humans are sexually attracted to the opposite sex. While estimates vary depending on the definition, about 5% of humans report having significant same-sex attraction. Unlike heterosexuals, homosexuals contradict both hypotheses about how sexual orientation develops. They are attracted to the same sex, despite the putative influences of either fetal hormones or social upbringing. Thus, homosexuality needs explaining more than heterosexuality, but not because homosexuals are "unnatural" (whatever that means), a minority, or any more appropriately considered an object of study than heterosexuals, or because any efforts are needed to prevent homosexuality. Rather, homosexuality needs explaining precisely because it disputes the only two hypotheses that we have about human sexual orientation generally. That means that homosexuality offers us an opportunity to understand sexual orientation generally, including the vast majority of cases when people are heterosexual. If we can discern whether fetal hormones or social influences play a role in instigating those few cases of homosexuality, then we will have evidence that such influences may be at work in heterosexuals, too.

In its simplest form, an organizational or programming hypothesis of homosexuality would posit that most boys grow up to be gynephilic, and most girls grow up to be androphilic, because of their differences in fetal exposure to androgens. From this perspective, perhaps some boys fail to receive enough fetal androgen exposure to develop gynephilia, and some girls are exposed to enough fetal androgen that they become gynephilic. In other words, perhaps there is some threshold amount of fetal androgen exposure that one must receive to develop gynephilia later in life, and some boys receive less than that threshold amount, while some girls receive more than that threshold amount. On the face of it, this simplistic hypothesis is refuted by anatomy. Since almost all gay men were born with a penis, and virtually all lesbians were born without one, we know that there is no simple threshold for fetal androgen to determine gynephilia. On the other hand, it is always possible that the fetal period when androgens organize the genitalia may be different than the period during which androgens might organize the brain. So although all gay men received more androgen stimulation than any lesbians during the fetal period forming the genitalia, there may be some other period of fetal development during which the sexes do overlap in androgen stimulation. It may be during this fetal period that hormones organize gynephilia in the brain. Alternatively it is possible that the brains and genitals differ, either in their sensitivity to androgen or in the mechanisms triggered by androgen stimulation, such that a step (enzyme–protein–epigenetic modification) required for full response in one tissue has no role in the other. In this way, the same hormone level could produce a maximal response in one tissue while failing to stimulate another tissue above some threshold.

Furthermore, if we accept that human sexual orientation is influenced by many things, including genes and social influences, then it is always possible that while there is no hard-and-fast threshold for androgenic induction of gynephilia at any stage of development, it is also possible that androgen levels at some point in fetal development play a contributing (not determining) role, and that in those cases where everything else is equivalent, slightly higher or lower androgen levels than typical for that person's sex may make the difference in whether heterosexuality or homosexuality unfolds later in life.

Disorders of Sexual Development

In the absence of experimental manipulation, determining whether sex differences in human behavior result from the same sorts of processes that account for sex differences in the behavior of nonhuman subjects is not easy. We can resort to relatively rare individuals in whom biological mechanisms unfold in an atypical way and ask whether that divergent biological process is correlated with any discernible divergence of behavior. These examples of disorders of sexual development (DSDs) are well studied, so we have some data about whether they are gynephilic and/or androphilic, which might relate to their atypical production and/or

response to fetal hormones. Unfortunately, in the end there is always room for argument, as we'll see.

Through most of the twentieth century, the little evidence that fetal hormones might have any influence on human sexual orientation came primarily from the study of individuals with various DSDs. For example, in AIS, XY individuals inherit a loss-of-function allele for the AR. The Y chromosome induces the indifferent gonads to develop as testes; the testes secrete androgens such as testosterone, but the genitalia cannot respond to the hormones because they lack a functional AR. Thus, the genitalia develop in a feminine fashion, and the child is born with a feminine appearance and raised as a girl. Upon reaching adulthood, the vast majority of women with AIS are sexually attracted to men.[366,367] Note that this outcome is equally compatible with a role of either fetal androgens or social influences molding sexual orientation. We don't know if women with AIS are attracted to men because their brains could not respond to prenatal androgens to induce gynephilia, or because they were raised as girls in a culture that teaches girls to marry men one day.

Nevertheless, the androphilia of women with AIS is still informative regarding mechanisms that might be at work in human sexual orientation because it contradicts one prediction that might arise from the animal literature. In several mammalian species, including laboratory rodents, there is incontrovertible evidence that testosterone reaching the brain is often converted, via a process called aromatization, into an estrogen, which then interacts with ERs, rather than the AR, to masculinize brain structures and behaviors. As women with AIS have fully functional ERs and ample circulating testosterone to be aromatized into estrogens, their androphilia argues against the idea that aromatized metabolites of testosterone, which play such an important role in masculinizing the rodent brain, have a major role in masculinizing the human brain, at least in terms of sexual orientation. The predominant androphilia of women with AIS tells us that if fetal androgens act upon the brain at all to affect sexual attraction, they probably act through ARs, not through aromatization and ERs. Consonant with this conclusion, those few men who have been identified as lacking a functional aromatase enzyme, and are therefore severely estrogen deficient, are described as masculine in outlook (gynephilic),[368,369] as was a man who, due to a mutation of the ERα, was severely estrogen resistant.[370] The androphilia of women with AIS, who carry an XY karyotype, would also seem to eliminate the possibility that sex chromosomes play any major role in human sexual orientation.

Another clinical condition suggests more directly that ARs may affect human sexual orientation. CAH describes several different conditions, which can result from alterations in several different genes, in which a fetus is unable to secrete sufficient levels of glucocorticoids from the adrenal glands. Lack of glucocorticoid feedback to the pituitary leads to higher adrenocorticotropic hormone secretion, which causes hyperplasia of the adrenal glands and higher than normal levels of adrenal androgen secretion. Usually, the genitalia of CAH individuals are partially masculinized at birth; specifically, the clitoris appears enlarged, which leads to diagnosis and supplemental glucocorticoids to promote the child's development and to avert further androgen secretion from the adrenal glands. It is clear that girls with CAH are masculinized in terms of several behaviors, especially juvenile play behaviors.[371] It is also clear that girls with CAH, upon reaching maturity, are more likely to have a homosexual orientation than controls.[372] This outcome has been presented as strong evidence that fetal androgens affect the development of sexual orientation, but the argument is far from compelling. First, the majority of women with CAH are heterosexual,[372] despite the fact that they all have seen higher levels of fetal androgen than control women, including, presumably, many lesbians. One could argue that more of these women would be lesbians but for societal pressures favoring heterosexuality. Indeed, it is interesting that the percentage of women with CAH reporting a homosexual orientation increases as the age of the women being surveyed increases,[373] suggesting that some of these late-blooming lesbians were previously conforming to social pressures.

But, as noted in this chapter, social pressures can work in several different ways. It is difficult to assess the extent to which ambiguity about the child's genital sex might affect parental attitudes. Likewise, these girls, unlike control subjects, have a history of medical interest in their genitalia, which may include cosmetic surgery to "correct" the appearance of the pudendum, especially the size of the clitoris. Does having one's genitals regularly examined by medical staff and parents affect a child's sexual development? In fact, surveys of women with CAH indicate that few of them have sex with anyone. Of those instances, even fewer are with a female partner. For example, in one study, only 16 of the 159 women with CAH had ever had sex with another woman.[373] Is it possible that these women are sufficiently self-conscious about their genitalia, either because they are atypical (for those who did not have plastic surgery as infants) or because there is a loss of sensitivity (for those who had plastic surgery), so that they are more sexually inhibited than controls? If so, then one can imagine that a young woman who was self-conscious about her genitalia might anticipate that a lesbian partner might be more accepting of her atypical genitalia than would a heterosexual male.

Unfortunately, the relatively public nature of a CAH diagnosis inevitably affects the child's social milieu,

which may in turn have a socially mediated influence on sexual orientation. This confounding variable clouds the assessment of whether prenatal androgens affected sexual orientation in these women by acting on the brain, as the organizational hypothesis would suggest, or by acting upon the genitalia to affect the social environment, as social theorists of orientation development suggest.

The famous John/Joan case, in which an otherwise healthy male child was raised as a girl after his penis was badly damaged during a botched circumcision, was first touted as proof that social environment was sufficient to establish gender identity and sexual orientation.[366] In college psychology courses around the world, or at least the one offered to one of the present authors, the John/Joan case was presented as an existing proof that socialization was sufficient to account for gender identity and sex differences in behavior. The boy had been exposed to normal male levels of androgen prenatally, but when reared and socialized as a female, grew up to be a perfectly typical teenage girl, we were told. However, the revelation that this story was untrue threw the case in a very different light. The subject at puberty rejected his female identity, which could have been due to prenatal androgen masculinizing his brain. He took on a masculine gender identity, choosing the name David; acquired a wife and stepchildren; and embraced the roles of husband and father. But here, too, there was plenty of room for social influences, as the child was raised as a boy until 7 months of age, after which he was raised as a girl and subjected to considerable scrutiny by doctors, including annual interviews about sexual attitudes that few other children endure.[374] It seems very unlikely that the parents, having lived with a son for 7 months, would be able to unambiguously treat the child as a daughter thereafter. So was David masculine because of prenatal androgens acting on his brain, or due to incomplete socialization toward a feminine identity?

The *guevedoces*—people who are raised as girls and then, at puberty, develop masculine genitalia—are sometimes offered as evidence that prenatal androgens masculinize the brain. This syndrome results from a deficiency in 5-α-reductase,[375] which normally amplifies the androgenic signal in peripheral tissues by converting testosterone to dihydrotestosterone, which has a greater affinity for AR. These individuals are born with only partially masculinized external genitalia. The onset of androgen secretions at puberty further masculinizes the genitalia so that the phallus now resembles a penis more than a clitoris, and the swelling testes (informally referred to as "eggs" in the community) are now apparent. In the Dominican Republic community where this syndrome was first recognized, these individuals take on a masculine identity and role.[375] The simplistic presentation is that these people who are raised as girls simply shrug off social influences to become boys at puberty. The fictional presentation of such a case in the United States, in Eugenides' novel *Middlesex*, adheres closely to this idea, presumably because it was informed exclusively by the medical literature, as the author claimed to have never met anyone with this condition or any other DSD.[376]

But because the Dominican Republic community has a nickname for such individuals (*guevedoces*, or "eggs at 12"), it is hard to know how early in life they are identified by their family, society, and themselves. Thus, it is possible that these "girls" are instructed early on in their development that they will one day turn into boys. If so, then the transition could, in theory, be entirely socially mediated, independent of prenatal androgen (except to the extent that the condition sets the stage for the child to sprout the requisite "eggs" at puberty).

Because gender is such an important component of our presentation to others, any DSD that is apparent to family and physicians could, in theory, affect the perceptions of other people and thereby affect the blossoming of sexual orientation and gender identity via social influences. In the end, it is not clear whether these "experiments of nature" are truly a boon to our understanding of the ontogeny of human sexual orientation, or are "sciency" Necker cubes that are perceived by those favoring a prenatal hormone influence on sexual orientation as more compelling than they actually are.

Correlates of Prenatal Androgen

Because all of these clinical cases (AIS, CAH, *guevedoces*, and John/Joan) leave ample room for social influences on sexual orientation, there was little independent evidence that prenatal androgens, independent of socially mediated effects, influence human sexual orientation until 1998. That year, Dennis McFadden and Edward Pasanen reported that lesbians significantly differ from straight women in terms of otoacoustic emissions—sounds emitted from the ear as part of the "cochlear amplifier" that aids hearing (Figure 47.19).[377] On average, females produce more of these emissions than do males, and this sex difference is present at birth. It seems likely that the sex difference is due to prenatal androgens masculinizing the auditory system of males, reducing the production of otoacoustic emissions, because women who had a male twin have slightly masculinized levels of otoacoustic emissions.[378] Thus, the reduction in emissions from lesbians, on average, compared to straight women could be due to the lesbians receiving, on average, greater exposure to prenatal androgen than the straight women. The great strength of this demonstration was that there seems to be little room for any socially mediated factors to be at play. Almost no one knew otoacoustic emissions existed, and they are cryptic, not perceived by either the individuals or those

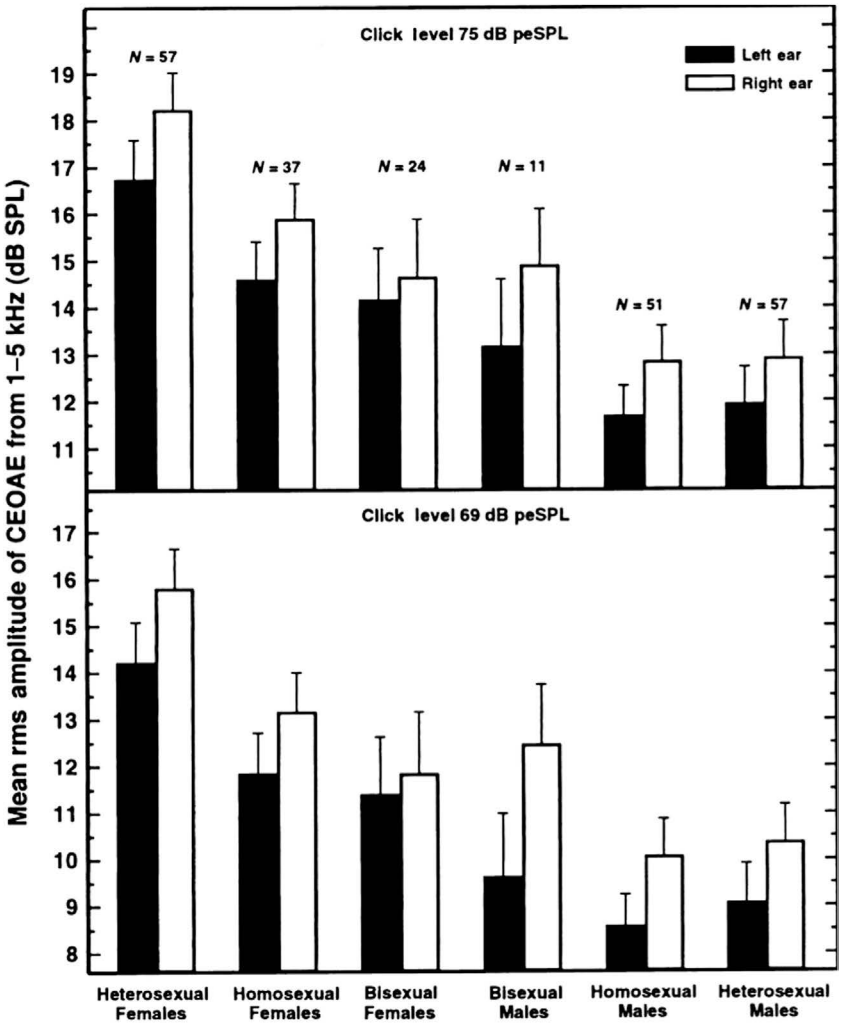

FIGURE 47.19 Otoacoustic emissions (OEAs) in response to clicks are sexually dimorphic and differ by sexual orientation in women. Shown is the root mean square (rms) amplitude of the averaged click-evoked OEA waveforms for the two highest click levels tested (75 and 69 dB peak equivalent sound pressure level (dB peSPL)), averaged across all subjects in each group. Responses to 250 clicks were collected for each click level. The error bars indicate one standard error. Amplitudes were higher for heterosexual women than for heterosexual men. OEA amplitudes of homosexual and bisexual females were reduced compared to heterosexual females, and were intermediate to those of heterosexual males and females. Sexual orientation did not affect OEAs in males. *Source: Reprinted with permission of the National Academy of Sciences from Ref. 377.*

around them. Thus, there seems little chance that any of the individuals, as children, noticed how masculine or feminine their otoacoustic emissions were, and their families surely didn't notice, either. It is difficult to conceive of any reasonable hypothesis to explain why lesbians, on average, had fewer and weaker otoacoustic emissions than straight women except that the lesbians, on average, had been exposed to greater prenatal androgen than the straight women. Nevertheless, the report from McFadden and Pasanen was subjected to a great deal of criticism, not only from the public, especially those who disapprove of homosexuality, but also among colleagues who had been studying the effects of perinatal hormones on animal brains and behavior. For whatever reasons, researchers who had placed great faith in the clinical cases, despite the inherent confounds of socialization accompanying them all, either rejected the data from otoacoustic emissions or acted as if they did not exist.

In this context, the report of a sexual dimorphism in the pattern of finger lengths that is present in 2-year-old children[379] offered a characteristic that could confirm or refute the findings of McFadden and Pasanen.[377] As described in this chapter, this sexual dimorphism in finger lengths refers to the ratio of the length of the second digit (2D) divided by the length of the fourth digit (4D). This 2D:4D ratio is greater, on average, in females than in males. It was later discovered that this sexual dimorphism is present before birth[380,381] and so cannot be caused by social influences. It is almost certainly due to sex differences in prenatal androgen exposure, because it is masculinized in people with CAH[382,383] and feminine in women with AIS.[384] The latter finding demonstrates that the sex difference in digit ratios cannot be due to sex chromosomes. In addition, in mice, in which females also display a larger 2D:4D ratio than males, AR is found in the cells of fetal digits, and several different pharmacological manipulations of AR stimulation affect digit ratios as predicted.[385] As with otoacoustic emissions, almost no one knew this sexual dimorphism existed, so it is difficult to believe that any girls' digit ratios were ever noticed by themselves or their families. Therefore, it seems unlikely that digit ratios ever influenced any social interactions.

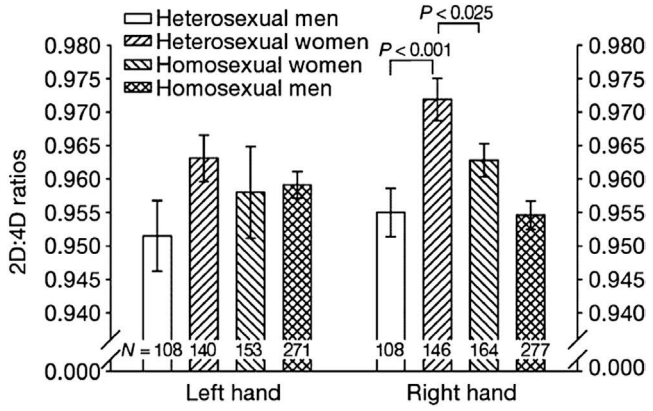

FIGURE 47.20 Finger length patterns vary with sex and sexual orientation. Among heterosexuals, the mean 2D:4D ratio is larger in women than in men, especially on the right hand. The right-hand 2D:4D ratio of homosexual women is more masculine (that is, smaller) than that of heterosexual women. *Source: Reprinted from Ref. 386, with permission from Nature Publishing Group.*

Nevertheless, lesbians, on average, have more masculine digit ratios (i.e., lower ratios) than straight women (Figure 47.20).[386] This finding has been replicated in many independent studies (but see Ref. 387) and confirmed in a metaanalysis.[388] Perhaps the most impressive replication was one with the smallest sample size—among seven pairs of female monozygotic twins discordant for orientation, the digit ratios of lesbians were smaller, on average, than those of their heterosexual sisters.[389] As with the differences in otoacoustic emissions, it is difficult to think of any reasonable explanations for why lesbians, on average, would have a lower 2D:4D ratio than straight women except that the lesbians, on average, were exposed to more prenatal androgen than the straight women. From one perspective, this finding is surprising because it is clear that at least some women are "fluid" in their sexuality, reporting having had a homosexual orientation at one period of their life and a heterosexual orientation at others.[390] Thus, it seems highly likely that some women develop a homosexual orientation that is completely unrelated to prenatal androgen. These instances of lesbianism would be expected to dilute any average difference in the digit ratios of homosexual versus heterosexual women. Indeed, in the only study that categorized lesbians, those who described themselves as "butch" had more masculine digit ratios than those who described themselves as "femme".[391]

Despite being firmly established, the difference in digit ratios between lesbians and straight women is often misunderstood, due to failure to distinguish between *average* differences between groups, and differences between particular *individuals*. The overlap in digit ratios between the sexes is extensive, as the male average is only about 0.5 standard deviations less than the female average. That extensive overlap means that one cannot reliably determine any individual's sex based on digit ratio, despite the fact that almost all females were exposed to less prenatal androgen than virtually any male. Presumably, any variation within a sex would be even less than that between the sexes. Thus, one cannot compare the digit ratios of any two individuals and reliably predict, based on that difference alone, which was exposed to greater prenatal androgen. This is even true if the two individuals are of opposite sexes! In other words, digit ratios do not offer a shibboleth to detect individual lesbians. Indeed, there is no need for such a shibboleth, as one can readily ascertain anyone's sexual orientation simply by asking them in a context where they can feel it is safe to answer.

In the meantime, several other sexually dimorphic traits, such as otoacoustic emissions discussed above, and prepulse inhibition, the phenomenon that a weak stimulus inhibits a startle response to an immediately following stronger stimulus,[392] also indicate that lesbians, on average, were exposed to greater prenatal androgen than heterosexual women. These traits also seem unlikely to directly affect anyone's social interaction and so contribute to the picture that prenatal androgen can prime the female fetus to make it more likely that she will develop a homosexual orientation by puberty. Interestingly, digit ratios, otoacoustic emissions, and prepulse inhibition, while differing between gay and straight women, do not differ between gay and straight men. This common finding across the three indices suggests that they all truly do reflect prenatal androgen or, at the least, that they all three reflect some prenatal factor.

These results in females conform reasonably well to the simple model that prenatal androgen might favor the development of gynephilia. Do digit ratios or otoacoustic emissions indicate that homosexual men were exposed to less prenatal androgen than straight men? The answer is a clear and resounding "No".[377,388] Despite the fact that gay men, on average, display less masculine play behavior as children across cultures[393] and less masculine career interests at maturity than straight men,[394] we are not aware of any morphological characteristic that indicates that homosexual men were underandrogenized in utero. In fact, if the most reliable morphological indicator of prenatal androgen influence is the genitalia, reports that gay men, on average, have a larger penis than straight men[395,396] suggest that, if anything, gay men saw more, not less, prenatal androgen than straight men.

We are left with the paradox that prenatal androgen seems to promote gynephilia in females, yet gay men, who are less masculine than straight men for certain behaviors, including gynephilia, show no somatic evidence of reduced perinatal androgen stimulation. On the other hand, there are some behaviors in which gay

men seem fully as masculine as straight men. Importantly, these behaviors are most closely associated with sexual behavior, namely, the male bias in propensity to masturbate, interest in visual pornography, interest in multiple partners and casual sex, and attraction to young, physically attractive sexual partners.[397] These behaviors are also precisely those that show the greatest sex differences among heterosexuals, far greater than the sex differences in rough-and-tumble play in children or verbal skills, math reasoning, or various memory tasks in adulthood. There is only one large sex difference in human behavior, other than gynephilia, for which gay men are reported to be undermasculinized, and that is throwing accuracy.[398] However, the sex difference in throwing accuracy could be magnified by experience if boys are more likely than girls to be drawn to activities involving throwing. Thus, the feminine throwing accuracy of gay men could well be a secondary product of their feminine play behavior and career interests, rather than a product of a deficit in prenatal androgen per se. Because gay men are hypomasculine for some behaviors but not for others, it would be difficult to see how any global deficit in prenatal androgen could be responsible.

Taken together, there is little or no evidence that gay men were underandrogenized perinatally. So it appears that the variance in sexual orientation cannot be accounted for by variance in perinatal testosterone exposure. Yet the fact is that most men are gynephilic, and that gynephilia in lesbians appears to be influenced by prenatal testosterone. How does one reconcile these findings? One possibility is that prenatal androgen does indeed foster gynephilia, and that all males receive enough prenatal testosterone to maximize whatever testosterone does to the developing brain to promote masculine sexual attitudes and gynephilia. This would explain why gay men can be so masculine in terms of sexual attitudes. What, then, can account for the variability across men in sexual orientation?

By definition, the final common pathway for testosterone's masculinizing influence, whether considering the well-established effects on genitalia or the putative effects on the brain, is the interaction of an androgenic hormone with the AR. But after that point, surely the set of AR-modulated genes that underlie growth of the penis are different from those that regulate brain development, leading, say, to a propensity to masturbate or to an interest in multiple partners or visual pornography. Presumably, there are at least some differences in the set of genes modulated by androgen even within the brain, such as in those circuits concerned with masturbation versus those concerned with young, physically attractive sexual partners. Thus, it may be that the variance in sexual orientation in men is not due to variability in prenatal androgen exposure, but to variability in the propensity of those brain circuits concerned with gynephilia to respond to that androgen exposure.

Indeed, there is ample evidence of genetic influences on human sexual orientation. Of necessity, that evidence is somewhat vague because, despite the irrefutable evidence that genes influence sexual orientation, it is already clear that this consists of a multitude of genes, each having a say, with none predominating over the others. That means, among other things, that no one has yet identified any particular gene that plays a role in sexual orientation. So it is difficult to speculate about how the genes might work. But it seems plausible that at least some of the genes, when identified, will turn out to be among those that are normally modulated by androgen influences.[399,400]

If, indeed, variability in genes that act downstream from testosterone activation of the AR accounts for variability in sexual orientation in men, then those genes will not be among those downstream from androgen's influence on masturbation or interest in casual sex. Rather, the genes modulated by androgen to affect gynephilia may also be among those that are hypomasculine in gay men—the more cognitive domains, such as verbal prowess, social acumen, spatial memory, and career interests. If correct, this reasoning may offer a strategy to identify genes involved in gynephilia by coordinating such a search with those looking for genes affecting spatial memory and social and spatial cognition.

One appealing aspect of this speculation is that it seems plausible that androgenic influences on the more "basic" aspects of male sexuality, such as a high sex drive and seeking many partners who are young and attractive, appear, in some sense, to be related to masculine genitalia. This could even be a direct effect. Perhaps it is being born with a penis, and therefore receiving the stimulation that comes from possessing an intromittent organ long before one has a chance to intromit, that leads to developing the high sex drive that males typically sport along with their penis. Ironically, this scenario resembles the sort of theorizing that was offered by Sigmund Freud, a favorite whipping boy of many psychologists. It is, in fact, a version of "anatomy is destiny". If boys, with their protruding penises, inevitably receive more genital stimulation during development than girls, and if that additional genital stimulation promotes a greater sex drive, with attendant desires for multiple partners and greater interests in visualizing potential partners, then maybe the reason why gay men share these behavioral proclivities with straight men is simply a result of something else they have in common—a penis.

In any case, if the suite of genes that promote penis development and masculine sex drive is different from those genes that promote gynephilia and the more cognitive aspects of sexual dimorphic behavior, then there is still room for more refined influences on behavior,

that is, those that result from differences solely within the brain rather than those driven by the accidents of peripheral structures. But in reality, the difference is not in terms of whether "anatomy is destiny" because anatomy matters in the brain, too. Indeed, for any behavioral differences, neuroanatomical measures, at some level of analysis (whether the number of neurons or the strength of synapses), must be responsible. The distinction then is between influences that androgen might wield over the brain indirectly, by affecting the body and therefore affecting experiences that shape the brain, and those that act directly upon the brain, altering behavioral potentials by influencing neurons directly.

Note that in this discussion we have skirted the issue of gender identity: whether one considers oneself to be male, female, or some alternative gender. For example, transsexuals are people who were born and raised as one gender but, at some point in their lives, begin to strongly feel that in fact they belong in another category. Thus, gender identity is separable from biological sex, and can also be independent of sexual orientation (e.g., not all male-to-female transsexuals are sexually attracted to men). There is woefully little research concerning any possible biological basis for transsexuality, in part because, compared to homosexuality, transsexuality is rare and has only recently come to the attention of the public, including researchers. There are reports of limbic regions that are more feminine in size and neuron number in male-to-female transsexuals than in control,[401,402] but it is difficult to eliminate the possibility that differences in exogenous steroid exposure did not affect the brain. Also, as with Swaab and Hoffman's and LeVay's findings in the early 1990s of differences in the hypothalamus of gay versus straight men,[345,403] such studies necessarily rely on postmortem materials, so that we can never follow the development of the hypothalamic region in a single individual. Thus we cannot know whether the brain difference preceded or followed the expression of transsexuality.

See Chapter 48 for additional discussion of the biological basis of sexual orientation.

WHAT WILL THE FUTURE BRING?

Although this chapter testifies to the impressive progress that has been made in the past half century in understanding sexual differentiation of the brain, many questions remain to be resolved. What follows is just a sampling.

How Pervasive are Sex Differences in the Brain?

The extent of sex differences in the brain is anybody's guess. For years, we have focused on sex differences that either are very obvious morphologically or are found in areas known to be involved in sexually dimorphic functions. From genome-wide expression studies performed in various tissues in the body, however, it is clear that we can expect sex differences in the expression of many genes, probably in just about any corner of the brain. Interestingly, these genome-wide expression studies do not suggest that the brain as a whole is more dimorphic than other tissues. In fact, in at least one study, sex differences in gene expression in the brain appeared less pronounced than they were in, for example, the liver.[174] This may be because the brain is quite heterogeneous, making it difficult for region-specific sex differences in neural gene expression to stand out when the "whole brain" is used as starting material. Gene expression studies in different brain regions and at multiple ages throughout the lifespan will help to sort out just how pervasive sex differences are.

To What Extent Does the Environment Play a Role in Sexual Differentiation?

There are more and more examples of context-dependent sexual differentiation. For example, environmental stressors, exposure to illnesses, the social environment, parenting styles, and many more factors all influence the nature and size of sex differences in behavior. Our understanding of the biological processes that mediate such environmental effects is rudimentary at best. Nevertheless, addressing this question is likely to help us identify key genes and gene pathways involved in sexual differentiation in general. For example, inflammatory processes affect sex differences, probably in part because the immune response and sexual differentiation share elements of each other's molecular machinery. Given the impressive inroads that the field of immunology has made in understanding the cellular and molecular basis of fighting foreign invaders, immunology may provide a treasure trove of ideas as to how brains sexually differentiate.

What Causes Sex Differences in the Vulnerability, Age of Onset, and Course of Disease, for Behavioral and Neurological Disorders?

Perhaps related to our ignorance of the extent of sexual dimorphisms in the brain, we have been remarkably unsuccessful in identifying the biological basis of sex differences in vulnerability to neurological and behavioral disorders, which in many cases are more spectacular than sex differences in cognitive function, nonreproductive behaviors, and the neural control of bodily functions. Understanding the extent of sex differences in the brain and the physiological significance of such functions may resolve some of these questions.

What is the Function of Sex Differences in the Brain?

As mentioned here, we do not understand the functional significance of most sex differences in the brain. Our field makes us painfully aware that finding the relation between structure and function is more difficult in the brain then it seems to be for pretty much any other tissue in the body. We pointed out in this review that sex differences may cause as well as prevent sex differences in behavior. With that perspective in mind, more progress may be made in pursuing the form–function question.

What are the Key Genes Involved in Sexual Differentiation of the Brain?

Although we have made a good start in identifying the cellular and molecular mechanisms involved in the masculinization and feminization of behavior, especially with regard to reproductive behavior in rodents, we have not made much progress in revealing the key genes or genetic mechanisms involved in sexual differentiation of other behaviors. And we have almost no insight into the molecular basis of sexual orientation and sexual attitudes in humans. In addition to identifying key genes, it is clear that epigenetic mechanisms contribute to the programming effects of steroids. It is unknown, however, whether the entire gamut of epigenetic mechanisms is used or whether gonadal hormones target a select group of epigenetic mechanisms in the process of sexual differentiation.

Putting It All Together: A Whole-Body Approach to Sexual Differentiation of the Brain

For many decades, the traditional way of looking at the development and maintenance of sex differences in brain and behavior has focused on direct interactions between gonads and the brain. Experiments outlined earlier in this chapter support the importance of these interactions. Gonadectomy and replacement of gonadal hormones during development and/or in adulthood can indeed reverse many of the known sex differences, and the presence of steroid hormone receptors in many neural areas where sex differences are found reinforces the idea that hormones directly target the brain. There are, however, many ways in which the message of the gonads can be relayed to the brain other than by a direct pathway via the bloodstream, and awareness of this is likely to become an important theme in the decades to come.

In a recent review, Arnold and Lusis introduced the term "sexome".[404] They pointed out that the function of every cell in the body can be seen as the product of an intricate network of interactions of all the different molecules that make up a cell. They define the sexome as "the sum of all sex-specific and sex-biased modulatory interactions that operate within [these] network[s]" (Figure 47.21). The sexome produces sex differences in emergent phenotypes, or it prevents such differences in other cases. These networks may be more dimorphic than one might expect. Genome-wide association studies show surprisingly pervasive sex differences in virtually every tissue studied. For example, 72% of all genes surveyed in the liver and 68% of the genes in adipose tissue show sex differences in expression level.[173] These percentages are much larger than one would intuitively expect to find based on the modest sex differences in the overt form and functions of liver and adipose tissue. Although the magnitude of sex differences in the expression of individual genes in most cases is small, the effect of all the differences combined may be quite significant. That is, there may be profound differences in the function of the molecular networks that make up the sexome, even when sex differences in individual gene expression are minimal.[404]

Differentiating factors for gene networks would be the same programming and modulating effects of gonadal steroids and sex chromosomes that we discussed in this chapter for sex differentiation of brain morphology and function. One can envision these factors to have stronger effects on some nodes in the network (e.g., genes with ER response elements in their promoter region) than in

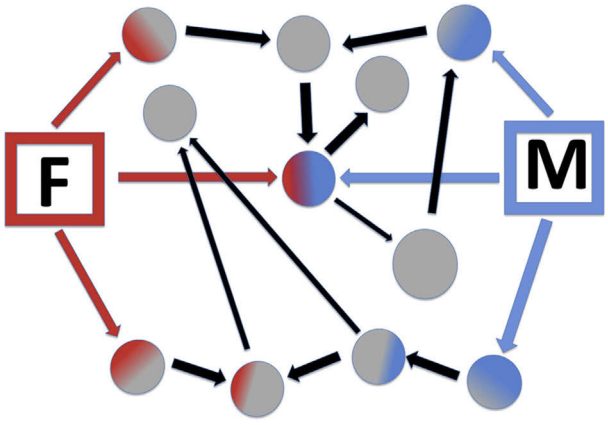

FIGURE 47.21 Schematic view of the sexome. This figure is reproduced in color in the color plate section. Male- and female-biasing factors (chromosomes, hormonal profiles, etc.) are represented by the M and F boxes, respectively. These factors act on specific nodes in the gene network causing male and female bias in gene expression represented by differently colored shading. Sex bias can be propagated to other nodes, thereby increasing or decreasing gene expression and in some cases canceling out sex-biasing effects. Arnold and Lusis define the sexome as the total of all sex-biasing actions within the network.[404] Although they focus on sex bias in gene products,[404] the circles and arrows in this figure may just as well represent interactions between different organ systems. *Source: Adapted from Ref. 404.*

others. As these genes form part of a network, however, changes in the expression of one gene will affect the expression of other genes in the network.

At its root, the sexome suggests a shift from focusing on individual genes to a more systems biology approach to sex differences. A similar type of approach can be applied to higher levels of analysis, for example by shifting the focus from individual, sexually dimorphic brain regions (nodes) to interacting neural networks. Nodes within the network participate in many, perhaps hundreds of, different functions. No single brain region can explain behavioral output, and no single region can fully explain sex differences in the functions it is involved in. But slight shifts in emphasis of one node, in combination with activity in other nodes, may have a marked effect on behavior. In other words, a full understanding of sexual differentiation of behavior may require new analytical tools, such as the use of "big data", to understand how a multitude of small changes can result in big differences in behavior or can prevent such differences.

It is unlikely that the sex differences in gene networks described here are confined to specific tissues. For example, sex differences in the function of the liver will affect the composition of the blood, and sex differences in the composition of the blood may affect the function of all other tissues in the body, including the brain. Obvious examples with respect to the topic of this chapter are sex differences in steroid metabolism and the secretion of steroid binding proteins by the liver.[405–408] Any other sex differences in the blood caused by peripheral organs may also have differentiating effects. For that matter, an initial signal from the gonads known to differentiate a neural system may have directly targeted that system but may just as well have acted indirectly by changing the production of molecules secreted by other tissues that then affect the brain. Recent work on, for example, sex differences in the cardiovascular[409,410] and immune systems[209,411] suggests that hormones acting at these peripheral sites could affect the brain and behavior. We can include the effects of prenatal androgen on the developing genitalia among these possible indirect pathways, because hormone effects on the genitalia may have a profound influence on the social influences that the individual receives, with consequences for the developing brain, as we discussed here.

It does not end there. One need not stop at other humans or human tissues as potentially mediating the sexually differentiating effects of hormones on target organs such as the brain. Recent studies suggest that the microbiome, the collection of microorganisms that live symbiotically on or within our bodies, may perform intermediary steps as well. For example, steroid hormones can influence the physiology and secretions of microbiota in our gut. Differences induced by these microbiota can influence the absorption of nutrients, secretion of lymphokines and cytokines by intestinal tissue, and even absorption of chemicals secreted by bacteria, all of which can influence the physiology of different tissues, including the brain. The interaction may operate in both directions. A recent study showed that the gut microbiome of mice becomes sexually dimorphic after puberty, likely reflecting sex differences in adult hormone levels. In turn, the microbiota influence circulating testosterone levels in male mice, and the transfer of gut microbiota from adult males to immature females alters both the hormone levels and autoimmune responses of the recipients![412]

CONCLUSION

As this review has made clear, in the 50 years or so that scientists have been actively researching the mechanisms underlying sexual differentiation of the brain and behavior, programmatic studies have revealed a more and more complicated picture. The relatively early discovery of sex chromosomes in *Drosophila* and mammals might have suggested a relatively simple process of genetic determination. In the years since, we have learned first that hormones play a crucial role in carrying out genetic instructions regarding sex, then that social interactions and other environmental factors can modulate those same hormonal messengers, with consequences for sexual differentiation. Even that view now seems somewhat dated, as we have learned that the sex chromosomes can also exert direct, non–hormonally mediated influences on the brain, and that experience can have long-lasting effects on gene expression via epigenetic mechanisms. If our vision of sexual differentiation of behavior has become more complicated, that is the price to be paid for a deeper understanding of any biological phenomenon. Rather than bemoan how many different mechanisms are at work, we can embrace the richness of the process and its deep, multilayered pervasiveness in all those vertebrate species that endure in a long succession of males and females. To borrow Darwin's phrase, there is grandeur in this view of sex.

INTRODUCTION

Sexual reproduction, as adopted by most vertebrate species, usually requires the interaction, sometimes for just a brief moment, of individuals of the opposite sexes to ensure the encounter of sperm and ova. In some cases, the interaction between the sexes will occur during a more extended period and a bond will develop between the male and the female, a bond that will last for a variable duration ranging from a single reproductive period to their entire life.

All aspects of sexual reproduction have always interested the general public, but it is only recently, around the middle of the twentieth century, that they have become the focus of scientific investigations from a physiological perspective. The selection of the sexual partner and potential formation of a bond were until recently frequently assumed to be species-specific characteristics that were essentially fixed for a given species. They were "innate" in the terminology used at that time. In 1935, Konrad Lorenz discovered, however, that some species of birds, such as ducks and geese, recognize as their own species and as potential mating partner(s) the first moving object that they see when they hatch from the egg. This aspect of mate choice is thus learned, contrary to what was commonly believed before, and other aspects of this critical behavior were later shown to be learned as well. Similarly, the sex of the subject that will be considered as a suitable sexual partner was and is often still now supposed to be fixed by some rigid, presumably "innate," mechanisms; in the human species, selection of a same-sex partner has often been considered a perversion. Under the influence of researchers such as Alfred Kinsey or William Masters and his collaborator and wife, Virginia Johnson, sex became a subject of scientific studies in the mid-twentieth century. This led to the realization that sexual partner preference or sexual orientation is actually influenced by the endocrine environment of the fetus or young infant. This aspect of mate choice is thus not as inflexible as previously thought.

The rapid technical and conceptual development of behavioral neuroendocrinology also resulted in a detailed analysis of the mechanisms that control pair bonding and to a fairly detailed understanding of why some species develop stable pair bonds whereas others do not. The pioneering work of Sue Carter and then Thomas Insel and colleagues on the endocrine control of reproduction in prairie voles (*Microtus ochrogaster*) formed the basis of the selection of this species that establishes a stable pair bond rapidly after a copulatory interaction and related vole species that do not establish such bonds as a model system to analyze the neuroendocrine mechanisms of pair bonding. This research has resulted in spectacular advances in our understanding of the neuroendocrine, neurochemical, and molecular basis of this complex behavior, with important potential implications in clinical psychology.

This chapter reviews the stunning progress that has been made in our understanding of these topics during the last few decades. The first part will be dedicated

Knobil and Neill's Physiology of Reproduction, Fourth Edition
http://dx.doi.org/10.1016/B978-0-12-397175-3.00048-X

to mate choice; we will consider in sequence the different aspects of this choice, including the selection of a partner belonging to the proper species and to the biologically relevant sex for reproduction. A substantial section will describe the research in animals and humans that suggests, when it does not demonstrate, that prenatal endocrine factors as well as genetic mechanisms influence, but probably do not fully determine, this selection of a member of the opposite sex as a sexual partner. Most of this research in humans is obviously based on the study of subjects demonstrating the alternative phenotype, i.e., who demonstrate same-sex sexual attraction. This section will review the available and obviously incomplete evidence indicating that differences in sexual orientation can often be partially correlated with data suggesting an atypical endocrine environment during early life. The characteristics that determine or influence the choice of a specific sexual partner will be reviewed in the last part of this first section. This is by far the topic about which we know the least, but it is clearly possible to submit this question to scientific inquiries, and hopefully the summary presented here will stimulate further work in the near future.

The second part of this chapter details the research analyzing the brain mechanisms that control pair bonding, with a particular focus on studies in the socially monogamous prairie vole. This research has revealed that the neuropeptides oxytocin (OT) and vasopressin interact with the mesolimbic dopamine system to facilitate the formation of enduring social bonds between sexual partners. The role of the opiate and stress systems in pair bond formation will also be reviewed. Once a pair bond is established, it must be maintained. The roles of dynamic changes in dopamine receptors, corticotrophin releasing factor, and opiates in pair bond maintenance will be discussed. This section then will examine evidence that early life experiences can influence the ability to form social bonds in adulthood. Finally, the chapter will conclude with a comparative perspective including what is known about the physiological mechanisms related to pair bond relationships in birds, primates, and human beings.

EVOLUTIONARY SIGNIFICANCE OF MATE CHOICE

The behavior and physiology of an individual are ultimately (in terms of evolution) controlled by its inclusive fitness measured (again in evolutionary terms) by his/her capacity to pass his/her genes to the largest possible number of offspring in the next and following generations. The different factors that contribute to this fitness are often difficult to identify and even more so to quantify, but it is clear that mate selection plays a critical role. Reproduction is indeed a very costly endeavor in terms of both time and energy invested, and making the wrong partner choice will obviously have dramatic consequences on the number of surviving offspring that a given individual will produce.[1]

Many examples of costs associated with bad mate choice are immediately evident. Mating or attempting to mate with a partner of the wrong species or wrong sex will obviously not produce offspring or will produce infertile ones. More subtly, mating with a partner that is not healthy, or who will be unlikely to raise the young, will also result in decreased reproductive success. Identification of adequate conspecific mating partners is also important to maintain species isolation as well as ensure genetic diversity, which ultimately has an impact on fitness.

Note also that two broad types of reasons can lead to the selection of specific characteristics in a mate. First of all, as already mentioned, a better partner will provide better offspring (higher fitness), which will increase transmission of genetic traits of a given individual to the next generation. This is usually referred to as *indirect* benefits.[2] *Direct* benefits can also be expected from a better partner if he/she will, for example, provide more help in raising the young and thus minimize the cost of reproduction for a given individual, which could therefore increase his/her survival.[3,4] Mate choice thus has a critical role in the biology of a species, and evolution has adopted multiple mechanisms to ensure that this partner selection is made in an appropriate manner.

Selecting an appropriate partner for reproduction involves selecting a mate based on a number of specific characteristics, namely the species, the sex, and finally the specific individual. This selection involves collecting information on morphological, physiological, and behavioral features of the potential partner, analyzing this information, and finally making the appropriate decisions. These processes obviously involve most, if not all, sensory modalities (vision, audition, smell, taste, touch) and very sophisticated cognitive brain processes. The underlying physiological mechanisms have been identified in some cases, but in most cases, they remain elusive. We thus have varying degrees of information on the physiological mechanisms mediating different aspects of mate choice. We will, in this chapter, attempt to cover these different aspects of mate choice in a manner that will be as systematic and comprehensive as possible. However, in many cases, information concerning underlying physiological processes is simply not available. It will therefore be impossible to discuss these aspects. These gaps in our knowledge represent important areas

of study for future research that will be highlighted in the concluding section.

MATE CHOICE AND MATING STRATEGIES

In evolutionary terms, mate choice is tightly linked to the notion of sexual selection, a concept originally introduced by Charles Darwin. The selection of a mate will ultimately be linked to the attractiveness of its traits, and these will evolve and be selected for during the course of evolution. This often leads to the evolution of sexually dimorphic features that are highly salient to the opposite sex.

Mate choice is obviously a two-way decision process: each individual is at the same time the chooser, but is also chosen by a potential partner. When such a mate choice exists, the choice is most often asymmetrical. Charles Darwin believed that this could be expected based on the fact that the female usually invests more in reproduction and is also producing a smaller number of gametes.[5] Females would thus be the choosiest sex; males would mate with every possible female they could find and attract. These ideas would form the basis for social systems based on polygamy, or more precisely polygyny, with one male mating with many females, while each female would mate with only one male who would be carefully selected. This social system (polygyny) is broadly found in the animal kingdom but there are nonetheless many exceptions. The opposite system, polyandry, where one female mates with multiple males, has also been described, although it is by far less frequent (see Ref. 1).

A relatively small number of species, except in birds where it is common, have in contrast adopted monogamy as a mating system.[6] In this case, one male and one female pair for an extended period of time that can last from one reproductive season up to the entire lifetime. There is usually the formation of a prolonged and exclusive social bond, referred to as a pair bond. There is a wealth of knowledge on the genetic, neural, and physiological mechanisms underlying pair bond formation and maintenance, which will be described in detail in the last part of this chapter. Note also that even if a female practices social monogamy and spends most of her time associated with a single male, she can nevertheless mate with many males over the course of her lifetime. Biologists now have solid evidence that socially monogamous pairs of animals are not always, or perhaps even rarely, sexually exclusive. With the advent of DNA fingerprinting, it has become clear that even socially monogamous birds often brood and feed chicks in their nest that have been sired by multiple males; sometimes not even a single chick was born to the male who is taking paternal responsibilities.[7] This is why it is critical to distinguish sexual monogamy from social monogamy. Social monogamy is relatively rare in the animal kingdom. Only 3% of mammalian species are socially monogamous, while in contrast over 90% of birds are socially monogamous.

Monogamous mating systems are thought to evolve under two circumstances: (1) when survival of the offspring is greatly facilitated when the mother and father cooperate to raise the offspring, as in cases where males can contribute resources to the offspring or when he can defend the offspring against predation, or (2) when population density is low or other factors make it difficult to find a mate who is fertile.[8,9] Monogamy is common in birds perhaps because the male and female are equally capable of providing nutrients, warmth, and protection to the offspring, and thus both can have a direct impact on the survival of the offspring. In mammals, however, only the female can produce milk and therefore provide nutrients to the young, so the potential contribution of the male to the survival of the offspring is much more limited. Consequently, in most mammalian species, the most adaptive strategy for males is to impregnate as many females as possible. However, if there are predators in the environment that tend to raid nests, and the male can help defend the nest from predation, the most successful males (i.e., evolutionarily fit) might be those that protect the offspring while the female forages. In cases where population density is low, it would be adaptive for the male to stay in close proximity to the female partner throughout pregnancy, display mate guarding behavior, and mate with her as soon as she becomes fertile again. Males who do not choose this strategy may fail to be successful at finding a female who is unmated and fertile. As we will see in the following discussion, low population density appears to be the reason for the evolution of monogamy in prairie voles.[9]

The human species is, in this context, traditionally considered as being socially monogamous. However, this largely relates to the predominance of Western societies in the world where marriages between a single man and woman are socially enforced. When individual societies are considered, it appears that the vast majority of them (~85%) are polygamous, or more precisely polygynous.[10,11] However, it is clear that humans possess the neural capacity to form enduring pair bonds, and there is growing evidence that common mechanisms underlie pair bond formation in socially monogamous mammals and humans. Thus humans may be highly adaptable with respect to mating strategy from a neurobiological perspective. Indeed it has been postulated that pair bonding in humans evolved as a consequence of the extended developmental period of dependency of infants,

necessitating cooperation between parents to ensure survival of the offspring.

DIFFERENT FACETS OF MATE CHOICE

The choice of a mate inescapably involves selecting a specific individual, his/her sex, and his/her species. The physiological processes involved in the preference for these different traits cannot be easily separated. For the sake of simplicity, we will consider in the next three sections of this chapter these different aspects of mate choice sequentially because they rely to some extent on different mechanisms. We shall move from the more general to the more specific, and will thus consider in sequence (1) the selection of the *species*, (2) the selection of the *sex*, and (3) the selection of the *specific individual* with whom mating will take place. Many signals convey information about these three aspects of a given individual. For example, body odors (e.g., pheromones) in mammals allow the identification of the species, sex, and some individual characteristics of a given subject.[6,12] However, these different types of information are not necessarily carried by the same chemical compounds. Furthermore, the way in which these signals are decoded and the underlying neurobiological mechanisms are not necessarily the same. The amount and type of information available to an individual for these different aspects of mate choice is also extremely different. It is therefore necessary to consider them in isolation even if some interactions and cross-referencing will have to take place.

SPECIES SPECIFICITY IN MATE SELECTION

By far, most matings observed in nature occur between members of the same species. Hybrid offspring can result from two organisms of distinct but closely related parent species, but these hybrids are in most cases infertile. Mating between related species has been encouraged in captive animals because the offspring sometimes display desirable characteristics (e.g., the mule resulting from the interbreeding of a female horse and male donkey that is comparatively stronger and shows greater patience, endurance, and sure-footedness), but they are almost always infertile. Thus mating between different species either produces no offspring or infertile offspring, and this obviously has a high cost for the reproductive success of a given individual.

Nature versus Nurture

While it is generally believed that sexual behavior is instinctive and therefore somewhat mechanistic, a fair amount of learning is involved in the establishment of mature adult sexual behavior.[13] Mate choice is no exception,[14] and there are now many examples in a diversity of species indicating that animals do not spontaneously, or innately, recognize their own species and need to learn its characteristic features.

The initial recognition of this learning process crystallized with the work of the Austrian ethologist Konrad Lorenz on filial and subsequently sexual imprinting (initially described by Spalding in 1873[14]). Lorenz demonstrated that young nidifugous (precocial) birds (e.g., ducklings and goslings) will soon after hatching follow any moving object that they see in the same way as they would follow their own parents.[15,16] Objects that are capable of inducing such a response can be as diverse as a matchbox, a ball, or a walking man. This does not mean that any object is equally effective. Round objects are more likely to be followed, and the effectiveness of an object increases with its conspicuousness. There are thus clear constraints on learning (see Ref. 16).

More relevant to the focus of the present chapter, filial imprinting often leads to sexual imprinting: birds who have followed inanimate objects or members of another species during their young life will, when adult, attempt to copulate with them. Sexual attraction to humans can for example develop in nonhuman animals, including birds and mammals, as a result of having been reared from birth by humans.[15,16] This phenomenon is, for example, common in falconry birds that are reared by humans. It also takes place in many domestic animals.

Examples of effects of early experience on the type of stimuli that will later in life elicit sexual behavior are known for nearly all vertebrate groups. Male zebra finches (*Taeniopygia guttata*), a small songbird commonly used in experimental studies, mate with females with an appearance similar to the female who has reared them rather than the appearance of their parents when they are different[17,18] (see also Ref. 15).

In mammals, extensive experimental evidence has been collected, at least in some species, demonstrating a role of early learning in determining the species of the mating partner. If sheep and goats are cross-fostered at birth, but raised in mixed-species groups, their play and grooming behavior resembles that of their foster rather than genetic species. More importantly, in adulthood, cross-fostered males strongly prefer to socialize and mate with females of their foster mother species, even if raised with a conspecific (Figure 48.1). Cross-fostered females also show significant preference for socializing with females and mating with males of their foster mother's species, although this effect is weaker than in males.[19,20]

Surprisingly, even if cross-fostered animals are placed in flocks containing members of only their genetic species for 3 years, male social and mating preferences for females of their adoptive mother's species remain

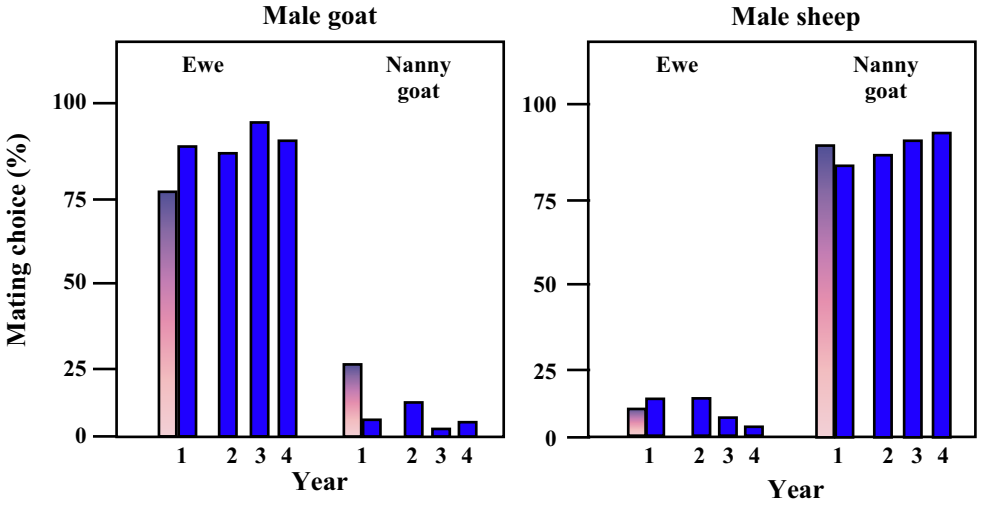

FIGURE 48.1 Percentages of mating choices made by male goats (left panel) and sheep (right panel) that had been cross-fostered at birth and raised by females of the other species. At 1 year of age, males were given a mating choice between tethered ewes and tethered nanny goats. Sheep and goats raised by females of their genetic species mated exclusively with members of their own species (data not shown). In contrast, cross-fostered males in both species mated with their maternal species. This reversed-mating choice was observed if young lambs and goats were raised alone or with a twin of their maternal species (dark column) as well as if they were raised with a twin of their genetic species (variable shaded column). Reversed choices expressed by 1-year-old males were maintained up till 4 years of age despite the fact that animals lived exclusively with members of their genetic species after year one. *Source: Redrawn from Ref. 19.*

virtually unaffected. In contrast, however, females raised in these conditions change to display an exclusive mating preference for members of their genetic species within 1 or 2 years, although they still retain some social interest in female members of their foster species.[20]

The sex difference in the magnitude of these effects of early experience suggests that they are likely affected by reproductive hormones. However, castration of male sheep and goats within 2 days of birth was shown to reduce only slightly the level of this altered social preference, and mating preference following short-term testosterone treatment in these males was the same as for gonadally intact animals.[20] The social preferences of these castrated subjects were also similar in the absence of testosterone treatment. The mating preferences in these species thus seem to be affected only marginally by pre- and/or early postnatal effects of sex steroids on the brain, but specific mechanisms, including site of action, remain unknown at present.

Early imprinting thus seems to have long-term effects not only on the object toward which the young animal will direct its following responses but also its adult sexual responses later in life. However, the juvenile experience is often in itself insufficient to determine mate preference in adulthood. The evidence supporting sexual imprinting indeed concerns only a limited number of species, and one must be careful before generalizing. Social interactions during adolescence seem to be equally important in terms of influencing mate preferences (see Ref. 16 for review). It is also clearly the case that learning does not determine all characteristics that will be recognized as species specific, and the preference for some features signaling species-specific information are surely hardwired. However, the data are currently lacking to evaluate in a general fashion the relative importance of learning versus "innate" (genetic) aspects of species recognition in the context of mating.

Sensory Modalities

The identification of the species-specific features of suitable mating partners is based on multiple sensory modalities that must in many cases interact. Additionally, it is often difficult to separate the different types of information conveyed by a given signal. A given pheromone may, for example, indicate at the same time the species, the sex, the social status (dominant-subordinate) and even the individual identity of the subject.[12] In a small number of cases, species identity has, however, been linked to a specific signal. We are providing a few select examples in the section that follows.

Vision

Because young ducks and geese may be imprinted on moving inanimate objects, it appears obvious that the stimuli that they recognize have, at least in part, a visual nature. In adult populations of ducks, males are usually more numerous than females, possibly due to the higher predation risk associated with nesting. Males engage in very extensive courtship displays to try to attract a

female and form with her a pair bond that will last for the entire reproductive season. These courtship displays were originally described by Lorenz and are highly stereotyped. The displays are shared by most species of surface-feeding (dabbling) ducks, although each individual species produces its own set of specific displays. Lorenz also discovered that different species (e.g., mallard, gadwall, green-winged teal) produce these displays in a particular sequence that is also species specific.[21–23] Furthermore these displays and their sequence are genetically inherited as demonstrated by cross-breeding experiments between several species.[22] Lorenz speculated that these sequences of fixed-action patterns (the displays) serve as a species-specific feature that prevents mating between different species. The brightly colored plumage of the males could also serve the same purpose.

Similar data are available in mammals. For example, an anecdotal study of three macaque monkeys cross-fostered at birth to mothers of another macaque species showed that as an adult, one of these monkeys preferred pictures of members of its adoptive rather than its genetic species; the study unfortunately made no direct assessments of social and sexual preferences.[24] It should be repeated in controlled conditions with a larger sample size and a formal control group.

In the cross-fostering experiment between goats and sheep described herein, normally raised male and female sheep and goats were also shown to initially approach and maintain proximity with pictures of the faces of female members of their own species, whereas in cross-fostered animals, males showed an almost exclusive preference for faces of female members of their foster species, but in females, faces of the two species were chosen equivalently.[20] It could thus be inferred that visual stimuli play a critical role in the selection of the mating partner in these species. These data, however, do not prove that these visual stimuli are the critical feature that determines the mating partner. Pheromonal signals are also likely to be involved, and more work would definitely be warranted on this topic.

Audition

Many animals are obviously capable of recognizing vocalizations of their own species. Songbirds even possess in one of the nuclei that processes their vocalizations, called nucleus HVC (a structure located in the dorsal telencephalon, originally erroneously called hyperstriatum ventrale pars caudale and subsequently high vocal center; HVC now stands as a proper name and is no longer used as an acronym[25]), sets of neurons that are specifically tuned to features of the conspecific vocalizations and even the bird's own song.[26,27] These vocalizations play a significant functional role in the biology of the species. For example, if a male great tit (*Parus major*) is captured and removed from his territory, this territory will be invaded by neighbors within minutes. It is sufficient to broadcast through loudspeakers songs of great tits to protect the territory.[28] Demonstrations that conspecific vocalizations play a key role in mate selection are rarer but nevertheless do exist.

In Japanese quail (*Coturnix japonica*), the playback by a loudspeaker of unmated male crows, a form of calling, is sufficient to attract a female. Females also showed a significant preference for a speaker broadcasting crows versus a similar speaker broadcasting reversed crows (same call but played backwards). Thus female quail, but not males, exhibit positive phonotaxis to the crows of the male.[29]

Similarly, many rodent species (including laboratory rats and mice) produce ultrasonic vocalizations during their sociosexual interactions.[30,31] It has been observed that male mice increase their ultrasonic vocalizations when exposed to females. Playback experiments with reproductively active females demonstrated that these vocalizations elicit approach behavior from the females. It is thus likely that these sounds play a role in social and species recognition, although to our knowledge this has not been fully demonstrated.

Olfaction

Species recognition may also be mediated by chemical (olfactory) signals. Animals are thought to learn at an early age the olfactory characteristics of their species in a manner analogous to visual imprinting.[32]

In 1965, Mainardi and colleagues demonstrated that female mice raised by parents scented with Parma Violet perfume preferred, as adults, a Parma Violet scented sexual partner to a nonscented one, whereas control females did not show this preference.[33] This finding was more recently confirmed by Alleva and colleagues.[34] Early olfactory learning thus has long-term consequences on mate choice.[35]

Accordingly, cross-fostered pygmy mice and house mice,[36] and cross-fostered hamsters of different species,[37] exhibit increased preferences for odors of the foster parent species later as adults. Similarly, it was shown that a male black-tailed deer raised with a surrogate mother scented with the rump gland secretion of a female pronghorn antelope will later prefer to associate with pronghorn rather than with a female of their own species.[38] A variety of studies have confirmed effects of early olfactory learning on olfactory preferences in vertebrates (for review see Refs 39,40).

SEXUAL PARTNER PREFERENCE AND SEXUAL ORIENTATION

Once a group of same-species congeners has been identified, it is still critical to select individuals of the opposite sex as mating partners in order to ensure

successful reproduction. This choice of the opposite sex for a mating partner is a sexually differentiated trait in all animal species that reproduce sexually, including humans. Most animals and people are indeed sexually attracted to individuals of the opposite sex; they are heterosexual, and this obviously conditions the success of their reproduction. In humans and in some other animal species, there is, however, a significant minority (3–10%) of subjects who are attracted to subjects of the same sex; they are homosexual. Viewed in this way, sexual orientation (hetero- versus homosexuality) is thus a behavioral feature that displays one of the largest degrees of sexual differentiation between males and females, since more than 90% of males are attracted to females (they are gynephilic or gynecophilic) and more than 90% of females are attracted to males (they are androphilic). Note, however, that an alternative view supported by a few researchers is that subjects of both sexes prefer to mate with subjects of the opposite sex, in which case orientation would be the same in both sexes (i.e., toward the other sex), and the sex difference would rather concern the sex of the subject and its perception (see Ref. 41).

The specific mechanisms that determine sexual orientation have been the subject of intense investigations and heated controversies, at least as far as humans are concerned. The focus of these disputes has usually been on homosexuality, since this orientation is less common and considered by some as "abnormal". It should instead be considered that homosexuality and heterosexuality are simply the two extremes in the natural variation of a phenotypic characteristic called sexual orientation. All intermediates do exist as already recognized in the work of Kinsey. It also must be noted that trying to understand the origins of homosexuality essentially represents the same problem as trying to understand heterosexuality: it is the question of the determinism of sexual orientation, i.e., the choice of the sex of the preferred mating partner.

Sex differences in behavior can either be learned or have a biological origin (genetic differences or endocrine controls). Although it is often assumed that human sexual orientation is determined by interactions with the parents (e.g., Oedipus complex in the theories of Freud) or by early sexual experiences (e.g., influence of the first sexual activities), little experimental evidence supports this common belief. In contrast, work in humans and various animal species has identified significant endocrine and genetic contributions to the determination of this aspect of mate choice.

Much is known on this topic concerning the sensory modalities implicated, endocrine controls, and even in some cases, brain mechanisms. We provide in this section a concise overview of the current knowledge of sexual orientation. More detailed reviews of this topic with a particular focus on humans were published recently.[42,43]

Endocrine Control of Sexual Partner Preference in Animals

Many behaviors in animals are sexually differentiated and produced preferentially or exclusively by one sex. It was originally believed that these behavioral differences between males and females were the result of the presence of different hormones in the adults of the two sexes: testosterone in males and estradiol (plus progesterone) in females.[44] Males and females indeed secrete different amounts of these steroids, and these differences in endocrine milieu could differentially activate a variety of behaviors. This is sometimes the case, and, for example, treatment of females with testosterone will activate crowing in quail, singing in canaries (*Serinus canaria*) and some degree of mounting in rats.[45]

Many behavioral sex differences are, however, not controlled by differential activating effects of steroids but rather by their perinatal action, which irreversibly differentiates the male and female brain and behavior, referred to as organizational effects.[41,45–49] Many sexually differentiated behavioral responses thus result from the early action of sex steroids that differentiate the brain along the male or female path. These differentiating effects occur very early in life, during the embryonic period or just after birth, and are, in general, completely irreversible.

In mammals, early exposure to testosterone produces a male phenotype: the behavioral characteristics typical of males are strengthened (masculinization), and the ability of males to show behavior typical of females is reduced or lost (defeminization).[41,49] The female phenotype develops in the apparent absence of hormone action (or in the presence of very low estrogen concentration; see Refs 50,51). In birds, by contrast, it appears that the male sexual phenotype (presence of mounting and copulatory behavior) develops in the relative absence of sex steroids and that embryonic ovarian steroids demasculinize this behavior in females. Female receptive behavior is not, or is only marginally, differentiated.[45]

It is therefore legitimate to ask whether the sex difference in partner preference (i.e., sexual orientation) is controlled by activational effects of sex steroids or, alternatively, is organized by their perinatal organizational action.

Activational Effects of Adult Hormones

The fact that sexual partner preference is sexually differentiated has been originally considered as evidence that it is controlled, like many other behavioral differences, by adult sex steroid hormones (e.g., testosterone and estradiol). Based on the observation that sex steroids control the activation of sexual behavior in animals and in humans, it was originally hypothesized that modifications in circulating concentrations of

these hormones were involved in the control of sexual preferences. Specifically, early investigators originally suggested that excessive concentrations of estradiol in men could be responsible for their sexual attraction to other men (a female characteristic), and that vice versa, high concentrations of testosterone induce female sexual attraction toward other women (a feature normally observed in men).

Many studies compared the concentrations of circulating sex steroids in men and women in relation to their sexual orientation, and this work clearly concluded that there are no hormonal differences between homo- or heterosexual men nor between homo- or heterosexual women.[52] The same conclusion has been reached in a few animal studies.

Human sexual orientation is thus not linked to an inadequate activation by sex steroids. This is consistent with the fact that all endocrine manipulations that attempted to modify the sexual orientation of homosexual subjects, including castration and hormone therapy, have always failed to have any significant effect. This conclusion is also in agreement with animal studies demonstrating that (1) the type of behavior patterns expressed by male or female rodents and the sex of the preferred sexual partner are not affected by steroid action in adulthood but rather depend on the early organizing effects of these steroids, and (2) circulating testosterone concentrations are not altered in male-oriented ("homosexual") sheep as compared with female-oriented ("heterosexual") subjects (see following). Adult sex steroids regulate sexual motivation but do not affect the sexual orientation of the behavior.

Organizational Effects of Embryonic or Perinatal Hormones

ORGANIZATIONAL EFFECTS OF STEROIDS ON SEXUAL PARTNER PREFERENCE IN ANIMALS

The organizing effects of embryonic sex steroids that were originally described concerned exclusively the type of behaviors (male- or female-typical) displayed by adult subjects. Studies carried out essentially during the last 20 years have, however, shown that sexual orientation (preference for a male or female mate) is also determined by prenatal hormones.

In mammals, exposure to testosterone (or its metabolite estradiol) induces male-typical orientation (preference of female over male sex partner), while in the absence of high concentrations of these steroids (or of their action), a female pattern of sexual orientation will develop (preference for male partner). A male- or female-typical sexual orientation (selection of female or male, respectively, as a sexual partner) can be experimentally induced by injections at the proper time (days or weeks preceding or immediately following birth, depending on the species) of sex steroids, or of blockers of sex steroid action. The sexual orientation determined at that time subsequently appears to be a stable characteristic of the individual.

This mechanism that now appears to apply to multiple species of rodents, and possibly more broadly, was originally identified in rat studies performed by Bakker and Slob.[53,54] It had been clearly established that during the perinatal period, testosterone masculinizes and defeminizes sexual behavior by acting essentially through its estrogenic metabolite, estradiol, produced in the brain by the enzyme aromatase.[55,56] Bakker and Slob demonstrated that the injection of an aromatase inhibitor during the end of embryonic life, or during the first week of postnatal life, blocks the development of the heterosexual partner preference in male rats.[53,54] Rats that were treated in early life with an aromatase inhibitor spent, as adults, unlike normal rats, the majority of their time in the compartment of a three-chambered arena containing another male, and largely ignored the compartment containing a sexually receptive female (Figure 48.2(A) and (B)). They also displayed lordosis behavior (i.e., sexual receptivity)

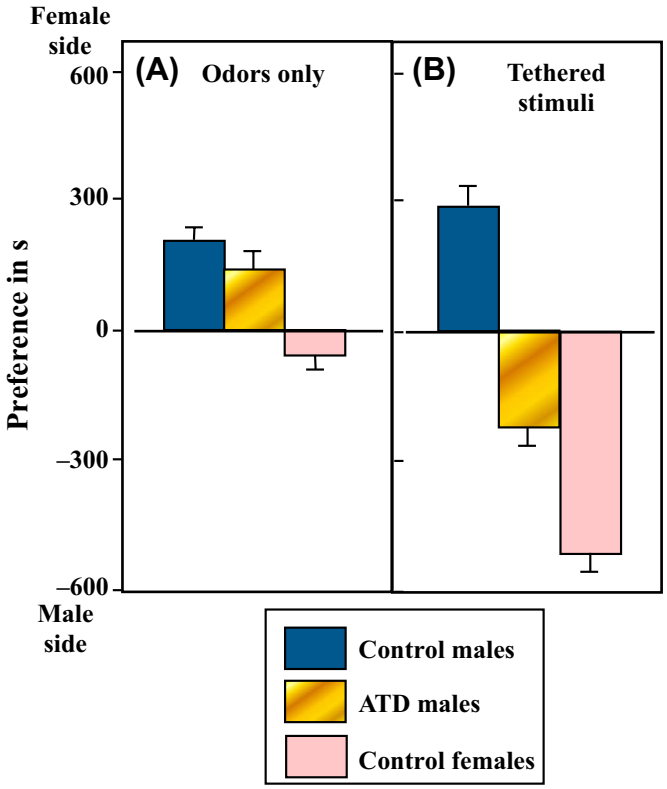

FIGURE 48.2 Perinatal inhibition of aromatase reverses the adult sex-partner preference of male rat expressed as time (seconds) spent in the female compartment minus time in the male compartment when subjects were tested with sexual odors only (A) or with tethered live subjects as stimuli (B). Experimental subjects were control males and females and males exposed to the aromatase inhibitor 1,4,6-androstatriene-3,17-dione (ATD) pre- and postnatally.[56]

when faced with another male and allowed this male to mount them, a behavior never observed in male rats that did not receive this perinatal treatment.

The brain of these male rats displaying a sex-reversed partner preference also responded in an atypical manner to the presentation of olfactory sexual stimuli. In control animals, the nuclei that process olfactory information related to sexual behavior are activated (as measured by induction of the immediate early gene *c-fos*) in males following presentation of female-typical odors (e.g., cage bedding soiled by female urine), while the female brain is activated by the odor of males. In contrast, the brain of a male is not activated by the presentation of a litter soiled by a male and vice versa. This is very different in male rats treated during the perinatal period with an aromatase inhibitor—their brain is highly activated by the odor of other males.[57] The experimental manipulation of the early hormonal environment has thus produced a profound change in the reaction to olfactory sexual stimuli of the neural circuit controlling sexual behavior.

More recently, similar experiments confirmed that the partner preference of females is also largely determined by their early hormonal environment. Treatment during the first 3 weeks of life of young female rats with an estrogen (estradiol benzoate) increased their preference for females, a male-typical characteristic (Figure 48.3).[58] These preference tests were conducted at the adult age in ovariectomized females exposed to various hormone treatments (estrogen alone or estrogen plus progesterone) to activate different aspects of sexual behavior. The preference reversal was observed in both hormonal conditions, which is in agreement with the conclusion presented in the preceding section that sexual partner preferences cannot be modified by hormones in adulthood.

These observations initially performed in rats were confirmed in mice, but in mice androgens themselves seem to play a more important role in the differentiation of sexual partner preferences. Sexual differentiation is deeply disturbed in mice suffering from the testicular feminized mouse (tfm) mutation of the androgen receptor that prevents the action of testosterone or the nonaromatizable androgen, dihydrotestosterone (DHT).[59] In adulthood, these tfm male mice, when gonadectomized and treated with estrogens to activate sexual behavior and motivation, have responses similar to those of females. For example, they spend more time investigating, like females, bedding soiled by the urine of males, whereas control males prefer bedding soiled by the urine of females. Moreover, females and tfm males show no preference for a partner of one sex or another in simultaneous choice tests, whereas control males show a strong preference for a female partner. Finally, exposure to bedding soiled by males (but not to clean bedding) induces neuronal activation in the preoptic area and the nucleus of the stria terminalis (as measured by an increased expression of the *c-fos* gene) in females and tfm males but not in control males. The same researchers also demonstrated that treatment of neonatal females with DHT masculinizes for life all of these behavioral features and the response of the nervous system to male odors. Estrogens are, however, also implicated in the sexual differentiation of mice as they are in rats.[60,61] Together all these findings support the idea that sexual partner preferences are controlled during perinatal ontogeny by the action of sex steroids, testosterone, and its estrogenic metabolite, estradiol.

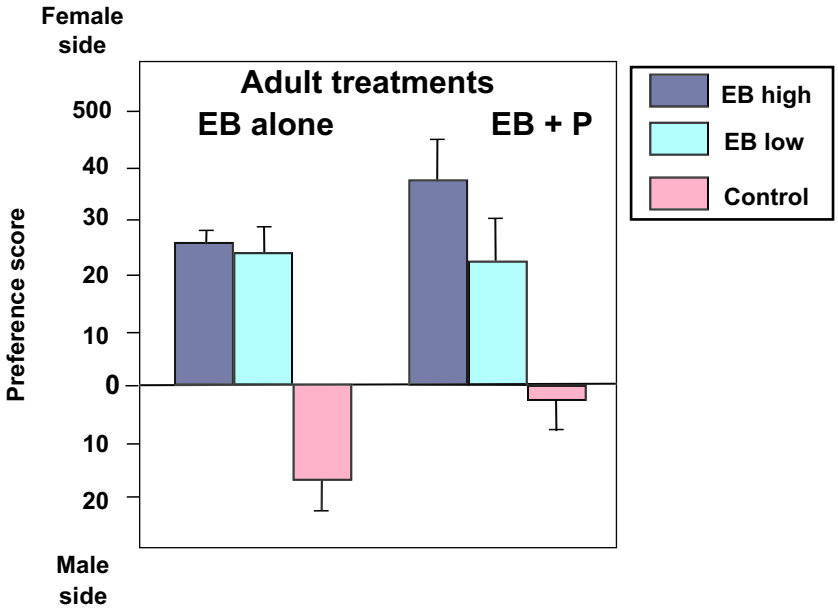

FIGURE 48.3 **Effect of treatment with estradiol benzoate (EB), at high or low dose, during the first 3 weeks of life on the sexual preferences of female rats.** The preference scores represent the time spent by the animal in the test chamber containing a female minus the time spent in the chamber containing a male during tests performed in adult ovariectomized subjects treated with estradiol benzoate (EB; left) or with EB plus progesterone (EB + P; right). A negative score indicates a preference for males (usually observed in control females). A positive score indicating a reversal of this choice (preference for females) was observed following treatment with EB at both doses used. *Source: Redrawn according to data in Ref. 58.*

Importantly, it cannot be overemphasized that these early hormonal manipulations have, as far as we know, completely irreversible effects on both the type of sexual behavior that will be displayed in adulthood (male- or female-typical) and its orientation (homo- versus heterosexual). In particular, these behavioral characteristics cannot be modified by hormonal treatments performed in adulthood.

BRAIN MECHANISMS

The medial preoptic area appears to be (one of) the likely site(s) of action of these early endocrine treatments for the control of sexual partner preference. Like rats and many species of reptiles, birds and other mammals, including humans[62,63] and ferrets (*Mustela putorius*) also have a sexually dimorphic nucleus in their medial preoptic area (SDN-POA); the volume of this nucleus is significantly larger in males than in females.[64]

Baum and his colleagues tested the effects of lesions aimed at this nucleus on male sexual partner preference, as measured in a three-compartment arena containing, in the two outer compartments, a male or a sexually receptive female as stimuli. After bilateral electrolytic lesions of this nucleus, male ferrets who previously were spending most of their time in the compartment containing a female displayed a nearly complete reversal of this choice, and spent during the postlesion tests most of their time in the chamber containing a stimulus male, a typically female preference[65] (Figure 48.4). Unilateral lesions, or lesions that missed their target, did not affect the partner preference of the males, demonstrating the anatomical specificity of the effect. Similar results have been reproduced in rats.[66] Male sexual preferences thus seem to be controlled to a large extent by the medial preoptic area. It is, then, remarkable that the organizing actions of embryonic steroids on sexual behavior and its orientation are paralleled by irreversible changes in the volume of this nucleus and other sexually differentiated structures in the brain.

The volume of the SDN-POA of rats is five to six times larger in males than in females, and this difference results almost exclusively from the action of testosterone and its estrogenic metabolites during late embryonic life and the first days of postnatal life. Once acquired, the size of the SDN-POA, which is characteristic of one sex, cannot be altered in adulthood by steroid hormones.[67,68]

It was shown that male rats treated perinatally with an aromatase inhibitor have, as adults, a small SDN-POA that is characteristic of a female.[69] As described in the previous section, these rats are behaviorally not masculinized and prefer other males over females in the three-compartment test arena. These rats also rarely attempt to mate with sexually receptive females that are present and allow stimulus males to mount them. They are showing a form of partner preference that would be qualified, in humans, as homosexuality, or at least bisexuality. Therefore, it appears that the deprivation of estrogen action during the perinatal life of male rats has a lasting effect on their sexual preferences and correlatively on the volume of their SDN-POA.

A PHYSIOLOGICAL MODEL OF ANIMAL HOMOSEXUALITY: THE DOMESTIC SHEEP

The studies discussed so far concern experimental models of homosexuality in animals based on early (perinatal) endocrine manipulations or lesions of the preoptic area. Spontaneous homosexual behavior (male mounting another male or female mounting another female) is observed quite frequently in a broad variety of animal species.[70,71] However, most often, these behaviors are only expressed when a suitable partner of the opposite sex is not available due to captivity (zoo or other captive populations), to a skewed sex ratio in the population, or to the lack of opposite sex partners because they are monopolized by dominant males (e.g., in monkey societies). These homosexual behaviors thus do not represent the expression of a preference for a partner of the same sex but simply serve as a channel for reducing sexual motivation that cannot be satisfied with the desired sex. In some cases, they also reflect a different nonsexual

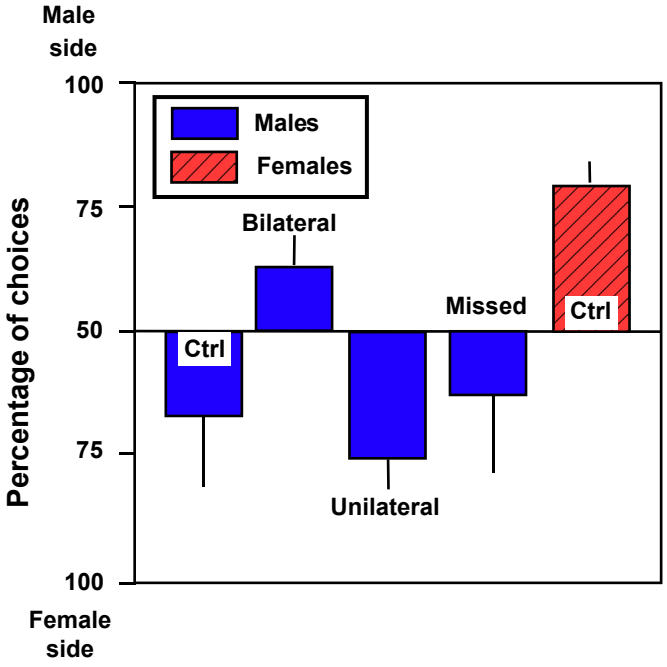

FIGURE 48.4 Effect of lesions of the medial preoptic area on sexual preferences in male ferrets. Control males (Ctrl) spend the majority of their time in the compartment containing a female and vice versa. Male preferences are reversed following a bilateral lesion of the preoptic area but not by unilateral lesions or lesions of a different, usually adjacent, brain site (missed). *Source: Redrawn from data in Ref. 65.*

function such as the appeasement of dominance/subordination relationships.

One instance of spontaneous (not experimentally induced) exclusive same-sex sexual preference that appears very similar to human homosexuality has, however, been detected and studied in some detail. This example concerning populations of domestic male sheep (*Ovis aries*) in Western USA (Idaho) thus deserves to be reviewed in detail.[72]

In this sheep population, a significant fraction of the males (~8%) show little or no reaction in the presence of females, but are nevertheless not asexual—they display active sexual behavior if given another ram as a sexual stimulus. These males even mate exclusively with other males when given a choice between a male or female partner.

Anatomical studies have shown that the sexually dimorphic nucleus of the preoptic area in these sheep differs significantly according to their sexual partner preference: the ovine sexually dimorphic nucleus of the preoptic area (oSDN) is approximately three times larger and contains about four times more neurons in males than in females, but in male-oriented rams (MOR) it is significantly smaller and contains fewer neurons than in female-orientated rams (FOR).[73] The oSDN of MOR also expresses aromatase at a reduced level as compared to FOR. The oSDN of MOR is thus quite similar to the oSDN of females and correlates with sexual orientation—subjects attracted to males (females and MOR) have a smaller oSDN and express less aromatase than subjects attracted to females (FOR).[72,74]

The small size, and other feminized characteristics of the oSDN in MOR, could technically be a consequence of their orientation, since the brain is plastic and responds to the social environment. However, Roselli and colleagues demonstrated that the oSDN is already sexually differentiated during embryonic life (around day 135), presumably under the influence of testosterone in males. Indeed, embryonic treatment of females with testosterone between 30 and 90 days of gestation results in a masculinized oSDN in females.[75] Furthermore, the size of this nucleus is no longer modified in adulthood by manipulations of plasma testosterone concentrations.[75] Therefore, the small size of the oSDN in MOR is presumably determined before birth, and before the subjects had an opportunity to express their sexual orientation. Given that this nucleus is located in the center of the preoptic area, a region involved in the control of sexual orientation, there is every reason to believe that the little oSDN of MOR is (one of) the cause(s) of their atypical sexual orientation resulting from an inadequate masculinization by testosterone during embryonic life.

In conclusion, available animal studies demonstrate that sexual partner preference (sexual orientation) in animals is a sexually differentiated feature exactly like other sexually differentiated behaviors or morphological characteristics. Sexual orientation is controlled at least in part by the preoptic area (like sexual behavior), and it differentiates under the influence of pre/perinatal sex steroids.

Endocrine Control of Sexual Partner Preference in Humans

Since embryonic sex steroids organize the genital morphology in humans as they do in rodents, and probably have similar effects of the organization of the brain and behavior,[76–79] it is legitimate to wonder whether these hormones also have an impact on the development of human sexual orientation. One could indeed imagine that exposure to a high male-typical concentration of testosterone during a critical phase of development would lead to a male-typical orientation (attraction to women), whereas a lower embryonic exposure to steroids would lead to a female-typical orientation (attraction to men; see Figure 48.5). There would be a minimal concentration of testosterone required to masculinize this feature like other aspects of behavior in animals (and humans).

It should also be noted that the critical mechanism here is testosterone action in the brain. This action could be affected by changes in circulating concentrations of the steroid, but also by any modification in the complex cellular processes that translate the presence of the steroid at its target into the activation of a cellular process. Remember that to produce its effects, testosterone must often be metabolized in its target structures (aromatized in the brain, 5α-reduced in the brain and genital area), bind to specific receptors and then activate in conjunction with various steroid receptor co-regulator (co-activators and co-repressors) complex intracellular signaling cascades eventually leading to changes in protein synthesis and/or neural activity.[80–82] Any aspect of this complex suite of actions could be affected in the brain, in the absence of changes in testosterone plasma concentrations, and consequently of testosterone action in the periphery (e.g., on the sexual differentiation of genital structures).

Since the embryonic steroid concentration and action are likely to vary between subjects due to genetic differences, exposure to diverse environmental factors, or specific endocrine pathologies, one could expect that male subjects at the lower end of the distribution could acquire a female-typical orientation (and be gay), whereas females at the high end of the concentration curve would acquire a male-typical sexual attraction (and be lesbian; see Figure 48.5). Even if they are probably not attracted by the same (type of) individuals, in terms of definition of the attractive sex, females and gay men are indeed similar, while males and lesbians share an attraction for women.

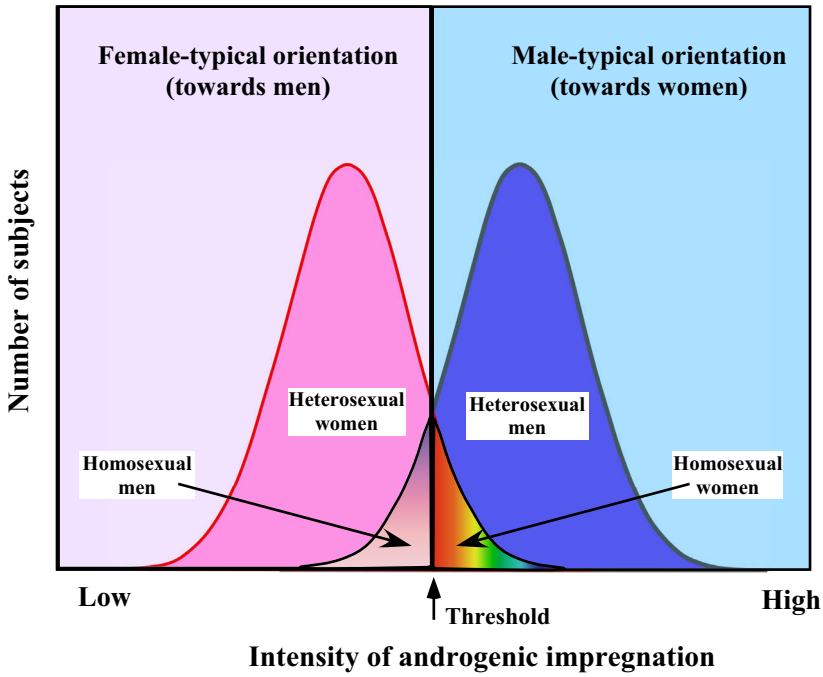

FIGURE 48.5 **Theoretical model illustrating how fluctuations around the average concentration or action of testosterone in male and female embryos in humans or other mammalian species could affect sexual orientation and partner preference.** Male embryos at the low end of the male distribution and female embryos at the high end of the female distribution are, in this model, beyond a critical threshold of testosterone action and thus exposed to a testosterone concentration or action able to produce a phenotype characteristic of the opposite sex. In this condition they would develop a homosexual orientation.

As described in the following sections, two types of evidence actually support this notion; they relate to (1) clinical studies demonstrating that pathologies affecting the embryonic endocrine milieu are associated with increased incidence of homosexuality and (2) the presence of sexually differentiated characteristics that are different in gays and lesbians as compared to corresponding heterosexual populations.

Clinical Studies

There are several clinical conditions in which substantial modifications of the prenatal endocrine environment are clearly documented. It can be hypothesized, based on the animal studies and on the theoretical models that were just reviewed, that these endocrine changes should affect the development of sexual orientation. In a few selected cases, the most interesting ones from a scientific point of view, the embryonic endocrine changes are expected to push sexual orientation in a direction opposite to the effects of the postnatal social/educational environment. These cases therefore provide a useful test of the relative role of both types of factors in the control of sexual orientation. Four such clinical conditions are important to discuss here since they were shown to be associated with a significantly increased incidence of homosexual orientation (in some studies up to 40% compared to less than 10% in control populations).

CONGENITAL ADRENAL HYPERPLASIA

Congenital adrenal hyperplasia (CAH), *formerly called adrenogenital syndrome or congenital virilizing hyperplasia*, is a genetic disease that affects one of the enzymes involved in the synthesis of cortisol (often 17α-or 21-hydroxylase) in the adrenal glands. This indirectly results in the hypersecretion of androgens in the affected embryos.[83,84] These girls exposed in utero to abnormally high levels of androgens show a more or less profound masculinization of genital structures and of a variety of behavioral traits (e.g., aggressive play, type of drawings produced spontaneously, high physical activity and toy selection, occupational interests).[79,83,85–88]

The masculinization of external genital structures in CAH girls is usually detected at birth and corrected surgically to remove part of the penis to reproduce a clitoris and reopen the vaginal opening. Their endocrine milieu is adjusted by administration of exogenous glucocorticoids that will also reduce the inappropriate production of androgens through their feedback action on the brain and pituitary gland to reduce adrenocorticotropic hormone (ACTH) secretion that drives adrenal steroidogenesis, and these genetically XX children are then raised as girls.

Despite being raised as girls, when they become adults CAH women display a markedly increased probability of commitment or desire to engage in a homosexual relationship in comparison to control females or to unaffected sisters[89–91] (see Ref. 79 for a recent review). Some studies reported up to 30–40% of CAH subjects showing some form of homosexual attraction as compared to 10% or less in control populations. Other recent studies, sometimes based on much larger sample sizes, have produced similar figures, although other studies indicated a lower incidence, in the 20% range.[92–94] Overall, only one out of 10 studies failed to find an increased

incidence of homosexuality in CAH women (see Ref. 79). Meyer-Bahlburg and colleagues[94] also showed that the degree of virilization in various forms of CAH correlates with the increased incidence of bi-or homosexuality (Figure 48.6).

Because the endocrine defect was corrected soon after birth, genital structures were surgically feminized, and these girls were presumably raised as girls; these data suggest that prenatal androgens are involved in the determination of sexual orientation in women, although alternative interpretations of these data have been proposed (e.g., suboptimal genital structures despite surgical correction making heterosexual activity difficult or painful; see Ref. 79).

It should also be noted that (1) even if the percentage of women with homosexual tendencies is significantly increased in CAH subjects, this only concerns less than half of the subjects[79] and (2) the reported percentages often concern subjects that display a sexual orientation that is not strictly heterosexual but not necessarily exclusively homosexual. Sexual orientation is frequently quantified on a seven-point ordinal scale, ranging from 0 (strictly heterosexual) to 6 (strictly homosexual), called the Kinsey score. The increased incidence of homosexual tendencies described in CAH subjects often refers to subjects with a Kinsey score greater than 1, but include only rare cases of exclusively homosexual subjects (Kinsey score of 6). Thus if these data strongly suggest a role for prenatal testosterone in the control of sexual orientation, they also clearly indicate that this steroid cannot be the only factor that determines this orientation. Accordingly, the vast majority of lesbians were not affected by CAH during their early life.

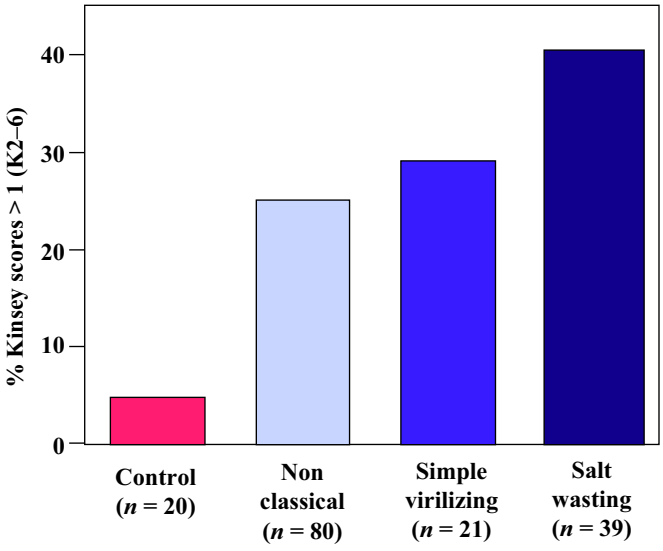

FIGURE 48.6 Percentages of bi- or homosexual subjects expressed as the ratio of the numbers of subjects rating between K2 (largely heterosexual but also distinctly homosexual) and K6 (completely homosexual) on the Kinsey scale to the total number of subjects (K0 to K6) in girls exposed to prenatal androgenization linked to the syndrome of congenital adrenal hyperplasia (CAH). This percentage increases with the severity of the CAH phenotype from the nonclassical (NC) to the simple virilizing (SV) to the salt-wasting (SW) type. The number of subjects in each category of CAH is indicated below the graph. *Source: Drawn from data in Ref. 93.*

TREATMENT OF PREGNANT MOTHERS WITH DIETHYLSTILBESTROL (DES)

Between 1939 and 1960, 1–5 million pregnant women were treated with DES in Europe and the United States to prevent miscarriage. This treatment was not only ineffective but even turned out to have detrimental long-term consequences (e.g., increased incidence of cancer in the vagina and cervix). One of the unexpected consequence of DES exposure was that girls born from these treated mothers showed, when adult, a significant increase in homosexual fantasies or nonheterosexual sexual activity (bi- or homosexual), despite the fact that their rearing had obviously been consistent with their genetic female sex (the change in sexual orientation was not anticipated).

This increased incidence of bi- or homosexuality was confirmed in several independent studies.[95–97] It affected a percentage of subjects ranging from 20% to 40% depending on the sample investigated. The reproducibility of this effect was, however, questioned by a more recent study based on a very large number of subjects,[98] but this study was probably less sensitive and only assessed the actual homosexual activity on a qualitative scale (presence/absence), whereas previous studies also analyzed other aspects of sexuality (fantasies, dreams) and used a graded scale (Kinsey scale in seven points).

If the effect of DES is real, which will be difficult to confirm since this treatment was abandoned a long time ago, this would indicate that estrogens as well as androgens are able to masculinize sexual orientation. This is consistent with rodent data, where many effects of testosterone on sexual differentiation are produced after conversion into estradiol by aromatase in the brain, but would conflict with other human data that tend to assign a prominent role to signaling via androgen receptors in sexual differentiation.

CLOACAL EXSTROPHY

Complex genitourinary malformation occasionally occurs during embryonic development, resulting in the birth of XY males who, in addition to various malformations of the pelvis, have no penis. These subjects have normal testes and were thus presumably exposed to a male-typical pattern of androgen secretions before birth. Historically, these subjects were submitted to vaginoplasty and removal of the testes soon after birth, and they were raised as girls.

A few follow-up studies have demonstrated that in a significant number of cases (usually about half), these subjects, as adults, chose to adopt a male identity and gender role. Information concerning the sexual orientation of these subjects is sparse, but in many cases, a typical male sexual orientation (attraction to women) was also observed that would once again relate to their embryonic exposure to androgens.[99–101]

Importantly, these masculine features developed in the absence of pubertal action of testosterone, since most subjects were castrated soon after birth. Prenatal or immediately postnatal androgens would thus explain the high incidence of changes in gender identity (and probably sexual orientation) observed later in life in these XY subjects, despite the fact that they were subsequently raised as girls. This change, however, did not occur in all individuals. It is thus consistent with a role of prenatal androgens, but these data also indicate that androgens are probably not the only determinant of sexual orientation.

5α -REDUCTASE DEFICIENCY

Testosterone induces the development of male external genitals by fusion of the genital folds to form a scrotum and the development of the genital tubercle in a penis through its conversion into DHT by the enzyme, 5α-reductase. In the absence of DHT, the genital folds do not fuse, and instead form the vaginal lips, while the genital tubercle develops only very little and turns into a clitoris. Imperato-McGinley and colleagues identified, in the Dominican Republic, a mutation of 5α-reductase, which prevents the production of DHT in the genital skin.[102,103] This recessive mutation has also been discovered in Papua New Guinea, another island where inbreeding is prevalent.

Individuals affected by this mutation are born with genital structures that are not masculinized and are (presumably) raised as girls. They provide, therefore, another test of the relative power of the potentially opposite effects of the embryonic endocrine environment (presence of testosterone and also probably estrogens) and rearing on sexual orientation. The rise in plasma testosterone associated with puberty later masculinizes (at least in part) the genital structures, and these individuals usually revert to a male gender and male-typical sexual orientation. This change of identity and gender role has even been observed in some individuals who had been married at a very young age to a man as a girl and who remarried with a woman after puberty. In terms of sexual orientation, these adults usually show a male-typical attraction to women.

It has been argued that the relative ease with which these subjects apparently change gender and sexual orientation at puberty, despite having been raised as females, was related to their exposure to androgens during embryonic life (testosterone secretion is apparently normal in these subjects, it is only its 5α-reduction that is deficient). However, the medical condition of these subjects is often identified at birth, so that their sex of rearing is not necessarily unequivocally female. Furthermore, the obvious social advantages related to adopting a male gender identity in the societies where this 5α-reductase deficiency frequently occurs raises additional questions about the reasons underlying the postpubertal sex change. Note, however, that Imperato-McGinley and colleagues showed that in a group of 18 affected subjects, who had completely female external genitalia at birth and had therefore been brought up in the firm belief that they were girls, 17 adopted a male sexual identity after puberty and were sexually attracted to women.[104]

OTHER EMBRYONIC ENDOCRINE CONDITIONS OF POTENTIAL SIGNIFICANCE

A number of other endocrine perturbations of hormonal secretion or action are known to occur in humans and are similarly associated with significant discrepancies between sexual orientation and genetic sex (see Ref. 97). The role of early hormones in these cases is, however, more difficult to separate from the role of postnatal rearing because these early endocrine disruptions lead to a (nearly) complete sex reversal, so that subjects are raised completely assuming a sex (and gender) that is opposite to their genetic sex. For example, XY subjects with complete androgen insensitivity syndrome are born with female genitalia and are typically raised as girls at least until puberty, when the absence of menstruation leads to medical examination and diagnosis. These subjects usually have a female gender identity and a female-typical sexual orientation (they are sexually attracted to men). This demonstrates that sexual orientation is not necessarily associated with the genetic sex. Their sexual orientation is consistent with their embryonic exposure to steroids (no action of androgens leading to a female-typical orientation) but it is impossible in these cases to discriminate between the role of prenatal hormones and the role of the education and postnatal environment, because both potentially concur to produce a female-typical orientation. The same potential confusion is, to some extent, associated with the 5α-reductase deficiency affecting XY subjects since one cannot be completely sure that they were really raised as girls.

Altogether, these clinical conditions (two in males and two in females) nevertheless support the idea that embryonic hormones play a substantial role in determining adult sexual orientation. It should be noted, however, that these changes in sexual orientation as a result of embryonic endocrine disruption always concern only a fraction of affected individuals (usually a maximum of 30–40% showing a partially reversed orientation) so that

at least 60–70% of subjects exposed to these altered endocrine conditions retain their heterosexual orientation.

Sexually Differentiated Characteristics

The optimal way to directly test the importance of embryonic steroids in the determination of sexual orientation would be to monitor these concentrations in a large number of subjects during their fetal, embryonic, and early postnatal life, and then correlate these data with the sexual orientation of these subjects 20–30 years later. However, practical reasons (risks associated with in utero blood sampling, long duration of the study, small percentage of subjects who will turn out to show a homosexual orientation as adults) make it nearly impossible to obtain this type of data. Researchers have therefore used an alternative strategy based on the use of proxies to indirectly assess the endocrine milieu to which specific subjects were exposed during development.

A number of morphological, physiological, and behavioral characteristics are sexually differentiated in animals and in humans. In many cases, these features are known to differentiate under the irreversible organizing influence of embryonic hormones. Many studies have thus quantified these sexually differentiated features comparatively in homo- and heterosexual populations to test, through these proxies, whether homosexual subjects had potentially been exposed to atypical hormonal conditions during their development. Positive results have been obtained in a substantial number of these studies.

The sexually differentiated characteristics that have been studied in this context include variables that are presumably influenced by prenatal androgens, but could also possibly be secondarily affected by the sexual orientation of the subject. This is namely the case for the performance of adult subjects in various cognitive tests (e.g., Ref. 105) or for the physiological brain responses to odors associated with androgenic or estrogenic steroids produced by males or females.[106,107] These traits are significantly different in homo- and heterosexual men and/or women, but it remains unclear whether these differences reflect a differential prenatal exposure to androgens or an indirect consequence of their sexual orientation resulting, for example, from conditioned responses. These differences will not be reviewed here since they do not represent conclusive evidence for exposure to an atypical prenatal endocrine milieu, but they are discussed in detail elsewhere.[42,43,108]

We will focus our attention here on a few morphological and physiological features that are, on the one hand, clearly influenced by prenatal testosterone and, on another hand, significantly modified in gays or lesbians. These features are also very stable characteristics, so that it is difficult to conceive of how they could possibly be affected secondarily by the adult sexual orientation. They provide, therefore, important evidence suggesting exposure to an atypical endocrine environment in early life. A more extensive presentation of these data is available elsewhere.[42,43,108]

THE RELATIVE LENGTH OF THE INDEX AND RING FINGERS

The ratio of the lengths of the second to the fourth fingers (D2:D4) is significantly smaller in men than in women and in males than in females in a variety of animal species.[109,110] It is masculinized in females of a variety of mammalian and even avian species by injection of androgens during embryonic life.[110–112] In humans, this ratio is masculinized (decreased) in CAH women exposed to an excess of androgens in utero,[113,114] and it is significantly increased in XY subjects affected by the complete androgen insensitivity syndrome.[115] This sex difference in the relative length of fingers in humans thus probably reflects differences in the embryonic androgen concentrations (male > females; see Ref. 116 for review).

Several studies have shown that this ratio is masculinized (smaller) in lesbians as compared to heterosexual women[117–120] (Figure 48.7). Interestingly, one study showed that only lesbians who identify as masculine (known as "butch") had this decreased D2:D4 ratio.[113] Although a failure to replicate this effect has been published[121] and the significance of the D2:D4 ratio has been questioned (e.g., does it reflect differences in bone length or in fat accumulation[122]), the masculinized D2:D4 ratio in lesbians has been confirmed by meta-analyses of

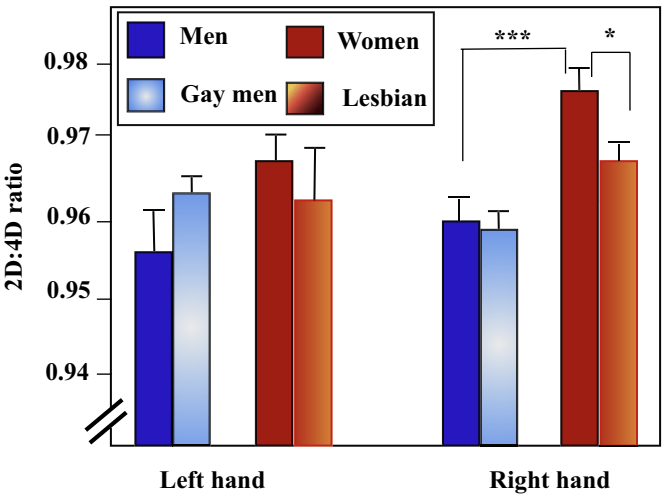

FIGURE 48.7 **Ratio of lengths of the index (2D) and ring finger (4D) as a function of sex and sexual orientation.** This figure is reproduced in color in the color plate section. The 2D:4D ratio is greater in women than in men, probably due to in utero exposure to testosterone of male embryos. It is close to the male level in homosexual women, suggesting that they have been exposed to abnormally high levels of testosterone during a part of their embryonic life. For unknown reasons, these differences are more pronounced in the right hand. *= $p < 0.05$, ***= $p < 0.001$. *Source: Redrawn from Ref. 117.*

available data,[116] suggesting that lesbians, as a group, were exposed early on to higher-than-typical concentrations of androgens.

In contrast, no consistent pattern of changes of this D2:D4 ratio has been so far detected in gay men. The D2:D4 ratio in homosexual men was shown to be lower than (more masculine, opposite to the prediction),[118,119] identical to,[117] or even higher[121] than the ratio in heterosexual men. Thus, only one of these four studies focusing on D2:D4 ratio, and sexual orientation in men is in agreement with the predictions of the prenatal hormonal theory.

THE RELATIVE LENGTH OF LONG BONES

Like the finger bones discussed in the previous section, the length of the long bones of the arm and leg are sexually differentiated and are thought to reflect the influence of the sex-specific embryonic hormonal environment. The length of bones that become sexually differentiated during infancy was shown to be significantly different between homo- and heterosexual individuals, while the bones that become different between men and women after puberty were not modified in a manner associated with sexual orientation.[123] Subjects attracted to men (heterosexual women and homosexual men) have a smaller growth of the bones of the arms, legs, and hands than subjects who have a sexual preference for women (heterosexual men and homosexual women). These differences were particularly noticeable in the analysis of the ratio of the hand width to hand length (see Figure 48.8).

These conclusions are based on the study of nearly 400 subjects, and although they have not been replicated to date, a few more anecdotal studies had already identified, in males, differences in ratios of the lengths of various parts of the body associated with sexual orientation (see Ref. 123). These data support the notion that androgen concentrations or actions were reduced in gay men during development and, conversely, more prominent in homosexual than in heterosexual women.

OTO-ACOUSTIC EMISSIONS

The inner ear, in addition to its obvious function in hearing, also emits sounds in the form of barely audible clicks, called oto-acoustic emissions (OAE). OAE are produced either spontaneously or in response to short noises in the environment (e.g., clicks). These OAE are significantly more frequent and have a larger amplitude in women than in men, and the differences are already present during childhood.[124] These sex differences in OAE have been reported in a variety of animal species, including sheep and monkeys. Most interestingly, in sheep, OAE are masculinized (they decrease in frequency and amplitude) following embryonic treatment of females with androgens, and they are no longer affected by castration in adulthood, indicating that they presumably reflect organizing effects of steroids during early ontogeny.[125]

OAE were shown to be significantly less frequent, and have a lower amplitude, in lesbians as compared to heterosexual women, again suggesting that lesbians have been exposed to higher concentrations of androgens than usual during early life[124,126] (Figure 48.9). In addition, women who had a twin brother and, therefore, presumably had been exposed to slightly higher levels of testosterone during embryonic life (testosterone

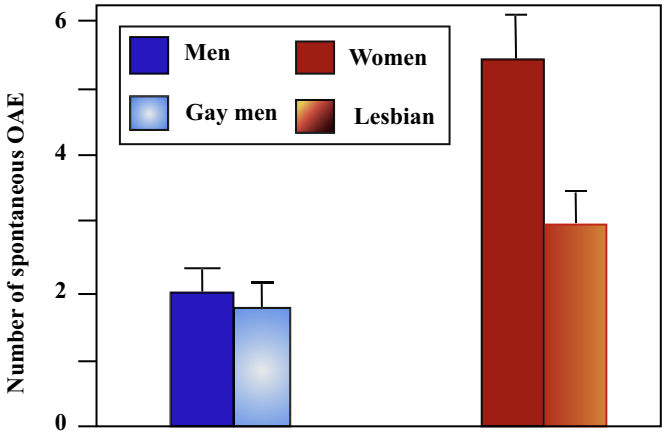

FIGURE 48.9 **Frequency of oto-acoustic emissions (OAE) evoked by click sounds measured in the right ear in men and women as a function of sexual orientation.** This figure is reproduced in color in the color plate section. OAE are sexually differentiated and significantly masculinized in homosexual females. *Source: Redrawn from data in Refs 124,127.*

produced by the twin would have diffused to the female embryo), had masculinized OAE, confirming sensitivity to androgens of the response in humans.[124]

These data are thus consistent with the hormonal theory of sexual orientation, stating that female fetuses destined to become homosexual or bisexual have been exposed to abnormally high levels of androgens. However, contrary to the simplest predictions that could be drawn from this theory, no difference in the OAE has been found between homo- and heterosexual men.

Similar studies have also identified a partial masculinization of evoked acoustic potentials (electrical responses induced in the brain by short auditory stimuli) in homo- or bisexual women compared to heterosexual women.[128] An independent study also demonstrated masculinization in lesbians of the "startle response",[129] another sexually differentiated response (women < men) by which the blink of the eyes following a loud noise is partially inhibited if the loud noise is preceded by a lower noise. In both cases, however, homosexual men failed to show a lack of masculinization of these, or even displayed a hypermasculinization, which disagrees with the hormonal theory of homosexuality in men.

THE POSITIVE FEEDBACK RESPONSE OF LUTEINIZING HORMONE TO ESTROGENS

During the ovulatory cycle in females, plasma estrogen concentrations progressively increase during the follicular phase of the cycle to reach a critical threshold that causes by positive feedback the release of a large peak of luteinizing hormone (LH), ultimately inducing ovulation. In rodents, this positive feedback is observed in females, but not in males, and this sex difference results from the organizing action of sex steroids during the perinatal life (see Chapters 26-28 for a detailed treatment of this topic in rodents, sheep, and primates, respectively).

Dörner originally demonstrated the existence of a differential feedback to estrogens, as measured by plasma LH concentrations, between homo- and heterosexual men.[130] In this study, gay men reacted to an injection of estrogen with a significant increase in blood levels of LH that was lower than in women, but still significantly higher than in heterosexual men.[131–133] For various scientific, but also sociological and ethical reasons whose description goes beyond the present review (see namely Ref. 134), this work raised a huge controversy and was received with skepticism. This differential neuroendocrine reaction to an injection of exogenous estrogens was, however, reproduced in an independent study performed in the United States. Gladue and colleagues demonstrated that after a single injection of Premarin, a mixture of compounds with estrogenic action, women showed 72–96 h later a major increase in LH plasma concentrations.[135] Such an increase was not observed in men, but again an increase of intermediate magnitude was observed in homosexual men (see Figure 48.10).

As noted previously, this increase in LH concentration in humans does not reproduce the preovulatory peak observed in female rats (see for discussion Ref. 134) because it is clearly delayed and less abrupt. It must also be stressed that the sex difference in positive feedback of estrogens on LH that is clearly observed in rats but also in mouse, hamster, and guinea pig, and results from the masculinization/defeminization of males by androgens during the perinatal period, is not present in rhesus monkeys[136] and thus also probably not in humans. This conclusion is, however, difficult to formally confirm in our own species since in order to compare the positive feedback response to estrogens in both sexes it is necessary to place all subjects (males and females) in a similar endocrine condition, which cannot be done in humans for obvious ethical reasons.

It is thus impossible to determine whether the difference observed between homo- and heterosexual men concerns a neuroendocrine mechanism that differentiates (is defeminized) under the influence of gonadal steroids during early life, as observed in rats,[137] or more likely reflects another type of difference (e.g., in testicular or pituitary physiology and thus in basal endocrine condition) that could interfere with the positive and negative feedback.[134,138] In any case, it appears that male homosexuality is associated with a difference in functioning

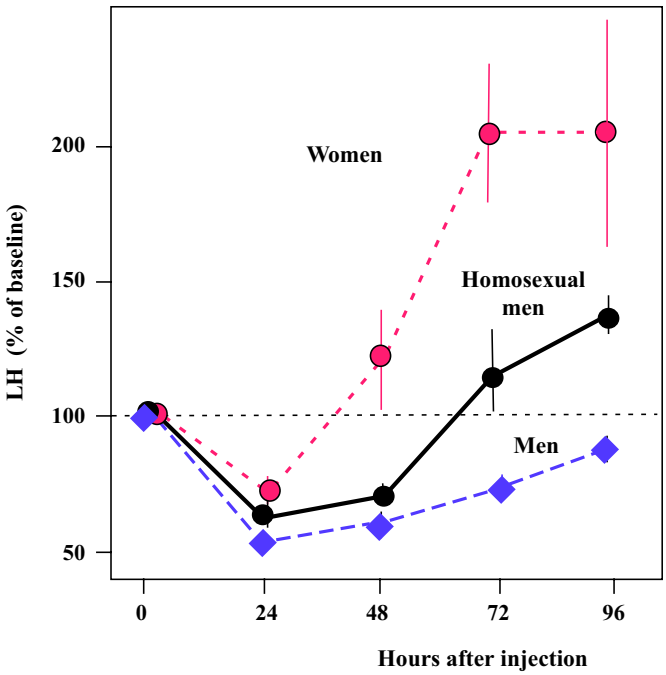

FIGURE 48.10 **Changes in blood concentrations of luteinizing hormone (LH) in response to injection of a single dose of the estrogenic compound Premarin in heterosexual men and women and in homosexual men.** *Source: Redrawn from Ref. 135.*

of the hypothalamic-pituitary-testicular axis that is very unlikely to be the result of a personal choice.

BRAIN STRUCTURES

Several sexually differentiated brain structures were also shown to be different between homo- and heterosexual subjects, although these studies have focused almost exclusively on males. Historically, the first identified brain difference concerned the suprachiasmatic nucleus, the central clock of the organism, that was shown to be significantly larger (1.7X) and contains twice as many neurons in gay men than in heterosexual subjects.[139] This nucleus is, however, not known to be sexually differentiated in control heterosexual populations, and its links to reproduction are only indirect. The significance of this difference and its potential relationship with sexual orientation is thus difficult to assess.

It was subsequently reported that the size of the anterior commissure, when measured in the mid-sagittal plane, is larger in gay men than in heterosexual control subjects.[140] This difference is more interesting for the purposes of the present discussion because the size of this commissure is known to be larger in women than in men. However the size of this commissure has no obvious relationship with sexual orientation (it could relate to functional lateralization), so that the meaning of the difference between homo- and heterosexual men remains difficult to interpret.

Gorski and colleagues (who had identified the SDN-POA of rats) also discovered in the human preoptic area four cellular condensations that they labeled interstitial nuclei of the anterior hypothalamus (INAH) 1 to 4. Two of these nuclei (INAH 2 and 3) are significantly larger in men than in women.[63] Subsequent studies showed that INAH3 is significantly smaller in homosexual men than heterosexual men, so that its size is essentially equal to what is observed in women[141] (Figure 48.11).

An independent study based on different brains confirmed the reduced size of INAH3 in male homosexuals compared to heterosexuals, though the magnitude of the difference observed in this replication was lower than in the original study and not statistically significant.[142] In this study homosexual men had a greater cell density (more cells per unit volume), but a similar total number of neurons in INAH3, when compared to heterosexual subjects—neurons were more densely packed potentially because they formed fewer synapses (during development?).

The mechanism(s) that control(s) the development of this nucleus in humans is unknown, but it does not seem to depend significantly on hormonal status in adulthood.[143] In rats and sheep, the size of a potentially homologous nucleus located in the same part of the preoptic area (SDN-POA in rat, oSDN in sheep) is irreversibly determined by the action of embryonic sex steroids.[68,75,144,145] Moreover, lesions of this nucleus in adult rats or ferrets modify male sexual partner preference, which can be considered an animal model of sexual orientation.[65,66]

If the same holds true in humans, the smaller INAH3 of gay men could then be a marker of deficient exposure to androgens during early ontogeny, and even could be a cause of the modified sexual orientation. There are, however, multiple considerations that severely limit this conclusion, the most important being that it has been, so far, impossible to determine whether the small INAH3 of gay men is a cause or consequence of their sexual orientation (see Ref. 141 for discussion). Based on analogies/homologies with animal models (see namely Refs 53,54,69) and on studies of the oSDN in ram-oriented

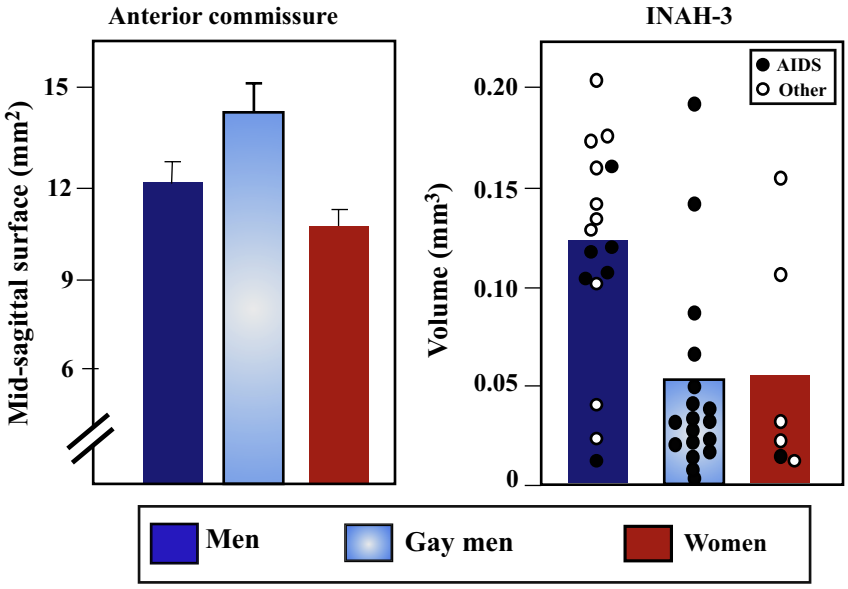

FIGURE 48.11 Average size of the anterior commissure as estimated by its surface in the mid-sagittal plane (left) and volume of the 3rd interstitial nucleus of the anterior hypothalamus (INA-3) (right) in men, gay men, and women. This figure is reproduced in color in the color plate section. Data for the anterior commissure are presented as means ± SEM, whereas for INAH-3 the average value in each group, as well as all individual data points, are shown to clearly illustrate the partial overlap between groups despite the significant differences between men and women and between men and gay men. Individual data points are filled in subjects who died from AIDS and open in subjects who died from other causes. The smaller average size of INAH-3 in gay men cannot be accounted for by the fact that all subjects included in the study had died from AIDS since in the control group, the INAH-3 of men who died from AIDS is not smaller than in men who died from other causes. *Source: Redrawn from data in Refs 140,141.*

male sheep,[73,75,146] we are, however, tempted to favor the first of these interpretations. The small INAH3 of homosexuals should, at the very minimum, represent the signature of an atypical embryonic hormonal environment (see Refs 43,108 for a detailed discussion).

Conclusions Concerning the Endocrine Control of Sexual Orientation

Taken together, these clinical studies and the analyses of phenotypic differences between homo- and heterosexual populations strongly support the notion that prenatal steroids, in particular testosterone, play a significant role in the development of adult sexual orientation in humans. Several aspects of these results clearly indicate, however, that this early testosterone action is not sufficient in itself to determine this orientation. On the one hand, clinical studies of subjects that were exposed to atypical endocrine conditions for their sex reveal an increased incidence of homosexual subjects, but this incidence never reaches more than 30–40%, which means that the majority of subjects (60–70%) remain heterosexual even after exposure to these atypical endocrine conditions. On the other hand, the sexually differentiated features that distinguish homo- and heterosexual populations do so in a statistical manner, but there is always a large degree of overlap between these features in the two populations. Furthermore, these phenotypic differences are often seen in one sex but not the other. For example, the masculinization of the D2:D4 finger ratio and of the frequency of OAE is observed in lesbians, but the opposite effect (lack of masculinization) has not been reliably detected in gay men as would be predicted by the simplest form of the endocrine theory of sexual orientation. Conversely, a lack of masculinization has been observed in the length of long bones and in the volume of the INAH3 of homosexual men, but the corresponding studies have not been performed in women, and it is thus unknown whether these features are masculinized in lesbians.

Multiple theoretical reasons identified in animal studies are available to potentially explain the limitations described herein. They are based on the existence of critical sensitive periods of testosterone action, on thresholds in the dose–response curves linking testosterone to its phenotypic effects, but also on probable differences between homosexual populations from different studies based on the sampling methods that were used (global analysis of college populations, recruitment in gay bars or in gay pride parades, etc.). It is also likely that homosexual populations are not homogenous (see, for example, the recognized differences between "butch" and "femme" lesbians) and testosterone might be implicated in the development of some, but not other forms of homosexuality. At this time, results are not available to discriminate between these different interpretations and to answer the question of the relative importance of the embryonic endocrine environment versus other factors in the control of sexual orientation. It can just be said that these hormones have a definite impact.

Changes in Hormone Action during Prenatal Life?

Two major questions are raised by this endocrine theory of sexual orientation: (1) how can sexual orientation be modified without changing other hormone-dependent sexually differentiated characteristics, such as genital structures, that do not differ between homo- and heterosexual subjects, and (2) what is the possible origin of the changes in hormone secretion or action that putatively induce a homosexual orientation?

The discordance between genital structures and sexual orientation can be understood in the context of an endocrine model if one assumes that these two steroid-dependent responses develop at different times (this is the case since the genitals are differentiated early during embryonic life when the brain is still poorly developed), or that they are associated with different dose responses (no clear data on this topic in humans) so that a change in hormonal environment will affect one but not the other, or finally, if the endocrine factor controlling the development of homosexuality is not the circulating level of the steroid (testosterone), but rather one aspect of its action in a specific part of the brain (change in local concentration of receptors, in expression of a steroid receptor co-activator, etc.). It is therefore easy, in theory, to reconcile an endocrine theory of homosexuality with the presence of sex-typical genital structure. The origins of the endocrine changes leading to homosexual orientation are in contrast less clear.

Studies in rats showed that stressing pregnant females partly blocks the masculinization of their male fetuses so that they display a decreased anogenital distance at birth, they mount females less frequently, and are even capable of presenting female-typical behaviors such as lordosis.[147] The volume of their SDN-POA is also smaller than in control males.[148,149] Dörner showed, through a retrospective analysis, the existence of a significant peak in frequency of gay men among cohorts of boys born in Berlin between 1942 and 1946, a period when mothers obviously experienced an unusually high level of stress.[133,150,151] There was also a positive correlation between stressful life events remembered by mothers and the likelihood that their boy born in this period would be homosexual.[151]

These studies have, however, been criticized on methodological grounds, and recent studies failed to reproduce this correlation between maternal stress and homosexual behavior[152,153] or produced only equivocal

data.[154] Thus the contribution of prenatal stress to human sexual orientation remain elusive.

Interestingly, recent work in rodents has indicated that the masculinizing effects of neonatal estrogens on sexual behavior and aspects of brain structure are often mediated at the cellular level by intracellular changes in the concentrations of prostaglandins (in particular PGE2) resulting from an increase in the activity of their synthesizing enzyme, the cyclo-oxygenase enzymes COX-1 and COX-2[155] (reviewed in Ref. 156). Prostaglandins are lipid signaling molecules that subserve cellular functions related to reproduction, but also inflammation, hyperalgesia, and fever.[157] It is conceivable that their increase during an episode of prenatal inflammation, or the blockade of their synthesis following ingestion of a COX-2 inhibitor such as indomethacin (a commonly used anti-inflammatory drug), could interfere with the normal differentiating effects of sex steroids on the brain and thus alter the development of sexual orientation. One would predict that exposure to indomethacin would block aspects of brain masculinization, resulting in male homosexuality, while an increased masculinization would follow an inflammatory episode and the associated increase in PEG2 resulting in female homosexuality. However, this potential mechanism has not been investigated to our knowledge.

It is also important to emphasize here that a huge amount of data has accumulated during the last few decades indicating that a variety of chemical compounds released in the environment, the "endocrine disruptors," affect endocrine physiology and, in particular, sexual differentiation in many animal species and possibly also in humans.[158–160] No study has, however, to our knowledge, related this exposure to environmental endocrine disruptors to changes in sexual orientation in humans, but this possibility deserves to be investigated.[159]

Genetic Influences

The Heritability of Sexual Orientation

An alternative explanation of the differences in embryonic steroid concentration or action potentially responsible for differences in sexual orientation is genetics. Numerous epidemiological studies have indeed demonstrated the presence of a significant degree of heritability of sexual orientation. Statistically, the concordance of sexual orientation is directly correlated with genetic relatedness. For example, if, in a given population, a son is gay, 20–25% of his brothers will share the same orientation, as compared to 4–6% in a control population.[105,161] Similarly, lesbians have a greater probability than heterosexual women of having a homosexual sister.

Twins studies strongly suggest that this correspondence in sexual orientation does not reflect a communality of postnatal experiences (psychosocial factors), but rather genetic similarity. There is indeed, a much better agreement of sexual orientation in monozygotic (identical) twins than in dizygotic (fraternal) twins born from different ova and sperm. A literature survey[161] showed that, on average, if a dizygotic gay twin has a brother, there is a 15% probability that the brother will also be homosexual, but this probability rises to 65% in monozygotic twins. Another study in the 1990s identified a similar correlation between genetic relatedness and concordance in sexual orientation (monozygotic twins: 52%, dizygotic twins: 22%, and adoptive brothers: 11%; see Ref. 162). Two more recent studies,[163,164] based on large populations of twins and a rigorous selection of subjects, reported, however, a lower concordance between monozygotic twins (20–30%), and a concordance between sexual orientation of twins was also detected in females (0.58, heritability[165]; see Ref. 105 for more detail).

Overall, these studies suggest that, in social conditions typical of Western societies, 30–60% of the variance in sexual orientation in humans should have a genetic origin.[97,105,166] The mechanism supporting this transmission has, however, not been identified to date despite relatively intensive research. Two experimental approaches were used in this context: a candidate gene approach and a genome-wide screening based on linkage analysis.

Candidate Gene Approach

Genetic differences could affect the synthesis of steroid hormones, or their activity, in the brain of the fetus. It is obvious that genes coding for androgen or estrogen receptors, or for aromatase, cannot be completely disrupted in homosexual subjects because these subjects would then suffer from multiple physiological and morphological deficits. Smaller variations (mutation or polymorphism) in these genes might, however, slightly alter the function of the corresponding receptors or enzymes, and in this way modify brain differentiation specifically without affecting peripheral morphology and physiology. Several studies have investigated this possibility in relation to the androgen receptor, and to aromatase, but to date none of them has been able to identify variations in these genes that are significantly linked to sexual orientation.[167,168]

"Direct" versus "Indirect" Genetic Effects

Historically, it has been accepted since the pioneering work of Jost,[169] and the seminal publications of Young and colleagues extending the concept to behavior,[46] that most if not all sex differences in morphology, physiology, and behavior are due to either a differential activation in adulthood by sex steroids or an irreversible organizing action exerted by these steroids during early life. The discovery of a few "apparent" exceptions to this rule has raised doubts about the generality of this rule. It was, for example, discovered that the scrotum in marsupials

develops before gonadal differentiation[170] and that the sexual differentiation of the song control system of zebra finches (*T. guttata*) does not react in the expected manner to pharmacological manipulations of early steroid action.[171]

During the last decade, genetic manipulations have allowed the development of a mouse model in which effects of the genetic sex (presence of XX or XY chromosomes) can be differentiated from the hormonal influence of the embryonic gonad (testes secreting testosterone or relatively inactive ovaries). In some of these mice, the SRY gene that determines the development of the testes has been inactivated by a mutation, whereas in other subjects this same gene has been added to an autosome such that XX genetic females can have a functional SRY gene and thus develop testes and be exposed to the hormonal action of androgens during embryonic development. This "four core genotypes" model thus discriminates on the one hand between subjects that have testes during development (XY and XX^{sry} subjects) and those who don't (XX and XY^{sry-}), and on the other hand between subjects that possess two X (XX and XX^{sry}) or an X and a Y (XY and XY^{sry-}) chromosomes.[172]

The review of data obtained with this model is beyond the goals of the present chapter (see Refs 173,174 for recent reviews), but it is critical to mention that the four core genotypes have revealed that multiple physiological or brain sex differences do not develop under the influence of embryonic testicular secretions but rather relate to the chromosomal complement of the subject. It is thus conceivable that individual differences in sexual orientation could relate to such "direct" genetic effects, i.e., to effects that would not be mediated through a change in steroid action during development.

Genome-Wide Screening

During the search for relevant genes, it was shown that sexual orientation in men tends to be transmitted through matriarchal lineage: a gay man has a higher probability of having gay men among his ancestors on the maternal side (uncles, cousins), but not the paternal side. This was originally interpreted as a sign of inheritance through gene(s) located on the X chromosome, and one study indeed identified a linkage with markers located in the subtelomeric region of the long arm of the X chromosome, a region called Xq28.[175] This association with Xq28 was replicated in two subsequent studies[176,177] but not in a fourth one.[178]

A comprehensive analysis of all available data, including negative results, however, indicates that approximately 64% of gay brothers have common alleles in the Xq28 region of chromosome X instead of the expected 50%,[179] and that this association is highly significant ($p < 0.0001$). However, this chromosomal region remains quite large and could contain many genes. Those that could potentially be responsible for the predisposition to a homosexual orientation have not been identified.[179,180]

In women, similar studies have also detected an increased rate of "nonheterosexuality" (sum of homo- and bisexuality) in nieces and cousins of the paternal lineage of lesbians. This transmission is also consistent with a link to the X chromosome, but it could come from the father as well as the mother. Other interpretations are also possible, and the interpretation of these data remains difficult.[105] Surprisingly, however, the gene(s) located on the X chromosomal regions that could predispose to homosexuality has (have) still not been identified.

Epigenetics

Because molecular studies have in general failed to identify a gene, or groups of genes related to sexual orientation, recent work has focused on the idea that the heritage of sexual orientation could be the result of epigenetic modifications of gene expression. The relevant genes could in this theory be located on sex chromosomes as well as other chromosomes (autosomes).

Studies have in particular focused on the phenomenon of X chromosome gene inactivation. Male cells indeed contain a single copy of the X chromosome, while female cells contain two. In mammals, each female cell randomly inactivates one X chromosome during ontogeny to avoid producing a double amount of proteins whose genes are located on the X chromosome. Bockland and collaborators showed that this inactivation is extremely asymmetrical (i.e., one of the X chromosomes inactivated in more than 90% of the cells instead of 50% predicted from random inactivation) more frequently in mothers of homosexual boys (13 of 97 = 13%) than in mothers of heterosexual sons (4 of 103 = 4%), and even more frequently in mothers of two or more gay boys (10/44 = 23%).[181] The specific link between this unusual pattern of X chromosome inactivation and the homosexual orientation of the sons is unclear at this stage. The unusual X inactivation could have a direct influence on the sexual orientation of sons, but it could also be only an indirect consequence of some unknown genetic mechanism influencing sexual orientation. However, these data clearly show that the homosexual orientation of sons correlates with a biological marker in the mothers, further supporting the notion that sexual orientation is influenced or determined by biological factors. These findings also support a role of the X chromosome in regulating sexual orientation.

A genome-wide linkage study that was not limited, like studies of chromosome X, to subjects with proven maternal transmission, identified a linkage of sexual orientation to loci on chromosome 7 (in 7q36) and 8 (in 8p12), with roughly equal maternal and paternal origin.[182] A marker of specific maternal origin was also found on chromosome 10 (position 10q26). This site with exclusive maternal heritability provides an alternative interpretation to

the transmission of homosexuality through the maternal line. Transmission could be through a gene on the X chromosome, as previously thought,[175] but alternatively, it could reflect maternal transmission of an epigenetic marker on chromosome 10 (see Refs 179,180 for details).

A recent theoretical paper of Rice and colleagues has explored how sex-specific epigenetic markers (epi-marks) could theoretically explain the heritability of sexual orientation in the absence of any identified genetic difference between homo- and heterosexual populations.[82] These authors noted that, although males have on average higher testosterone plasma concentrations than females during embryonic and early postnatal life, this sex difference in circulating concentrations of testosterone has a limited amplitude associated with a large interindividual variance. This is true in both rats and humans, and, furthermore, the sex difference in plasma testosterone concentrations is statistically significant only during short periods of time during development (with often a residual overlap between male and female values). As a consequence, Rice et al. argue that it is difficult to imagine how these limited sex differences in plasma testosterone could by themselves explain the very reliable sex differences in genital structures (sex-atypical genitalia are extremely rare) and even sexual orientation (only a maximum of 10% of subjects have a sex-atypical orientation). Experimental treatment with sex steroids or hormone antagonists reliably modify these characteristics, but the magnitude of endocrine changes that they induce is much larger than the physiological sex differences in circulating steroid concentrations.

Rice and colleagues therefore argued that male and female embryos must have an intrinsic difference in sensitivity to steroid action (hypersensitivity in males and/or hyposensitivity in females) in order to generate the sexually differentiated phenotypes in response to circulating concentrations of testosterone that are only marginally different.[82] This differential sensitivity could relate to sex differences in plasma steroid-binding proteins, in steroid-metabolizing enzymes, in steroid receptors, in steroid receptor co-regulators (activators or inhibitors), or in any subsequent step in the intracellular actions of steroids. Mechanistically, the differences in sensitivity to steroid action could be related to the fact that expression of many genes is already differentiated well before the differentiation of the gonad, at least in the mouse embryo.[183] In the absence of identified differences in gene structure between homo- and heterosexual populations, they propose that sexually antagonistic epigenetic differences transmitted between generations in a sex-specific manner could explain the differential expression of genes that control steroid action in a critical manner. There is actually substantial evidence indicating that already at the blastula stage in cattle, and on day 10.5 postcoitum in mice, which is far in advance of androgen production, there are widespread sex differences in the expression level of hundreds of genes, most of which are autosomal.[184,185] Recent research supports the existence of an early period during development when epigenetic programming of the germ line occurs and permits transmission of aspects of the phenotype to subsequent generations.[186] Rice et al. also indicate, by a mathematical model, that this transmission of sexually antagonistic epi-marks is likely, and would result in the selection and generalization of the relevant epi-marks.[82]

This model seems compatible with all currently available data, and could clearly explain why specific gene(s) implicated in the development of homosexuality have not been identified so far despite the fact that the heritability of this process is clearly established. Whether or not (epi-) genetic mechanisms affect sexual orientation by modifying steroid action during ontogeny or in a more direct manner has not been determined.

The Older Brothers Effect

Finally, to complete the picture on biological factors affecting sexual orientation, we must mention the factor most reliably associated with homosexuality in males, namely, the presence of older brothers born in a family. The incidence of homosexuality increases by 33% for each older brother born to the same mother and is accompanied by a small, but statistically significant, decrease in weight at birth. These effects do not appear to be explained by differences in education or family background (brothers born after the focal subjects, numbers of sisters born to the same mother before or after, whether brothers live together or not, and age of the mother or father are not important) and would be the result of accumulation in the mother, during successive pregnancies, of antibodies against one or more proteins expressed specifically by the male brain. The specific mechanism underlying this phenomenon has not yet been identified, although candidate Y-linked proteins, such as those encoded by genes SMCY, PCDH11Y (protocadherin 11 Y-linked), NLGN4Y (neuroligin 4 Y-linked), and TBL1Y genes have been suggested as potential target(s) for this immune reaction.[187,188]

Interactions between Biological (Hormones, Genes) and Social Factors

Despite their limitations, the endocrine and genetic theories of sexual orientation provide the best explanations to this aspect of mate selection to date. Alternative explanations of homosexuality that are based on psychoanalytical, psychological, or sociological analyses of postnatal social factors may be attractive at first glance and are actually broadly accepted in some societies, have received little, if any, experimental support.[189–191]

These negative results do not necessarily imply a complete lack of influence of the postnatal environment on the development of sexual orientation. This orientation only becomes apparent after initiation of puberty, and there are thus plenty of opportunities for postnatal experiences to influence this phenotypic characteristic. More research is definitely warranted on this topic. It is clear that even if the prenatal factors explain a significant part of the variance and create important predispositions toward homo- or heterosexuality, they do not seem to fully explain sexual orientation, unless one assumes that several of the currently identified prenatal factors must interact to fully determine the adult phenotype.

Alternatively, the postnatal educational or social environment could interact with prenatal biological factors (hormones, genes) to determine adult sexual orientation. Little experimental work on this topic has been made in animal models, but in one species of songbirds, the zebra finch (*T. guttata*), which is known to form long-term sociosexual bonds, research in the Adkins-Regan laboratory has clearly demonstrated that young females treated with estrogens during the first 2 weeks post-hatch will prefer other females over males in two-choice proximity tests, and will pair with females in mixed-sex aviaries where they have ample choice of partners[192–194] (see Refs 193,195 for discussion of a few puzzling aspects of this research, including the fact that unexpectedly treatment with an aromatase inhibitor produces a similar change in partner preference).

However, this reversal of partner preference only develops if the estrogen-treated females are housed in mono-sex female groups during their development. Neither all-female housing alone nor estrogen treatment alone produces a significant modification of the sexual partner preference. The heterosexual partner preference also cannot be modified by steroid treatments in adulthood.

These findings raise the obvious question of what is actually modified by the early estrogen treatment. It has been speculated that the steroid masculinizes the way in which females learn (or become imprinted on) the sex of their partner, but additional work would be needed to resolve this question.

Similar evidence is also emerging in humans suggesting that pre- and postnatal factors could contribute to the control of sexual orientation. Children learn during their first few years that they are male or female and model some of their choices (for a fruit for example) to choices of individuals of the same sex.[196] Recent research suggests that CAH girls exposed prenatally to abnormally high concentrations of androgens are differentially sensitive to these social influences and, in particular, are less prone to copy the behavior of a human model of their own sex.[196,197] These data suggest important new ways in which the prenatal hormonal environment could affect sexual orientation by changing reactions to postnatal social interactions.

Sensory Modalities

Little research has been devoted specifically to the question of the specific signals that are used to distinguish the sex of a potential sex partner. In many mammals, including rodents and possibly humans, olfactory signals seem to play a key role. We already mentioned that cage bedding soiled by rats of the opposite sex induces brain activation, as measured by enhanced expression of the *c-fos* gene, in the olfactory circuits and in areas implicated in the control of sexual behavior.[198,199] This activation was sex reversed in males treated neonatally with an aromatase inhibitor (brain activation after exposure to male rather than female odors[57]).

Similar data have been obtained in humans by imaging techniques such as fMRI or positron emission tomography (PET). The preoptic-hypothalamic area is activated by the odor of specific sex steroids (sometimes considered as putative pheromones, although this idea is far from being universally accepted) of the opposite sex in heterosexual subjects,[200] but these activations are largely sex reversed in homosexual subjects (activation by same sex odors).[106,107] These data were, however, obtained by presenting subjects with concentrations of the steroids that are much higher than in physiological conditions, and the physiological relevance of these results has thus been questioned. A recent study actually indicates that the sex difference in the fMRI response to these odors seems to depend on their concentration.[201] It should also be noted that these activations essentially concern regions of the brain stem and limbic systems that have no or few connections to the telencephalic structures supporting consciousness. There is therefore no indication that these brain activations relate to a conscious selection of the sex of the mating partner.

Other sensory modalities (vision, audition) obviously allow discriminating between males and females in most species, including humans, but to our knowledge, their specific role in sex recognition, independently from recognition of the species or specific individual, is not clearly established.

SPECIFIC INDIVIDUAL FEATURES INFLUENCING MATE CHOICE

Introduction

Once the proper species and sex have been identified, males and females of most species will still not mate indiscriminately. Female fishes in many species will lay their eggs in the open ocean, and males will fertilize

them without making any selection or contact with the female, but in many species, especially those relying on internal fertilization, the specific mating partner will often be selected very carefully.

In ultimate terms, the differential fertility and differential parental investment of males and females has prompted the evolution of different reproductive strategies and leads males and females to select their mate based on different characteristics in order to maximize the survival of their gene pool in the following generations. As mentioned at the outset of this chapter, females who invest large amounts of energy and resources in their reproduction will try to mate with a male in the best possible condition and possessing large amounts of resources (e.g., a large feeding territory) who can not only provide optimal help in raising the offspring (when parental care is present; this is called the direct benefit[3]) but who will also transmit "good" genes to the offspring and thus enhance their survival (indirect benefit). Males in contrast are able to fertilize many eggs and can in many species reproduce at a very low energetic cost. They will therefore pay special attention to the fertility of the females and often try to mate with as many of them as possible. These evolutionary constraints are at the basis of sexual selection and of the polygynous mating system observed in so many species. Sexual selection has thus prompted the evolution and selection during mate choice of secondary sexual characteristics that demonstrate the physical or genetic qualities of the males but the fertility of females.

Phenotypic Traits as Markers of (Genetic) Quality in Males

In order to identify the best possible mate, females rely on indirect markers of genetic quality. A huge amount of ethological research has been carried out, largely in birds and to a lesser extent in mammals, to identify the traits that females are paying attention to when selecting a male partner.[202] These traits are extremely variable. They include morphological as well as behavioral features, and they obviously vary from species to species, so that it would be impossible, and beyond the scope of this chapter, to review them in detail. Morphological characteristics include, for example, the general body size (muscular mass), the color of the plumage and/or its reflectance in ultraviolet light in birds, the development of secondary sexual characteristics such as horns or antlers, wattles and comb in chickens, the color of the penis and testis in some monkey species, and body odors or pheromones[12,203,204] (see Ref. 205 for a detailed presentation and the following section on Optimal Outbreeding).

At the behavioral level, it has been shown in multiple experiments on birds that the complexity of the song repertoire, the length of the song bouts produced by males, the number of different syllables they incorporate, and the amount of songs produced markedly influence female choice.[206–209] The song repertoire has been specifically shown to represent an honest signal predicting the future parental (paternal) investment of a male bird[206] (see Ref. 205).

In humans and other animals, the symmetry of the body is thought to reflect the genetic quality of a subject.[210] The ability of an individual to develop successfully (and symmetrically) in the face of variable environmental pressures is therefore a proposed indicator of genetic quality, and asymmetric features would be the signature of genetic or developmental problems.[211] Accordingly, a large number of studies in different human societies as well as in macaque monkeys have demonstrated that in a choice test females will prefer males with symmetrical faces over males with asymmetrical faces.[211,212]

Under the principles originally articulated by Darwin, those features that are used by females as signals for male quality should be subjected to sexual selection and become more prominent from generation to generation. This would explain the larger body size of males in polygamous species, but also the development of extravagant ornaments, such as the tail of the peacock, that eventually become a serious handicap for the male's survival in face of predators.

To explain the paradoxical development and survival of such apparently maladaptive features (in morphology or behavior), it has been argued that, in order to be a reliable ("honest") signal for the receiver (the female), a signal has to be costly for the sender (the male), since otherwise there would be an obvious temptation to bluff or deceive the receiver. In this context, the biologist Zahavi proposed the notion of a "handicap principle," according to which females would only (preferentially) pay attention to signals that are costly and could not be afforded by an individual of inferior quality.[213]

Although this principle is not universally accepted, it helps explain several paradoxical aspects of intersexual interactions. One major challenge is of course to formally assess the objective cost of morphological or behavioral signals and their causal relationship with the male's quality. Based on theoretical considerations, and on experimental studies in an insect species, the rhinoceros beetle (*Trypoxylus dichotomus*), Emlen and collaborators suggested that the evolution of trait exaggeration depends on an increased sensitivity to insulin and insulin-like growth factors (IGF) signaling within the growing structure that would amplify otherwise subtle differences in body size growth and condition of the male.[214] Circulating concentrations of insulin and IGFs are sensitive to nutritional status, as well as stress and infection, so that the insulin/IGF pathway can be considered as a central mechanism integrating physiological conditions during growth and translating them into morphological

features in multicellular animal taxa. These authors showed in this rhinoceros beetle that the experimental downregulation (disruption by a double-stranded RNA) of insulin receptor expression differentially affects the development of various body parts (genitalia, wings, forked horn on the head). Wing size was only reduced by 2% but horn size by 16%, confirming their higher sensitivity to perturbations during development.

It is currently unknown whether such a mechanism based on insulin/IGF or another central intracellular signaling pathway is also implicated in the growth of other exaggerated male sexual signals in other species, but insulin/IGF signaling is an ancient (>500 million years) and conserved physiological pathway that connects rates of cell proliferation with available nutrients. It is thus conceivable that this signaling pathway (or another fundamental intracellular signaling pathway) has been repeatedly selected to control the differential growth of signaling structures and make them reliable signals of male quality.

At the physiological level, the preference for specific male characteristics seems to be controlled by the endocrine condition of the female. In humans, it has been demonstrated that women in their fertile phase of the menstrual cycle (high circulating estrogens) demonstrate stronger preferences for masculine men (supposedly carrying "better" genes) than in the nonfertile phases of the cycle (see Ref. 215 for a recent discussion of the status of this controversial research). Preference for more masculine faces around ovulation is associated with an increased interest in extra-pair mating (sexual fantasies about other men, increased receptivity to men's courtship invitations, dressing in more attractive and revealing clothing, etc.) and is interpreted in evolutionary terms as reflecting a search for genetic benefits for offspring.[215]

Indirect Markers of Fertility in Females

Although Darwin developed his theory of sexual selection to account for the evolution of weapons and ornamental secondary sexual characteristics of males that are used to monopolize access to females and determine their mating preference,[5] females also display sexually differentiated characteristics. It is now accepted that the evolution of these features is the result of the competition with other females for breeding opportunities.[216] Male mating preferences vary widely between species, but since males are often able to fertilize multiple females, they do not seen to pay as much attention to the resources that will be provided by the females but rather to their potential fertility and capacity to produce and raise viable offspring. Selection may thus favor the evolution of signals that indicate fecundity. For example, in Barbary macaques (*Macaca sylvanus*), there are discernible differences between mating calls of fertile and infertile females, and calls of fertile females are more likely to attract attention of the males and elicit ejaculation.[217] Similarly, women's voices are rated as more attractive when they are fertile,[218] and one study reported that lap dancers earn significantly more tips from their clients when they are in the follicular (fertile) than in the luteal (infertile) phase. The nature of the stimuli mediating this differential response in men during the fertile period of women (voice, odor, behavior, etc.) was however not identified. Interestingly, this difference was abolished in women taking oral contraceptives that establish a stable endocrine condition across time.[219]

Males thus assess the fertility of their female partner based on indirect markers that reflect the endocrine conditions controlling reproductive physiology, most prominently the circulating concentrations and action of estrogens and progesterone. This idea has been particularly elaborated in the evolutionary psychological literature for the human species. Two secondary sexual characteristics in the human female show this endocrine dependence and have been reported to be major determinants of female attractiveness: (1) the hip-waist ratio, and (2) the enlargement of breasts in females independent of lactation.

Hip Width

In humans, the hip bones are much wider in females than in males, a difference that is not found in other animal species. This sex difference, that is required to facilitate childbirth in a species that has adopted the upright walking position, appears during puberty under the influence of ovarian steroids.[220] The female's broad hips are thus associated with fertility and represent an obvious marker of sexual maturity. They have been considered as an attractive trait of women for thousands of years. Already in the statues of the upper Paleolithic age in Europe (Venus figurines), created some 35,000 years ago, females were represented with precise artistic conventions including an exaggeration of certain parts of the anatomy such as the large hips and breasts. Paleolithic artists had thus already made the link between large hips and fertility, and this morphological feature that is a proxy of the female endocrine condition is still a major feature of female attraction in modern societies.

Breast Size

The human female is the only primate, and even mammalian species, that maintains in a permanent manner fully formed breasts when not pregnant. Females in other species develop full breasts only when there are pregnant. The zoologist Desmond Morris proposed that the shape of the woman's breasts evolved as a frontal, secondary sex characteristic that plays a key role in sexual attraction in relation to the development of frontal copulation.[221]

The development of the breast at puberty and in adulthood reflects the endocrine environment of the subject (mostly estrogens), and it has thus been argued that in ultimate terms, the sexual attractiveness of women's breasts is linked to the fact that they represent a proxy of their fertility.

Furthermore, the breasts' symmetry, like the general symmetry of the human body discussed in the previous section, influences what men and women consider physically attractive in a mate with whom to reproduce. Similar to the general body, breast symmetry is supposed, according to evolutionary psychology, to be a marker of high quality females who developed without interference by disease. Breasts are indeed especially sensitive to developmental interference (genetic and environmental), and breast symmetry thus indicates a woman in good health with a good genetic background, who shall successfully bear more (surviving) children than a woman with asymmetrical breasts.[210] An alternative hypothesis of male attraction to breasts concerns the potential impact of breast stimulation on the neurobiological mechanisms stimulating pair bonding (see following).[222]

Choosing a Healthy Mate

When choosing a potential mate, females often show a preference for a healthy male over a parasitized male. In mice, this choice is achieved through the detection of olfactory signals.[223] There is evidence that the neuropeptide OT plays an important role in the ability of female mice to discriminate between healthy and parasitized mice. For example, female mice can easily distinguish the chemical cues from uninfected males, and males infected with several pathogens, including the nematode, *Heligmosomoides polygyrus*. Female mice show a preference for the odors of the uninfected males, suggesting that those odors are more attractive. Female mice with a disrupted OT gene fail to distinguish healthy and parasitized male odors, or show a preference for healthy males.[224–226] The extent to which OT regulates mate choices based on other features that discriminate better or worse quality mates (e.g., symmetry) is unknown.

Achieving Optimal Outbreeding

It is also advantageous to choose mating partners that minimize inbreeding to avoid its potentially negative influence on the offspring.[227] Males and females are thus faced with the tricky task of selecting as partner subjects who are similar to their father and mother (same species) but sufficiently different to avoid the negative impact associated with genetic similarity.[35,228] Species recognition is often the result, as described in the first part of this chapter, of early learning processes that have been assembled under the term of *imprinting*. But how is inbreeding avoided?

The work of Konrad Lorenz and others indicated that early experiences have a prominent influence on the mating preference in birds and that "sexual imprinting" determines the species with whom an adult will attempt to mate when adult.[15] Although this notion was confirmed and generalized to many other species, including mammals (see first section of this chapter), it was also shown that a bird could show a preference for its own species in the absence of any experience with any congener except itself. Birds could thus have a predisposition to mate with their own species, but if this is the case, then what is the specific role of imprinting? Bateson hypothesized that imprinting is required for the recognition of close kin, allowing birds to select as mates subjects that are similar but slightly different, and thus striking the optimal balance between inbreeding and outbreeding.[229] Working with Japanese quail (*C. japonica*), he tested this idea in a series of experiments and could indeed demonstrate that (1) male quail will mate with slightly unfamiliar females in preference to females to which they were exposed in early life,[229] and (2) more specifically, quail of both sexes prefer first cousins over third cousins, but also over familiar or unfamiliar siblings or novel unrelated birds[230] (Figure 48.12). The dependent variable in these last experiments was the time spent in front of the different stimuli, but they argued that this is a reliable proxy for mating preferences; males were also observed to court the preferred females in these experiments. Taken together, these experiments strongly suggest that

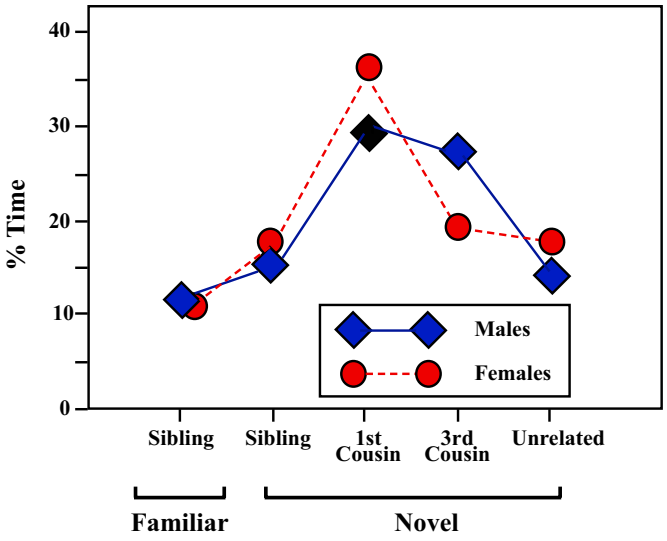

FIGURE 48.12 Mean percentage of time spent by adult male or female Japanese quail near subjects of the opposite sex that were either familiar siblings (birds were raised together) or unfamiliar subjects with varying degrees of relationship (siblings, 1st or 3rd cousins, unrelated). *Source: Redrawn from Ref. 230.*

an interaction between "innate" and learned preferences actually determines the selection of a mate that is similar but not too similar, thus striking the optimal balance between in- and outbreeding.

In mammals, inbreeding avoidance is often controlled by olfactory signals. Remarkably, inbred strains of laboratory mice can discriminate odors of mice that differ genetically only at a single chromosomal region occupied by genes that code for the immune system.[231] This complex of genes is known as the major histocompatibility complex (MHC). These genes regulate important immunological functions and cell surface recognition elements during development,[232] but they are also the source of chemosensory information present in the urine that enables mice to identify one another as individuals.[12,233,234] These odors allow individual recognition but also identification of genetic relatedness, and they are therefore playing a key role in the control of in/outbreeding. Inbred mice were shown to display mating preferences for mice of the opposite MHC type.[233,234] Heterozygosity produced by such matings is suggested to increase the immune system's vigor and range of operation, so that such matings could be of considerable adaptive significance.[232,235]

Individual recognition based on olfactory cues has also been demonstrated in hamsters[236] and in rats.[237,238] Individual preferences then relate to the past sexual interactions: male hamsters prefer the odor of novel females, either mated or unmated[239] while male rats demonstrate a preference for the odor of their previous partner but only until the first ejaculation of a copulatory sequence with a new partner has occurred (see following). After that time, the odor of the novel female will become more attractive.[237] Quite obviously, the formation of stable pair bonds in prairie voles (*M. ochrogaster*) described in the next section of this chapter also requires a capacity for individual recognition, and this recognition is based largely on olfactory signals.[240,241]

MHC-associated mate choice has been suggested in primates and even humans.[242] Although in many primate societies mate choice is constrained by social context, evidence has accumulated indicating that in a variety of sociosexual systems, mating occurs preferentially with subjects possessing a dissimilar/diverse genotype. Primates are supposed to rely less than rodents on olfactory cues in their social and sexual life,[243,244] and these data could be considered as evidence that these cues still play a role in this context. However, the proximate mechanisms mediating this MHC-related mate choice have not been investigated much, and other markers of MHC status (e.g., colors and ornaments, long calls), independent of odors, could be used in the control of mate choice.[242]

In humans, a species that has apparently lost a functional vomeronasal system[245–247] but still retains a functional primary olfactory system, women find the odor of MHC-diverse males more attractive than the odor of less diverse males,[248] suggesting that similar mechanisms still exist in our species. There is also a preference for MHC-dissimilar potential partners.[249] The situation is, however, complex since (1) odor-based studies consistently show a preference for disassortative preferences (preference for different MHC pattern), but (2) in contrast, studies of facial attractiveness indicate a preference for MHC-similar individuals, while (3) analysis of MHC compatibility in actual couples provides conflicting evidence, indicating MHC dissimilarity in some studies but random distribution in others.[249] These results could reflect methodological differences, but could also reflect the fact that the olfactory and visual signals work in a complementary manner to achieve an optimal level of genetic variability in the offspring. The tendency to mate based on visual similarity has been suggested to be influenced by a form of sexual imprinting on the opposite-sex parent during childhood based on studies of visual preference in adopted daughters.[250] More work would definitely be valuable on this fascinating topic.

PAIR BONDING

Introduction

In polygamous species, the decision of who to mate with, followed by the actual mating, is the end of the relationship between the pair. The male immediately seeks another female partner, while the female becomes pregnant and prepares to give birth. However, in monogamous species, a selective pair bond must be developed. Fortunately, in recent years, there has been remarkable progress in understanding the neurobiological and genetic mechanisms leading to the formation and maintenance of the pair bond. Much of this work has been done in the socially monogamous prairie vole. There has also been some work in birds, nonhuman primates, and humans that suggests that at least some aspects of the process leading to pair bonds in voles can be generalized to other species as well. In this section we will detail the current state of understanding of the neurobiology of the pair bond.

The Prairie Vole as a Model Organism

Prairie voles are hamster-sized socially monogamous rodents that evolved in the tall grass prairies of the Midwestern United States (Figure 48.13).[9,251] Prairie voles are highly affiliative and form enduring pair bonds with their mates that typically last a lifetime. Studies in the field have demonstrated that most prairie voles form pair bonds with a single partner, nest together or communally with a single breeding pair, and individuals rarely form a subsequent pair bond if the partner dies.

FIGURE 48.13 Photograph of prairie vole family. Pair-bonded male and female prairie voles share a nest and territory and both parents provide parental care to the offspring. *Source: Photo by Todd H. Ahern.*

In fact, 73% of breakups in prairie vole partnerships are due to death of a partner.[252] Not all prairie voles end up in a monogamous relationship though. Forty-five percent of males do not pair bond and nest with a female, but instead adopt a wandering lifestyle and mate opportunistically with females that they encounter, including partners of other males.

It is thought that social monogamy evolved in prairie voles as an adaptation to habitats with low food prevalence, which results in low population densities. Female prairie voles do not exhibit a regular ovarian cycle like many other rodents, but instead are induced into estrus by the pheromones from a male.[253] Therefore, under low population densities, it is thought that males are unlikely to find a female and be able to stay with her for long enough for her to be stimulated into estrous, and therefore the most adaptive strategy is to bond with a female so that he can immediately impregnate her after she gives birth. However, under higher population densities, wandering males may have an opportunity to produce more offspring, accounting for the variation in mating strategies in natural populations. Male prairie voles share overlapping territories with their partners and display a high degree of selective aggression after they pair bond, and it is thought that this functions to prevent his partner from being mated by a wandering intruder male. However, as we shall see, this may also be an important mechanism to prevent extra-pair copulations with other females as well, which acts to maintain the pair bond. Prairie voles are not strictly genetically monogamous, and extra-pair copulations do occasionally occur.[254]

In contrast to prairie voles, meadow (*Microtus pennsylvanicus*) and montane (*Microtus montanus*) voles are relatively asocial and do not form pair bonds. This species variability in mating strategy among closely related species has provided an opportunity for comparative studies to identify brain mechanisms and genetic elements that may contribute to pair bond formation. Consequently, there is now a significant body of knowledge regarding the neurobiological mechanisms underlying the formation of a pair bond.

Neurochemistry and Neural Circuitry of Pair Bond Formation

OT and Vasopressin

OT and arginine vasopressin (AVP) are evolutionarily related neuropeptides that play an important role in regulating several aspects of social behavior, including pair bond formation. OT and AVP are nine amino acid peptides that differ only by two residues, and originated from a single gene that was duplicated early in vertebrate evolution.[255] Both peptides have important regulatory functions in the periphery. OT stimulates uterine contractions during labor and milk ejection during nursing (see Chapter 13). AVP regulates urine concentration in the kidney and vascular constriction. Both peptides are produced in the paraventricular and supraoptic nuclei of the hypothalamus and projected to the posterior pituitary for peripheral release. However, OT and AVP projections are also found in the brain. We will focus here on those systems that have been implicated in regulating social behavior. OT fibers originating from the magnocellular neurons of the hypothalamus project to several forebrain regions, including the nucleus accumbens (NAcc) and amygdala.[256–259] Many of the AVP projections in the brain originate from extrahypothalamic neurons from the medial amygdala and bed nucleus of the stria terminalis.[260,261] The production of AVP in these neurons is androgen sensitive, and AVP secreted by these neurons regulates male-typical social behaviors.

OT AND PARTNER PREFERENCE FORMATION

The first studies to implicate a role for OT in the regulation of social behavior were focused on the onset of maternal behavior. Pedersen and Prange demonstrated that centrally administered OT resulted in the rapid onset of maternal nurturing behavior in ovariectomized, estrogen-progesterone primed rats.[262] Subsequent studies in sheep by Kendrick and Keverne revealed that OT not only induces the motivation to care for young, but also is involved in formation of the mother–infant bond.[263–265] Infusion of OT centrally to an estrogen-primed ewe causes her to develop a selective bond to a foreign lamb within minutes. OT release in the brain is stimulated by vaginocervical stimulation that occurs during labor and following nipple stimulation during nursing.

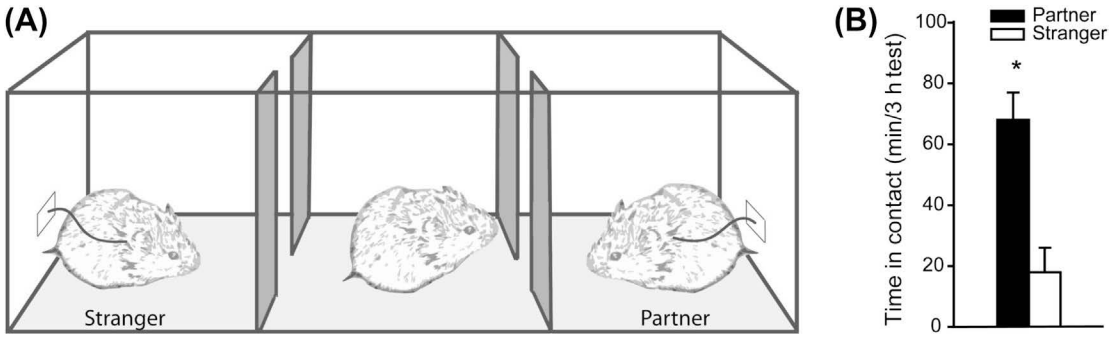

FIGURE 48.14 (A) Illustration of the Partner Preference Test initially developed by Carter and colleagues[266] as a proxy for pair bond formation in prairie voles. Prairie voles are cohabited with an opposite-sex partner for a set amount of time. Mating can be controlled by inducing receptivity in the female with estrogen or preventing receptivity by ovariectomy. Drugs may be infused just prior to or during the cohabitation. The partner preference test takes place in a three-chamber testing arena in which the partner is tethered in one chamber, a novel opposite-sex "stranger" is tethered in the opposite chamber, and the experimental subject is placed in the center and is free to interact with either stimulus animal for 3 h. Time in each cage or time huddling with the partner is quantified. An animal is said to have developed a partner preference if it spends more than twice as much time with the partner than with the stranger. The partner preference test can be easily automated using video-based behavioral analysis software.[270] (B) Typical results following a 24-h cohabitation with mating. *Source: Adapted from Ref. 271.*

OT's role in the formation of the mother–infant bond inspired Sue Carter, Thomas Insel, and colleagues to ask whether OT may also play a role in pair bond formation in prairie voles. Pair bonding in prairie voles is typically assessed using a partner preference test,[266] although mating-induced aggression may also be used as a proxy of pair bonding in males. In a partner preference test, the experimental subject (male or female) is placed in a three-chamber arena in which the partner is tethered to the side of one chamber and a novel stimulus animal of equal stimulus value is tethered to the side of the opposite chamber, with the center chamber empty (Figure 48.14). Females who cohabitated with a male for 6 h without mating typically fail to display a partner preference, defined as spending twice as much time with the partner than the stranger.[266] Cohabitation for longer periods, e.g., for 24 h, without mating can result in a partner preference. However, if the females mate with the male during a 6 h cohabitation, they will display a partner preference.[266] Thus mating facilitates partner preference formation in female prairie voles. However, an intracerebroventricular (ICV) infusion of OT immediately before pairing facilitates the formation of partner preference in female prairie voles after a 6 h cohabitation in the absence of mating. The effect could be blocked by co-infusion of an oxytocin receptor (OTR) antagonist.[267] Furthermore, infusion of an OTR antagonist blocks mating-induced partner preference, suggesting that endogenously released OT is critically involved in partner preference formation in females.[268] A central infusion of OT in males can also facilitate the onset of a partner preference,[269] but one study reported that infusion of an OTR antagonist did not block mating-induced partner preference formation, leading to speculation that endogenous OT does not play a role in partner preference formation in males.[268] However, the role of OT in male pair bonding needs further evaluation as more recent studies using highly selective OTR antagonist suggest that OT is important for partner preference formation in males (A.C. Keebaugh and L.J. Young, unpublished data), although most studies in males have focused on AVP instead (see following).

OT AND SOCIAL INFORMATION PROCESSING

Studies in mice and comparative studies in voles have provided clues as to the precise neurobiological mechanisms by which OT promotes the formation of a partner preference. First, studies in OT knockout mice reveal that both males and females lacking OT display impaired social recognition abilities.[223,272–274] That is, OT knockout mice are incapable of forming olfactory memories to discriminate other mice that they have previously encountered. However, an infusion of OT immediately before, but not following, a social encounter rescues social recognition, suggesting that OT is critically involved in the neural processing of the olfactory signals used to discriminate individuals.[272] More specifically, OT infusion into the medial amygdala rescues social recognition in mice.[272] Since developing a partner preference relies on the ability to learn and recognize the olfactory signature of the mate, it is hypothesized that OT is necessary for partner preference formation because it increases the saliency of the olfactory cues of the partner, facilitating the formation of a memory of the partner.[258] However, the partner preference is more than a memory of the partner, and involves the association of the partner's cues with reward, as we shall see in the following discussion.

OT AND THE REWARD SYSTEM IN PAIR BONDING

Clues to the neural mechanisms by which OT facilitates partner preference formation in female prairie

voles initially came from comparative studies of the distribution of OTR in prairie voles and nonmonogamous meadow and montane voles.[275] Prairie voles have higher densities of OTR binding in the prefrontal cortex and NAcc than do nonmonogamous vole species.[276,277] Furthermore, infusion of OTR antagonists into the prefrontal cortex or NAcc prevents mating-induced partner preferences[278] (Figure 48.15). The prefrontal cortex and NAcc receive rich dopaminergic input from the ventral tegmental area (VTA), and are thus are part of the mesolimbic dopamine reward pathway.[279] As we will see later, dopamine also plays an important role in pair bonding. Given the impact of OT in the neural processing of social signals, and the role of the mesolimbic dopamine pathway in reinforcement learning, it is hypothesized that OT and dopamine interact to form an association memory between the olfactory signature of the partner and the reinforcing aspects of mating.

To characterize OT release in the NAcc in prairie voles, Heather Ross and colleagues at Emory University performed in vivo microdialysis in female prairie voles during cohabitation and mating with a male.[256] OT concentrations in the microdialysates were undetectable under basal conditions when the female was alone, or when a male was placed in the cage, but restricted in a wire cage. However, there was a significant increase in samples with detectable OT in females after they mate with a male. It is likely that the vaginocervical stimulation accompanying the mating stimulated central OT release in a manner similar to that which occurs during parturition.

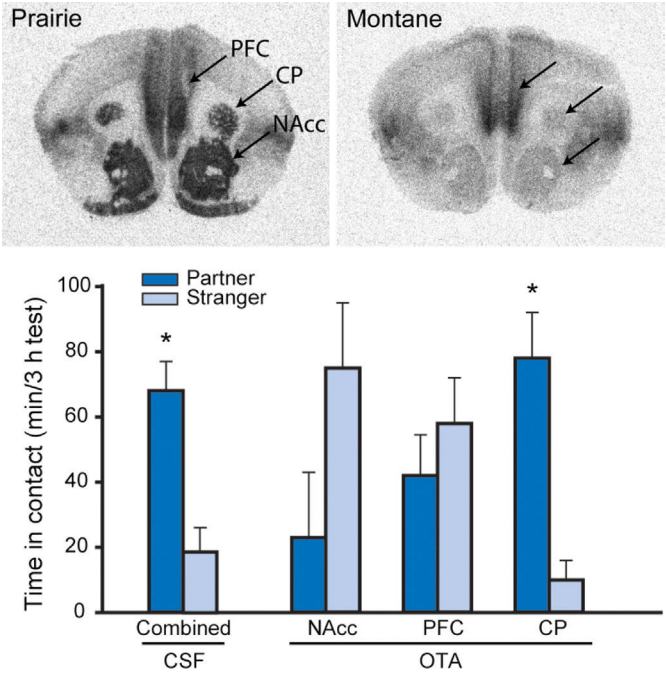

FIGURE 48.15 Receptor autoradiography showing the distribution of oxytocin receptor (OTR) binding in the prairie vole and nonmonogamous montane vole brain. Prairie voles have higher densities of OTR in the nucleus accumbens (NAcc) than do nonmonogamous species. The bar graph illustrates the effect of infusing artificial cerebrospinal fluid (CSF, control) or an OTR antagonist into the NAcc, prefrontal cortex (PFC), or the caudate putamen (CP) on mating-induced partner preference formation in female prairie voles after a 24-h cohabitation with a male. Note the OTR antagonist infused into the NAcc and PFC blocked the partner preference. Asterisks indicate statistically significant differences ($p < 0.05$) in the time spent with partner versus stranger. *Source: Adapted from Refs 277,278.*

There is significant individual variation in the density of OTR binding in the NAcc, and this variation has been associated with variation in alloparental, or spontaneous maternal care.[280–282] There is evidence that individual variation in OTR binding in the NAcc is also relevant to pair bonding. Using viral vectors to increase OTR expression in the NAcc of prairie voles, Ross and colleagues found that artificially increasing OTR expression in the NAcc, thereby making it more sensitive to OT, accelerated partner preference formation in female prairie voles. However, that same study found that increasing OTR expression in the NAcc of meadow voles was not sufficient to confer the capacity to form partner preferences,[257] suggesting that other systems involved in partner preferences are different between these species as well. A study looking at individual variation in mating strategies in prairie vole males in naturalistic enclosures found that males that developed pair bonds had higher densities of OTR binding in the NAcc than did "wandering" males who did not pair bond.[283]

VASOPRESSIN AND PARTNER PREFERENCE IN MALE PRAIRIE VOLES

While OT may play a role in male pair bonding in prairie voles, AVP has received much more attention. In hamsters, AVP stimulates scent marking behavior and territorial aggression.[284–287] It is interesting to consider that AVP's role in scent marking and territorial behavior may be linked to a more ancient role in urine concentration, since urine is commonly used for scent marking.[288] Like OT, AVP also plays an important role in social recognition. Blocking vasopressin V1a receptors (V1aR) inhibits social recognition in rats, and V1aR knockout mice fail to display social recognition.[289–291] The effect of AVP on enhancing social recognition is mediated by V1aR in the lateral septum.[289,291] In male prairie voles, infusion of AVP centrally, via an osmotic minipump, facilitates selective aggression associated with pair bond formation and partner preferences.[292] Furthermore, a selective V1aR antagonist prevents mating-induced partner preference and selective aggression. Central infusion of AVP can induce a partner preference in female prairie voles, but V1aR antagonists fail to prevent mating-induced partner preferences in females.[268] AVP appears to be involved both in the initial formation of the partner preference (acquisition) as well as the expression of

partner preference (recall) but not in the consolidation of the preference. A V1aR antagonist infused centrally just prior to a 24 h cohabitation with a receptive female, or just prior to the partner preference test 72 h after the cohabitation during which time the male was isolated, blocked the display of the partner preference. However, if the V1aR antagonist was given immediately after the cohabitation, 72 h before the partner preference test, the males displayed the usual partner preference.[293]

Comparative analysis of V1aR distributions in monogamous and nonmonogamous voles and behavioral pharmacological studies have revealed two brain regions in which AVP facilitates partner preference formation. Prairie voles have higher densities of V1aR binding in the ventral pallidum, amygdala, and thalamus than meadow or montane voles[294,295] (Figure 48.16). Lim and colleagues infused a V1aR antagonist into each of these regions and found that only blocking the V1aR in the ventral pallidum prevented mating-induced partner preferences in male prairie voles[296] (Figure 48.16).

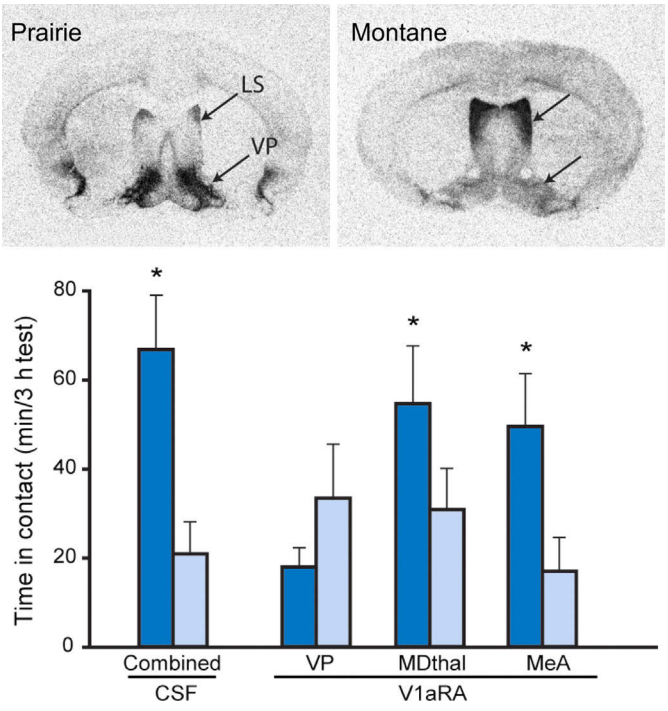

FIGURE 48.16 Receptor autoradiography showing the distribution of vasopressin V1a receptors (V1aR) in the prairie vole and montane vole forebrain. Prairie voles have higher densities of V1aR in the ventral pallidum (VP) than meadow voles. The bar graph illustrates the effect of infusing a V1aR antagonist into the VP, medial amygdala (MeA), and mediodorsal thalamus (MDthal) on mating-induced partner preferences in male prairie voles. Note that the V1aR antagonist only blocked partner preferences when infused into the VP. Other studies have also shown that blocking V1aR in the lateral septum (LS) also blocks partner preference formation. Asterisks indicate statistically significant differences ($p < 0.05$) in the time spent with partner verses stranger. *Source: Adapted from Refs 277,296.*

Furthermore, increasing V1aR density in the ventral pallidum of male prairie voles, using viral vector gene transfer, results in accelerated partner preference formation.[297] Remarkably, when a similar experiment was performed in male meadow voles, to artificially stimulate V1aR densities in the ventral pallidum to the levels found in prairie voles, the meadow vole males displayed a partner preference.[298] This suggests that, at least in voles, the emergence of expression of the V1aR in the ventral pallidum was sufficient to create the capacity to form a pair bond. However, it should be noted that this may not be the mechanism leading to monogamy in other species as density of V1aR binding in the ventral pallidum is not associated with monogamy in several *Peromyscus* species examined.[299]

Like the NAcc, the ventral pallidum is part of the mesolimbic dopamine reward pathway.[279] In fact, the ventral pallidum lies just ventral of the NAcc and is a major output of the NAcc. Interestingly, both the NAcc and ventral pallidum are sites involved in addiction to drugs of abuse, and there are many parallels between addiction and pair bonding as we shall later see.[300] Thus, while different molecules and brain regions regulate partner preference formation in male and female prairie voles, there is a common neural circuit underlying this process.

In addition to the ventral pallidum, V1aR in the lateral septum are involved in partner preference formation in male prairie voles. Infusion of AVP into the lateral septum induced a partner preference in the absence of mating, while infusion of V1aR antagonist into the lateral septum prevents mating induced partner preferences.[301] Interestingly, this study also found that infusion of an OTR antagonist into the lateral septum prevented AVP- and mating-induced partner preference. It is not clear whether this reflects a real role for OTR receptors in this process or promiscuity of the OTR antagonist. As V1aR in the lateral septum are involved in social recognition, which is olfactory based in rodents, the septal V1aR may be critical for processing the olfactory information and formation of a memory of the olfactory signature of the partner.

VASOPRESSIN AND MATE GUARDING IN MALE PRAIRIE VOLES

In addition to the formation of a partner preference, pair bonding in male prairie voles is accompanied by an increase in selective aggression directed to novel males or even females. It is thought that this mating-induced selective aggression serves a mate-guarding function, although this has not been tested. Mating-induced selective aggression is inhibited by a central infusion of V1aR antagonist and is stimulated by an infusion of AVP in the absence of mating.[292] It appears as though V1aR in the anterior hypothalamus mediates

the onset of selective aggression. Gobrogge and colleagues at Florida State University reported that male prairie voles that had been paired with a partner for 2 weeks show an increase in AVP neuron activation in the anterior hypothalamus after a resident intruder test in which the intruder was either a novel male or novel female.[302] They then found, using in vivo microdialysis, that extracellular AVP concentrations were elevated in the anterior hypothalamus of pair bonded males during an aggressive encounter with an unfamiliar female, but decreased during periods of huddling with the partner.[303] Furthermore, infusion of AVP directly into the anterior hypothalamus induced selective aggression in sexually naïve males, while infusion of a V1aR antagonist in the anterior hypothalamus inhibited selective aggression in pair bonded males, demonstrating that V1aR activation in the anterior hypothalamus is necessary and sufficient for the induction of selective aggression.[303] Interestingly, these authors also reported an increase in V1aR density in the anterior hypothalamus of pair bonded males compared to sexually naïve males. They then showed that increasing V1aR expression in the anterior hypothalamus using viral vector–mediated gene transfer increased aggression toward novel females even in sexually naïve males. Thus, it is possible that the increase in V1aR expression in the anterior hypothalamus after pair bonding may serve to decrease the probability that a male will associate, mate, and pair bond with a novel females, although it is clear that pair bonded males do occasionally display extra-pair copulations.

GENETIC MECHANISMS CONTRIBUTING TO DIVERSITY IN PAIR BONDING IN MALES

Since species differences in V1aR receptor distribution in the brain, particularly in the ventral pallidum, are associated with mating strategies in voles, there has been investigation into the genetic mechanisms underlying diversity in V1aR expression. The V1aR is encoded by the *Avpr1a* gene. The species differences in V1aR binding pattern in the brain are likely mediated by differences in *Avpr1a* gene expression since variation in V1aR binding is associated with species differences in *Avpr1a* mRNA.[304] To explore the potential genetic mechanisms underlying this diversity in gene expression, Larry Young and colleagues at Emory University in Atlanta sequenced the *Avpr1a* locus in monogamous prairie and pine voles as well as nonmonogamous montane and meadow voles. While most of the sequences in both coding and noncoding regions were 99% conserved across species, a complex repetitive region, referred to as a microsatellite, in the 5′ flanking region of the gene was strikingly different between the monogamous and nonmonogamous vole species.[305] The microsatellite element is approximately 350 base pairs in the monogamous prairie and pine voles, but only about 50 base pairs in the meadow and montane voles (Figure 48.17). Since the 5′ flanking region of a gene directs gene expression, it was hypothesized that this species difference in microsatellite could be responsible for the species differences in *Avpr1a* expression in the brain. Indeed it was initially hypothesized that the expansion of this microsatellite could be responsible for the evolution of V1aR distribution and therefore of monogamy. However, subsequent analysis of many other *Microtus* species does not support this hypothesis since several nonmonogamous species also have the longer microsatellite.[307] However, there is still evidence, although somewhat contradictory in some cases, that variation in the microsatellite has important implications for behaviors associated with monogamy.[308]

Microsatellites like the one in the vole *Avpr1a* tend to be unstable over evolutionary time scales, which makes them a potential mechanism for generating diversity in gene expression both between and within species. Indeed, there is a significant amount of variability in the *Avpr1a* microsatellite even among laboratory populations of prairie voles.[309] Likewise, there is significant individual variation in V1aR density among wild and laboratory populations of prairie voles.[310] Finally, there is significant individual variation in mating strategies in wild male prairie voles, such that while most males become monogamous resident males with a territory and a single mate, others (about 40%) adopt a "wandering" lifestyle and mate opportunistically with multiple females. Elizabeth Hammock and Larry Young began to explore the relationship between microsatellite length, V1aR distribution, and social behavior by selectively breeding prairie vole pairs with either homozygous long or homozygous short microsatellites. In this laboratory study, Hammock and Young found that, indeed, the length of the microsatellite predicted V1aR density in several brain regions as well as partner preference behavior. For example, male prairie voles homozygous for longer microsatellites have higher densities of V1aR in the lateral septum (which are known to regulate pair bond formation) and were more likely to form a partner preference after cohabitating with a female than males with a short microsatellite[306] (Figure 48.17). Whether the microsatellite affects monogamous behavior in natural settings is more controversial. Alexander Ophir and colleagues examined this in prairie voles in naturalistic enclosures, and while they did find that the microsatellite length affected V1aR densities, they did not find any association with mating tactics or reproductive success.[311] The authors concluded that the precise relationship between microsatellite length, V1aR density, and behavior may be complicated by the fact that microsatellite length is an imperfect metric of the functional elements of the microsatellite that may regulate expression. Other studies in free-living prairie voles, or voles housed in naturalistic enclosures, have also failed to detect a

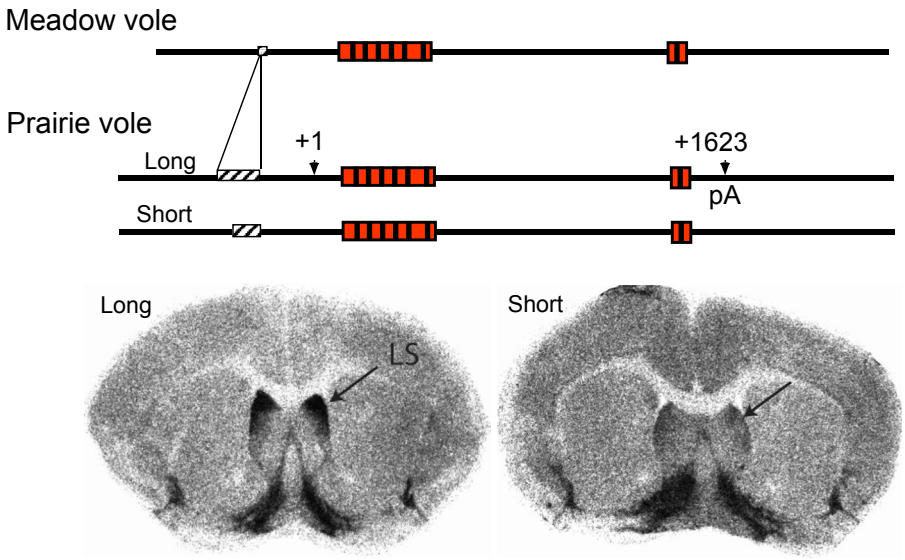

FIGURE 48.17 Schematic of the vasopressin V1a receptor gene (*Avpr1a*) in monogamous prairie voles and nonmonogamous meadow voles. The boxes indicate exons, and the black bars in the exon represent the transmembrane domains of the receptor. The sequences are highly homologous except for a complex repetitive element, referred to as a microsatellite, in the 5′ flanking region of gene (hatched box upstream of the transcription start site, +1). The prairie vole microsatellite is larger than that of the meadow or montane vole. The microsatellite length is polymorphic in prairie voles, and the length has been associated with variation in V1aR binding in the brain as well as behavior in the laboratory, but not in field studies. The brains illustrate the differences in V1aR binding in the lateral septum (LS) between prairie voles with long versus short microsatellites. *Source: Adapted from Refs 305,306.*

strong relationship between mating behavior and the microsatellite.[312,313]

While the precise nature of the impact of variation in the *Avpr1a* microsatellite structure on gene expression and monogamous behavior has yet to be elucidated, more recent studies have further examined these gene-brain-behavior relationships in relation to the V1aR. Ophir and colleagues reported that V1aR density in the posterior cingulate cortex and laterodorsal thalamus, brain regions involved in spatial memory, were correlated with space use and sexual fidelity in animals housed in seminaturalistic enclosures.[314] A recent study used viral vectors expressing shRNA targeting the *Avpr1a* to examine the causal relationship between variation in V1aR density and pair bonding behavior. This approach resulted in a 30% reduction, not an ablation, of V1aR binding in the ventral pallidum, essentially recreating the degree of diversity seen among individuals in wild-caught prairie voles[310] (Figure 48.18). Those males receiving shRNA vector infusions in the ventral pallidum, and thus with reduced V1aR binding in the ventral pallidum, showed a significant impairment in partner preference formation.[315] Finally, Donaldson and Young examined the hypothesis that variation in the *Avpr1a* microsatellite directly impacts V1aR expression in the brain by creating knock-in mice in which 3.5 kb of the mouse *Avpr1a* promoter was replaced with one of three versions of the prairie vole *Avpr1a* promoter. The three versions of the targeting allele differed only in the microsatellite element, which was either a meadow vole microsatellite or a long prairie vole or a short prairie vole microsatellite. Each of these strains displayed significantly different levels of V1aR expression in the brain, confirming that the microsatellite has the potential for diversifying brain V1aR distribution.[316]

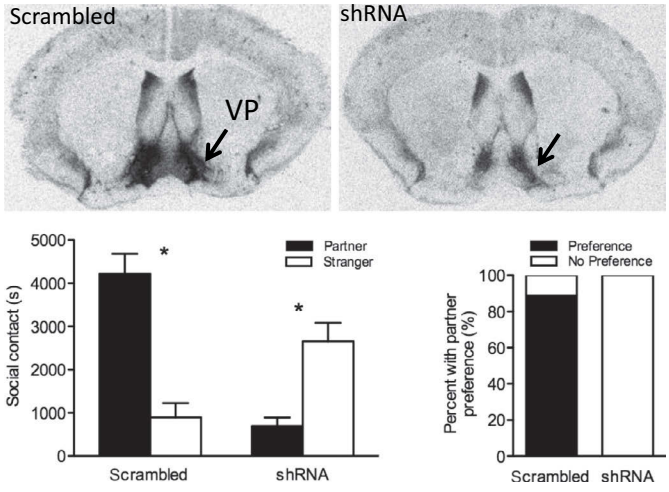

FIGURE 48.18 Viral vector-mediated shRNA knockdown of the prairie vole V1aR in the ventral pallidum (VP) prevents mating-induced partner preference formation in males. Receptor autoradiography reveals an average reduction in V1aR binding in the VP of 30%, consistent with natural variation in V1aR binding, in shRNA-treated males (upper right brain) compared to males injected with a virus expressing a scrambled sequence (upper left brain). This reduction in V1aR binding impaired partner preference formation is illustrated in the bar graphs below. Asterisks indicate statistically significant differences ($p<0.05$) in the time spent with partner versus stranger. These data support the hypothesis that natural variation in *Avpr1a* gene expression contributes to variation in pair bonding behaviors. *Source: Adapted from Ref. 315.*

SEX DIFFERENCES IN THE EVOLUTIONARY HISTORY OF THE NEURAL MECHANISMS UNDERLYING PAIR BONDING

OT and AVP are both involved in the neural processing of social cues required for individual recognition and presumably mate recognition. However, there are some interesting differences in the role of OT and AVP in regulating behavior. It is likely that OT is widely involved in regulating maternal nurturing and maternal bonding in mammals. Thus during the evolution of pair bonding, those neural systems were modified slightly, perhaps through a redistribution of OTR distribution, to facilitate the bonding not only between the mother and the offspring, but also between the female and the male partner who stimulated OT release through mating-induced vaginocervical stimulation. In contrast, AVP in nonmonogamous species is involved in territorial behavior, including scent marking and territorial aggression. Thus it is plausible that these neuroendocrine systems were modified, through an alteration in V1aR distribution, to regulate mate guarding and pair bonding. If this concept is accurate, it would suggest interesting implications for sex differences in the nature of the pair bond between males and females. For example, the female bond with the male may be neurobiologically similar to the nurturing bond of a mother to her infants, while the bond of the male to the female may be the result of the male considering the female as an extension of his territory.[222] While plausible, this is likely an oversimplification as OT may well be critically involved in both male and female pair bonding.

Dopamine and Partner Preference Formation

There is considerable evidence that dopamine plays a critical role in pair bond formation in both male and female prairie voles (for a review, see Young et al.[317] and Young and Wang[277]). Dopamine is involved in reward and reinforcement, and more specifically, reinforcement learning. Wang and colleagues at Emory University first observed that the nonselective dopamine antagonist haloperidol blocked mating-induced partner preferences, while the nonselective dopamine agonist apomorphine induced partner preferences without mating in female prairie voles.[318] Furthermore, a dopamine D2 receptor antagonist inhibited, while a D2 agonist facilitated, partner preference formation when given peripherally or centrally (Figure 48.19). By contrast, a dopamine D1 receptor antagonist failed to inhibit, and D1 antagonist failed to facilitate, partner preference formation.[318] Extracellular dopamine is increased in the NAcc during mating, and site-specific infusion of D2 receptor antagonist into the NAcc, but not into the prefrontal cortex, prevented mating-induced partner preference without affecting mating. Finally, infusion of quinpirole, a selective D2 receptor agonist into the NAcc facilitated partner preference formation in females in the absence of mating.[319] Although both OT and a D2 receptor agonist can stimulate partner preferences when given alone, simultaneous activation of both receptors is necessary for partner preference formation. Liu and Wang demonstrated that infusion of either D2 agonist or OT directly into the NAcc facilitated partner preference formation in the absence of mating. However, an

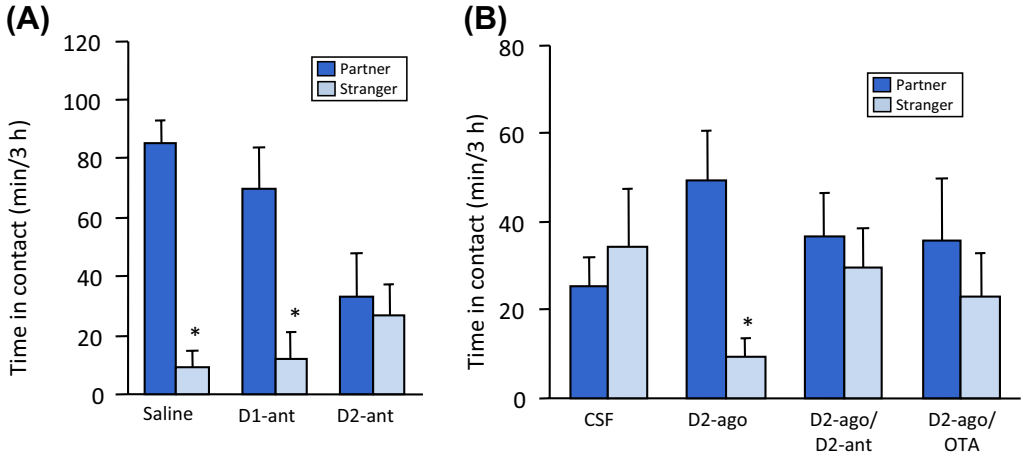

FIGURE 48.19 The role of dopamine in partner preference formation. (A) Female prairie voles were injected intraperitoneally with saline, a dopamine D1 receptor antagonist (D1-ant) or a D2 receptor antagonist (D2-ant) prior to a 24-h cohabitation with mating. The saline and D1-ant groups displayed a robust partner preference, however, the D2 antagonist prevented partner preference formation. It was subsequently shown that D2 antagonist infused into the nucleus accumbens shell blocks partner preference.[319] (B) Female prairie voles that spend 6 h with a partner, without mating, do not form a partner preference under control conditions (cerebrospinal fluid (CSF) infused into the NAcc shell). However, microinjection of a D2 agonist (D2-ago) induces the formation of a pair bond during this 6-h cohabitation, an effect that is blocked by coinfusion of a D2 antagonist (D2-antag). An OT antagonist (OTA) also blocks D2 agonist-induced partner preference, suggesting that concurrent activation of D2R and OTR is necessary for pair bonding. Asterisks indicate statistically significant differences ($p < 0.05$) in the time spent with partner versus stranger. *Source: Adapted from Ref. 277.*

OTR antagonist prevented D2 agonist-induced partner preference, and a D2 antagonist prevented OT-induced partner preference when the drugs were infused in the NAcc of females.[320]

Similar results demonstrating a role of dopamine, including a role for the VTA, have been reported for male prairie voles,[321–323] although an interaction with OT has not been demonstrated. Aragona and colleagues demonstrated that activation of D2 receptors in the rostral shell, but not the caudal shell or core of the NAcc, play a critical role in partner preference formation in male prairie voles.[324] In contrast, D1 receptor activation in the rostral NAcc prevented both mating-induced and D2 agonist-induced partner preferences in males, suggesting that D1 and D2 receptors in the NAcc play opposing roles in pair bond formation.[324] As we shall see later, this opposing role appears to play an important part in preventing partner preference formation in pair bonded males during extra-pair copulations with novel females.

The intracellular mechanisms by which dopamine receptor activation facilitate or inhibit partner preference formation have been investigated by manipulating the downstream signaling, namely cAMP. D1 dopamine receptors are coupled with stimulatory G-proteins, and their activation leads to an increase in intracellular cAMP, which in turn leads to activation of protein kinase A (PKA). Conversely, D2 receptors are coupled to inhibitory G-proteins and consequently lead to a decrease in intracellular cAMP. Aragona and Wang explored the role of changes in intracellular cAMP in the NAcc in male prairie voles by manipulating the production or action of cAMP. Infusion of 3′,5′-phosphorothioate, a PKA antagonist that binds to the cAMP binding site of PKA, into the shell but not the core of the NAcc, facilitated partner preference formation in male prairie voles in the absence of mating in a manner similar to a D2 agonist.[325] These investigators also found that infusing a cAMP agonist (Sp-cyclic adenosine 3′,5′-phosphorothioate), an activator of stimulatory G-proteins (CTX), or a blocker of inhibitory G-proteins, into the NAcc shell blocks mating-induced partner preferences. These data are consistent with the hypothesis that the opposing actions of D1 and D2 receptors on partner preference formation are mediated by their opposite effects on intracellular cAMP signaling.

Opioids and Partner Preference Formation

The opioid system has long been known to mediate the rewarding or positively reinforcing properties of unconditioned stimuli, including food, water, sex, and drugs of abuse. Social stimuli are often rewarding, and the opiate system has been implicated in maternal motivation, infant–mother attachment, and social learning.[326,327] The μ-opioid receptor (muOR) mediates a wide variety of natural rewards, including hedonic "liking" of palatable food.[328] Thus it is not surprising that muOR and the opioid system play a role in pair bond formation as well. Burkett and colleagues found that a peripheral injection of a nonselective opioid receptor antagonist blocked mating-induced partner preference formation, and even induced a stranger preference (or partner aversion) if given repeatedly in female prairie voles.[329] Infusion of the selective muOR antagonist, CTAP, into the dorsal caudate putamen, but not into the NAcc, also prevented mating-induced partner preferences in females (Figure 48.20). This finding was contrary to the initial prediction that NAcc muOR, which mediate the "liking" of food stimuli, are involved in pair bonding. However, the dorsal caudate projects to dopaminergic neurons in the VTA, which in turn project to the NAcc, providing a possible link between the muOR and dopamine systems involved in partner preference formation. An alternative

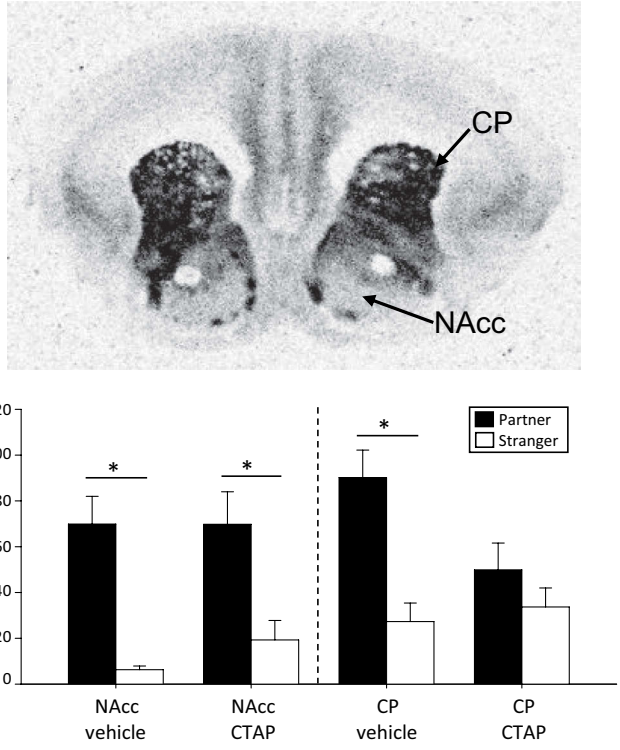

FIGURE 48.20 Mu-opioid receptor (muOR) regulation of partner preference formation. Receptor autoradiography showing muOR ligand binding in the prairie vole striatum. muOR density in the nucleus accumbens shell (NAcc) is moderate, but much lower, than muOR density in the caudate putamen (CP). The bar graph illustrates the effects of infusion of a muOR antagonist (CTAP) or vehicle into the NAcc or CP of female prairie voles prior to 24-h cohabitation with a male partner with mating. Females receiving vehicle to the NAC shell or CP formed pair bonds as normal. muOR antagonist injected into the NAcc shell did not affect pair bonding, while muOR antagonist in the CP prevented the formation of a pair bond. These data show that muOR in the CP is necessary for pair bond formation in female prairie voles. Similar experiments have not been performed in males. Asterisks indicate statistically significant differences ($p < 0.05$) in the time spent with partner versus stranger. *Source: Adapted from Ref. 329.*

explanation is that the dorsal caudate is involved in the shift from goal-directed learning, which involves stimulus-response learning, to habitual learning, which becomes independent of stimulus reward. Pair bonding likely involves a transition from stimulus-response learning, associating the pleasure of mating with the partner, to a more habitual learning where the subject prefers to affiliate with the partner well after mating has ceased.[329]

Partner Preferences and Classical Conditioning

The pharmacological studies outlined herein suggest a neural model of pair bonding involving classical conditioning, utilizing evolutionarily conserved reward learning pathways that have become sensitized to neuropeptides involved in the processing of social stimuli. Nonmonogamous species are also capable of displaying partner preferences under certain circumstances if conspicuous nonsocial cues are provided. James Pfaus and colleagues at Concordia University have shown that both male and female rats form partner preferences similar to that described earlier for prairie voles if repeated mating experiences occur with partners scented with neutral (e.g., almond or lemon), nonsocial scents.[330] For example, if male rats mated over several sessions with a female scented with almond, and are then given a choice between an almond-scented female or a novel female, they will choose the almond-scented female. If the female is not scented with the artificial scent, the males will not show a preference, suggesting that they are incapable of associating the natural social olfactory cues with the reinforcing aspects of mating. Likewise, female rats will display a conditioned partner preference for an artificially scented male if she is allowed to control the frequency of mating through pacing, which is known to be associated with increased dopamine release. Mating-induced conditioning in rats is inhibited by infusion of an opioid antagonist.[330,331]

The ability to associate unconditioned stimuli to conditioned stimuli is an evolutionarily ancient ability. However, some stimuli are more easily paired with sexual reward than others. It is hypothesized that monogamous prairie voles have an exceptional ability to use the complex set of olfactory odors used for individual discrimination as the unconditioned stimulus in sexual conditioning. What is the neural mechanism of this derived capacity? The precise mechanism is not clear, however, it is likely that the localization of OTR and V1aR within the mesolimbic dopamine reward pathway may contribute. As mentioned before, both OTR and AVP are necessary for simple individual recognition in rats and mice. In mice, which do not form pair bonds, OTR in the medial amygdala and V1aR in the lateral septum are essential for individual discrimination.[272,289] Perhaps OTR and V1aR enhance the neural sensitivity to social olfactory cues, allowing for easier detection of individual differences in the mixture of odorant constituents. Endogenous opiates released during mating produces a sense of reward and pleasure, and perhaps stimulates dopamine release. In prairie voles, OTR is concentrated in the NAcc, and concurrent OTR and D2 receptor activation are required for conditioned partner preference formation in females. V1aR is concentrated in both the lateral septum and ventral pallidum, and both V1aR and D2 receptor activation is required. It is hypothesized that the release of OT stimulated by vaginocervical stimulation in female, or AVP in males, results in enhanced transmission of neural coding of olfactory signatures of the partner in the NAcc and ventral pallidum. Simultaneous activation of D2 dopamine receptors in the NAcc, which facilitates reinforcement learning, may strengthen synapses between neurons representing the unique olfactory signature of the partner, and sexual reward.[222,277,332,333] A schematic of this neural model of pair bond formation is illustrated in Figure 48.21.

Stress and Pair Bonding

In addition to the neuropeptide and dopamine systems discussed previously, the stress system modulates pair bond formation in prairie voles. Devries, Carter, and colleagues found that stress has sexually dimorphic effects on partner preference formation.[335] In males, exposure to the stress of a forced swim test, or an injection of corticosterone, just before pairing with a female, facilitated partner preference formation. Furthermore, adrenalectomy inhibits partner preference formation in males. By contrast, swim stress and corticosterone treatment interferes with partner preference formation in female prairie voles.[335,336] Corticosterone interferes with the formation, but not the expression, of the partner preference, since corticosterone given after the cohabitation with the male did not prevent the display of the partner preference. Adrenalectomy facilitates partner preference formation in females even after a 1 h cohabitation with a male.[336] Interestingly, females display a significant decline in plasma corticosterone concentrations after a 60 min or 180 min cohabitation with a male, but not after cohabitation with a female.[336] This decline in corticosterone was not seen in pair bonded females who were exposed to a novel male, suggesting that the decline in corticosterone parallels the formation of the partner preference.

Interestingly, these sexually dimorphic effects of stress axis activation in prairie voles parallel the modulation of the stress axis by OT and AVP. AVP is anxiogenic and enhances stress responses centrally, and stimulates ACTH secretion from the pituitary, and subsequently corticosterone from the adrenals. OT, by contrast, is anxiolytic, and central OT suppresses the HPA axis, inhibiting ACTH and corticosterone secretion.[337] Thus there

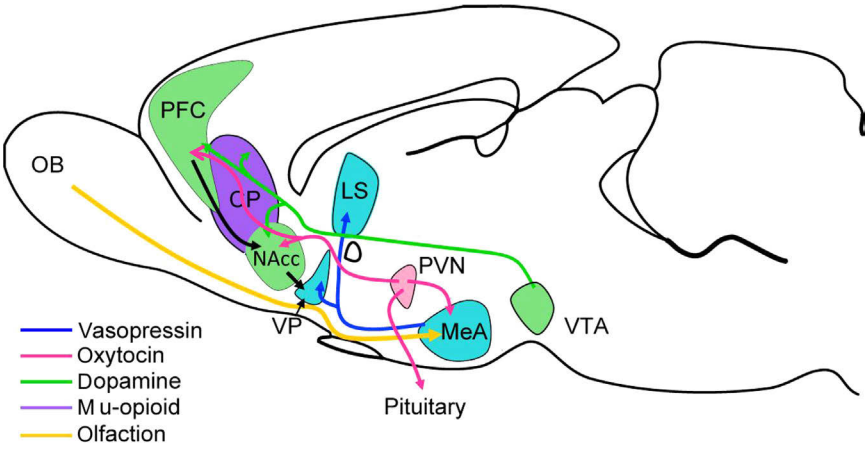

FIGURE 48.21 A schematic of the proposed neural circuitry of pair bond formation in prairie voles. This figure is reproduced in color in the color plate section. Mating stimulates the release of oxytocin from neurons in the paraventricular nucleus of the hypothalamus (PVN) into the nucleus accumbens (NAcc) and prefrontal cortex (PFC) in females, and the release of vasopressin from neurons in the medial amygdala (MeA) into the ventral pallidum (VP) and lateral septum (LS) in males. Mating also stimulates the release of dopamine from neurons in the ventral tegmental area (VTA) into the NAcc and PFC. The MeA receives olfactory input from the partner and conveys the neural encoding of the olfactory signature of the partner to the striatum and LS. Mu-opioid receptors in the CP stimulate the rewarding aspects of mating. OT and AVP facilitate the processing of the olfactory signatures of the mate, and dopamine facilitates an association between the neural encoding of the social cues of the partner and the opioid-based reward and reinforcement. The actions of these neurochemicals in these circuits lead to a conditioned partner preference. *Source: Adapted from Refs 271,334.*

may be an important interaction between the stress axis and the OT and AVP systems in the regulation of pair bond formation. In addition, the effects of OT and AVP on anxiety may also contribute to their modulatory effects on partner preference formation, although this possibility has not been explicitly tested. For example, OT released during mating may decrease anxiety in both males and females, resulting in increased approach behavior.

There is also evidence that the inhibitory effect of corticosterone on partner preference formation may involve an interaction with the dopamine system. RU486, a glucocorticoid receptor antagonist, facilitates partner preference formation in female prairie voles. However, if the females had dopamine receptor antagonist infused into the NAcc, RU486 was ineffective at stimulating partner preference.[338] However, this observation does not preclude an interaction with the OT system, since blocking dopamine receptor inactivation also prevented OT-induced partner preference formation.

In addition to corticosterone, corticotropin-releasing factor (CRF) can also stimulate partner preferences, although it is not known whether endogenous CRF naturally plays an essential role in partner preference formation. CRF produced in the PVN and released into the portal system of the anterior pituitary stimulates the release of ACTH. However, CRF is produced in other brain regions and there are CRF receptors distributed throughout the prairie vole brain that regulate anxiety-related behaviors.[339] ICV infusion of 0.1 or 1.0 ng of CRF facilitated partner preference formation in male prairie voles after a 3 h cohabitation with a female without mating.[340] Higher doses failed to facilitate a social preference. Co-infusion of a nonselective CRF antagonist prevents the CRF-induced partner preference. To further investigate the neural mechanisms by which CRF facilitates partner preferences in males, Lim and colleagues demonstrated that CRF acts in the NAcc to facilitate partner preferences. Infusion of CRF directly into the NAcc, but not into the caudate putamen, facilitated partner preferences in males. This effect was blocked by either a CRF type 1 (CRF-R1) or a CRF type 2 (CRF-R2) receptor antagonist.[341] Immunocytochemistry has revealed that CRF-containing fibers are present in the NAcc.[342] However, there have been no published experiments determining whether infusion of a CRF antagonist prevents mating-induced partner preferences, which is needed to determine whether CRF receptor activation participates in natural pair bond formation.

Neural Mechanisms of Pair Bond Maintenance

Thus far we have discussed the neural mechanisms involved in the formation of a pair bond, many of which involve systems involving positive affective states (e.g., reward). However, recent studies have revealed additional mechanisms that serve to maintain the pair bond that may be acting through modulating negative affective states.[343,344] That is, while activation of the mesolimbic dopamine reward system is involved in the initial establishment of the partner preference, CRF, dopamine D1, and k-opioid receptors all appear to maintain the pair bond by stimulating aversive states when the pair bond is threatened or when the pair is separated.

Dopamine and Selective Aggression

A pair bond in male prairie voles is associated with both a social preference for the partner and an increase in selective aggression toward novel individuals. This aggression toward novel animals, particularly toward females, likely served to prevent subsequent pair bond formation after the initial pair bond is formed. There is evidence that a reorganization of the NAcc dopamine system plays an important role in pair bond maintenance. As mentioned before, D2 signaling facilitates, while D1 signaling inhibits, partner preference formation. Male prairie voles that have mated and been paired with a female partner for 2 weeks display a significant increase in D1-like receptor density in the shell and core of the NAcc, but not in the caudate putamen.[324] This increase was not apparent after only 24 h of mating and cohabitation. Males that mated and cohabitated with a female for 2 weeks display high levels of aggressive behavior toward unfamiliar females. Infusion of a D1 receptor antagonist into the NAcc abolished this selective aggression and increased affiliative behavior toward novel females. Thus, in addition to antagonizing the development of a partner preference, D1 receptors in pair bonded animals facilitate aggression toward novel females, thereby preventing the possibility of pair bonding with additional females. This upward shift in D1:D2 ratio ensures that dopamine release in pair bonded animals leads to greater D1 activation than occurs in non-bonded males during their initial sexual encounter with their partner. But if this D1 receptor-mediated increase in selective aggression prevents extra-pair copulations in pair bonded males, what explains the incidence of infidelity in male prairie voles in natural populations? The authors of this study proposed an interesting possibility. While as a group pair bonded males had a significant increase in D1 receptor binding, 28% of the males in the study did not show a robust reorganization of D1 receptors after pair bonding. Perhaps males that fail to upregulate their D1 receptors are more likely to engage in extra-pair copulations. This possibility remains to be tested.

Kappa-Opioid Receptors and Selective Aggression

The opioid system has also been implicated in the maintenance of the pair bond through the regulation of selective aggression in male prairie voles. Dopamine D1 receptors are expressed on dynorphin-producing neurons. Dynorphin is the endogenous ligand for kappa-opioid receptors (KOR). In contrast, dopamine D2-like receptors are expressed on neurons producing enkephalin, the endogenous ligand for muOR. While enkephalin and muOR are involved in motivation and positive hedonics, dynorphin and KOR are involved in regulating aversion and negative affect. Because of this interaction between KOR and D1 receptor systems, Resendez and colleagues explored the possibility that KOR may contribute to the maintenance of the pair bond in a manner similar to D1 receptors. These investigators found that a peripherally administered KOR antagonist, but not a muOR antagonist, blocked mating-induced selective aggression in males.[345] KOR antagonist was then infused into the NAcc shell, core, and ventral pallidum, all regions showing KOR binding, in both male and female prairie voles. KOR antagonist infused into the NAcc shell, but not the core or ventral pallidum, significantly decreased resident intruder aggression in pair bonded males and females. Thus KOR in the NAcc serves to maintain the pair bond by inducing aggression toward novel individuals of both sexes.

CRF and Separation-Induced Negative Affect

The D1 receptor and KOR systems directly maintain the pair bond by inducing avoidance or aggression to novel individuals, even potential mates. There is also evidence that the CRF system maintains the pair bond by inducing a negative affect upon separation from the partner. Bosch and colleagues investigated the behavioral and physiological impact of losing a partner in male prairie voles. Male prairie voles that were paired with a female for 5 days and then separated from their partner for 4 days displayed a robust increase in passive coping strategy in the forced swim test and tail suspension test, a response indicative of depressive-like behavior, compared to males that remained with their partner.[344] That is, the males spent significantly more time immobile when placed in a beaker of water or when suspended by their tail (Figure 48.22). Interestingly, males that were housed with a sibling for 5 days, and then isolated for 4 days, showed no increase in depressive-like behavior. Furthermore, males separated from their partner, but not from their sibling, displayed a significant increase in corticosterone and adrenal weights. This suggests that important changes occur in the brain mechanisms affecting the stress axis during the pair bonding process that evoke a significant stress response when separated from their partner, which does not occur in nonpair bonded animals experiencing social isolation.

Examination of changes in CRF expression, as a function of pair bonding and separation from the partner, revealed that CRF expression in the bed nucleus of the stria terminalis increases significantly upon mating and cohabitation (and presumably pair bonding) in males, but there was no further increase in synthesis upon separation from the partner. Suspecting that mating and pair bonding increases the set point of CRF expression to essentially increase CRF tone and maximize release upon separation, Bosch and colleagues tested the hypothesis that central CRF release following separation from the partner induces the negative affect and passive coping behavior. When

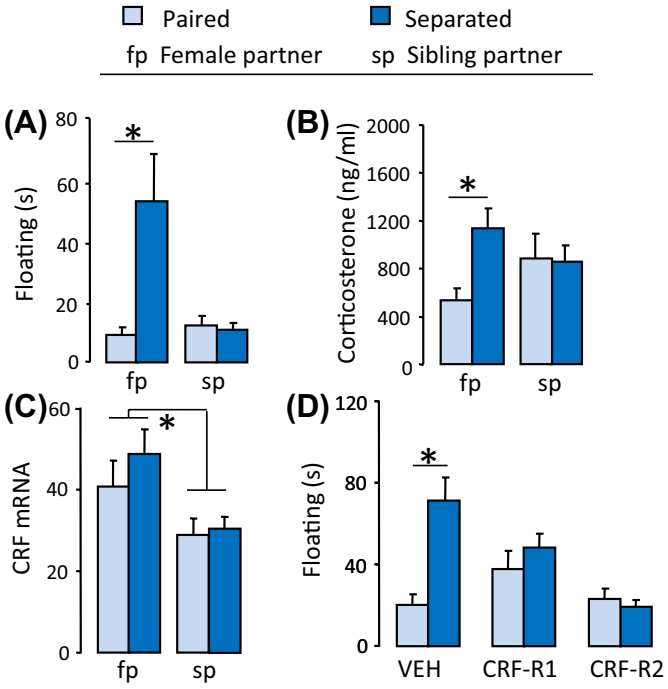

FIGURE 48.22 Loss of a partner leads to an increase in passive coping strategy in male prairie voles. (A) Following 4 days of separation from the bonded partner, males display more time floating (e.g., not actively swimming to escape) in the forced swim test than males who remained paired with their partner, or who were not pair bonded, cohabitated with a same sex sibling, and then separated from their sibling. fp = female partner, sp = sibling partner (B) Males also display an increased plasma concentration of corticosterone when separated from their bonded partner. (C) CRF mRNA expression in the bed nucleus of the stria terminalis is elevated in pair bonded animals compared to nonbonded males. (D) ICV infusion of either a CRF-R1 or CRF-R2 receptor antagonist during the separation period blocks the passive coping strategy in the forced swim test. *Source: Adapted from Ref. 344.*

a nonselective CRF antagonist, a selective CRF-R1 antagonist, or a CRF-R2 antagonist was infused ICV continually via an osmotic minipump beginning on the day of separation, no increase in immobility was observed in either the forced swim test or the tail-suspension test (Figure 48.22). The CRF antagonists did not disrupt the display of a partner preference. Interestingly, CRF-R2 receptors are nearly 100% co-localized with OT neurons in the PVN and are localized to OT immunoreactive fibers in the NAcc, thus there may be an interaction of CRF and OT release in the onset of social loss-mediated depressive-like behavior.[346]

Bosch and colleagues speculate that the CRF system becomes potentiated during pair bond formation, and CRF release during separations from the partner results in a negative affect, which can be alleviated only by reunion with the partner. However, in the case where reunion with the partner is impossible, a maladaptive depression-like behavior develops such that the animal reacts passively in difficult situations. Indeed, in the vast majority of cases where a prairie vole loses their partner in nature, the surviving individual does not take a new partner.

Parallels between Pair Bonding and Addiction

There are several notable parallels between the neural mechanisms of drug addiction and pair bonding, particularly with regard to dopamine, opioid, and CRF systems (for a review, see Ref. 300). Drugs of abuse lead to an increase in dopamine release in the NAcc, as does mating. Chronic cocaine use, which leads to addiction, results in an increase in D1 and a decrease in D2 dopamine receptor signaling in the NAcc, and it has been suggested that the disruption in balance between D1 and D2 receptors underlies the behavioral changes seen in addiction. Opioids are involved in every stage of the addiction process, including initiation, maintenance, withdrawal, and relapse. The positive reinforcing effects of drugs are mediated largely by muOR in the NAcc, ventral pallidum, and VTA. In fact, opioid antagonists have some efficacy at treating drug addiction. During withdrawal, there is an upregulation of KOR, and it is thought that KOR activation by dynorphin may contribute to the negative affect of withdrawal and therefore plays a role in addiction maintenance. Finally, CRF plays an important role in withdrawal. CRF release in the brain is potentiated during withdrawal from a variety of drugs of abuse. This CRF release induces a withdrawal-induced anxiety state that can be revered by a CRF antagonist. This negative affect creates drug craving and is a strong motivation to take the drug.

Thus with the exception of OT and AVP, all of the known mediators of pair bonding are also involved in addiction. Indeed, there is an interaction between social bonding and the effects of drugs of abuse. Amphetamine induces a conditioned place preference (analogous to a conditioned partner preference) in sexually naïve male prairie voles but fails to do so in pair bonded males under the same condition.[347] Based on several pharmacological manipulations, the authors concluded that the pair bonding experience diminishes the rewarding properties of amphetamine through its impact on the D1 dopamine receptor. The difference between drug addiction and pair bonding is the subject of the craving. OT and AVP may serve to link the neural coding of the social cues of the partner to the neural mechanisms involved in addiction through its role in facilitating social information processing.[300]

Pair Bonding as a Model of Social Cognition

Partner preference formation is a complex cognitive process that involves social reward and reinforcement, social information processing, and learning and memory.

As such, it has been proposed that partner preference may be a useful paradigm for screening compounds that may enhance many aspects of social cognition in psychiatric disorders such as autism spectrum disorders and schizophrenia.[348,349] The fact that intranasal OT has been shown to enhance social cognition in autistic subjects supports this notion.[350,351]

With this translational approach in mind, Modi and Young tested whether D-cycloserine (DCS), a partial agonist for the N-methyl-D-aspartate receptor (NMDA) glutamate receptor, would facilitate partner preference formation. The authors used partner preference formation as a proxy for socially reinforced learning. DCS is a cognitive enhancer that has been given peripherally to treat phobias and psychiatric conditions. When given intraperitoneally, DCS facilitated partner preference formation in female prairie voles after a 6-h cohabitation in the absence of mating.[349] DCS did not facilitate a partner preference in female meadow voles. To determine the sites of action in the brain, DCS was microinjected into the NAcc, the amygdala, and the caudate putamen. Infusion of DCS in the NAcc and the amygdala, but not the caudate putamen, facilitated partner preference formation.

In another study, the same authors tested the hypothesis that a drug that is known to stimulate OT release would enhance partner preference. Buspirone, a serotonin 1a receptor agonist, induces a significant increase in plasma OT. As predicted, buspirone injected peripherally facilitated the development of a partner preference in females after a 6-h cohabitation in the absence of mating.[348] Finally, α-melanocyte stimulating hormone (α-MSH) has been shown to stimulate central, but not peripheral, OT release in rats via a melanocortin 4 receptor (MC4R) mechanism.[352] Not surprisingly, melanotan II, an MC4R agonist, facilitates partner preferences in female prairie voles after a 6-h cohabitation without mating (Modi and Young, submitted). Furthermore, even if the partners are separated following the treatment and cohabitation, the partner preference is still displayed 1 week after the drug treatment. Modi and Young suggest that drugs like MC4R agonists, or DCS, enhance socially reinforced learning, and thus might be used in conjunction with behavioral therapies that utilize socially reinforced learning, to improve social functioning in autistic subjects.

Intranasal OT is now being investigated in clinical trials for improving social functioning in autism and schizophrenia. Bales and colleagues have devised a technique to administer OT intranasally in voles to model chronic intranasal OT therapy in psychiatric populations. Intranasal OT was delivered in doses equivalent to those used in clinical studies with autistic patients. Treatment started at 21 days of age, the time of weaning, and continued daily for 3 weeks. Intranasal OT enhanced affiliative behavior toward cagemates in male prairie voles when tested acutely immediately after administration.[353] However, when given chronically and tested 2 weeks after the final treatment, intranasal OT resulted in an impairment of partner preference formation in males, but had no impact in females. The authors conclude that this finding suggests that chronic intranasal OT treatment in humans should proceed with caution as it could have unintended negative effects on social function, but see Ref. 354 for alternative interpretations.

Thus in addition to providing insights into the neural mechanisms of pair bonding and social attachment, partner preferences in prairie voles appear to have important translational potential relevant to disorders characterized by social impairment. Indeed, the prairie vole may prove useful for identifying drugs to improve social functioning in several psychiatric disorders, ranging from autism to bereavement-induced depression.[333,344,355,356]

Effects of Early-Life Experiences on Adult Pair Bonding

There is considerable evidence that early life experiences, including parental nurturing, can have an impact on the ability to form partner preferences as adults.[357] Bales, Carter, and colleagues found that variation in animal husbandry can affect partner preference formation in prairie voles. They compared pups that were transferred during normal cage change in cups or with a gloved hand. Females transferred in cups were less likely to form partner preferences later in life than females handled by a gloved hand.[358] This effect was not seen in males. Although not tested, the authors speculated that the different transfer techniques resulted in differences in parental stimulation.

Variation in family dynamics can also affect later-life pair bonding behaviors. In nature, prairie voles can be reared by a single mother, a breeding pair, or in a communal nest.[9] To investigate the impact of these different types or rearing environments, Ahern and Young created breeding pairs of prairie voles and removed the male in half of pairs just prior to birth of the pups.[359] Daily observations revealed that pups raised by a single mother were exposed in the nest (i.e., no adult was present) more, and received significantly less licking and grooming, than biparentally reared pups. Males and females were then paired with an opposite-sex partner and tested for partner preference after 24 h, 48 h, and 1 week. Biparentally reared males and females displayed partner preferences at all three time points. In contrast, single mother–reared males and females failed to show a significant partner preference after 24 or 48 h, but did after 1 week. No differences between the groups were detected in OTR or V1aR binding, however, the single mother–reared pups had an increased number of OT neurons in the PVN.[359]

Though counter intuitive, this alteration in OT neuron number may reflect some dysregulation in the OT system during development in the single mother–reared pups. Single mother–reared males and females also showed less licking and grooming behavior to their own pups, suggesting a transgenerational impact of early life social experience.[360]

A potential mechanism by which early experience can be functionally translated into altered adult pair bonding behavior is through OT release. There is evidence that parental nurturing and contact stimulates OT release in rodent pups.[361] In male prairie voles, peripheral injections of OT within 24 h of birth leads to increased partner preference formation when the subjects reach adulthood.[362] In females, there appears to be an inverted U-shaped response in which a low dose treatment on the first day of life facilitates partner preferences later in life, a middle dose had no effect, and the highest dose actually led to the development of stranger preferences in adulthood.[363] Furthermore, neonatal OT injections lead to sexually dimorphic alterations in V1aR expression in adulthood,[364] which could explain some of the sexually dimorphic effects of neonatal OT on adult social behaviors.

Pair Bonding in Birds

Despite the fact that 90% of birds form pair bonds and are socially monogamous, and that birds have been widely used to investigate the neural mechanisms of song and communication, there are remarkably few studies investigating the neural mechanisms of pair bond formation in avian species. However, there is some evidence that the avian homolog of OT, mesotocin, and OT-like receptors (VT3) play a role in pair bond formation in zebra finches.

In an initial study, Goodson and colleagues reported that central infusions of mesotocin, vasotocin, and their antagonists did not influence partner preference formation in male or female zebra finches.[365] However, the authors cautioned that the paradigm used may not be ideal for demonstrating that the mesotocin or vasotocin systems are not involved in pair bonding. In a subsequent study involving a seminatural mixed sex setting, an ICV infusion of vasotocin antagonist had no effect on any measure of partner preference formation in male zebra finches.[366] Another group used a testing procedure to allow mate competition and a choice of mates over a 3-day period to test whether an OTR antagonist would alter pair bonding. In this study, peripheral injections of an OTR antagonist disrupted partner preference formation in both male and female zebra finches.[367] Specifically, after 2 days of treatment and three pairing sessions, significantly more OTR antagonist-treated males and females remained unpaired compared to saline-treated controls. However, it is not clear from this study whether the behavioral effects were mediated by central or peripheral mesotocin receptors. Klatt and Goodson followed this study with an experiment where male and female zebra finches were cannulated and given ICV infusions of an OTR antagonist in a colony setting.[368] In contrast to their earlier finding, central OTR antagonist infusion prevented pair bonding in females in this more complex setting, but a decrease in males was not observed. The OTR antagonist used in this study shows a binding distribution, using receptor autoradiography, which is identical to the VT3 receptor mRNA, which is most similar to the OTR of mammals. Thus it appears that mesotocin acting on the VT3 plays a role in partner preference formation in female zebra finches. A role for vasotocin in pair bonding has yet to be demonstrated, and in fact, the evidence does not support a specific role for VT in pair bonding.

There is also evidence that the sex steroid progesterone plays a role in pair bond formation in female zebra finches. Progesterone facilitated pair bonding behaviors in females who had previously never been paired, however, there was no impact on sexual behaviors or behaviors related to parenting.[369] In a second study, male and female zebra finches were allowed to pair bond for 2 weeks, and progesterone was administered on the third week. This study found no impact of progesterone on pair bonding behaviors or extra-pair behaviors. Thus progesterone facilitates pair bonding but does not alter behaviors associated with pair bonding once the bond is formed. It would be informative to determine whether a progesterone antagonist would disrupt an established pair bond. Interestingly, estrogens and androgens do not appear to play a significant role in pair bond formation in zebra finches. When male and female finches were treated with both an aromatase inhibitor (1,4,6-androstatriene-3,17-dione) and an antiandrogen, there was no impact on pairing behavior or the likelihood that an individual would be chosen as a partner.[370]

Pair Bonding in Nonhuman Primates

There are a few studies examining the neurobiological correlates and neurochemistry of pair bonding behaviors in nonhuman primates. Daily intranasal delivery of OT in black-pencilled marmosets (*Callithrix penicillata*) during a 3-week period in which males and females were paired with opposite sex conspecifics resulted in increased huddling with their partner in both sexes, and daily delivery of an oral OTR antagonist caused decreased proximity to their partner.[371] The OTR antagonist also nearly eliminated food sharing with their partner. This study also included partner preference tests similar to those performed in prairie voles, but in this 24-h test, all animals preferentially affiliated with the

novel subject and OT manipulations did not affect this behavior. Interestingly, common marmosets, which are also monogamous, have high densities of OTR in the NAcc.[372] However, it remains to be determined whether these receptors play a role in pair bonding as they do in prairie voles. Nonmonogamous rhesus macaques do not have OTR in this region (S. Freeman and Larry J. Young, unpublished data).

In cotton-top tamarins (*Saguinus oedipus*), urinary OT, thought to reflect plasma concentrations, are correlated with affiliative behavior toward mates in both males and females. Snowdon, Zeigler, and colleagues examined OT concentrations in urine three times per week over a 3-week period in bonded pairs of tamarins and found that OT concentrations varied as much as 10-fold across individuals. However, there was a close correspondence in OT concentration within pairs, and the values were closely correlated. Furthermore, OT concentrations were correlated with affiliative behavior in the pairs. In females, affiliative duration and frequency explained a significant portion of the variance, while in males sexual behavior was the best predictor of urinary OT concentrations. It should be noted that this is a correlational study, and it is not clear if the high concentrations of urinary OT reflect brain levels, which are responsible for the elevated affiliative behavior, or are a consequence of experiencing affiliative behavior, or possibly a combination of the two. Nevertheless, this study suggests a potential role for OT in regulating affiliative behavior in pair bonded primates.

Another study examined the effect of AVP on pair bond related behaviors in coppery titi monkeys (*Callicebus cupreus*) using intranasal administration. Males that had been paired for at least a year with a female were used as subjects. Thirty minutes after an intranasal administration of AVP, the partner, or a novel female, was consecutively placed in the subject's home cage in a smaller transport cage and their interactions were recorded. An empty transport cage was used as a control. Control males receiving saline contacted the stranger's cage more often than the partner or empty cage, similar to the novel partner preference in marmosets mentioned earlier. However, males receiving the highest dose of AVP contacted the partner's cage significantly more than the stranger's cage or the empty cage.[373] While this study did not examine partner preference formation, it does suggest that exogenous AVP induces a preference for contact with an established partner, paralleling the study in voles showing that AVP is necessary for the expression of the partner preference.[293] However, since a V1aR antagonist was not given, it cannot be concluded that endogenous AVP plays a role in partner-directed behavior. This study also does not differentiate between an increased affiliative response toward the partner and an increased neophobia or stress response. However, neophobia is an unlikely mechanism for the preference since there was a clear increase in partner contact and no decrease in stranger contact.

Bales and colleagues also used 2-deoxy-D-glucose PET and MRI to examine neural correlates of pair bonding in titi monkeys. Glucose uptake is thought to reflect neural activity. When they compared males that were in long-term pair bonds to lone males, they found that pair-bonded males had significantly more glucose uptake in the NAcc, ventral pallidum, medial preoptic area, medial amygdala, and supraoptic nucleus (which synthesizes OT and AVP).[374] The authors then compared glucose uptake in animals before and after pairing with a female, and again saw an increase in glucose uptake in the NAcc and ventral pallidum, but not in any other areas. These results are in agreement with the neural mechanisms of pair bonding in male voles, suggesting that similar mechanisms may be involved in pair bonding in rodents and primates.

Pair Bonding in Humans

There is intriguing evidence that mechanisms parallel to those discovered in prairie voles may be involved in romantic pair bonding and relationship quality in humans,[222] however, much of this work is correlational in nature. Feldman and colleagues examined plasma OT concentrations in 60 couples in the early stages of their relationship, within three months, and 43 nonattached singles.[375] Dyadic interactions and interviews regarding relationship-related thoughts and behavior were recorded in a subset of the couples that remained together six months later. Plasma OT concentrations were significantly higher in the new romantic couples compared to the single individuals, and the OT concentrations remained high after six months. Furthermore, plasma OT concentrations were correlated with the couple's interactive reciprocity, including social focus, positive affect, affectionate touch, and synchronized dyadic states. OT was also correlated with anxieties and worries regarding the partner and the relationship. The findings were similar in men and women. While these results are intriguing, and consistent with the work in voles and primates showing a causative role for OT in regulating pair bonding quality, there are two very important caveats to this and other studies examining plasma OT, particularly when the samples are not extracted prior to the assay.[288] First, there is no real evidence that plasma OT concentrations reflect OT concentrations in the brain. However, there is evidence that the OT neurons that are releasing OT from the pituitary are the same neurons projecting to the forebrain, including the NAcc, so plasma OT could reflect neural OT release, but this remains to be determined.[258,259] Second, there is a serious question as to whether OT concentrations determined in

unextracted plasma by commercial ELISA really reflect OT. In fact, one study compared enzyme-linked immunoassay results from unextracted plasma to radioimmunoassay in extracted and purified plasma and found that the values reported by the enzyme immunoassay were 100-fold higher than the gold standard radioimmunoassay results.[376] It is unclear if the values obtained from unextracted plasma samples reflect OT plus its degradation products or also additional unrelated factors, or even OT bound by carrier proteins that is removed in the extraction process.

One intriguing study examined the impact of intranasal OT on personal space in men in a stable monogamous relationship as well as in single men. Scheel, Hurlemann, and colleagues performed the experiment where after intranasal OT or placebo, the male subjects were approached by an attractive female or male experimenter, and the subjects were asked to indicate the distance at which the approach began to be uncomfortable.[377] The authors initially hypothesized that OT would decrease the personal space between the subjects and the female experimenter. However, they found that while OT had no impact on the optimal distance for single men, OT-treated men in monogamous relationships actually displayed an increase in the distance between themselves and the attractive female, but not the male experimenter. The authors suggest that this increased social distance between OT-treated men in a monogamous relationship and attractive females is a mechanism to promote fidelity. Furthermore, women can induce this fidelity-enhancing effect in their partners by engaging in behaviors that stimulate OT release in men, such as sexual intimacy.

Gene-association studies are also consistent with the hypothesis that the neural mechanisms underlying pair bonding in humans are parallel with those discovered in voles. Like in voles, the human V1aR gene (*AVPR1A*) has microsatellite elements in the 5′ flanking region that are polymorphic. In voles, the length of the *Avpr1a* microsatellite influences pair bonding behavior and V1aR binding in the brain, at least in laboratory studies (see previous discussion). Walum and colleagues examined the relationship between the human *AVPR1A* microsatellite and pair bonding behavior in 552 same-sex twin pairs and their spouses or partners.[378] Each subject was assessed with respect to various indices of the quality of the marital relationship, including a partner bonding scale, which is composed of items that correspond to the behavioral patterns observed when measuring features of pair bonds in nonhuman primates. There was a significant association between one of the microsatellites, referred to as RS3, and the partner bonding scale in men but not in women. One particular allele of the RS3 polymorphism, 334, displayed a particularly robust association, and men homozygous for this 334 allele were twice as likely to report a marital crisis in the past year and were also twice as likely to be living with their partner but not legally married. Interestingly, the partners of men carrying the 334 allele reported more dissatisfaction with the relationship. As with most gene-association studies in humans, the effect size of the relationship between pair bonding behavior and the RS3 microsatellite was modest, and this polymorphism clearly does not determine behavior alone, but the fact that an association was detected suggests that the V1aR may contribute to some aspects of romantic relationships in humans.

Walum and colleagues followed the *AVPR1A* study with an examination of the relationship between polymorphisms in the OTR gene (*OXTR*) and the partner bonding scale and other measures of relationship quality in over 2300 subjects who had been in relationships for at least 5 years.[379] A significant association was found between a single nucleotide polymorphism (SNP) in the *OXTR* and scores on the pair bonding scale in women. A similar association was detected between this SNP and scores on another scale of pair relationship quality referred to as the affection scale, in an independent sample of 1240 subjects. Interestingly, these associations were present only in women, not men. Additionally, men married to women carrying the A-allele at this SNP reported significantly lower scores on measures of relationship quality than men married to women not carrying this allele. The study looked at the same SNP in girls and found that carriers of the A allele had more "social problems" than noncarriers, which may be related with the later-life relationship quality issues.

Assuming that the OT system plays an important role in pair bond formation in women (but also in men possibly), it is intriguing to consider whether selection of pair bond formation in humans has shaped human sexuality. The two most potent releasers of OT in the female brain are vaginocervical stimulation and nipple stimulation, which occur during labor and nursing. In most species, females engage in sex only during the times when they are fertile, but human females can be sexually aroused at any time. This allows for sex (and thus vaginocervical stimulation) to occur more frequently, often in a face-to-face position. This lack of obligate linkage of sexuality with fertility suggests that sex may be playing a role in humans other than simply reproduction. Humans are also the only species in which the breasts have become a secondary sexual characteristic and in which nipple stimulation is a common component of sex. It is intriguing to consider that human sexuality has been shaped by evolution to recapitulate the physiological stimuli of birth and nursing, to stimulate OT release and therefore strengthen the bond between the female and her partner.

Brain imaging has also been used to examine the neural correlates of romantic love in humans, and these results are consistent in many ways with the vole

studies.[380] Bartels and Zeki used fMRI to examine brain activation patterns in male and female subjects when they viewed color photographs of their lover, or friends of the same sex as their lover, and then contrasted the two situations to identify brain regions specifically activated by images of the lover. Areas more strongly activated by pictures of loved ones include the middle insula, mainly on the left, the anterior cingulate cortex, the posterior hippocampus, the head of the caudate nucleus, and the putamen.[381] Several areas also showed a decrease in activation while viewing romantic partners compared to friends, including prefrontal, parietal, and middle temporal cortices, the posterior cingulate gyrus and medial prefrontal cortex and the posterior amygdala. This study was followed by a study contrasting the activation pattern of mothers seeing photographs of their infant and lovers seeing photographs of their lovers. As would be predicted based on the hypothesis that pair bonding evolved through adaptations in neural systems involved in maternal bonding, there was a significant overlap in brain activation and deactivation patterns between these two groups.[382] Areas showing similar patterns of activation include the striatum (putamen, globus pallidus, caudate nucleus), the middle insula, and the dorsal part of the anterior cingulate cortex. The VTA and the substantia nigra were also activated by both types of love. Based on these studies, the authors concluded that a push–pull mechanism of attachment—which on one hand deactivates areas mediating negative emotions, avoidance behavior, and social assessment, and on the other hand triggers mechanisms involved in reward—is involved in both romantic and maternal love. The authors also suggested that there was substantial overlap between brain activation patterns when viewing photos of loved ones and the distribution of OTR and V1aR. A more recent study by the same group examined whether brain activation while viewing one's lover would be different between heterosexual and homosexual individuals. The authors found no differences in brain activation patterns between these groups, suggesting that the neural bases for same-sex and opposite-sex romantic love are similar.[383]

Using a very similar paradigm looking at intense, early stage romantic love, another group found activation of dopamine-rich areas associated with reward and motivation, namely the right VTA and the right posterodorsal body and medial caudate nucleus.[384] This group also examined brain activation in people who reported to be in love but were rejected by the loved one. They noted activation in areas associated with gains and losses, craving, and emotion regulation and included the VTA bilaterally, ventral striatum, medial and lateral orbitofrontal/prefrontal cortex, and cingulate gyrus.[385] The results were similar to those found in people who were happily in love. The authors noted the striking similarity to brain regions involved in cocaine addiction, in line with the previous discussion of the parallels between love and addiction.[300]

CONCLUSION

During the last few decades, thanks to progress in neurobiology, molecular biology, and also in animal behavior analysis, we have developed a reasonably coherent understanding of how vertebrates select their mate. In many species of vertebrates, species recognition appears to be based partly on a learning process that takes place during early life (imprinting) and interacts with a hardwired (innate?) knowledge of species-specific characteristics, which places constraints on learning. However, only a small number of species have been investigated in detail, and it is likely that a large degree of species variation in these processes will ultimately be discovered.

The mechanisms that lead to the selection of a sexual partner of the opposite sex have also received much attention both in animals (sex partner preference) and humans (sexual orientation). It has been clearly demonstrated, in rodents at least, that the perinatal endocrine environment plays a critical role in this choice. In humans, clinical and epidemiological studies suggest that the same mechanisms are still active, but at the same time genetic and potentially epigenetic influences appear to play a significant role. Contrary to beliefs that are widespread in the general population, there is currently little experimental evidence demonstrating that postnatal social experiences control in a significant manner sexual orientation in humans.

Finally, the specific subject that will be selected as mate is determined by a variety of criteria that are thought to optimize the success of reproduction and therefore reflect the quality and reproductive potential of the mate. However, to date, there is very little information on the brain mechanisms by which individuals choose the opposite sex conspecific to mate with. There will likely be large sex differences in these mechanisms, especially in polygamous species where the females must be particularly choosy and males can afford to be much less discriminant.

There has been intensive investigation of the neural mechanisms underlying pair bond formation, particularly in the monogamous prairie voles. These studies suggest that the mechanisms of pair bonding share many commonalities with the neural mechanisms of addiction. Indeed, pair bonds can be thought of as conditioned partner preferences in which the cues of the partner have been associated neurally with the reinforcing nature of mating and interacting. The precise cellular mechanisms by which this occurs remain to be elucidated. Despite the great detail provided by studies in the prairie vole, there

is little information in other species. Studies in birds, nonhuman primates, and humans suggest that at least some aspects of the pair bonding processes in voles can be generalized to other species. However, as monogamy, and thus pair bonding, have evolved independently multiple times, it is very likely that there will be species-specific mechanisms underlying pair bonding.

Future Directions

Great progress has been made in understanding the mechanisms of mate choice and pair bonding, but these studies have also revealed many questions that still have no satisfactory answer at this time. These questions concern to various degrees the three aspects of mate choice and pair bonding that were discussed in this chapter.

Species recognition is likely to be quite variable between species, and future studies should try to systematize information collected so far to determine whether there are any evolutionary trends in how species recognition takes place. In particular, it would be fascinating to determine whether the relative role of nature ("innate" identification of species-specific features) versus nurture (learning by sexual imprinting) has changed during vertebrate evolution or as a function of ecological and physiological adaptation.

The topic of sexual partner preference and sexual orientation in humans has attracted much attention. It has been shown, both in animals and in humans, that genetic and prenatal endocrine factors play a significant role in these processes. Their relative importance remains, however, unclear, and in particular, it would be critical to determine whether genetic factors affect sexual orientation by modifying the action of prenatal steroids (changes in receptors, metabolism, receptor co-regulators) or by a direct action on brain development that is independent of steroid action. The relative importance of genetic differences and of differences in gene expression mediated by epigenetic mechanisms obviously also awaits further investigation.

There is substantial clinical and epidemiological evidence suggesting that prenatal testosterone affects, in a significant manner, adult sexual orientation, but to date few experimental data support the notion that individual differences in androgen exposure during prenatal life could have an effect on adult sexual orientation. Baron-Cohen has initiated a program trying to correlate postnatal phenotypic traits with prenatal androgen concentrations measured in amniotic fluid samples that were collected for independent medical reasons. Significant correlations have to date been identified between prenatal testosterone and morphological,[111] behavioral,[386–388] or neuroanatomical[389] differences. Subjects included in these studies are now reaching puberty, and it can be hoped that in the not-too-distant future, it will be possible to analyze potential correlations with adult sexual orientation.

Another area that clearly demands additional work concerns the potential interaction between prenatal (endocrine, genetic) and postnatal (rearing, relation with parents and peers, first sexual interactions) factors in the control of sexual orientation. The role of prenatal factors has now been clearly identified, but they seem to explain only a limited part of the variance (40–50% at best). There is no clear evidence that postnatal factors alone are playing an important role, but suggestive evidence has been collected indicating that they might be important in association with prenatal endocrine modifications.

Individual features that ultimately determine mate choice have obviously been the subject of strong evolutionary pressures so that they provide honest signals of mate quality and reproductive potential. Much remains to be discovered, however, about the nature of these signals, how they are perceived, and how they evolve(d) to ensure transfer of relevant information between potential mates. Monogamous species would be particularly useful for studying partner choice, since the choice of the mate can have a life-long impact on their reproductive success, and thus should be under strict control. Prairie voles have been particularly useful for identifying the mechanisms of pair bond formation and maintenance, but there have been no studies to assess how they choose a mate when there are multiple potential partners.

Regarding pair bonding, it will be particularly important to explore the neural mechanisms underlying pair bond formation and maintenance in a wide variety of species. This would allow us to understand which components of the physiological regulation of pair bonding are general principles and which are species specific. There is likely to be much species specificity in the detailed mechanisms, particularly across diverse taxa. Since 90% of bird species form pair bonds, it is unfortunate that there have been very few studies investigating pair bonding in birds. Those that have been performed suggest that the avian analog of the OT system may be playing a role.

While it is true that we have learned much about the mechanisms of pair bonding in the past 20 years, there are clearly a lot of things we do not know. For example, precisely how do the chemical players affect neurophysiology in the brain regions involved in pair bonding? Electrophysiological analysis to examine neural communication combined with behavioral pharmacological approaches would provide important insights into how OT, AVP, dopamine, opioids, CRF, and their receptors modulate neural circuitry to create and maintain the pair bond. It is also likely that other, yet unidentified, mechanisms play a significant role in pair bond formation.

Future studies should also investigate the extent to which the neural mechanisms of pair bonding can be

generalized to other forms of social relationships. There certainly is a high degree of similarity in the mechanisms underlying pair bonding and parental care and bonding. But might these also play a role in friendships or other relationships? Indeed, there is significant translational potential exploiting partner preference formation to identify drugs to enhance social learning in psychiatric disorders like autism. This potential for biomedical discovery needs to be further developed in prairie voles and other organisms.

The prairie vole model needs to be exploited to its full potential to identify the roles of genes in pair bond formation using state-of-the-art genomic approaches. Genomic tools are being developed and made available to the prairie vole research community. Bacterial artificial chromosome libraries have been developed and used to isolate many of the genes implicated in the pair bond process.[390,391] A genetic linkage map and a panel of gene polymorphisms in prairie voles have been established.[392] The prairie vole genome sequence has recently been made available on a public database. Germ line transgenesis has been successful in prairie voles, but so far this approach has not been utilized to probe the role of specific genes on pair bonding.[393] Finally, inducible pluripotent stem cells have been developed from prairie vole tissue, a first step in the process of developing homologous recombination, which has been so useful in mouse genetics to create knockouts and conditional gene manipulations.[394] As more investigators utilize these tools, the growth in our understanding of the mechanisms of pair bonding shall continue on its impressive trajectory.

CHAPTER

49

Male Sexual Behavior

Elaine M. Hull

Department of Psychology, Florida State University, Tallahassee, FL, USA

Juan M. Dominguez

Department of Psychology, University of Texas, Austin, TX, USA

INTRODUCTION

Although the physical effects of hormones were described by Aristotle as early as the fourth century BC, it was Arnold Berthold who, in 1849, published the results of the first experiment that recognized the behavioral effects of hormones, which—apropos of this chapter—focused largely on the hormonal induction of male behaviors. Berthold castrated roosters and implanted into their body cavity either one of their own testes or one from another rooster. They developed into adults with both the physical and behavioral characteristics of gonadally intact roosters: large comb and wattles, sexual mounting of hens, aggressiveness, and crowing. Before this experiment, it was thought that only neural inputs could affect behavior. However, it took many years before "internal secretions" became recognized as having physiological and behavioral effects.

Frank A. Beach was a major pioneer in more modern times. His PhD dissertation in 1937 reported the effects of cortical lesions on maternal behavior of first-time mother rats. He then expanded his research to include effects of brain lesions and of hormones on male rat sexual behavior and published the book *Hormones and Behavior* in 1948. Numerous current behavioral endocrinologists studied with Beach or one of his students. William C. Young, another pioneer in the field, studied the prenatal effects of androgens on male guinea pigs; later, his ideas were extended to rhesus monkeys, with his colleague Robert Goy, who became director of the Wisconsin Regional Primate Center after Harry Harlow. In 1959, a seminal article was published by Charles H. Phoenix, Robert W. Goy, Arnold A. Gerall, and William C. Young: "Organizing Action of Prenatally Administered Testosterone Propionate on the Tissues Mediating Mating Behavior in the Female Guinea Pig." This article reported that testosterone could organize male-typical behaviors in a female. Previous work had shown that hormones can activate behavior patterns characteristic of a specific sex, but now it was shown that the organizational effects of hormones during development could profoundly impact or even determine the behavior of adults. Daniel S. Lehrman extended the research on organizational effects of hormones to ring doves and also emphasized that behavior can feed back to influence hormones, which in turn influence the brain. Study of the organizational and activational effects of hormones continues to be a thriving research enterprise and has been expanded to include the genetic and epigenetic influences on reproduction in a number of species.

More recent research in the area of male sexual behavior has emphasized the physiological bases of erection and the different stimuli and contexts that can elicit erection. Benjamin Sachs pioneered this area and described noncontact erections (NCE) in male rats (elicited by an inaccessible estrous female or her odor or by drugs), touch-based erections (elicited by retraction of the penile sheath of a restrained male rat), and *in-copula* erections. Different hormonal regimens and time courses maintain these types of erections. Elaine Hull and colleagues extended this research area with the discovery and elucidation of the specific neurotransmitters and brain areas that regulate male sexual behavior. They determined that the prosexual (i.e., sexually excitatory) effects of dopamine (DA), glutamate, nitric oxide (NO), and oxytocin in the medial preoptic area (MPOA) are complemented by facilitative effects of orexin/hypocretin on the mesolimbic DA system and opposed by the inhibitory effects of serotonin (5-HT) in the lateral hypothalamus. An important emphasis from the Hull lab and others was the role

Knobil and Neill's Physiology of Reproduction, Fourth Edition
http://dx.doi.org/10.1016/B978-0-12-397175-3.00049-1

of motivation in male sexual behavior, referred to as appetitive behavior by some. Parallel studies in birds by Jacques Balthazart and Greg Ball extended these concepts outside of mammals. On the consummatory end of male sexual behavior, Lique Coolen and colleagues discovered an ejaculation-specific circuit in the spinal cord and several brain areas while Kevin McKenna's research probed the physiological mechanisms of erection, including the neural innervation of the penis and the various disorders that can result in erectile dysfunction. In the modern era an entire field of research on erection arose out of the discovery that NO initiates the major pathway to erection. NO activates guanylyl cyclase to produce cGMP, which mediates the vasodilation of the penis. Indeed, sildenafil (Viagra), vardenafil (Levitra), and tadalafil (Cialis) inhibit the enzyme, phosphodiesterase 5 (PDE5), which breaks down cGMP, thereby prolonging the vasodilation. Numerous brain and spinal areas, neurotransmitters, and hormones interact in an extensive, highly integrated network to promote sexual arousal and behavior. This chapter will first dissect and analyze that network by its specific components and then integrate those components into functional circuits.

Sexual behavior in animals, including the courtship that precedes it, is characterized by enormous diversity. This diversity assures that mating will occur with the optimal partner at the most appropriate time and place, in order to pass parental genotypes on to the next generation. Sexual behavior is an expression of reproductive physiology that developed days, months, or years earlier, in complex neuroendocrine interactions. Because this chapter focuses on male reproductive physiology, we will emphasize his behavior; however, the contributions of the female cannot be overemphasized. Mating requires the active participation of two individuals, and when mating is viewed from the female perspective, a different interpretation often emerges. However, a male-oriented perspective is warranted in the present endeavor, as long as one is mindful that neither the male- nor the female-centered perspective provides a full description of the complex reproductive interaction.

In this chapter, we summarize recent contributions to our understanding of how hormones, the central nervous system, and peripheral structures interact to regulate male sexual behavior. We begin by describing copulatory behaviors of the most commonly studied species, including the measures used to study them and the conceptual contexts that provide the rationales for those studies. We next review the innervation and functional mechanisms of penile erection and ejaculation. We then turn to the behavioral and physiological effects of gonadal hormones and systemically or intraventricularly administered drugs. Next we summarize the functions of the brain areas most clearly implicated in the control of male sexual behavior, including effects of lesions and stimulation, local hormonal and pharmacological manipulations, and measures of neural activity. Finally, we describe the functional interactions among the structures that mediate male sexual behavior. We conclude with a set of questions raised by previous research that remain unanswered. This chapter is an updating of Hull et al.,[1] Meisel and Sachs,[2] and Hull et al.[3]; we urge readers to consult those publications for more in-depth coverage of some of the older research.

PATTERNS OF SEXUAL BEHAVIOR OF MALE MAMMALS

Description of Behavioral Elements

We begin with a very brief description of the components of mating behavior in species commonly studied in the laboratory. A more thorough description can be found in Refs 3,4. Male animals use species-specific displays to advertise their fitness and suitability as a partner. In rodents, both partners may emit ultrasonic vocalizations, which are mutually arousing. During copulation, receptive females typically remain immobile while the male approaches, clasps her flanks with his forepaws, and begins a series of shallow pelvic thrusts (see Figure 49.1). The female may assume a rigid lordosis posture, with her back flat or concave and her tail deflected to one side. The male usually has one or both hindfeet on the ground, although male macaques use a double foot-clasp mount, in which their hindfeet grasp the female's hindlegs.[5] The male begins a series of rapid, shallow thrusts, with his penis at least partially erect. If the male detects the female's vagina, he will perform a deeper, intravaginal thrust, followed by a rapid, springing dismount. This behavior pattern is used as the measure of intromission in rats and many other rodents. In some species, the male shows repeated intravaginal thrusts throughout the intromission, whereas in ungulates, the male may ejaculate immediately after vaginal insertion. Increased numbers of intromissions preceding ejaculation can increase the number of sperm in the ejaculate and also facilitate sperm transport in the female. Females of some species require sufficient vaginocervical stimulation to ovulate or to trigger a progestational state (reviewed in Ref. 6).

Most male mammals ejaculate only after multiple intromissions. Ejaculation is characterized behaviorally by a deeper, longer thrust and a slow, relaxed dismount. Among canids (dogs, wolves, foxes) ejaculation begins soon after penile insertion and is followed by swelling of the base of the penis, which results in a prolonged "lock" of the male to the female.[7] Technically, seminal emission refers to the transfer of semen into the proximal urethra, whereas ejaculation refers to the forceful expulsion of

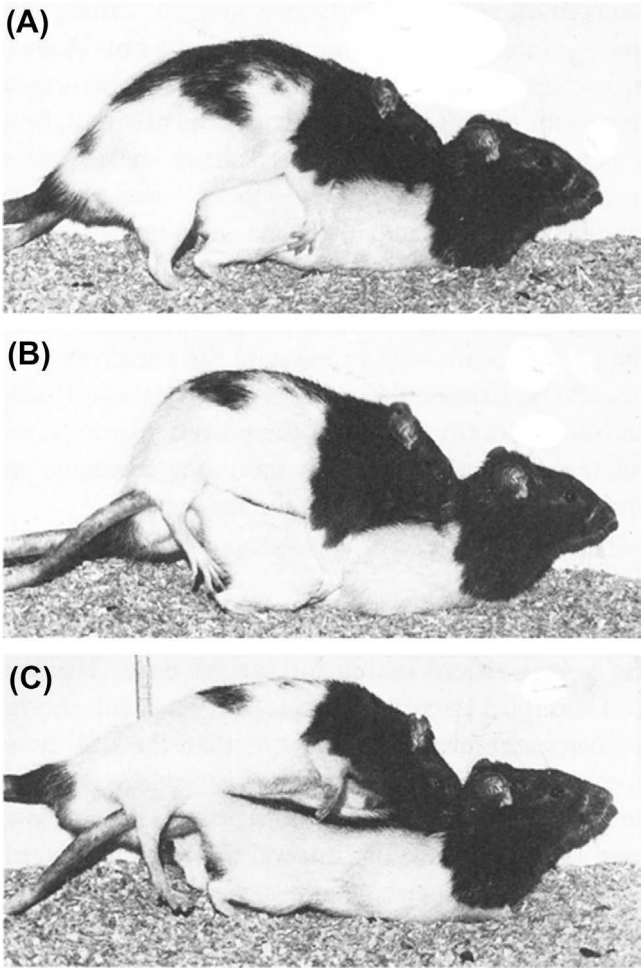

FIGURE 49.1 Three views of copulating rats. Usually, as in A, one is unable to see the genitals. Therefore, without a physiological means of detecting intromission, scoring of copulatory behavior in rats and other small mammals relies upon relatively subtle differences in the patterns of movement to discriminate among mounts, intromissions, and ejaculations. Occasionally the genitals can be seen. In B, insertion is in progress, and the tight clasp suggests that this is an ejaculatory intromission. In C, the engorged glans penis can be seen extending forward just in front of the male's right hindleg. The position of his forelegs indicates that he is dismounting after ejaculation. In all three figures the female is in the characteristic receptive posture of lordosis, with body lowered and rump and head elevated. *Source: We thank Ronald J. Barfield for contributing these photographs.*

the semen from the distal urethra. Rhythmic contractions of skeletal and striated perineal muscles, including the bulbospongiosus, ischiocavernosus, and anal sphincter, usually accompany ejaculation. In human males and females, such muscle contractions are associated with orgasm.

Postejaculatory Behavior and Satiety

After ejaculation, the male typically grooms himself and enters a period of sexual quiescence. The postejaculatory interval may be as short as 30 s in Syrian hamsters or as long as hours to days in other species[8]; in rats it lasts 5–10 min. During the postejaculatory interval, male gerbils footstomp and rats emit ultrasonic (22 kHz) vocalizations. In rats, the failure to copulate during the postejaculatory interval does not result from a failure of erectile function; indeed, *ex-copula* erections may even be enhanced after ejaculation.[9] After achieving seven to eight ejaculations most male rats reach sexual satiety, during which they may not copulate for 1–3 days. Recent data showing a dramatic reduction in androgen receptors in the medial preoptic nucleus and related areas, unrelated to circulating androgen levels, led the authors to suggest that this reduction may underlie the sexual satiety.[10]

Effects of Sexual Experience

Previous sexual experience increases sexual "efficiency." Experienced males copulate with shorter latencies to mount, intromit, and ejaculate and with fewer mounts and intromissions preceding ejaculation. Furthermore, experienced males may be less susceptible to the effects of castration, various brain lesions, and exposure to a novel environment (reviewed in Refs 3,4). In addition, ejaculation elicited more cells that were immunoreactive for Fos, the protein product of the immediate-early gene *c-fos* and considered to be a marker of neuron activation, in the MPOA[11] and in the shell region of the nucleus accumbens (NAc)[12] of sexually experienced male rats, compared to sexually naive males. Similarly, in Japanese quail previous plus acute sexual experience in the presence of a conditioned stimulus (CS) increases Fos immunoreactivity in two brain areas that are important for mating (MPOA and bed nucleus of stria terminalis, BST), compared to exposure to that CS without mating or mating without the CS.[13] Therefore, the threshold for neural excitation is reduced in experienced males, especially in a context associated with mating.

MEASURES OF PENILE FUNCTION

Observations during Copulation

The most direct method to study penile erection is observation during copulatory behavior. This is relatively straightforward in many species, but can be difficult in rodents, because erections are very brief and often obscured from view. Erection, intromission, and ejaculation are often assumed based on the animal's behavior. Direct observations of penile erections can be made using a mirror placed beneath a clear cage. Because genital reflexes are difficult to measure while the male is copulating, paradigms have been developed for monitoring them *ex copula*. However, *in-copula*

and *ex-copula* erections may differ significantly in their physiological, CNS, neurochemical, or hormonal control.[14] To overcome these problems, techniques have been developed to measure physiological responses during copulation, including chronic implantation of electrodes to measure the electrical activity of the striated perineal muscles.[15]

Ex-Copula Measures of Penile Function

Spontaneous or Drug-Induced Erections

Erections can often be observed when a male is alone in his home cage or a neutral arena, in the absence of an apparent sexual stimulus. Therefore, these erections are referred to as spontaneous. The number of spontaneous erections can be increased by administration of various drugs systemically or into specific CNS sites. These erections are referred to as drug-induced erections. These usually involve extension of the engorged glans beyond the sheath and are typically accompanied by genital grooming.

Noncontact Erections

Male rats develop penile erections (noncontact erections; NCE) in response to the presence of an estrous female even when physical contact is prevented; volatile odors from the estrous female are necessary and sufficient for this response.[16,17] Their motor pattern is similar to spontaneous and drug-induced erections and may be the closest model for psychogenic erections in humans. This model is an important contribution, because the response is produced by supraspinal mechanisms and not spinal reflex pathways.

Touch-Based Erections, Anteroflexions, and Seminal Emissions

Reflexive, or touch-based, erections have been elicited by manually stimulating the penis, primarily in the dog.[18] However, penile erection is inhibited by tactile stimulation of the penis in rats.[19] A different method for evoking erection in rats was developed by Hart.[19] A similar technique has been described in mice.[20] With the rat restrained on his back, the penile sheath is retracted, exposing the glans penis. This gives rise to a series of erections, which are seen as tumescence of the glans penis due to engorgement of the corpus spongiosum (see Figure 49.2). Penile anteroflexions ("flips") also occur. These are caused by erection of the corpora cavernosa and contractions of the ischiocavernosus muscles, causing the penis to rise up from its normal posteroflexed position. The *ex-copula* and *in-copula* erections are both based on parasympathetically mediated vasodilation in the penis and contractions of the striated penile muscles (reviewed in Ref. 3). It is thought that the continuing pressure of the sheath around the base of the penis provides the sensory basis.

Urethrogenital Reflex

A model for both erection and orgasm, the urethrogenital (UG) reflex, has been described in anesthetized male and female rats.[22] In urethane-anesthetized, acutely spinalized male rats, the UG reflex consists of clonic contractions of the perineal muscles, rhythmic firing in the cavernous nerve, penile erections, and ejaculation (reviewed in Ref. 3). The somatic muscle bursts are synchronized with bursts in the cavernous nerve, driven by both pelvic (parasympathetic) and hypogastric (sympathetic) nerve bursting, indicating a multisegmental organization. This reflex can be evoked only in animals

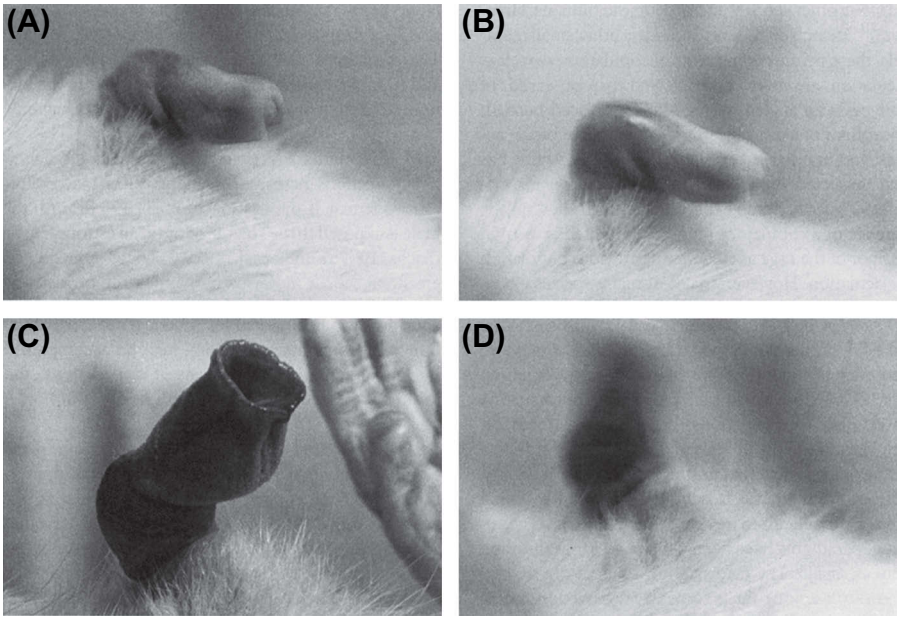

FIGURE 49.2 **Reflexive erections displayed by supine male rats after retraction of the penile sheath.** Several days earlier the suspensory ligaments had been surgically removed, thereby preventing retraction of the penis during the test and permitting better visualization of the distal penile body (perpendicular to the torso in B) and of the entire glans (parallel to the torso in B). In A to C, the glans is directed toward the tail, its normal orientation. In D the glans points rostrally, the orientation necessary to achieve intromission. (A) The quiescent (flaccid) penis. (B) Tumescence and elevation of the penile body without glans erection. (C) Intense erection of the glans ("cup") and of the penile body. (D) Anteroflexion ("flip") of the penis due to a straightening of the penile body. The blurring is due to the speed of the response relative to the shutter speed (1/30 s). *Source: The photographs are from Ref. 21, with permission.*

that have high spinal transections or lesions in certain brain areas.

THE ROLE OF THE PENIS IN MALE SEXUAL BEHAVIOR

Anatomy of the Penis and Mechanics of Erection

The anatomy of mammalian penises varies between a fibroelastic and a highly vascular organ. In ungulates such as sheep and goats, erection occurs primarily by extrusion of the fibroelastic penis by the action of penile muscles. In other animals, including rodents, cats, dogs, monkeys, and humans, erection involves penile enlargement and stiffening, produced by coordinated vascular relaxation and contraction of striated penile muscles. The relative importance of these two components differs across species.

The general arrangement of the penis is common among all mammalian species (see Figure 49.3). The erectile structures consist of the paired corpora cavernosa, which occupy most of the shaft of the penis, and the corpus spongiosum, which surrounds the urethra and expands at the end into the penile bulb and the glans penis (reviewed in Ref. 3). In most species, the two corpora cavernosa are fused into a single vascular

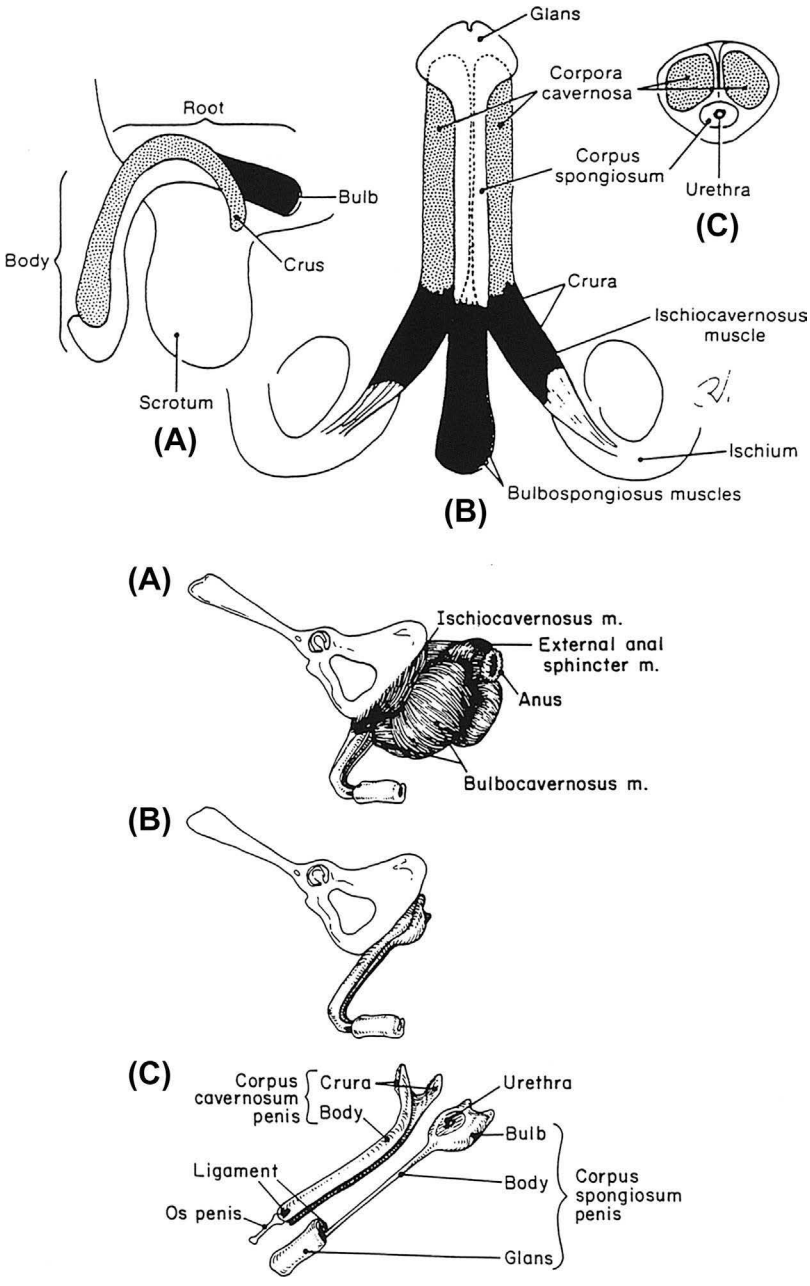

FIGURE 49.3 Some basic structural similarities in penile anatomy for the human and rat. Human (top: (A) lateral view; (B) inferior view with penile body lifted; (C) cross-section) and rat (bottom: (A) lateral view including all muscles; (B) lateral view with muscles removed; (C) "exploded" view). In both species, the penile crura, attached to the ischium, are covered by the ischiocavernosus muscles and are continuous with the body of the penis, composed primarily of the paired corpora cavernosa. The penile bulb, wrapped by the bulbospongiosus (bulbocavernosus) muscles, gives rise to the corpus spongiosum, which terminates in the glans penis. The rat muscle identified as the external anal sphincter is also known as the levator ani or the dorsal bulbospongiosus. *Source: Figures of human penis from Ref. 23 are reprinted by permission of Oxford University Press. Those of the rat penis from Ref. 24 are reprinted by permission of Pergamon Press.*

space, which allows a drug injected anywhere into the corpus cavernosum to reach the entire structure. The corpora cavernosa are composed of vascular sinuses (trabeculae), which receive blood from the helicine arteries, which in turn are fed from the cavernosal artery. The trabeculae are drained by subtunical venules that ultimately join to form the cavernosal veins. The corpora cavernosa are surrounded by a tough capsule, the tunica albuginea, which allows the penis to become hard when the corpora are filled with blood. The proximal ends of the corpora taper into tails called crura, which are anchored onto the ischiopubic ramus and surrounded by the ischiocavernosus muscles. The corpus spongiosum is spongy erectile tissue, which provides a cushion to allow semen to be expelled during ejaculation. Its proximal portion is surrounded by the striated bulbospongiosus muscle. Some animals' penises (but not humans') contain a bone (the os penis), which extends forward to the glans.

The erection and detumescence of the corpora cavernosa and corpus spongiosum are usually coordinated. However, in some conditions they may act independently, because there is some independence of their vascular[25] and neural[26] systems. In humans, erection usually refers only to the penile shaft. However, in rats and other rodents, *ex-copula* erections refer to engorgement of the glans, and changes in the penile body are called anteroflexions or flips. Furthermore, intense erections in rats result in the formation of a cup at the end of the penis, which fits around the female's cervix and directs the flow of semen into her uterus.

Erection is caused by relaxation of smooth muscles in the arteries supplying the erectile tissue and in the trabeculae. The resultant inflow of blood fills the corpora, increasing intracavernous pressure and occluding the venous outflow, trapping blood in the corpora. Contraction of the striated muscles overlying the penile bulb and crura increases penile rigidity.

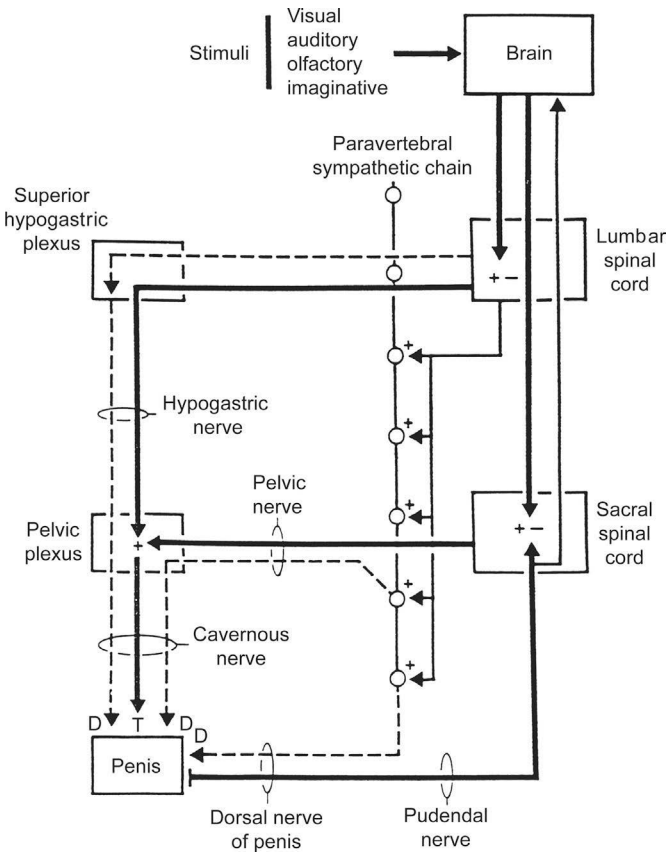

FIGURE 49.4 Schematic diagram of the excitatory (+) and inhibitory (–) innervation of the penis for the regulation of tumescence (T) and detumescence (D). Note that the motor branch of the pudendal nerve is not depicted, nor are the striated muscles to which the pudendal nerve projects. Also, the penis is shown as a single structure, although recent evidence suggests that the innervation of the penile body and glans are not identical. The depicted innervation may better represent that of the body than that of the glans. *Source: Diagram is from Ref. 27 and is reprinted by permission of Harwood Academic Publishers.*

Neural Innervation of the Penis

Penile erection requires coordination of sympathetic, parasympathetic, and somatic input to the penis and perineal structures (see Figure 49.4). The three major pathways include the pelvic nerves (primarily parasympathetic and proerectile), the hypogastric nerves (primarily sympathetic and antierectile), and the pudendal nerves (somatic sensory and motor). The pelvic nerve originates in the lumbosacral spinal cord and travels via the pelvic plexus and cavernous nerve to the corpora and vasculature of the penis. Although it is primarily parasympathetic, it also carries some sympathetic postganglionic fibers, at least in rats.[28] This is the major proerectile pathway in all mammals studied so far.[29,30] The pelvic plexus sends sympathetic and parasympathetic axons to the penis via the cavernous nerve.

The bulbospongiosus and ischiocavernosus striated muscles are innervated by the pudendal nerve, which originates in Onuf's nucleus, in the ventral sacral cord. The pudendal nerve divides into distinct sensory and motor branches near the ischium, both of which also carry sympathetic fibers.[31] The contraction of these muscles does not elicit erection in a flaccid penis, but can dramatically increase penile rigidity of an erect penis.[32]

The third pathway is the sympathetic innervation of the penis, which reaches the penis via the lumbar splanchnic nerves or via the paravertebral sympathetic chain.[33] They synapse on neurons in the hypogastric plexus or in the paravertebral sympathetic chain ganglia. Sympathetic postganglionic axons reach the penis through the hypogastric nerve or the paravertebral sympathetic chain and use norepinephrine (NE) as their neurotransmitter. There are also anti-erectile sympathetic neurons in the

paravertebral sympathetic chain,[34–36] which tend to keep the penis in a flaccid state. Indeed, intracavernous injection of the α-adrenergic antagonists phenoxybenzamine and phentolamine elicits erection in humans.[37]

However, sympathetic neurons may also promote erection.[38] Stimulation of the MPOA elicited penile erection (see Figure 49.5). Bilateral section of the parasympathetic input to the penis blocked the erectile response, confirming that the primary proerectile influence is the parasympathetic innervation. However, section of the paravertebral sympathetic chain or destruction of sympathetic fibers by the catecholamine neurotoxin 6-hydroxydopamine (6-OHDA) significantly decreased the erectile response. The investigators suggested that stimulation of the MPOA may have increased vascular tone in other pelvic structures, thereby diverting blood away from those structures and toward the penis. Therefore, the MPOA can coordinate both parasympathetic and sympathetic influences to elicit erection.

Autonomic and Somatic Control of Ejaculation

Ejaculation consists of both emission and expulsion phases. Emission includes parasympathetically controlled secretion of seminal fluids from epithelial cells and accessory sex glands, as well as sympathetic responses that move those fluids to the proximal urethra (reviewed in Ref. 3). The emission pattern includes closure of the bladder neck and contraction of the seminal vesicles, prostate, and ductus deferens.[40] Emission is primarily controlled by sympathetic mechanisms, with some contribution from parasympathetic nerves (see Figure 49.6).

Expulsion of the semen results from rhythmic contractions of smooth muscles of the urethra and striated perineal muscles, primarily the bulbospongiosus muscle. Both sympathetic and somatic outputs contribute. Ejaculation is initiated primarily by sensory receptors of the glans penis (reviewed in Ref. 42). However, ejaculation during nocturnal penile tumescence may not require

direct stimulation of the glans. Sensory input travels via the dorsal penile nerve and pudendal nerve to the spinal cord and also via the hypogastric nerve to the paravertebral chain of sympathetic ganglia. Expulsion of semen is initiated by fibers from the ventral horn of S2-S4 spinal segments, which travel in the motor branch of the pudendal nerve to the pelvic floor muscles, including the bulbospongiosus and ischiocavernosus muscles. A nucleus in the lumbar spinal cord generates the ejaculatory response[43] (reviewed in Ref. 41).

Cellular Mediators of Erection

Both arterial and trabecular smooth muscles contribute to erection. Arterial smooth muscle relaxation increases penile blood flow, whereas trabecular smooth muscle contractions open the sinusoids in the penile erectile tissue. Trabecular smooth muscle cells have gap junctions through which electric current and second messenger signals can flow from cell to cell. Therefore, the autonomic input can synapse with relatively few cells, which in turn functionally connect in a tissue-wide network.[44]

The gaseous messenger NO is the main mediator of vascular relaxation in the corpora cavernosa (reviewed in Ref. 45). See Figure 49.7(A). NO is produced by the enzyme nitric oxide synthase (NOS), of which there are two isoforms in the penis. Neuronal, or nNOS, is in the parasympathetic nerves that innervate the erectile tissue. Endothelial, or eNOS, is in the endothelium of the erectile tissue. Parasympathetically produced NO may directly induce smooth muscle relaxation and also stimulate the production of NO by eNOS in the endothelial cells, which would further relax the penile smooth

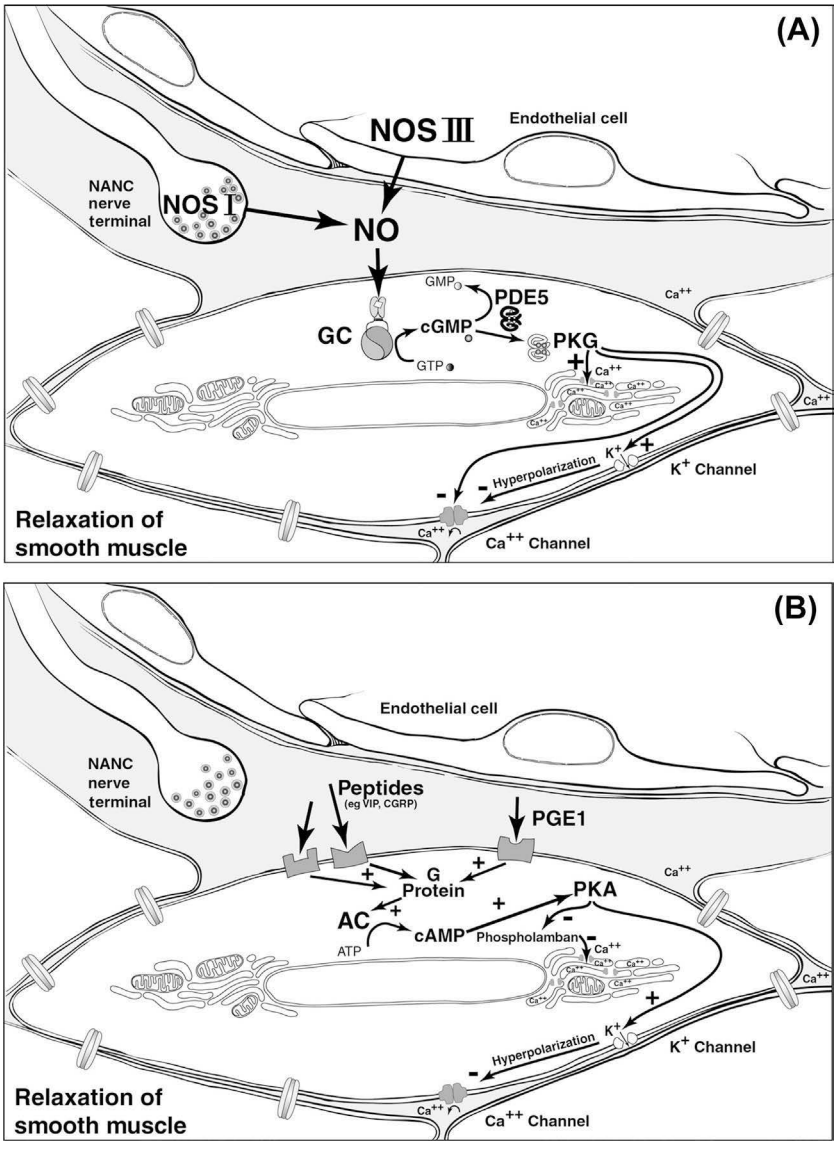

FIGURE 49.7 Mechanisms for penile smooth muscle relaxation. (A) Relaxation of penile smooth muscle: cGMP mechanisms. NO produced by nitric oxide synthase type I (NOS I) in NANC nerves and nitric oxide synthase type III (NOS III) in endothelial cells activates guanylyl cyclase (GC) in smooth muscles cells. This results in the production of cGMP from GTP. cGMP is metabolized by phosphodiesterase type 5 (PDE5). cGMP causes the activation of protein kinase G (PKG). PKG causes an increased uptake of calcium into intracellular stores and a reduction of calcium entry into the cell through calcium channels. PKG also opens potassium channels, leading to hyperpolarization, which also closes the calcium channels. The resulting decrease in intracellular calcium concentration from these mechanisms leads to relaxation of the smooth muscle. (B) Relaxation of penile smooth muscle: cAMP mechanisms. Peptides such as vasoactive intestinal peptide (VIP) and calcitonin gene related peptide (CGRP), and prostaglandins such as PGE1, bind to specific receptors on the smooth muscle cell membrane. These are linked to G protein that activates adenylyl cyclase (AC) in smooth muscles cells. This results in the production of cAMP from ATP. cAMP causes the activation of protein kinase A (PKA). PKA causes an increased uptake of calcium into intracellular stores by inhibiting an inhibitor of calcium uptake, phospholambin. PKA also opens potassium channels, leading to hyperpolarization, which closes the calcium channels. The resulting decrease in intracellular calcium concentration from these mechanisms leads to relaxation of the smooth muscle. *Source: Reprinted from Ref. 45a, with permission from the Society for the Scientific Study of Sexuality.*

muscle.[46] Therefore, the neural stimulation engages an amplification mechanism, which greatly enhances NO release in the erectile tissue.

NO diffuses into smooth muscle cells and activates guanylyl cyclase, producing cGMP, which in turn activates protein kinase G (PKG), and to a lesser extent protein kinase A (PKA). These enzymes phosphorylate certain proteins within the cell, which ultimately results in a decrease in intracellular calcium concentration, which in turn relaxes the tissue.[47] The cGMP can relax smooth muscle in several ways: (1) activating PKG; (2) activating ion channels that sequester or extrude calcium; (3) opening potassium channels to hyperpolarize smooth muscle cells; (4) activating myosin lightchain kinases; and (5) inhibiting the contractile inositol triphosphate (IP_3) pathway.[45,48–50] Phosphodiesterase type 5 (PDE5) terminates the activity of cGMP; sildenafil prolongs cGMP activity by inhibiting PDE5.

Other processes that may contribute to erection include activation of adenylyl cyclase by vasoactive intestinal peptide (VIP), calcitonin gene related peptide (CGRP), and prostaglandin E_1 (PGE_1) (see Figure 49.7(B)).[51–53] These increase levels of cAMP, which activates PKA, and to a lesser extent PKG. These in turn sequester calcium and hyperpolarize the cell. At least some of the proerectile effects of PGE_1 result from an increase in NO, and repeated administration of PGE_1 increases the content of both nNOS and eNOS.[54]

Sympathetic adrenergic nerves induce and maintain detumescence via α_1 receptors on smooth muscle cells in the corpora cavernosa, which increase intracellular calcium concentration by activating the IP_3 pathway, which releases calcium from intracellular stores and allows its entry through plasma membrane calcium channels. Calcium then activates a series of events that result in contraction of smooth muscle cells, decreased blood inflow, and detumescence.[55,56] Stimulation of α_1 receptors can also increase sensitivity of smooth muscle to calcium via the Rho-kinase pathway.[57] A Rho-kinase antagonist has been shown to relax smooth muscle cells and promote erection (reviewed in Ref. 3). Therefore, antagonism of Rho-kinase may provide a new treatment for erectile dysfunction.

PRINCIPLES OF HORMONE ACTION

Male sexual behavior depends heavily on testosterone (T) and its metabolites estradiol (E2) and dihydrotestosterone (DHT). T is secreted by the Leydig cells of the testes and reaches nontesticular targets via the blood. However, the importance of gonadal steroids in male sexual behavior varies among species.[58] In most rodents, testicular steroids are essential, and castration eliminates mating. By contrast, T is more a modulatory factor for male sexual activity of humans.[59]

For most male rodents, masculinization of brain mechanisms controlling sexual behavior is primarily caused by estradiol, produced from testosterone by the enzyme aromatase (See Chapter 47). Actions via estrogen receptor α (ERα) masculinize brain circuits, whereas actions via ERβ defeminize circuits.[60] However, androgens are the masculinizing and defeminizing hormones for primates and guinea pigs (reviewed in Ref. 61). Although most aspects of sex differentiation occur perinatally, hormonal and social influences during puberty can enhance the differences that were initiated perinatally (reviewed in Ref. 62). The stimulatory effects of T on sexual behavior of adult males are termed activational effects, to distinguish them from T's organizational effects during sexual differentiation.

Genomic Effects

Because hormones circulate throughout the body, their specificity of action depends on the type of receptors in the target tissues. Most receptors that are important for sexual behavior either initiate or repress transcription of certain genes (reviewed in Refs 63,64). The steroid molecule binds to its receptor in the cytoplasm of the cell, after which the hormone-receptor complex enters the cell nucleus and dimerizes (links to another hormone-receptor complex). The dimer then binds to a hormone response element upstream of a structural gene and initiates transcription of the appropriate mRNA, which is in turn translated into a protein. That protein may be an enzyme, a receptor, or a structural protein, or it may regulate transcription of additional genes (please see Chapter 9 for more details on steroid receptor signaling). Some hormonal effects may be indirect, as a result of increased activity impinging on downstream neurons.

Besides being activated by steroid hormones, steroid receptors can be activated in a "ligand-independent" fashion (reviewed in Ref. 65), in which neurotransmitters, growth factors, peptide hormones, or intracellular messengers activate gene transcription via the steroid hormone receptors. In addition, transcriptional activity of steroid receptors can be altered by receptor coactivators and corepressors. These effects allow environmental factors to affect transcription without altering steroid hormones.

Rapid, Nongenomic Effects

Steroids may also have rapid effects via receptors on neuron membranes[66] or in an agonist-like manner at $GABA_A$ receptors,[67] thereby hyperpolarizing neurons by increasing chloride influx. Testosterone has affected neural activity in MPOA of castrated

rats within minutes[68] or in the lateral hypothalamus within seconds,[69] and estrogen or testosterone affected firing of neurons in MPOA slices within minutes.[70] However, behavioral restoration requires hours or days of steroid hormone replacement. Furthermore, rapid membrane effects may contribute to behavioral recovery, even though they are not sufficient to restore mating in castrated rats. For example, testosterone elicited activity in penile muscles within 5 min in some castrated rats, although it was not sufficient for restoration of touch-based erections at that time.[71] However, 12 or 24 h after testosterone implantation, NCE did occur, and the protein synthesis inhibitor anisomycin did not affect testosterone's activation of touch-based erections at either of those times.[72] Therefore, genomically mediated protein synthesis was not necessary for the hormonal activation of those erections.

ACTIVATION OF MALE SEXUAL BEHAVIOR BY GONADAL HORMONES

Dependence of Copulation on Recent Exposure to Testosterone

Male sexual behavior in most species is heavily dependent on hormones. Increasing production of T at puberty increases sexual activity, and sexual activity declines after castration. T is usually present in considerably greater quantities than is necessary to stimulate sexual behavior; the levels in blood reflect testicular T content, an important determinant of sperm production.[73,74] In most species, relatively small fluctuations in circulating T levels should not affect behavior.[58]

Time Course of Changes in Copulation Following Castration

Although androgens decline to unmeasurable levels within 24 h after castration,[75] male rats often continue to copulate for days or weeks.[76] In fact, in male rats the number of intromissions required to trigger ejaculation may actually decrease for a few days after castration, although intromission latencies and postejaculatory intervals increase (reviewed in Ref. 4). Therefore, one of the normal functions of T may be to increase the number of intromissions preceding ejaculation, thereby increasing the number of sperm in the ejaculate, facilitating sperm transport, and triggering a progestational state in the female.[77,78]

The postcastration decline in sexual behavior follows a sequence that is consistent across species, with loss of ejaculation first, then intromission, and later mounting (reviewed in Ref. 3). The differential loss of copulatory elements after castration is due in part to their different peripheral target cells or mechanisms. For example, mounting does not require tactile sensitivity of the penis or its ability to become erect, as intromission does, and ejaculation requires even more penile sensory input and motor output than does intromission. The various behaviors may also depend on different neuronal circuits, which have different degrees of hormonal dependence.

There are mixed reports of the effects of castration on sexual desire and copulation in men. Kinsey[79] relied on anecdotal accounts to conclude that the assertion that castration impaired sexual function in most men had little basis. Subsequently, more detailed reports revealed considerable variability. Heim and Hursch[59] reviewed the results of prospective studies of men who had been castrated as "treatment" for sexual offenses. Half to two-thirds of those men reported a rapid loss of sexual desire and interest, whereas sexual activity in the remaining men waned gradually, with as many as 10% reporting sexual intercourse for up to 20 years. There was a greater effect the older the individual was at the time of castration.[59] Imaging studies revealed that visual sexual stimuli activated regions of men's brains that control autonomic and neuroendocrine functions, and this activation was correlated with testosterone levels.[80] In imaging studies of hypogonadal men some of those same regions showed less activation, compared to eugonadal men, whereas hormone replacement therapy led to partial recovery of stimulus-induced brain activation.[81] Finally, hypogonadal patients reported recovery of erectile activity after testosterone treatment, as indicated by nocturnal erections, similar to levels observed in eugonadal men.[82]

Time Course of Changes in Copulation Following T Restoration

Exogenous testosterone restores copulatory behaviors in the reverse order in which they were lost, with mounting occurring first, followed by intromission, and finally ejaculation.[83] In long-term castrates, 5–10 days of T exposure is usually required to reinstate copulation.[76,84–86] However, T increased neural firing in the MPOA within minutes[68] and increased firing in the lateral hypothalamus within seconds.[69] Furthermore, E stimulated chemoinvestigation and mounting in castrated rats within 35 min,[87] and in castrated mice T facilitated mounting within 60 min.[88] Therefore, steroids begin to act immediately within the brain, but longer-term genomic effects are necessary for complete restoration of mating. In support of this, the protein synthesis inhibitor anisomycin blocked the effects of T on copulatory behavior.[89] However, T restoration of touch-based erections was not disrupted by anisomycin, and in some conditions anisomycin actually facilitated restoration of those erections.[72]

The Amount of Testosterone Required for Restoration

Higher doses of hormone are necessary to restore copulation in long-term castrates than in those receiving hormone soon after castration.[76] Apparently, continuous exposure of neural and peripheral tissues to T maintains tissue responsiveness, whereas reactivation of dormant copulatory systems requires greater hormonal input. Furthermore, the dose of T influences the degree of recovery. Rat castrates that received a high dose of T, which restored normal physiological levels, experienced the greatest recovery, compared to those receiving vehicle or low and medium doses of T.[90] After 16 days of hormone replacement, 100% of those receiving the high dose could ejaculate, whereas no vehicle-treated animal ejaculated, and 30% and 80% of those receiving low and medium doses, respectively, displayed ejaculations.[90] However, individual males vary widely in their copulatory abilities, and once an individual's pre-castration ability is reached, additional T treatment produces little benefit.[91,92]

The Role of T Metabolites in Maintaining and Restoring Copulation

T is the principal steroid hormone produced by the testes. However, T is converted in target organs to potent estrogenic or androgenic metabolites. Estradiol (E2), formed by the P450 enzyme aromatase, binds to ERs, of which there are at least two types: ERα and ERβ. The major androgenic metabolite of T is DHT, which is formed by the enzyme 5α-reductase. Both T and DHT bind to the androgen receptor (AR), but DHT binds with approximately fivefold greater affinity.[93] Furthermore, DHT cannot be aromatized to E2, and therefore is considered to have a "pure" androgenic action. Some target cells may produce both E2 and DHT and have both ERs and ARs.

Estrogens and DHT have differential effects on copulation. In male rats E2 is the main steroid that maintains or restores most copulatory elements, and systemic aromatase inhibitors or ER antagonists inhibit restoration of copulation by testosterone (reviewed in Ref. 4). Furthermore, synthetic androgens (5α-androstanediols) that can be aromatized to E2, but not 5α-reduced to DHT, are even more effective than T in restoring sexual behavior in castrated rats[94] or mice.[95] Similar inhibitory effects of an aromatase inhibitor are found in castrated, T-treated monkeys.[96] Furthermore, plasma concentrations of E2 and of the 5-HT precursor tryptophan, but not of T or DHT, are correlated with the ability of male macaques to copulate to ejaculation; however, sexual motivation is more related to androgen concentrations.[97] The effectiveness of E2 in restoring or maintaining copulation, and the lack of effectiveness of DHT and other nonaromatizable androgens, in several rodent species is similar to the organizational "aromatization hypothesis". That is, the aromatization of T to E2 is the critical step in the masculinization of the brain in early development.

However, E2 alone cannot maintain full copulatory behavior. Frequently, E2-treated castrates are unable to ejaculate or have fewer ejaculations than males treated with T or with a combination of E2 and DHT.[98,99] Furthermore, E2 alone did not restore partner preference, and the aromatase inhibitor fadrozole did not block T's restoration of partner preference [99]. A similar lack of effect of fadrozole was observed in male hamsters.[100] However, a recent study of male Syrian hamsters reported that co-administering DHT with T restores sexual behavior more rapidly than does T alone, suggesting an additive interaction between DHT and T.[101] The steroidal ER antagonist RU-58,668 also does not block T's restoration of copulation or partner preference in male rats, but does inhibit T's restoration of scent marking.[102] Therefore, activation of estrogen receptors is not always sufficient to stimulate copulation or partner preference in male rats or hamsters, and ER antagonists do not always render testosterone ineffective.

Also supporting the role of androgens in rodents, the antiandrogen flutamide reduces T's restoration of copulation, partner preference, scent marking, and 50 kHz ("attraction") vocalizations in castrated rats.[102] An androgen antagonist with greater affinity for the androgen receptor (SCH-16423) eliminates copulation in most castrates treated with a dose of T that restores ejaculation in all control males.[103]

Androgens may be more important for the appetitive aspects of sexual behavior than for copulation per se. DHT treatment in castrated rats stimulates NCE and ultrasonic vocalizations, but E2 does not.[104,105] Similarly, flutamide impaires T's restoration of partner preference, scent marking, and 50-kHz vocalizations in castrated rats, while the ER antagonist RU-58,668 inhibits only scent marking and ultrasound.[102] In related studies, the aromatase inhibitor fadrozole does not prevent partner preference in castrated rats with T replacement.[99] Fadrozole does reduce anticipatory level searching for a female in a bilevel motivation test, but E2 treatment only partially restores the behavior.[106] Taken together, these studies suggest that stimulation of ER is not sufficient, and in some cases may not be necessary, to restore or maintain full copulatory behavior in male rats or Syrian hamsters.

Studies of genetically altered mice lacking either ERα or ERβ have furthered our understanding of the roles of androgens and estrogens in male sexual activity. Both ERα and ERβ are normally expressed in the brain.[107] Gonadally intact male mice lacking the ERα (ERα "knockout" mice, or ERαKO) mount normally, but have fewer intromissions than wild-type mice, and almost no ejaculations.[108,109] This is not due to endocrine dysfunction, because ERαKO males secrete more T than

do wild-type mice, because of decreased ER-mediated negative feedback of E2 on LH secretion.[110] Furthermore, castration of ERαKO males and replacement with normal levels of T[110] or with higher than normal levels of DHT[109] increase mounting, but do not restore ejaculation. However, concurrent treatment with T and a DA agonist can activate masculine sexual behavior in ERαKO males.[111] AR immunoreactivity[108] and ERβ mRNA[112] are comparable in ERαKO and wild-type mice, indicating a lack of compensatory upregulation. Deficits in sexual behavior have also been reported in aromatase knockout (ArKO) mice.[113,114] Although ArKO mice can sire litters when housed with females, they are less able to discriminate odors from conspecifics.[113] In contrast to the dramatic effects of ERαKO or ArKO on male sexual behavior, there are no deficits in adult mating behavior of ERβ knockout (βERKO) mice,[115] although βERKO males have a later onset of ejaculation at puberty. Therefore, ERα and aromatase, perhaps in concert with androgens, appear to play a substantial role in male sexual behavior in mice.

In a number of species, the aromatization hypothesis has little or no support. DHT can maintain or restore copulation in male rabbits, guinea pigs, hamsters, deer mice, monkeys, mice, and humans, but not in gerbils, pigs, or sheep (reviewed in Ref. 3). In ferrets, either T or E facilitate partner preference in sexually experienced males,[116] and E2 appears to contribute to libido in dogs[117] and to sexual activity in monkeys.[96] However, although the optimal balance of androgenic and estrogenic stimuli may vary among species, males are normally exposed to both androgenic and estrogenic metabolites of T, and both may contribute in some way to mating.

Effects of Hormone Deprivation and Replacement on *Ex-Copula* Penile Responses

Animal Studies

Touch-based and NCE are lost more rapidly after castration (2–3 days) and are also restored more rapidly (2–3 days) by exogenous T than is copulation (5–7 days) (reviewed in Ref. 3). Therefore, the hormonal stimulation of noncontact and touch-based erections may differ from hormonal control of copulation, at least regarding temporal factors.

Another difference in hormonal control of penile reflexes, compared to copulation, is the lack of effect of E2, and the effectiveness of DHT, in restoring or maintaining touch-based or NCE in rats (reviewed in Refs 3,4). The DHT regimens that maintain or restore penile reflexes are not effective in copulation tests. Therefore, as with temporal factors, the hormonal mechanisms that control *ex-copula* erections are different from those that regulate copulation.

Although E2 is not effective in *ex-copula* reflex tests, it can maintain erections during copulation. Also, the duration, frequency, and average amplitude of EMG responses of the bulbospongiosus muscle are at least as great in E2-treated castrates as in T-treated castrates.[118] Sachs[119] suggested that a copulatory "behavioral cascade" is organized in the brain and activates reflexes that are observable only in copulatory contexts. Reflexive erections may be elicited primarily by disinhibition of lumbosacral spinal circuits. Although E2 cannot disinhibit reflexes *ex copula*, it apparently can activate those same reflexes during mating.

Studies on Human Males

Testosterone concentrations in men with erectile dysfunction usually differ little from those of normally functioning men.[120,121] However, exogenous T does improve erectile function in aging men with moderate decreases in T.[122,123] Also, administration of T to hypogonadal men (which results in normal levels) or to eugonadal men (which produces supraphysiological levels) does increase arousal in response to sexual audiotapes.[124] T and DHT are equally effective in agonadal men, and neither an ER antagonist nor an aromatase inhibitor inhibits T-induced sexual function. Thus, androgenic stimulation in men can facilitate sexual interest and ability (reviewed in Ref. 125).

Men with low to normal T concentrations, given short-term T replacement together with sildenafil, experience increased arterial inflow to the penis.[126] Furthermore, hypogonadal men can have erections stimulated by fantasy or viewing erotic films; their loss of erection is restricted to nocturnal and spontaneous erections.[127] Thus, the effect of androgen on erection in men is context-sensitive, as it is in rats.

EFFECTS OF SYSTEMICALLY OR INTRACEREBROVENTRICULARLY ADMINISTERED DRUGS

Sexual behavior requires rapid sensory and motor processing and complex moment-to-moment interactions with a partner. Consequently, the slower effects of hormones must be translated into more rapid neural responses. Hormones bias sensory inputs to favor processing of sexually relevant stimuli and also prime central integrative areas and motor outputs to promote appropriate sexual responses. Major targets of steroid priming are enzymes that synthesize (or catabolize) neurotransmitters or neuromodulators, mechanisms that govern neurotransmitter release, receptors, or second messenger systems.

Dopamine

DA has long been known to facilitate sexual function. Administration of L-DOPA to Parkinsonian patients often results in increased libido and sexual potency,[128,129] and the classic DA agonist apomorphine has been used

to treat erectile dysfunction.[130–132] A new sublingual form of apomorphine appears to be clinically effective, with fewer side effects than subcutaneous injections of apomorphine, such as increased libido or nausea.[133,134]

In rats, systemically administered DA agonists have also facilitated male sexual behavior (reviewed in Refs 134–136). L-DOPA and/or apomorphine can induce sexually sluggish males to copulate, increase the numbers of ejaculations, and decrease ejaculation latency and the numbers of intromissions preceding ejaculation. Apomorphine can also elicit copulation in sexually satiated male rats[137,138] and in socially stressed mice[139] and rats.[140] In male rats that were sexually sluggish because of medial frontal cortex damage, DA agonists have decreased their usual long mount and intromission latencies,[141] and in short-term[142] and long-term[143] castrated rats, apomorphine has partially restored copulation. Mice lacking the Esr1 gene, which codes for ERα, usually show little copulatory behavior, yet they can copulate normally after receiving systemic injections of apomorphine.[111] Therefore, stimulation of DA receptors appears to render both organizational and activational effects of ERα unnecessary for male copulatory behavior, at least in some animals. Systemic administration of apomorphine also elicits penile erections and genital grooming in mice.[144] Its effects are blocked by the centrally active antagonist haloperidol, but not by domperidone, which does not cross the blood–brain barrier. Cocaine, which inhibits DA reuptake and thereby increases synaptic DA, increases the percentage of rats that copulate and produces additive effects with paradoxical sleep deprivation, which the authors suggest may increase sensitivity of DA receptors.[145] Apomorphine administered systemically to hamsters has produced only slight decreases in ejaculation latency and postejaculatory interval, although it has also abolished long intromissions (a sign of approaching sexual satiety) in 60% of the animals.[146]

Daily injections of amphetamine, which releases endogenous DA, result in increased locomotor responsiveness to amphetamine (sensitization). Similar injections in sexually naive male rats facilitate copulation on their first test.[147] Therefore, the presumably dopaminergic mechanisms that result in drug sensitization also "cross-sensitize" to a natural motivated behavior. Furthermore, similar mechanisms may at least partially explain the enhanced copulatory ability and resistance to surgical and environmental insults of sexually experienced animals.

As expected, antagonists that block the effects of DA interfere with sexual behavior of experienced and inexperienced male rats (reviewed in Ref. 3). The effects of DA antagonists range from failure to copulate to increased latencies to intromit and ejaculate. The numbers of touch-based erections are also decreased by a centrally active antagonist, haloperidol, but not by an antagonist that does not cross the blood–brain barrier, domperidone.[148]

The DA antagonist haloperidol inhibits measures of sexual motivation, as well as copulation. Sexually naive male rats were given 10 daily trials on which they traversed a runway to be near an estrous or a nonestrous female on different days.[149] They were then injected with vehicle or one of three doses of haloperidol and allowed to copulate to one ejaculation; no copulatory measure was significantly affected by the drug. Two days later vehicle-treated animals ran faster after sexual experience than before and also ran faster for the estrous than for the nonestrous female. However, haloperidol dose-dependently decreased running speed and preference for the estrous female. Haloperidol-treated males also showed more retreats as they approached the goal box, as if it were aversive. The drug was given two days before the runway test and had sufficient time to be metabolized before that test. Also, no dose significantly affected copulation on the experience day. Thus, a systemically administered DA antagonist selectively impaired the experience-induced enhancement of sexual motivation.

A similar experiment from the same lab supported their earlier conclusion. Two doses of haloperidol or vehicle were given to sexually naive males before traversing a runway for an empty goal box, an estrous female, or a nonestrous female, following a 4-min exposure to the target through a perforated barrier.[150] Run times for the empty goal box and for the nonestrous female were not affected by the drug, suggesting that motoric ability was not compromised. However, run times for the estrous female were slower, compared to vehicle-treated animals, and were not significantly different from their own run times to the other two targets.

DA receptors are classified into two families. The D_1 family comprises D_1 and D_5 receptors, while the D_2 family consists of D_2, D_3, and D_4 receptors. The D_1-like receptors stimulate adenylyl cyclase, whereas the D_2 family members inhibit adenylyl cyclase and also influence certain ion channels and the phosphoinositide system. DA and apomorphine activate both families, but drugs that are relatively selective for a given subtype have been used to analyze the roles of the subtypes in various aspects of copulation.

There is some agreement that stimulation of D_2-like receptors facilitates ejaculation. A D_3-selective agonist (7-OH-DPAT) and two D_2/D_3 agonists (SND 919 and B-HT 920) decreased ejaculation latencies and the numbers of intromissions that preceded ejaculation in sexually active male rats, but not in sexually inactive animals.[151–153] Conversely, a D_2/D_3 antagonist (eticlopride) blocked the pro-ejaculatory effects of 7-OH-DPAT[154] and of SND 919,[155] confirming their receptor specificity. However, cholinergic muscarinic receptors may mediate

the pro-ejaculatory effects of D_2-like receptors, as the muscarinic antagonist atropine inhibited the effects of both dopaminergic and muscarinic agonists.[156] The effects of dopaminergic agonists are dose dependent, with low doses facilitating and high doses inhibiting copulation, probably as a result of stereotypic behaviors elicited by the high doses.[157] A D_1 agonist (SKF 81292) facilitated mounting in genetically DA-deficient mice, whereas a D_2 agonist (quinpirole) inhibited mounting as it increased stereotypic behavior.[158] A different D_1 agonist (SKF 38393) also increased the time spent in a goal compartment with a receptive female.[159] The drug increased the number of copulatory behaviors but did not affect motoric measures. Thus, a measure of sexual motivation was again affected independently of obvious motor confounds.

There are apparently contradictory effects of D_1- and D_2-like agonists on *ex-copula* genital reflexes. In some experiments, a presumed-selective D_2 agonist elicited erections in a neutral arena, whereas a D_1 agonist inhibited such erections; however, a D_2/D_3 antagonist administered with a presumed-selective D_2 agonist actually increased drug-induced erections, suggesting that stimulation of D_2-like receptors may inhibit, rather than stimulate, erections (reviewed in Ref. 3). It is likely that the presumed-selective D_2-like agonists also had substantial activity at D_1 receptors. D_2-like receptors may also inhibit touch-based erections in restrained male rats. A D_2/D_3 agonist (quinelorane) decreased touch-based erections following either systemic or intra-MPOA administration.[160] As will be discussed below in the section on the MPOA, intense stimulation of D_2-like receptors appears to shift autonomic balance to favor sympathetically mediated seminal emission and ejaculation, and away from parasympathetically mediated erection. However, two selective D_2/D_3 agonists (7-OH-DPAT and B-HT 920) elicited erections, as well as stretching, yawning, and sedation in sexually naive male rats in a neutral arena.[161] It is not clear whether different dose ranges or different test regimens (touch-based erections versus drug-induced erections in a neutral arena) may account for these divergent findings.

The facilitative influence of D_1–like receptors on male sexual behavior appears to be conserved across phyla. Systemic administration of a D_1 agonist (SKF 81297) to two species of lizards increased the proportion of animals that mated after gonadectomy and decreased mount latencies.[162] Conversely, systemic injections of a DA receptor antagonist in leopard geckos inhibited courtship behavior in castrated, T-implanted males (reviewed in Ref. 163). Similarly, in quail systemic injections of a D_1 agonist (SKF 38393) increased two measures of appetitive behavior: the amount of time near a window through which a female could be seen and the time looking through the window; it also increased two copulatory measures: the numbers of mount attempts and of cloacal contact movements.[164] Conversely, a D_1 antagonist (SCH 23390) decreased the approaches to the female's window and the number of mount attempts. Administration of D_2-selective drugs produced the opposite pattern of results: the D_2 agonist (quinpirole) decreased both appetitive and copulatory measures, and a D_2 antagonist (spiperone) increased mount attempts but decreased the number of times the male approached the area of the window. An earlier article reported that the classic DA agonist apomorphine inhibited both appetitive and copulatory measures, apparently by stimulating primarily D_2 receptors.[165] The inhibition by the two higher doses was associated with intense stereotyped pecking; however, the lowest dose inhibited sexual behavior without significant increases in pecking. Two indirect DA agonists (nomifensine, which inhibits reuptake, and amfonelic acid, which primarily increases release) produced mixed facilitative and inhibitory effects. A more recent article from the same lab reported that intracerebroventricular (ICV) injections of DA itself inhibited sexual behavior in quail, and suggested that alpha-2 noradrenergic receptors, rather than DA receptors, mediated the inhibitory effects.[166] However, the earlier studies using selective DA agonists and antagonists probably avoided the problem of cross-reactivity with alpha-2 receptors.

In summary, there is impressive agreement that systemically administered DA agonists facilitate several aspects of mammalian sexual behavior, including sexual motivation, genital reflexes, and copulation itself, and that DA antagonists inhibit those same measures. Systemically administered DA agonists have restored sexual behavior in castrates, in stressed or sexually satiated males, in males with prefrontal cortex lesions, in males lacking ERα, and in males lacking endogenous DA (reviewed above). DA agonists have also facilitated erections in several contexts, although the relative importance of D_1- and D_2-like receptors for genital reflexes is not clear. Conversely, DA antagonists have inhibited both conditioned and unconditioned sexual motivation, in several cases without confounding motor effects; have decreased genital reflexes; and have decreased the incidence, rate, and efficiency of copulation. There is also conservation of the facilitative role of D_1-like receptors in reptiles, birds, and mammals.

A critical review has suggested that DA has no importance for sexual motivation, because several of the studies that reported inhibition by DA antagonists either used measures of approach to a female, which can confound motoric and motivational factors, or studied sexually experienced males.[167] However, several of the studies using approach to a female specifically ruled out motoric effects, as noted above. Furthermore, the increase in sexual motivation that follows copulatory experience is an

important issue, and experiments have separately studied dopaminergic effects on both the initial conditioning and the subsequent expression of sexual motivation. DA antagonists have inhibited both the initial sensitization and the subsequent expression of the enhanced motivation, without confounding motor effects. While no procedure has been devised to measure motivation selectively, without any possibility of sensory, learning, or motoric contributions, the preponderance of evidence suggests that DA contributes to sexual motivation, as well as to genital reflexes and copulatory performance.

Norepinephrine

Experiments using noradrenergic drugs and lesions of NE pathways have produced inconsistent results. Electrolytic lesions of the ascending dorsal noradrenergic bundle in the midbrain, which destroy both cell bodies and fibers of passage, resulted in decreased postejaculatory intervals and increased ejaculations in a 1-h test.[168,169] However, cytotoxic (6-OHDA) lesions of the same area were without effect on copulation.[169] Electrolytic lesions of the locus coeruleus or systemic inhibition of NE synthesis inhibited copulation in one experiment[170] but not in a more recent one.[171] However, lesions of the locus coeruleus blocked the "Coolidge effect"(the facilitative effect of introduction of a new female to a sexually satiated male) and decreased the facilitative effects of 8-OH-DPAT, a 5-HT_{1A} agonist in satiated and nonsatiated males.[171]

Presynaptic α_2 autoreceptors exert inhibitory control of NE release. Inhibition of α_2 autoreceptors with yohimbine can increase mounts and intromissions by sexually sluggish males,[172,173] castrated males,[174] and males with anesthetized penes.[172] Yohimbine can also reverse sexual satiety.[138,175,176] However, yohimbine's effects on satiety were inhibited by the DA antagonist haloperidol, suggesting that activation of the DA system mediated yohimbine's effects.[138] A more selective α_2 antagonist (delaquamine) can also facilitate copulation in sexually naive males and increase mounting by castrates.[177] Copulatory behavior was facilitated by two other α_2 antagonists; rauwalscine decreased the intercopulatory and postejaculatory intervals, and phentolamine decreased the number of intromissions and time preceding ejaculation.[178] In hamsters, too, yohimbine appears to facilitate copulation, increasing the number of ejaculations and the numbers of long intromissions (usually a sign of approaching satiety).[146] Therefore, increasing NE release by blocking α_2 autoreceptors appears to enhance sexual performance in both rats and hamsters. Conversely, stimulating α_2 autoreceptors with clonidine can inhibit copulation and touch-based *ex-copula* erections in rats.[179] However, high doses of yohimbine inhibited copulatory behavior,[180] and the NE precursor dl-threodihydroxyphenylserine increased mount and intromission latencies.[141] Therefore, increased NE activity may increase or decrease sexual behavior. Moderate doses of yohimbine may facilitate sexual behavior by increasing NE release and thereby stimulating α_1 receptors; blocking α_1 receptors with prazosin or methoxamine can impair copulation.[181] Yohimbine also facilitates erections in men with moderate erectile dysfunction, with greater success in men with less severe dysfunction and higher levels of T.[182]

As the major postganglionic neurotransmitter of the sympathetic nervous system, NE promotes penile detumescence and inhibits penile reflexes. In contrast to its facilitation of copulation, yohimbine inhibits *ex-copula* touch-based erections and seminal emission.[183] However, the α_2 agonist clonidine also inhibits touch-based erections.[179] Because both stimulation and inhibition of α_2 receptors can decrease penile reflexes, it appears that low to moderate levels of NE may facilitate erections, whereas high levels are inhibitory.

Systemically administered drugs affect both central and peripheral sites that control genital reflexes. However, guanethidine, which depletes peripheral noradrenergic nerve terminals without affecting central sites, has been used to separate these influences. A single injection increased the number of anteroflexions ("flips") in restrained supine males; however, treatments over 4–8 weeks decreased touch-based erections and especially seminal emissions.[184] Therefore, there appears to be a facilitative influence of the sympathetic nervous system on erection, as also demonstrated by Giuliano and colleagues,[38] in addition to its major role in seminal emission. The mixed excitatory and inhibitory influences of NE on male sexual behavior may be relevant to human sexual function, as reviewed insightfully by Bancroft & Janssen.[185]

Serotonin

Serotonin (5-hydroxytryptamine, 5-HT) is generally inhibitory to sexual behavior. A common side effect of selective serotonin reuptake inhibitor (SSRI) antidepressants is difficulty achieving orgasm or ejaculation, accompanied sometimes by decreased sexual interest (reviewed in Ref. 186). These inhibitory effects typically increase over the same time course as the antidepressant effects. The physiological mechanisms that mediate these effects are unclear, but they may include increased prolactin secretion, anticholinergic effects, decreased NO production,[186] or decreased penile sensitivity.[187] SSRIs have also been used to treat premature ejaculation (reviewed in Ref. 3), although unwanted side effects may include anorgasmia and decreased sexual interest.[188]

Chronic administration of the SSRI fluoxetine to rats has also resulted in decreased sexual motivation and

ejaculation (reviewed in Ref. 3). Injections of the neuropeptide oxytocin (see below) can reverse fluoxetine's inhibition of ejaculation but not of sexual motivation, measured as level changes in a bilevel apparatus, in which the male climbs from one level to a higher one, or descends back to the lower level, in search of a female.[189] Therefore, one possible mechanism for fluoxetine's inhibition of ejaculation may be a decrease in oxytocin in some area. In hamsters, too, a 5-HT reuptake inhibitor, clomipramine, administered for 14 days in sugar water, decreased the number of ejaculations.[190] One mechanism of the inhibition of ejaculation may be a decreased pressure response of the seminal vesicle to splanchnic nerve stimulation.[191] Ejaculation was not inhibited in most studies of acute, as opposed to chronic, administration of fluoxetine.[189,192] However, in one study acute injections slowed copulation, an effect that was reversed by amantadine, an NE releaser, suggesting an interaction between 5-HT and NE influences.[193] Acute injections of fluoxetine inhibited one measure of sexual motivation (level changing in search of a female) but not time spent near a receptive female.[194] Injections of the 5-HT precursor, 5-hydroxytryptophan, also increased the latencies to intromit and ejaculate and increased the intromissions preceding ejaculation.[195] Similarly, administration of 5-HT intrathecally (around the spinal cord) abolished the urethrogentital reflex, which was restored by systemic injections of methysergide, a 5-HT antagonist.[196]

Copulation has been facilitated by drugs that deplete 5-HT and by lesions of the medial, but not the dorsal, raphe nucleus (reviewed in Ref. 3), a major source of 5-HT in the brain. Facilitative effects are found most often in animals that were originally noncopulators, in sexually naive males, or in castrates maintained on suboptimal T replacement (reviewed in Ref. 3). Similarly, 5-HT depletion resulting from lesions of the median and pontine raphe nuclei has increased intense touch-based penile erections (cups) and anteroflexions,[197] and neurotoxic lesions of 5-HT terminals in the brain and spinal cord have disinhibited the UG reflex.[198] Inhibition of 5-HT synthesis by p-chlorophenylalanine (pCPA) decreased the latency to the first touch-based erection, but also decreased the numbers of erections.[199] pCPA-treated males were more likely to have NCE in the presence of a female, but not when tested alone.[199] Thus, 5-HT inhibits erections in response to a female, and has mixed, but mostly inhibitory effects on touch-based erections.

In contrast to 5-HT's generally inhibitory effects on sexual behavior, stimulation of one receptor subtype, the 5-HT_{1A} receptor, facilitates ejaculation. The classic 5-HT_{1A} agonist 8-hydroxy-2-(di-*n*-propylamino)tetralin (8-OH-DPAT) has decreased both the time and number of intromissions preceding ejaculation, with some rats ejaculating on their first intromission (reviewed in Ref. 3). Flesinoxan, another 5-HT_{1A} agonist, has also facilitated ejaculation, although no animals ejaculated on their first intromission.[200] Because the effects of 8-OH-DPAT are opposite those of 5-HT itself, and because some 5-HT_{1A} receptors are autoreceptors on serotonergic somas and dendrites, it was initially thought that 8-OH-DPAT facilitated sexual behavior by inhibiting 5-HT release. However, lesions of serotonergic nuclei did not alter the effects of 8-OH-DPAT, suggesting that postsynaptic receptors mediated its effects.[201] In addition, microinjections of the drug into terminal fields (MPOA and nucleus accumbens), where all 5-HT_{1A} receptors are postsynaptic, also facilitated sexual behavior.[202,203] The effects of 8-OH-DPAT are dependent on normal levels of T and on sexual experience. In castrates with subnormal T replacement, 8-OH-DPAT did not facilitate copulation, and in those with threshold T levels, only sexually experienced males copulated after 8-OH-DPAT administration.[204] Males with high levels of T showed a strong effect of the drug.

A likely mechanism of 8-OH-DPAT's effects is an increase in noradrenergic activity in some brain area(s). 8-OH-DPAT, the α_2-adrenergic receptor antagonist yohimbine, and the opioid antagonist naloxone all increased the percentage of sexually satiated males that copulated on the following day.[175,176] Furthermore, neurotoxic lesions of noradrenergic neurons blocked the facilitation by 8-OH-DPAT and naloxone in satiated males, but not that of yohimbine.[176] Similar lesions also decreased the effects of 8-OH-DPAT in non-exhausted males.[171]

The most common effect of 8-OH-DPAT is facilitation of ejaculation, which is mediated in part by the sympathetic nervous system. In agreement with a prosympathetic, anti-parasympathetic influence, 8-OH-DPAT inhibited touch-based erections, cups, and anteroflexions in male rats, in addition to decreasing the time and number of intromissions preceding ejaculation.[205] A moderate dose of 8-OH-DPAT also decreased NCE[206] and facilitated ejaculation in monkeys, although a high dose delayed ejaculation.[207] Thus, stimulation of 5-HT_{1A} receptors appears to shift autonomic balance to favor ejaculation, in addition to promoting copulation in sexually inactive males. However, the effects of 8-OH-DPAT show some species specificity. Low doses had no effect in male ferrets, and the same doses that facilitated ejaculation in male rats inhibited copulation in ferrets.[208]

Stimulation of other 5-HT receptor subtypes results in generally inhibitory effects on copulation, as expected from the inhibitory effects of 5-HT itself. In rats the 5-HT_{1B} agonist anpirtoline inhibited ejaculation; its effects were blocked by two selective 5-HT_{1B} antagonists.[209] Co-administration of an SSRI (citalopram) and a 5-HT_{1A} antagonist lengthened ejaculation latency, and that effect was blocked by a 5-HT_{1B} antagonist.[210]

A 5-HT_{1B} antagonist also blocked the increased ejaculation latency resulting from administration of the 5-HT precursor 5-hydroxytryptophan (plus a peripheral decarboxylase inhibitor to restrict the increase in 5-HT to the CNS).[211] 5-HT_{1B} knockout mice were less debilitated by several serotonergic drugs than were wild-type mice, again suggesting an inhibitory effect of the 5-HT_{1B} receptor[212] Consistent with a facilitative effect of 5-HT_{1A} receptors on ejaculation, a 5-HT_{1A} antagonist, co-administered with the SSRI, produced a further lengthening of ejaculation latency. Therefore, 5-HT_{1A} and 5-HT_{1B} receptors have opposite effects on ejaculation, with 5-HT_{1A} receptors facilitating ejaculation and 5-HT_{1B} receptors inhibiting it.

In contrast to the opposing effects of 5-HT_{1A} and 5-HT_{1B} receptors in rats, two studies of mice reported inhibitory effects of both the 5-HT_{1A} agonist 8-OH-DPAT and two 5-HT_{1B} agonists. The 5-HT_{1A} agonist 8-OH-DPAT decreased both the time spent near a receptive female[213] and copulatory performance.[212] The 5-HT_{1B} agonist CGS-12066A also decreased time spent near a receptive female,[213] and the 5-HT_{1B} agonist TFMPP inhibited the execution of copulation. On the other hand, 5-HT_{1B} knockout mice required more stimulation to achieve ejaculation, but were less sensitive to the inhibitory effects of 5-hydroxytryptophan, the 5-HT precursor.[212] The authors suggested that compensatory mechanisms may have rendered the knockout mice less sensitive to the inhibitory effects of high levels of 5-HT.

Stimulation of 5-HT_{2C} receptors may have effects opposite those of 5-HT_{1A} agonists: facilitation of erection and inhibition of ejaculation. The 5-$HT_{2C/1D}$ agonist mCPP increased the number of male monkeys that had drug-induced and NCE, but decreased the number of males that initiated copulation and achieved ejaculation.[206 a] mCPP has also increased firing of the cavernous nerves and increased intracavernous pressure in anesthetized rats[214] and resulted in drug-induced erections in awake rats.[215] A more selective 5-HT_{2C} agonist (RO60-0175) also increased erections in awake rats.[216] Therefore, 5-HT_{1A} receptors appear to promote sympathetically mediated ejaculation, whereas 5-HT_{2C} receptors facilitate parasympathetic effects on erection, but may inhibit ejaculation.

A relatively nonselective 5-HT_2 agonist, DOI, has inhibited copulation, and a 5-HT_2 antagonist facilitated copulation (reviewed in Ref. 3). To summarize, 5-HT_{1B}, 5-HT_{2C}, and other 5-HT_2 agonists inhibit ejaculation and may impair copulation, although 5-HT_{2C} agonists may also promote erection. The 5-HT_{1A} agonists, on the other hand, facilitate ejaculation and, in otherwise inactive males, stimulate copulation.

Acetylcholine

Acetylcholine (ACh) is produced from choline and acetyl coenzyme A by choline acetyltransferase. Eight major groups of cholinergic cell bodies (Ch 1–8) lie in the basal forebrain and brainstem. ACh is also the neurotransmitter for peripheral motor nerves, preganglionic autonomic neurons, and postganglionic parasympathetic neurons. There are five types of muscarinic receptors, coupled to either $G_{q/11}$ or $G_{I/O}$ G-proteins. Their effects may be either excitatory or inhibitory, depending on the tissue.[217] Nicotinic receptors have been divided into nine subtypes and are excitatory, acting on sodium channels.[217]

Increasing levels of ACh by slowing its degradation (using the acetylcholinesterase antagonist physostigmine) or administration of the muscarinic agonist pilocarpine increased the number of ejaculations; these effects were blocked by the muscarinic antagonist atropine.[156] Pilocarpine also induced erections in a neutral chamber.[218] The muscarinic agonist oxotremorine also facilitated copulation in both experienced and naive castrates with T replacement, but not in males without T.[219] Therefore, systemic administration of muscarinic drugs appears to facilitate copulation and *ex-copula* erections. However, because systemically administered cholinergic drugs affect striated muscles and parasympathetic targets, it is difficult to discern whether their effects are centrally or peripherally mediated.

Gamma-Amino Butyric Acid

Gamma-amino butyric acid (GABA) is the most common inhibitory neurotransmitter in the brain. Systemic injections of both $GABA_A$[220] and $GABA_B$[221] agonists impaired copulation without effects on motor activity. Similar effects of the $GABA_A$ agonist were seen in rabbits.[222] However, a different $GABA_A$ agonist, as well as an inhibitor of GABA synthesis and an inhibitor of GABA catabolism, all impaired social and drinking behaviors, as well as sexual behavior, suggesting that these treatments had nonspecific effects on motivated behaviors.[223] Furthermore, some inhibitory effects on copulation may have been mediated by decreased EMG activity in ischiocavernosus muscles during thrusting, a peripheral, rather than central effect.[224]

Opioids

Opiates and endogenous opioids have mixed, dose-dependent effects on male sexual behavior (reviewed in Ref. 3). The suggestion that opioids and opiates

[a] mCPP was classified as a 5-$HT_{1C/1D}$ agonist when these studies were conducted. More recently the 5-HT_{1C} receptor has been renamed the 5-HT_{2C} receptor in Ref. 709. We have changed the originally published nomenclature to be consistent with the current classification.

generally inhibit sexual behavior is based in part on the facilitative effects of antagonists, especially in sexually sluggish males,[225] sexually satiated males,[176] or sexually naive males tested in a novel environment.[112] Male quail also showed facilitation of copulatory behaviors, but not anticipatory behaviors, by centrally administered naloxone.[226] However, systemic administration of the opiate antagonists naloxone and naltrexone have also had inhibitory effects, including increased postejaculatory intervals[227,228] and decreased ability of mild tail pinch to stimulate copulation in castrates with subnormal T replacement.[229]

A second line of evidence for inhibitory effects of opiates is that morphine or the agonists U-50,488H or bremazocine inhibited sexual behaviors in active copulators.[230,231] However, inhibitory effects of the opioid antagonist naloxone on active copulators[230] suggests that at least a minimal amount of activity at opioid receptors can facilitate copulation, but that an excess may impair sexual behavior. Some inhibitory effects of systemically administered morphine may result from inhibition of genital reflexes. All doses of morphine suppressed seminal emissions and touch-based erections.[232] However, naloxone also inhibited touch-based erections in those experiments, again suggesting that some opioid activity can facilitate sexual function. Furthermore, naloxone also inhibited anticipatory level-changing in a bilevel apparatus,[228,233] suggesting that some endogenous opioid activity facilitates sexual motivation. Opioid facilitation may result from disinhibition of the mesolimbic DA system, as there are receptors on inhibitory GABAergic neurons in the VTA. Increasing levels of enkephalins, by intraventricular administration of an enkephalinase inhibitor, decreased both the time and number of intromissions preceding ejaculation, but also increased mount and intromission latencies.[234] Thus, low levels of opioid activity may facilitate genital reflexes and sexual motivation; however, excess activity can interfere with sexual behavior, and some measures of behavior may be more sensitive than others to such interference. Enkephalins were increased in tissue from several brain areas following copulation either to one ejaculation or to exhaustion, with no significant difference between the two groups.[234a] These authors also reported that sexually inactive males had generally higher enkephalin content than did sexually active males, again supporting an inhibitory effect of relatively high opioid levels.

Oxytocin

Oxytocin is a nonapeptide that is synthesized in the paraventricular (PVN) and supraoptic nuclei of the hypothalamus and released both from terminals in the posterior pituitary and into the CNS. Circulating oxytocin from the PVN and posterior pituitary stimulates smooth muscles, thereby facilitating seminal emission and, in humans, contributing to orgasm. In female mammals it stimulates milk let-down and parturition (see Chapter 13). Plasma oxytocin was increased by copulation in naive, but not sexually experienced, male rats.[235] In the naive males, plasma oxytocin was correlated with intensity of copulation. Systemically administered oxytocin also restored copulation in males whose copulatory behavior had been impaired by chronic fluoxetine.[189] Facilitative effects of low doses of oxytocin have been observed in rats[236] and dominant squirrel monkeys,[237] but high doses have inhibited copulation in prairie voles[238] and rats.[239] A facilitative effect of endogenous oxytocin on copulation was supported by the dose-related inhibitory effects of an oxytocin antagonist, administered ICV.[240]

Intraventricular injections of oxytocin also increased spontaneous erections, and this increase was blocked by an oxytocin antagonist or an anticholinergic drug (atropine), but not by a DA antagonist.[241] The oxytocin antagonist also blocked erections elicited by the DA agonist apomorphine,[241] suggesting that DA is "upstream" of oxytocin in the control of drug-induced erections; ACh may, in turn, be "downstream" from oxytocin. Finally, an oxytocin antagonist, administered ICV, inhibited NCE, suggesting a role for oxytocin in the control of erections elicited by normal physiological stimuli, as well as drug-induced erections (reviewed in Ref. 242).

Nitric Oxide

NO is a soluble gas produced in the conversion of L-arginine to citrulline by NOS. NO contributes both peripherally and centrally to vasodilation, erection, and other parasympathetic functions. Both neuronal (nNOS) and endothelial (eNOS) isoforms of NOS are present in the corpus cavernosum and dorsal penile nerve and are upregulated by T or DHT.[243–247] Castration decreased, and exogenous T restored, erectile responses elicited by cavernous nerve stimulation, systemically administered apomorphine, and/or injection of the nonspecific phosphodiesterase inhibitor papaverine into the penis (reviewed in Ref. 248). Phosphodiesterases inactivate cGMP, the most common second messenger of NO, as well as cAMP; therefore, their inhibition would prolong NO's effects. Indeed, sildenafil, vardenafil, tadalafil, and other drugs used to treat erectile dysfunction inhibit PDE5, which is more selective for cGMP (reviewed in Ref. 3). Sildenafil did not affect erections in healthy men but did decrease the interval between ejaculation and a subsequent erection.[249] Therefore, sildenafil can increase penile vasodilation in men with erectile dysfunction and can facilitate postejaculatory erections in healthy men, but not pre-ejaculatory erections. In rats, too, sildenafil increased the occurrence of

penile erections, as well as genital grooming and homosexual mounting,[161] and vardenafil increased intracavernous pressure in anesthetized rats to a greater extent than did sildenafil.[250]

Although castration decreased NOS in the penis and epididymis, it actually increased NOS in the seminal vesicles and lateral prostate; exogenous T in castrates decreased NOS to normal levels in the latter structures.[251] Furthermore, systemic administration of L-arginine impaired fertility in male rats, without inhibiting sexual behavior.[252] Thus, excessive NO in some parts of the reproductive tract may impair aspects of ejaculation or sperm motility.

Systemically administered NOS inhibitors have decreased the numbers of sexually experienced[253,254] and inexperienced[255] males that could ejaculate, increased their mounts, and decreased their intromissions. NOS inhibitors have also decreased the number of NCE[256] and touch-based erections,[254] but increased the number of seminal emissions,[254] consistent with a facilitative role for NO on parasympathetic function and inhibition of sympathetic activity. Sexual motivation, measured as percent choice of a female in an X-maze[254] or as increased mount latency,[253] was not affected by NOS inhibitors, although another study reported a decrease in motivation, measured as decreased precoital activity and decreased numbers of animals that mounted.[257] In the latter study, the numbers of spermatozoa were normal, but the number of pregnancies and the number of implanted embryos per pregnancy were lower than in controls. One explanation for the impaired fertility may be the requirement for NO to be injected by the sperm into the egg to elicit release of internal stores of calcium, which in turn triggers cell division.[258] In nNOS "knockout" mice, normal penile function was found, as a result of increased production of eNOS.[259] Indeed, nNOS−/− mice required fewer mounts and intromissions to ejaculate,[260] again suggestive of NO's normal role in activating parasympathetic and inhibiting sympathetic function. Thus, NO may help to prevent premature ejaculation.

There have been inconsistent results of systemically administered NO donors or precursor. L-arginine increased the number of naive male rats that copulated and improved the performance of sexually experienced males.[255] Production of NO in the corpus cavernosum was also increased by L-arginine.[54] However, the NO donor sodium nitroprusside increased intracavernosal pressure only in untreated castrates, not in T-replaced males.[246] Also, there were only marginal facilitative effects of L-arginine on touch-based erections,[254] and no effects on intracavernosal pressure elicited by electrical stimulation in castrates, with or without T replacement.[246] Therefore, NOS activity in many gonadally intact males may be sufficient for normal copulation and may not benefit from excess precursor or NO donors.

Gonadotropin-Releasing Hormone

Gonadotropin-releasing hormone (GnRH), a decapeptide, is produced by neurons in the mediobasal hypothalamus, the lamina terminalis, and the MPOA.[261] After release in the median eminence, GnRH is carried into the hypophyseal portal system to the anterior pituitary, where it stimulates gonadotropin release. It also acts as a neuromodulator in several brain areas, including the MPOA and amygdala.[261,262] It is released in response to female pheromones in mice and hamsters (reviewed in Ref. 263).

Administration of GnRH has resulted in inconsistent effects. Moss and his colleagues reported that GnRH, administered to castrated male rats maintained on a low dose of T, decreased their intromission and ejaculation latencies; gonadally intact males were not affected.[264] Myers and Baum,[265] however, reported facilitative effects only in intact males, not in T-replaced castrates; indeed, GnRH lengthened the postejaculatory interval (PEI) of quiescence in T-treated castrates. Lengthened PEI was also observed in old rhesus monkeys.[266] GnRH had no effects in male rats in another study,[267] but increased the mount rate in male rats with anesthetized genitalia in another experiment[268] and decreased intromission and ejaculation latencies in gray-tailed voles.[269] GnRH administered ICV also promoted the mating behavior of sexually naive male hamsters whose vomeronasal organs had been removed (VNX).[270] Previous sexual experience is usually necessary for VNX male hamsters to copulate normally; thus, administration of GnRH compensated for the lack of sexual experience. Similarly administered GnRH increased Fos immunoreactivity (IR) in the MPOA of male hamsters in response to female pheromones; it also increased the MPOA Fos response in sexually experienced VNX hamsters.[271] Sexually naive VNX males showed enhanced Fos-IR in the medial amygdala (Me), but not the MPOA, in response to pheromone plus ICV GnRH. In hypogonadal men with decreased LH release, GnRH improved sexual function.[272] The authors suggested that the improvement was not due to increased androgen levels, because free T was well below the normal adult range when the improvement in function began. However, GnRH resulted in little[273,274] or no[275] improvement in other men with erectile dysfunction.

Chronic administration of a synthetic GnRH agonist ([6-*D*-(2-napthyl)-alanine]GnRH) disrupted copulation in gonadally intact male rats and also decreased levels of T.[276] The likely explanation for this inhibitory effect is that endogenous GnRH is released in a pulsatile fashion, and continuous high doses of GnRH inhibit LH release and gonadal function.[277,278] Thus, GnRH agonists have

been suggested as antifertility drugs.[279] Apparently, they also inhibit sexual behavior, perhaps as a result of the decrease in T.

Alpha-Melanocyte Stimulating Hormone and Related Peptides

Alpha-melanocyte stimulating hormone (α-MSH) is secreted into the systemic circulation from the intermediate lobe of the pituitary; it and related melanocortin peptides, derived from the precursor proopiomelanocortin (POMC), are also expressed in numerous CNS and peripheral structures. Besides α-MSH, these peptides include adrenocorticotropic hormone (ACTH) and β-lipotropin, released from the anterior pituitary; the opioid endorphin; and other variants formed by posttranslational processing. They bind to a family of five G-protein-coupled receptors (MC-1 to MC-5), all of which activate adenylyl cyclase (see Ref. 280 for an excellent review).

Alpha-MSH and ACTH, administered ICV, have been shown to increase erections in dogs, cats, rats, mice, and rabbits as early as the 1960s (reviewed in Ref. 280). Other commonly reported effects have been decreases in the numbers of mounts and intromissions preceding ejaculation and in latency to ejaculate. Both α-MSH and ACTH elicited penile erections, and stretching and yawning in rats, when injected into the third ventricle; the stretching and yawning were blocked by an MC-4 receptor antagonist, but penile erection was not,[281] suggesting that a different MC receptor was important for facilitation of erection (but see below). However, ACTH-induced erections were inhibited by either ICV or systemic injections of the NOS anatagonist L-NAME, suggesting that the effects of ICV ACTH were mediated by increased central production of NO.[282]

There has been a resurgence of interest in these peptides with the production of several synthetic peptides that are selective for subtypes of melanocortin (MC) receptors. Two of these have been reported to increase erections and sexual interest in men (melanotan-II (MT-II)[283–286] and PT-141[287]), with nausea, stretching, yawning, and decreased appetite reported as side effects of MT-II. MT-II is a selective melanocortin-4 (MC-4) agonist that has also increased erections in rats, especially after intrathecal injections, although ICV and IV injections were also effective.[288] The MC-3/MC-4 receptor antagonist SHU 9119 blocked the effects of MT-II, confirming its receptor specificity. Intracavernosal injections had no effect, suggesting that MC receptors in the spinal cord and brain mediate the pro-erectile activity. In rabbits, too, IV injections of MT-II increased cavernosal pressure, and again isolated cavernosal tissue was unresponsive.[289] Both SHU 9119 and the NOS inhibitor L-NAME abolished the effects of MT-II, indicating that stimulation of central MC-3/MC-4 receptors achieves the proerectile effects by releasing NO. L-NAME also blocked the proerectile effects of ICV administration of ACTH[282] and of α-MSH and oxytocin[290] in rats. Furthermore, MT-II enhanced copulatory behavior and augmented erections elicited by cavernous nerve stimulation in wild-type, but not MC-4 receptor knockout, mice.[284] In addition, MC-4 receptors were expressed in nerve fibers and mechanoreceptors in both rat and human penis, but not in cavernosal smooth muscle; expression was also observed in rat spinal cord, brainstem, hypothalamus, and pelvic gangion.[284] Intranasal administration of the MC-4 agonist PT-141 also elicited drug-induced erections in rats, as well as in men with erectile dysfunction.[287] Finally, both systemic and ICV administration of a different, highly selective MC-4 receptor agonist, THIQ, increased intracavernous pressure and elicited reflexive erections in rats; these effects were blocked by both the endogenous nonselective antagonist, agouti-related protein, and a synthetic MC-4-preferring antagonist, MBP10.[291] These effects were also attenuated by an oxytocin antagonist.

In summary, endogenous α-MSH and ACTH, as well as synthetic MC-3 and MC-4 receptor agonists, may promote erection by acting synergistically at nerve endings in the penis, in the lower spinal cord, and in several areas of the brain. Some of these effects are mediated by NO, and perhaps also by oxytocin.

Injection of prostaglandin E_2 (PGE_2) into the fourth ventricle of male rats decreased the postejaculatory interval (see Ref. 292; reviewed in Ref. 293). This treatment also increased basal forebrain temperature, measured in the MPOA. As noted above, temperature in this area increases during copulation and decreases during the postejaculatory interval. It is not clear whether PGE_2 influences copulation directly, or through the increase in brain temperature. It is interesting that manipulations of PGE_2 during early development influenced masculinization of rats.[294]

Other Peptides

Vasoactive Intestinal Peptide

Vasoactive intestinal peptide (VIP) contributes to penile erection through stimulation of adenylyl cyclase in the corpus cavernosum, thereby relaxing smooth muscle (reviewed in Ref. 52). Antagonists to VIP and ACh additively reduced erection elicited by pelvic nerve stimulation; however, the additive facilitative effects of VIP and ACh did not elicit a full erectile response.[295] Thus, while both VIP and ACh contribute to erection, they do not appear to be principal neurotransmitters for that effect. VIP may facilitate copulation, apart from its effects on

erection. Systemic injection of VIP to castrated male rats, maintained on suboptimal T replacement, reduced intromission latency and interintromission interval; these effects were blocked by a VIP antagonist administered with VIP.[296]

Galanin and Galanin-Like Peptide

Better known for its role in stimulating feeding, galanin, microinjected ICV, decreased mounts and intromissions in male rats.[297] A galanin antagonist (galantide) increased those behaviors.[298] In contrast to these apparently inhibitory effects of galanin, microinjection of the peptide into the MPOA of castrated, T-replaced rats facilitated their copulatory behavior,[299] and ICV injections of a galanin antagonist in ferrets decreased their time spent near a receptive female, although the injections did not affect copulation.[300] It is not clear whether these contradictory findings reflect site, species, dosage, or other differences. Galanin-like peptide (GALP) shares partial sequence homology with galanin but is derived from a different gene. ICV administration of GALP facilitated several measures of male sexual behavior in male rats, whereas similar administration of galanin inhibited those same measures.[301] GALP is known to stimulate GnRH secretion; however, GALP increased sexual behavior even in castrated males, suggesting that effects on testosterone secretion did not mediate the behavioral effects.

Neuropeptide Y

Neuropeptide Y (NPY) is widely distributed throughout the brain and is often co-localized with NE.[302] NPY, administered ICV, stimulated feeding, but inhibited copulation in male rats.[303,304] Consistent with an inhibitory effect of NPY, ICV administration of an NPY antagonist facilitated copulation.[305] However, systemically administered NPY failed to affect reflexive erections.[303]

Prolactin

A large number of studies in the 1980s revealed inhibitory effects of chronic prolactinemia, induced by implanting excess pituitary glands or prolactin-secreting tumors, by injecting drugs that stimulate PRL release, or by direct injection of PRL (reviewed in Ref. 3). The most commonly reported effects were increased mount and ejaculation latencies and general slowing of copulation. However, there were some contradictory effects, and the mechanism by which chronically elevated prolactin may impair sexual behavior is not clear. A review of hormonally induced dysfunction in men found that severe hyperprolactinemia, often caused by a pituitary tumor, resulted in low T, erectile dysfunction, and decreased desire, likely due to suppression of gonadotropin secretion.[306]

Corticotropin-Releasing Hormone

Injections of corticotropin-releasing hormone (CRH) into the third ventricle increased mount, intromission, and ejaculation latencies and increased the numbers of mounts and intromissions preceding ejaculation.[307] These inhibitory effects of CRH were attenuated by co-administration of the opioid antagonist naloxone. Furthermore, CRH can inhibit GnRH release, possibly acting through endogenous opioids.[308] The promotion of freezing and flight behaviors by CRH, in addition to its inhibition of sexual behavior, suggests that it organizes a constellation of behaviors appropriate to stressful or threatening situations.

Cholecystokinin

There have been mixed reports of cholecystokinin (CCK) effects on male sexual behavior. One study found that systemic administration of sulfated CCK decreased the numbers of intromissions and the time preceding ejaculation; these effects were reversed by the CCK antagonist proglumide.[309] However, other studies found no effect of systemic[310,311] or ICV[310,312] administration of CCK. On the other hand, there are at least two subtypes of CCK receptor,[313] which may have opposite effects. Thus, the failure to find significant effects of CCK may be due to opposing excitatory and inhibitory effects (see the section Mesocorticolimbic DA Tract later in the chapter).

Angiotensin II

Angiotensin II, microinjected into the third ventricle, increased intromission latency, the number of intromissions preceding ejaculation, and postejaculatory interval.[314] The most effective dose also increased drinking during the test. A more recent study confirmed the inhibitory effects, which were blocked by an angiotensin I receptor antagonist administered in the drinking water.[315] However, it is not clear whether the sexual impairment was a direct effect or a result of thirst.

BRAIN AREAS IMPLICATED IN CONTROL OF MALE SEXUAL BEHAVIOR

Sensory Systems

Olfactory Bulbs

Chemosensory cues contribute to male sexual behavior across a wide variety of species, from rodents to primates. However, the relative importance of chemosensory stimuli, compared with other sensory cues, differs widely among species. Chemosensory cues are especially important for mating in rodents and other nocturnal species that mate in underground burrows.

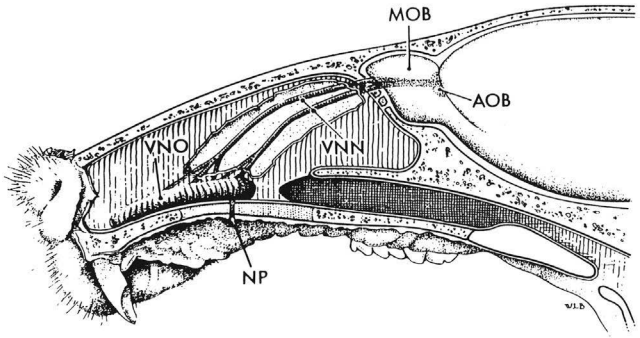

FIGURE 49.8 Relation between the vomeronasal organ and the olfactory bulbs of the Syrian hamster. The vomeronasal organ (VNO) projects to the accessory olfactory bulb (AOB) via the vomeronasal nerve (VNN). The vomeronasal nerve travels medial to the main olfactory bulb on the way to the accessory olfactory bulb. Olfactory information is presumed to reach the vomeronasal organ through the nasopalatine duct. In contrast, the main olfactory bulb receives innervation from the olfactory nerve originating from receptors in the nasal mucosa (pathway not shown). AOB, accessory olfactory bulb; MOB, main olfactory bulb; NP, nasopalatine duct; VNN, vomeronasal nerve; VNO, vomeronasal organ. *Source: We appreciate the generosity of Sarah W. Newman for providing this illustration adapted from one previously published in Ref. 316.*

The olfactory system includes two functionally and anatomically distinct components (see Figure 49.8). The main olfactory bulbs (MOBs) receive information about volatile odors from receptors in the nasal epithelium, which project through the cribriform plate to the MOBs. The accessory olfactory bulbs (AOBs) receive both volatile and nonvolatile species-specific information from receptors in the vomeronasal organ (VNO), which consists of bilateral tunnels along the base of the nasal cavity.[317] The main and accessory olfactory bulbs have parallel but overlapping projections to amygdaloid nuclei through the lateral olfactory tract; bilateral transection of that tract blocked mating, presumably by interrupting olfactory bulb efferents to the amygdala.[318]

Stimuli transduced in the VNO are especially important for social behavior, including mating, aggression, affiliation, and maternal behavior. However, in species with relatively poorly developed olfactory systems, including humans, the VNO and AOB are greatly diminished, and some have argued that they may be nonfunctional (reviewed in Ref. 319).

EFFECTS OF LESIONS

Damage to the olfactory system impairs male sexual behavior of numerous species (reviewed in Ref. 3). In hamsters, bilateral bulbectomies abolished sexual behavior and the mating-induced increase in extracellular MPOA dopamine, which was seen in hamsters with sham lesions and also contralateral to unilateral lesions.[320] Sexually naive hamsters showed a more pronounced reduction in sexual behavior after vomeronasal organ removal, compared to experienced males.[321] Destruction of receptors in the nasal epithelium of hamsters, together with vomeronasal nerve cuts or deafferentation of the vomeronasal pump, which normally sucks mucus with dissolved chemosensory stimuli into the VNO, also severely disrupted copulation.[322] There was minimal disruption of sexual activity after deafferentation of the main olfactory bulb by irrigation of the nasal cavity with zinc sulfate to destroy olfactory receptor neurons (reviewed in Ref. 3). However, combined deafferentation of the main and accessory olfactory systems eliminated mating, similar to the effects of bilateral olfactory bulbectomy.[316]

In rats, olfactory bulbectomy reduced the percentage of males that copulated to ejaculation and delayed the onset of copulation in those males that did mate (reviewed in Ref. 3). However, preference for a receptive female over a nonreceptive female was unaffected.[323] In rats, olfactory bulbectomy also eliminated NCE elicited by female rat urine.[16] As in male hamsters, sexually naive male rats may be more sensitive to anosmia,[324] although severe copulatory dysfunction has also been reported following olfactory bulbectomy in sexually experienced males.[325,326] However, increasing general arousal could activate copulation in male rats after olfactory bulbectomy. Mildly painful flank shock or tail pinch stimulated copulation in olfactory bulbectomized male rats, but these anosmic animals still exhibited longer intromission and ejaculation latencies compared with controls, and the effects of stimulation were transient.[325,326] Interestingly, NCE appear to be stimulated by the main olfactory system, since lesions of the vomeronasal organ had no effect, but zinc sulfate lesions of the olfactory epithelium significantly decreased NCE.[16] Also, deafferentation of both the MOB and AOB severely decreased NCE and inhibited mating.[327]

Chemosensory cues are also important for mating in male mice. Olfactory bulbectomy eliminated mounting in essentially all male mice, although zinc sulfate destruction of receptors in the olfactory epithelium did not interrupt mating (reviewed in Ref. 3). Although early studies reported that VNO lesions sharply decreased the proportion of male mice that intromitted and ejaculated,[328] recent studies have found no significant reduction in mating or in the ability to discriminate estrous from nonestrous urine.[329] Male mice with null mutations of the transient receptor potential 2 (TRP2) cation channel to disrupt VNO receptors showed high levels of mounting of male intruders as well as normal sexual behavior with females.[330] However, bilateral lesions of the VNO or AOB did decrease the amount of time that male mice spent investigating the urinary volatiles from estrous females.[329,331] Based on these recent results, it appears that the vomeronasal system in mice has an important,

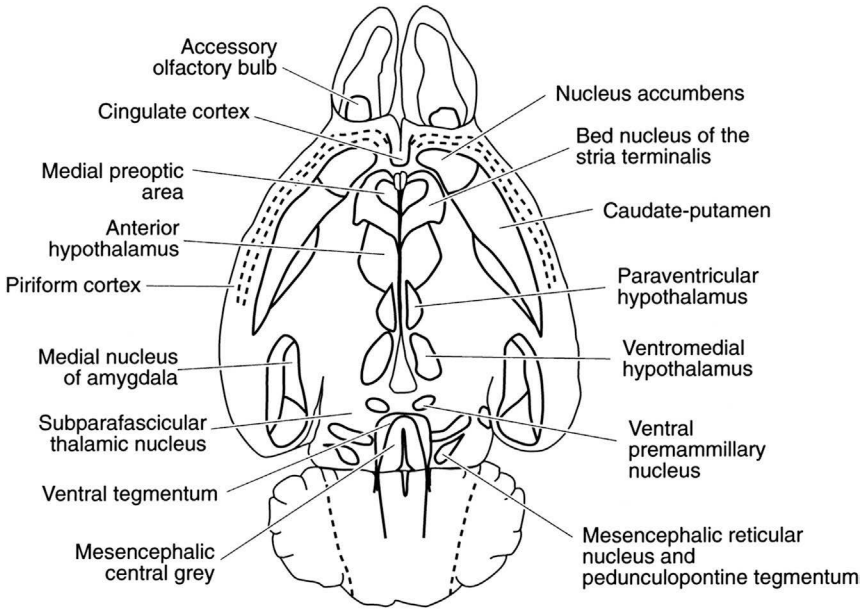

FIGURE 49.9 Regions within a horizontal section of rat brain in which Fos induction is observed after sexual stimulation in females and males. With some notable exceptions, Fos has been observed in similar regions in hamsters and gerbils. *Source: Figure is reprinted from Ref. 332, with permission.*

but not critical, role in copulation. Destruction of the main olfactory receptors by zinc sulfate did significantly impair detection of the volatile estrous odors.[331] Thus, only the main olfactory system is necessary for male mice to detect estrous odors at a distance, but the VNO system contributes to detection in close proximity and to preference for estrous odors.

The role of the olfactory system in male sexual behavior in other species has received less attention. Olfactory bulbectomy produced variable deficits in the behavior of male guinea pigs, and failed to block copulation in male dogs, cats, rhesus monkeys, gerbils, sheep, or ferrets, although naris occlusion blocked heterosexual partner preference in ferrets (reviewed in Ref. 3). In early studies, the effects of olfactory bulbectomy were attributed to the resulting anosmia. However, the olfactory bulbs receive ascending inputs from olfactory-related structures and from nonolfactory subcortical areas, so both olfactory and nonsensory functions of the olfactory bulbs may contribute to reproductive and social behaviors.

ACTIVATION OF *C-FOS* OR OTHER IMMEDIATE–EARLY GENES

Although lesions provide information about brain areas that are critical for behavior, they may fail to identify other areas that contribute to behavioral performance. Activation of immediate-early genes provides a complementary approach to map brain circuits that are activated during behavior (reviewed in Ref. 332; see Figure 49.9). Copulation by male hamsters increased Fos-IR in the AOB and their central projection sites; this increase was also observed in males whose main olfactory system was ablated with zinc sulfate.[333] (See Figure 49.9 for a diagram of the brain areas activated by sexual behavior in male rodents.) Similarly, Fos expression in efferent targets of the MOB was maintained after vomeronasal lesions in sexually experienced male hamsters,[334,335] but in sexually naive males with vomeronasal lesions, odors alone were not able to stimulate Fos-IR.[335] Therefore, pheromonal stimulation of the vomeronasal organ is sufficient for Fos induction in the accessory olfactory bulb and its central targets, but odors transmitted through the main olfactory system may also induce Fos-IR, particularly in males with prior sexual experience. The increase in Fos-IR in the olfactory bulbs of male hamsters was specific to chemosensory stimuli rather than mating, because female odors alone induced Fos-IR (reviewed in Ref. 3). Although T is required for sexual activity, Fos expression in the olfactory bulb was unaffected by castration,[336] suggesting that castration may alter downstream responses to sex-related chemosensory cues, but not the detection of those cues.

As in hamsters, mating or exposure to estrous female bedding stimulates Fos in the AOB and downstream structures in male rats and mice.[337–339] Mating elicits more Fos than does chemosensory stimulation alone[340]; however, NCE in male rats fail to enhance Fos expression.[341] Within the accessory olfactory bulb in male mice, Fos induction by female stimuli is concentrated in the rostral region, and is blocked by removal of the vomeronasal organ.[342,343] This supports the existence of functional heterogeneity in the accessory olfactory system.

Although the accessory olfactory system appears to be more important than the main olfactory system for Fos induction in rodents, male ferrets, which are carnivores,

rely on the main olfactory system.[344] Both estrous female bedding and peppermint odor increased Fos in the main olfactory bulb of castrated male ferrets. However, female pheromones failed to stimulate Fos in the accessory olfactory bulb. In male ferrets, unlike male hamsters, T treatment increased the Fos response to female odors, but not to peppermint. Moreover, the ferret olfactory bulb has ARs. Thus, in this species, T has the potential to increase the responsiveness of olfactory bulb neurons to sex-related chemosensory stimuli.

Somatosensory Systems

Mechanoreceptors in the penis provide somatosensory information to the brain and stimulate sexual arousal. They are more responsive when the penis is erect[345] or near core body temperature, as it is during erection.[346] Somatosensory input from the penis enters the spinal cord mainly via the dorsal nerve of the penis (reviewed in Ref. 347). Ejaculation-specific information from the lumbar spinal cord is relayed to the thalamus; targeted toxin lesions of these cells completely disrupted ejaculation in rats.[43]

Auditory System

Male and female rats produce ultrasonic vocalizations before and during copulation; these vocalizations are believed to facilitate copulation (reviewed in Ref. 348). During mating, both male and female rats produce 50-kHz vocalizations, which are associated with arousal, and males produce a 22-kHz vocalization following ejaculation.[349] Vocalizations are influenced by hormones, as Silastic capsule implants with a high concentration of testosterone reinstated mating-induced vocalization in castrates, but blank implants did not.[90]

Amygdala

There is some controversy as to whether the amygdala should be considered an entity at all, rather than a conglomeration of dissimilar areas related to learning, motivation, and fear (central nucleus and basolateral division) or to chemosensory stimuli and social behavior (corticomedial division) (see Figure 49.10).[351] In rodents, the corticomedial amygdala is a key nodal point for integration of chemosensory, somatosensory, and hormonal stimuli. In particular, the Me relays chemosensory stimuli from the olfactory bulbs to midline nuclei of the preoptic area and hypothalamus.

During mating, the amygdala receives chemosensory, somatosensory, and hormonal stimuli via the main and accessory olfactory bulbs, the thalamic subparafascicular nucleus, and steroid receptors, respectively. Chemosensory information is then transmitted by the projections of mitral and tufted cells in the olfactory bulbs through the lateral olfactory tract, terminating in the medial and cortical amygdaloid nuclei. Efferent projections of the accessory olfactory bulb target the medial and posteromedial nuclei, while the main olfactory bulbs project widely to the anterior and posterolateral cortical nuclei and to olfactory processing areas in ventral allocortex (see Figure 49.11). In addition, the Me receives ascending somatosensory cues from the penis and perineal region relayed through the subparafascicular nucleus. However, projections of the subparafascicular nucleus are not limited to the amygdala; somatosensory cues are conveyed directly to the MPOA, as well.

The medial and posteromedial cortical nuclei have abundant receptors for androgens and estrogens. T promotes male sexual activity, at least in part, through

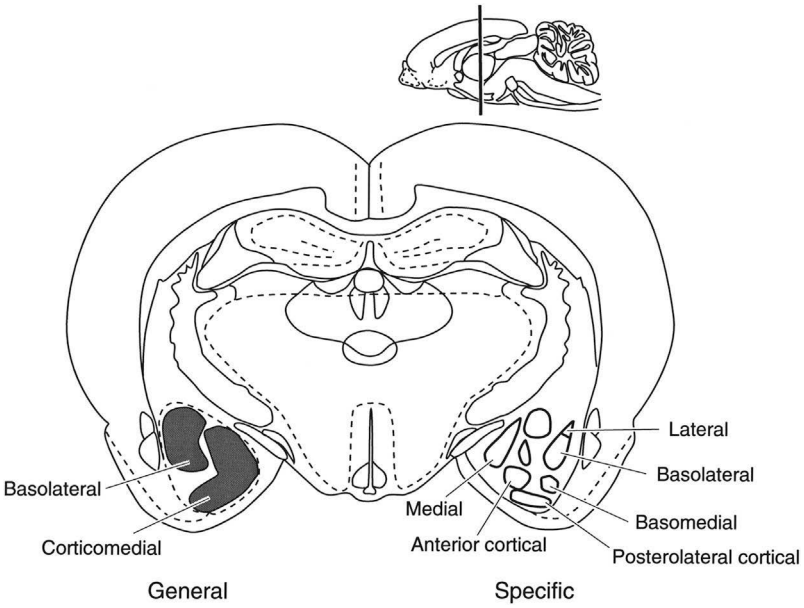

FIGURE 49.10 The amygdala, an almond-shaped structure located in each temporal lobe, seen in a schematic drawing of a coronal section of the rat brain. Two general amygdaloid regions, the basolateral and corticomedial nuclei (left), have been studied extensively. Destruction of the corticomedial nuclei, but not the basolateral nuclei, severely affects male copulatory behavior in rodents. The specific nuclei of the basolateral and corticomedial amygdala are depicted (right). *Figure is reprinted from Ref. 350, with permission.*

binding to amygdaloid ARs or to ERs after local aromatization. However, steroid receptors are also concentrated in midline nuclei of the preoptic area and hypothalamus, including the medial preoptic area (MPOA). Within the Me, ARs and ERs are localized preferentially in the posterior subnucleus, whereas olfactory bulb efferents terminate preferentially in the anterior subnucleus.

Effects of Lesions

The impact of amygdala lesions on male sexual behavior depends on the specific sites within the amygdala. In general, lesions of the central nucleus or the basolateral division (basolateral, basomedial, and lateral nuclei) do not disrupt copulation in male rats or hamsters, although there is some indication that male rats copulate more rapidly following basolateral amygdaloid lesions (reviewed in Ref. 3). The central and basolateral regions of the amygdala have connections with the frontal cortex, brainstem areas for autonomic control, and ventral striatum (see Ref. 351), and are important for conditioned responses during fear and reinforcement. Everitt and co-workers showed that basolateral amygdala lesions abolished an operant task (bar-pressing) for a secondary reinforcer that had been previously paired with access to a receptive female; however, those lesions did not affect copulation (reviewed in Ref. 353). Therefore, the basolateral amygdala may be important for motivational aspects of mating, and for learning appropriate associations, but not for copulatory performance. In support of this conclusion, exposure to sexually conditioned almond odor increased activation of the basolateral amygdala, while exposure to soiled bedding from an estrous female did not.[354]

In contrast, corticomedial amygdala lesions do impair copulation in rats,[355,356] hamsters,[357] and gerbils.[358] These lesions reduced copulatory efficiency, increased mount and ejaculation latencies, increased intromissions preceding ejaculation, increased inter-intromission intervals, and decreased the number of ejaculations before sexual exhaustion. In addition, Me lesions blocked the facilitative effects on copulation of pre-exposure to an estrous female[359] and reduced the number of NCE.[199] Thus, the Me facilitates the response to and assimilation of sexually exciting stimuli.

Through its efferent projections to the MPOA, the Me facilitates appetitive sexual behavior and subsequent

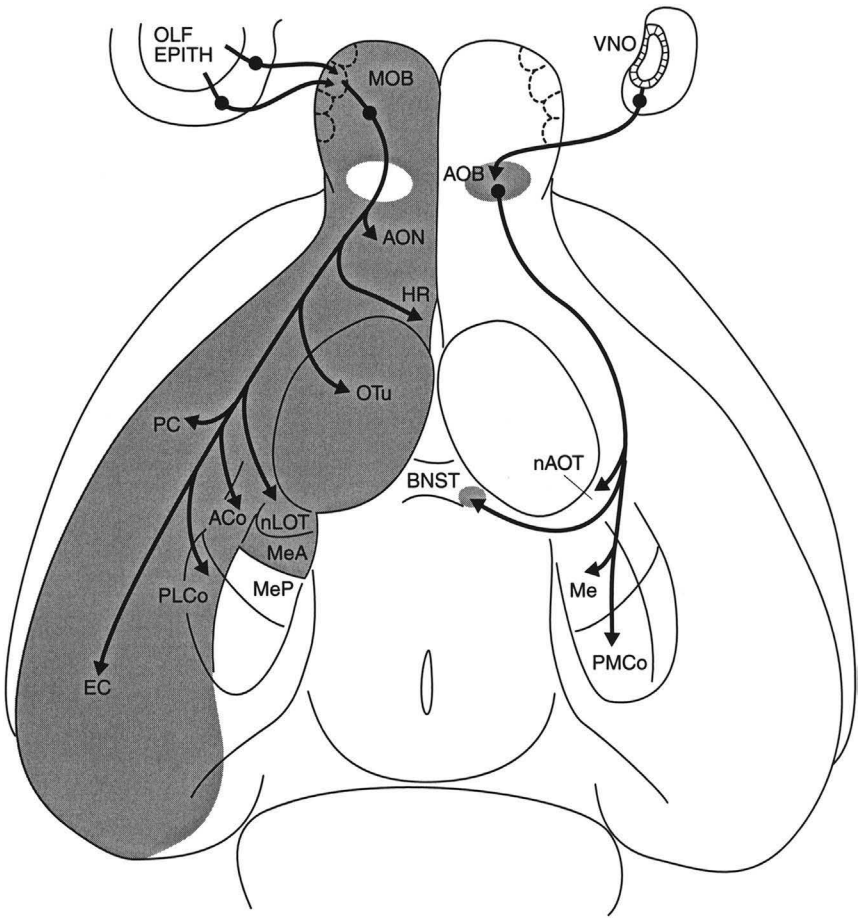

FIGURE 49.11 Diagram of the ventral surface of the hamster brain. Shaded areas indicate brain regions that receive efferent projections of the olfactory system, via the main olfactory bulb (left), and of the vomeronasal system, via the accessory olfactory bulb (right). copulation. Unilateral lesions of the MPOA impaired, but did not eliminate mating in male rats.[360] However, when combined with lesion of the contralateral Me, copulatory behavior was severely disrupted. Similar effects have been reported in gerbils.[358] Likewise, chemical stimulation of the Me increased DA release in the MPOA,[361] and microinjection of the DA agonist apomorphine into the MPOA restored sexual behavior inhibited by Me lesions.[355] As measured by microdialysis, basal DA levels in MPOA were unaffected in males with Me lesions, but there was no DA release in response to a receptive female or during copulation.[355] These observations suggest that the Me is critical for copulatory behavior organized through the MPOA. Because there are no DA-containing neurons in the Me of rats, amygdala efferents apparently synapse, either directly or indirectly, on dopaminergic cell bodies or terminals in the MPOA. Using a somewhat different model for sexual motivation, lesions of the posterior Me abolished NCE and reduced preference for an estrous female in a partner preference test, but had no effect on copulatory behavior.[362] Finally, a subregion of the posterodorsal Me appears to be associated with sexual satiety. Lesions of this area in male hamsters increased the number of ejaculations preceding satiety, and Fos expression correlated with the onset of satiety.[363]

Activation of c-fos *or Other Immediate–Early Genes*

The olfactory system projects to the medial and anterior cortical nuclei of the amygdala (reviewed in Ref. 364). Both chemosensory stimuli from estrous female rats and increasing amounts of copulation elicited increasing amounts of Fos-IR in the Me and in several "downstream" sites that are important for male sexual behavior.[337,339,365] Chemosensory stimuli and copulation also induced increasing Fos-IR patterns in hamsters, gerbils, prairie voles, and musk shrews (reviewed in Ref. 3). Information about opposite-sex odors in hamsters is processed in the anterior Me and is then relayed to the posterodorsal Me (MePD), which generates attraction for those odors.[366] Disconnection of these subregions eliminated male hamsters' preference for opposite-sex odor.[367]

Anesthetizing the penis of male rats with lidocaine resulted in few intromissions, but a significant increase in Fos-IR in both the Me and MPOA,[368] suggesting that chemosensory stimuli are the primary determinants of the mounting-induced increments in neuronal Fos expression. Likewise, exposure of male rats to bedding from estrous females increased Fos-IR at each level of the vomeronasal circuit, including the Me.[369] In hamsters, exposing males to a cotton swab containing female hamster vaginal secretions elicited similar results.[333,370,371]

Chemosensory cues for Fos induction in the Me can be further subdivided into those transduced by the main and accessory olfactory systems. Intranasal zinc sulfate treatment to damage the olfactory mucosa without affecting the vomeronasal system decreased copulation-induced Fos-IR in the anterior Me of male hamsters,[372] suggesting that input from the main olfactory system contributes to the activation of neurons in this area. In sexually experienced male hamsters, vomeronasal lesions had minimal effect on Fos expression in response to female stimuli, but similar lesions practically eliminated this Fos in the Me in naive males.[335]

The MePD contains a high concentration of ARs. Some of those androgen-sensitive neurons in male rats project to the MPOA and are activated selectively by ejaculation.[373] In male gerbils, too, the lateral part of the MePD was activated only following ejaculation, whereas the medial part was activated by sex-related odors[374] (see the section Circitry and Anatomical Interconnections later in the chapter). Many of those mating-activated (Fos-IR) cells in the lateral MePD of gerbils, as well as in two preoptic nuclei (posterodorsal and medial preoptic nuclei), contained NOS, and many of those NOS neurons also expressed Fos or AR.[375] The authors suggested that NO may help synchronize neural activity in those areas to either trigger ejaculation or respond to ejaculation. The MePD is also part of an interconnected ejaculation-specific circuit that may promote sexual satiety in rats, hamsters, and gerbils (reviewed in Ref. 3). Male rats had a higher regional and neuronal optical density of NADPH-diaphorase (NADPH-d), a marker of NOS, in the MePD; however, there was no sex difference in numbers of cells that express NADPH-d.[376] Thus, there may be similar numbers of NADPH-d neurons in males and females, but there is more NADPH-d, and presumably NOS, in each neuron in males.

The androgen-sensitive cells may also be important for sexual arousal, as the androgen receptor antagonist flutamide in the medial amygdala decreased the number of, and increased the latency to, "psychogenic" NCE.[377] Furthermore, activation of "downstream" forebrain areas following glutamatergic stimulation of the medial amygdala is steroid dependent.[378]

Mating did not induce significant Fos expression in the central and basolateral nuclei. Interestingly, the distribution of mating-induced Fos within the Me does not precisely accord with the results of tract tracing and lesion studies. Although the anterior subdivision receives the majority of direct olfactory bulb efferents, and lesions of this area produce greater deficits in copulatory behavior,[357] the largest concentration of Fos-positive neurons is found in the posterior subnucleus of the Me.[379] Furthermore, activation of the posterodorsal subdivision of the Me (MePD) appears to be associated specifically with ejaculation (see the section An Ejaculation-Related Circuit later in the chapter). Co-localization of Fos-IR with either glutamate or glutamic acid decarboxylase (GAD),

the enzyme that produces GABA, revealed that half of the activated cells in the lateral MePD were GABAergic, while a quarter were glutamatergic.[380] Finally, Fos-IR in the Me, but not in the MPOA, was positively correlated with the duration of the postejaculatory interval, suggesting that this area may contribute to postejaculatory quiescence.[11]

As determined by co-localization of Fos with steroid receptors, many hormone-sensitive neurons in the Me are activated during mating. In male rats and hamsters, AR-containing neurons in posterior Me express Fos after mating. Furthermore, neurons that co-localize Fos-IR and AR-IR are interconnected, as determined in tract tracing studies (see the section An Ejaculation-Related Circuit later in the chapter). On the other hand, castration does not appear to reduce Fos in the Me and other central chemosensory targets of male rats[381] or hamsters.[336] Likewise, the pattern of Fos expression in Me and MPOA was similar in wild-type mice and in those lacking the aromatase gene.[382] Therefore, gonadal steroids can have a long-term permissive action on mating behavior circuitry, but are not required acutely for Fos activation.

Effects of Hormone Implants

As noted above, the Me is sensitive to gonadal steroid hormones. ARs and ERs are concentrated in the posterior subdivision of the Me (reviewed in Ref. 3). This subnucleus and the encapsulated area of the bed nucleus of the stria terminalis (BST) are twice as large in males as in females, and contain more substance P, CCK, and vasopressin.[383] Likewise, the posteromedial cortical amygdaloid nucleus is also larger in males.[384] The MePD also shows a different pattern of synaptic contacts, compared with females (reviewed in Ref. 3). Castration in male rats[104] caused the MePD to shrink; however, androgen treatment of adult female rats increased the MePD to male-typical size, by enlarging soma size. Therefore, hormone treatment in adulthood can completely reverse a sexual dimorphism in a brain area important for sexual behavior.

Hormone implants in the Me can facilitate the maintenance or restoration of male sexual behavior. Bilateral T implants into the Me of castrated male rats delayed the loss of both copulation and NCE.[385] Similarly, either T[386] or E2[387] implants into the Me restored copulatory behavior in castrated male hamsters. Likewise, E2 stimulated sexual activity in male rats,[388] including those treated systemically with an aromatase blocker.[389] However, DHT implants were ineffective in facilitating sexual behavior, suggesting that stimulation of ARs in the Me is not sufficient for behavioral restoration in male hamsters.[386] On the other hand, DHT implants into the Me were sufficient for behavioral activation in castrated rats receiving subthreshold systemic injections of E2.[390] Implants of the AR antagonist hydroxyflutamide into the Me of T-replaced castrated male rats partially inhibited copulation,[391] but the E2 antagonist tamoxifen likewise failed to block mating in castrated male hamsters with systemic T replacement.[392] Therefore, stimulation of ARs in the Me contributes to male copulatory behavior in

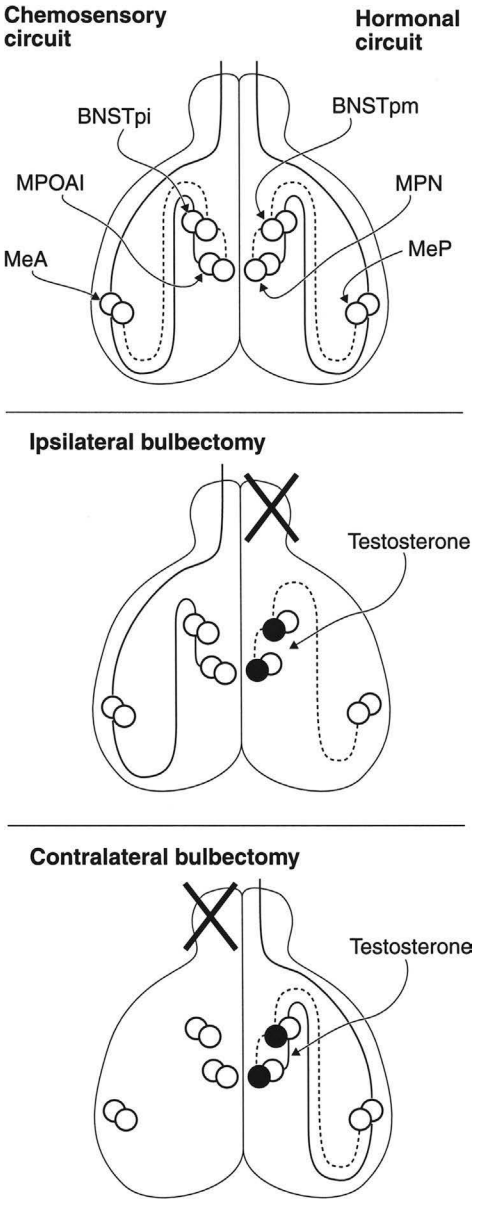

FIGURE 49.12 Schematic diagram of mating behavior circuitry through the nucleus of the medial amygdala (Me), bed nucleus of the stria terminalis (BNST), and medial preoptic area (MPOA) in the male Syrian hamster brain, illustrating the separate pathways for receipt of chemosensory and hormonal cues. Top, Normal male. Elements of the chemosensory circuit (left) include the anterior subdivision of the Me (MeA), posterointermediate subdivision of BNST (BNSTpi), and the lateral subdivision of MPOA (MPOAl). The hormonal circuit (right) consists of the posterior subdivision of the Me (MeP), the posteromedial subdivision of BNST (BNSTpm), and the medial preoptic nucleus (MPN). Middle, Testosterone stimulation of BNSTpm and MPN (solid circles) combined with removal of the ipsilateral olfactory bulb prevents communication between the chemosensory and hormonal circuits. Bottom, Removal of the contralateral olfactory bulb permits chemosensory and hormonal integration. *Source: Figure is reprinted from Ref. 393, with permission.*

both rats and hamsters. However, androgens in Me are not necessary, and may not be sufficient for copulation in male rats or hamsters.

Because the Me receives chemosensory and hormonal stimuli, both of which are essential for mating in male hamsters, the interactions between hormonal and chemosensory stimulation were probed. Olfactory bulbectomy, either ipsilateral or contralateral to a T implant into the Me, rendered the implant ineffective (see Figure 49.12).[387] Similar implants into the MPOA were less susceptible to the loss of olfactory input.[393] Cottingham and Pfaff[394] suggested that steroid-responsive networks should exhibit redundancy, amplification, stability, and selective filtering. Because both the Me and the MPOA transduce steroid cues and receive chemosensory input, Coolen and Wood[395] tested whether steroid implants into these two areas exhibit steroid amplification. Although there is some redundancy, in that steroid implants into either area were sufficient to activate copulation, there appears to be no amplification, in that males with dual implants into the Me and MPOA showed no greater copulatory ability than did males with single implants.

Microinjections of Drugs

Microinjection of angiotensin II into the Me impaired sexual behavior in male rats.[396] This effect was prevented by antagonists to both angiotensin I and II receptors. Therefore, both angiotensin I and II receptors may contribute to angiotensin II's inhibitory effects on copulation. Angiotensin II[397] and its AT1 receptor[398,399] are found in the amygdala of male rats.

Amygdaloid Efferents

Efferents from the corticomedial amygdala travel via the stria terminalis and ventral amygdalofugal pathway to innervate the BST, MPOA, VMH, and other midline hypothalamic nuclei.[400] In male hamsters, cutting the stria terminalis increased mount and ejaculation latencies and interintromission interval.[401] Knife cuts of the ventral pathway produced a less severe loss of mating; however, combined knife cuts of both the strial and ventral projections of the corticomedial amygdala eliminated copulation.[401] Similar pathways may contribute to male sexual behavior in rats (reviewed in Ref. 3).

Through the stria terminalis and ventral pathway, the anterior and posterior subdivisions of the Me maintain distinct, yet parallel connections with subnuclei of the BST. While the posterior subnucleus of Me projects to the posteromedial BST, the anterior Me sends projections preferentially to the intermediate subdivisions of posterior BST.[402] These connections are part of the extended amygdala, a ring of interconnected nuclei linking the central Me with the BST.[403]

Bed Nucleus of the Stria Terminalis

Like the amygdala, the bed nucleus of the stria terminalis (BST) is a heterogeneous brain region with functionally and anatomically distinct subnuclei (reviewed in Ref. 404). The posteromedial regions of the BST are particularly relevant to male mating behavior.[405] As part of the extended amygdala, the Me and BST share overlapping functions and connections; in particular, the posteromedial BST and posterior Me each have abundant steroid hormone receptors (reviewed in Ref. 3). Anatomically, the BST is intermediate between the Me and MPOA; however, chemosensory cues transmitted through Me can also bypass the BST to reach the MPOA directly.

Effects of Lesions

Lesions of the BST did not block mating in male rats or hamsters; however, they reduced NCE, increased the number of intromissions preceding ejaculation, and slowed copulation in rats (reviewed in Ref. 3). These lesions did not affect intromission ratio in rats, suggesting that *in-copula* erections were not affected. These results are in contrast to the effects of lesions of the MPOA, which had little effect on NCE, but dramatically impaired copulation.[406] In male hamsters, large lesions of BST did prevent copulation, but smaller lesions of the posteromedial BST reduced anogenital investigation without preventing ejaculation.[407]

In male gerbils, bilateral lesions of either the caudal medial BST or the sexually dimorphic area (SDA) of the preoptic area severely impaired copulation.[408] Furthermore, unilateral lesions of the caudal medial BST and the contralateral SDA also decreased copulation; ipsilateral lesions had much less effect. Therefore, the caudal medial BST appears to perform an important integrative function. It is not clear whether the different effects of BST lesions in rats, hamsters, and gerbils reflect species differences or differences in experimental procedures.

Activation of c-fos *or Other Immediate–Early Genes*

Exposure to a sexually relevant olfactory stimulus, NCE, or mating increased Fos-IR in the BST of male rats[340] and hamsters.[333] In common with effects in the Me, exposure to estrous odors, but not sexually conditioned almond odor, increased activity in the BST of male rats.[354]

The pattern of mating-induced Fos expression in BST is similar to that for Me, with increases in BST, especially in the posterior and medial subdivisions, in rats, hamsters, and gerbils (reviewed in Ref. 3). By contrast, mating reduced Fos in the BST of male macaques.[409] In rodents, exposure to chemosensory cues from estrous females or their bedding also stimulated Fos, although mating

to ejaculation induced further increases (reviewed in Ref. 3). In contrast, there was no increase in Fos-IR in the BST of male ferrets exposed to estrous female bedding.[344] In hamsters, Fos induction in posteroventral BST and MPOA appears to be selective for mating and sexual stimuli, because aggression failed to induce Fos in these regions.[370]

Hormonal Effects

Posteromedial BST has abundant steroid receptors that extend ventromedially from the stria terminalis to the medial preoptic nucleus.[410–412] Castration decreased immunoreactivity for CCK in the encapsulated portion of BST.[413] T treatment restored CCK to normal levels. Similar effects were observed in sexually dimorphic areas of the Me and medial preoptic nucleus.

Central Tegmental Field/Subparafascicular Nucleus of the Thalamus

The midbrain tegmentum is reciprocally connected to the MPOA, Me, and anterior hypothalamus (reviewed in Ref. 3). Subregions of the midbrain tegmentum have been referred to as the central tegmental field (CTF) or the dorsolateral tegmentum (DLT). This region lies immediately dorsal to the lateral half of the substantia nigra and includes the subparafascicular nucleus, part of the caudal zona incerta, the peripeduncular nucleus, the mesencephalic reticular nucleus, and the anterior pretectal nucleus (see Figure 49.13). In particular, the medial parvocellular portion of the subparafascicular nucleus (SPFp) relays somatosensory cues from the penis and perineum to the MPOA and Me. The SPFp is part of an ejaculation circuit in rats, hamsters, and gerbils (see the section Circuitry and Anatomical Interconnections later in the chapter).

Effects of Lesions

Bilateral lesions of the CTF virtually eliminated mating behavior of male rats, as well as sniffing, pursuit, self-grooming, and genital exploration of the female.[415] Similarly, bilateral lesions of either the MPOA or the CTF, or unilateral lesions of the MPOA and contralateral CTF, inhibited both copulation and the preference for an estrous female,[416] suggesting that connections between these two areas are essential for copulation.[415]

Subsequent lesion studies emphasized the importance of the CTF in general, and the SPFp in particular, in transmitting ascending genitosensory information to the MPOA. Combined ipsilateral excitotoxic lesions of the CTF and Me in male rats abolished copulation-induced Fos-expression in the MPOA.[337] Unilateral lesions of either the CTF or Me alone did not affect Fos in the MPOA. Likewise, unilateral MPOA lesions did not affect Fos in the CTF or Me. In gerbils, bilateral lesions of the SPFp did not affect copulation, suggesting that ejaculation-induced Fos expression represents a response to ejaculation-related stimuli, rather than participation in the control of ejaculation.[358] However, tract tracing studies with male rats show that the SPFp receives projections from lumbar spinothalamic neurons,[417] which are essential for sexual behavior[43] and express ejaculation-induced Fos.[418]

Expression of c-fos *or Other Immediate–Early Genes*

Ejaculation selectively increased Fos in the SPFp of rats, gerbils, hamsters, and musk shrews (reviewed in Ref. 3). Fos was not induced by chemosensory investigation, mounts, or intromissions. In human male volunteers, ejaculation stimulated cerebral blood flow in SPFp as measured by positron emission tomography.[419] Likewise, electrical stimulation of CTF accelerated mating in male rats.[420]

To test whether SPFp Fos expression was selective for ejaculation, Coolen et al.[421] administered the 5-HT_{1A} agonist, 8-OH-DPAT, to male rats to decrease the number of intromissions preceding ejaculation. Indeed, some animals ejaculated on their first intromission. Males that ejaculated after few or no mounts or intromissions had almost as many Fos-IR neurons in the SPFp as did those that ejaculated following the normal numbers of mounts and intromissions. Furthermore, male and female rats have very similar patterns of Fos-IR following ejaculation, again suggesting the importance of ejaculation-related stimuli rather than motor control.[365]

Presence of Steroid Receptors

SPFp neurons have ARs,[422] and many androgen-responsive neurons in SPFp that project to MPOA express Fos following ejaculation.[373]

Connections

The SPFp consists of medial and lateral subdivisions. Neurons of the lateral subdivision express calcitonin gene-related peptide and transmit visual and auditory stimuli for conditioned fear.[423] The medial portion of the SPFp contains a high concentration of galanin-IR fibers.[365] Mating induces Fos in the medial subdivision, and Fos-positive nuclei are surrounded by galanin-IR fibers. Medial SPFp receives projections from neurons in laminae 7 and 10 of the lumbosacral spinal cord and has bidirectional connections with forebrain nuclei controlling sexual behavior.[417] Many of these connections also contain AR and mating-induced Fos.[373] Thus, galanin may be used to relay ejaculation-related somatosensory information through SPFp.

CENTRAL INTEGRATIVE AREAS

Medial Preoptic Area

The medial preoptic area (MPOA) is a critical integrative site for male sexual behavior in all vertebrate species that have been tested. This is remarkable considering the range of sensory stimuli that elicit mating and the diversity of motor patterns that express copulation. Such behavioral flexibility is possible because the MPOA receives indirect input from every sensory modality and sends reciprocal connections back to those sources.[424] These reciprocal connections allow the MPOA to modify the processing of sensory input. Furthermore, the MPOA and its principal afferents contain steroid receptors, which provide the means to bias sensory input to favor sexually relevant stimuli. Efferent connections from the MPOA are critical for the initiation and patterning of copulation. They project to hypothalamic, midbrain, and brainstem nuclei that regulate autonomic or somatomotor patterns and motivational states (reviewed in Ref. 425).

Like other elements of the circuitry for male sexual behavior (e.g., Me and BST), the MPOA is a heterogeneous region comprising separate subnuclei, each with a distinct profile of functions, connections,[424] and neurotransmitter content.[424] The MPOA includes a medial periventricular zone chiefly concerned with neuroendocrine regulation, and a medial zone that functions in male sexual behavior and maternal behavior. Subnuclei within the MPOA are heavily interconnected. In particular, there is potential for reciprocal interaction of sexual behavior and neuroendocrine function via connections between nuclei of the medial and periventricular zones. Within the medial zone of the MPOA, the medial preoptic nucleus (MPN) and posterodorsal preoptic nucleus (PdPN) are particularly important for sexual behavior. Using a variety of experimental approaches, it appears that the MPOA is essential for copulation, and contributes to sexual motivation as well.

Effects of Lesions

Lesions of the MPOA severely impair copulation in male rats, hamsters, mice, guinea pigs, gerbils, dogs, cats, ferrets, goats, marmosets, rhesus monkeys, birds, lizards, snakes, and fish (reviewed in Ref. 3). Large lesions of the MPOA, extending into the rostral anterior hypothalamus, eliminated copulation in sexually experienced male rats; indeed, none of the lesioned males mounted a receptive female rat in periodic tests up to 3[426] or even 8 months[427] after surgery. It is important to note that similar results were obtained using either electrolytic lesions or axon-sparing excitotoxic lesions. Inactivation of the MPOA by lidocaine also impairs motivation, as well as copulation.[428] Therefore, neurons within the MPOA play a critical role in both sexual motivation and the activation of copulation.[429]

A number of attempts have been made to reactivate copulation in male rats that have MPOA lesions. In the early studies of Heimer and Larsson,[426] stimulation of lesioned males by handling or exposure to different females failed to elicit copulation. Chronic T administration was similarly ineffective, an indication that the effects of the MPOA lesions were not an indirect result of diminished gonadal output. Even more extreme forms of excitation, such as repeated flank shock, could not compensate for MPOA damage.[430] However, systemic injection of lisuride, a nonspecific monoamine receptor agonist, transiently activated copulation in 100% of male rats with MPOA lesions, with 50% copulating to ejaculation.[429] When these animals were subsequently treated with saline, they once again failed to copulate. Under similar conditions, administration of GnRH[267] or naloxone[429] was ineffective.

Smaller lesions of the MPOA typically produced less severe deficits. In marmosets, lesions confined to the MPOA decreased copulation, while lesions at the junction of the MPOA and anterior hypothalamus eliminated intromission and ejaculation.[431] Similarly, in rats, lesions placed in rostral MPOA produced less severe copulatory deficits, with many of the males copulating to ejaculation; males that were still able to copulate after small preoptic lesions had prolonged intromission and ejaculation latencies, were inconsistent from test to test, and in some cases recovered normal copulatory ability over time (reviewed in Ref. 3). Small lesions targeting the posterodorsal preoptic nucleus, which is selectively activated by ejaculation in male gerbils,[374] decreased mounting and delayed ejaculation, suggesting that this

area normally facilitates copulation.[358] By contrast, damage to caudal MPOA, which included the rostral anterior hypothalamus, was associated with a severe copulatory deficit.[432] In male hamsters, lesions of caudal MPOA centered in the magnocellular region of the medial preoptic nucleus eliminated copulation.[407]

In rats and gerbils, the MPOA has sexually dimorphic subregions that are attractive candidates to regulate male sexual behavior. In gerbils, the sexually dimorphic area consists of three interconnected subnuclei that are part of a critical circuit for the control of male sexual behavior (reviewed in Ref. 433). Unilateral excitotoxic lesions of the medial SDA, paired with similar lesions of the contralateral lateral SDA, were as effective as bilateral lesions of each.[434] Conversely, Arendash and Gorski[435] found that lesions of the sexually dimorphic nucleus of MPOA (SDN-POA) in the male rat had no effect on copulation in experienced rats, and produced only a transient mating delay in sexually naive males.[436] However, lesions dorsal to SDN-POA reduced the percentage of male rats that ejaculated.[435] Also, perinatal administration of an aromatase inhibitor decreased the size of the SDN-POA and inhibited copulation in adulthood, and there was a significant correlation between the size of the SDN-POA and males' preference for a female partner rather than a male.[437]

It was surprising that MPOA lesions in juvenile male rats reared in isosexual or heterosexual groups produced only minimal copulatory deficits when these animals were tested as adults.[438,439] The only discernable effects were that lesioned males had fewer ejaculations before sexual exhaustion and showed a more rapid decline in copulation following castration.[438] In contrast, males lesioned as juveniles and reared in social isolation did not copulate as adults.[439] However, similar detrimental effects of social isolation in male rats without brain damage have also been reported (e.g., see Ref. 440). Furthermore, copulation was observed in male rats that received lesions as juveniles and were socially isolated, but were handled daily until adulthood,[441] suggesting that interactions with conspecifics are not critical for the development of copulatory behavior in these animals. Another study in rats reported incomplete behavioral recovery following MPOA lesions in juvenile male rats.[441] However, the MPOA lesions in these studies were larger and more caudal, and would be expected to produce the most severe deficits in adult male rats. Thus far, juvenile plasticity in copulatory behavior after MPOA lesion seems to be specific to rats, as MPOA lesions in juvenile dogs[442] and cats[443] eliminated copulation, despite extensive social experience.

It is significant that large MPOA lesions eliminate not only ejaculation, but also the initiation of copulation. This has been interpreted as a reduction in sexual arousal or motivation (e.g., see Refs 416,427,444). However, male rats with MPOA lesions pursued estrous female rats and investigated their anogenital region, climbed over them, and occasionally clasped and mounted them without thrusting.[426,430,445] A similar pattern of behavior has been described for male cats and dogs with MPOA lesions. Indeed, male dogs with MPOA lesions mounted and sometimes showed shallow thrusting, but did not copulate effectively.[446,447] Although monkeys or rats with preoptic area lesions rarely showed female-directed sexual contact, they would press a bar for access to a receptive female or for a secondary reinforcer that had previously been associated with a receptive female (reviewed in Ref. 353). Furthermore, the frequency of masturbation by the monkeys was unaffected by MPOA lesion; although they were clearly sexually aroused, they did not appear to recognize or respond to the female as a sexual partner. Similarly, MPOA lesions that dramatically impaired copulation had little or no effect on NCE.[406] Based on this apparent dissociation between sexual motivation and copulatory performance, Everitt[353] suggested that the MPOA controls only copulatory performance and does not influence sexual motivation.

However, lesions of the MPOA have diminished sexual motivation in other contexts, including the preference for a female partner in rats and ferrets, pursuit of a female by male rats, or precopulatory behavior (anticipatory erections, tongue flicking, and anogenital investigations) in marmosets (reviewed in Ref. 3). Therefore, while sexual motivation is not eliminated by MPOA lesions, it is clearly diminished. The evolutionary conservation of MPOA influence on both sexual motivation and performance is apparent in studies of Japanese quail and starlings. In quail, small lesions of subregions of the MPOA differentially impaired copulatory performance and sexual motivation, measured as time spent in front of a window through which the male could view a female.[448] In starlings, MPOA lesions selectively reduced singing and the gathering of green nesting materials.[226]

The specificity of effects of MPOA lesions is highlighted by contrast with the effects of lesions in the lateral preoptic area (LPOA). Like humans, rats have erections during episodes of paradoxical sleep.[449] Schmidt et al.[450] showed that rats with MPOA lesions experience no disruption of sleep or of erections during sleep. In contrast, LPOA lesions dramatically reduced the occurrence of erection during paradoxical sleep, whereas erections during the waking state were unchanged. The reduction in erections was not attributable to impaired paradoxical sleep, although males with LPOA lesions had extended insomnia and less slow-wave sleep. Although most of the affected males also had some damage to the ventral BST, case analysis suggested that it was LPOA damage that contributed most to the observed effects. This study also exemplifies the context-specificity of the regulation of erection.

Effects of Electrical or Chemical Stimulation

As expected from the inhibitory effects of lesions, stimulation of the MPOA has resulted in facilitation of copulation in male rats, guinea pigs, and opossums (reviewed in Ref. 3). The typical effects included decreases in mounts and intromissions preceding ejaculation, ejaculation latency, and postejaculatory intervals. Lesions of the medial forebrain bundle, which carries the major efferents from the MPOA, diminished the effects of stimulation in opossums.[451] Indeed, stimulation of the hypothalamic area that encompasses the medial forebrain bundle produced facilitation of the same measures as MPOA stimulation (reviewed in Ref. 3).

Electrical stimulation of the MPOA failed to restore copulation in male rats 24 h after they had copulated to sexual satiety, although it facilitated several measures in nonsatiated males.[452] Furthermore, combining the electrical stimulation with subthreshold doses of the DA agonist apomorphine or the α_2-adrenoceptor antagonist yohimbine was also ineffective in satiated males. Higher doses of both drugs had previously restored copulation in satiated animals.[138] The authors suggested that different mechanisms may underlie sexual satiety and the postejaculatory interval, and that stimulation of an excitatory site is not sufficient to reverse sexual satiety.

Repeated electrical stimulation (four per day, separated by 2 h) of the MPOA of previously noncopulating rats led to "kindling" (increased after-discharges, leading eventually to a seizure) and the subsequent ability of most males to copulate on tests without stimulation.[453] Males that initially copulated without stimulation were not further facilitated. Therefore, kindling in the MPOA decreased the threshold for initiating copulation but did not affect normal copulatory performance. Kindling-like stimulation that did not result in seizure activity resulted in permanent facilitation of copulation in previously noncopulating rats, even after 8 months.[454] Similarly, MPOA kindling in T-treated female rats induced male-like copulatory behavior.[455]

Electrical stimulation of the MPOA or medial forebrain bundle has also elicited ex copula erections and/or seminal emissions in monkeys and rats; however, other researchers, using different stimulation parameters, reported erections only following the end of stimulation trains (reviewed in Ref. 3). Either electrical or glutamatergic stimulation of the MPOA elicited increases in intracavernous pressure in anesthetized rats[456,457] and also elicited the UG reflex, even without genital stimulation.[458] The effects of MPOA stimulation were enhanced by intrathecal application of an NO donor, a cGMP analog, and sildenafil, and were decreased by the NOS inhibitor L-NAME.[457] MPOA neurons do not project directly to the lower spinal cord, where genital reflexes are controlled; therefore, MPOA efferents must activate downstream sites that in turn regulate erection and seminal emission. Furthermore, the MPOA appears not to be necessary for penile erection or seminal emission, since MPOA lesions have had little effect on NCE,[406] touch-based erections,[459] or spontaneous seminal emission.[460]

Effects of Direct Applications of Steroids or Steroid Antagonists

In view of the substantial numbers of steroid receptors in the MPOA, it is not surprising that intracerebral application of T facilitates mating in castrated males. Fisher[461] first tested brain localization of T effects on copulation, using a water-soluble derivative of T. Although detailed methods and data are not available, Fisher indicated that the preoptic area was the most effective site for the activation of copulation in castrated male rats. A more detailed study, using crystalline T implants, reported that 100% of the males receiving MPOA implants copulated to ejaculation.[462] Cholesterol control implants were ineffective, and T implants in hypothalamic, hippocampal, and "other" sites yielded 0–81% of animals copulating to ejaculation. The effectiveness of T implants in the MPOA has been confirmed in studies of castrated male rats, ferrets, birds, and anole lizards (reviewed in Ref. 3). Therefore, androgenic mechanisms in the MPOA that stimulate copulation are highly conserved in evolution.

Nonetheless, stimulation of sexual activity in castrated males by intracerebral steroid implants is variable. For instance, in one study, although 100% of the males implanted with T in the MPOA copulated to ejaculation[462] these males ejaculated in only 57% of the tests. Even among males that copulated to ejaculation, mating behavior was not always normal (e.g., see Ref. 463). Similar observations have been reported for male hamsters and mice (reviewed in Ref. 3). Intracerebral T implants in mice increased ultrasonic vocalizations, preference for a female, and urine marking in response to female urine; however, little copulation was observed.[464] Most likely, this is due to selective stimulation of only a limited portion of the male mating behavior circuitry, and the absence of systemic androgens. In this regard, combined implants of T in the MPOA and Me did not further stimulate sexual activity above that induced by single MPOA implants in male mice[465] or hamsters.[395]

Estradiol in the MPOA stimulated sexual activity in castrated male rats[466] and hamsters.[467] Some investigators have not observed ejaculation with E2 implants.[468] However, when Christensen and Clemens[469] compared the efficacy of T or E2 in the MPOA to activate copulation, only 30% of T-implanted males copulated to ejaculation, whereas 70% of males implanted with E2 ejaculated. In a subsequent study, infusion of T or E2 into the rostral anterior hypothalamus stimulated mounting.[466] However, concurrent treatment with ATD (an aromatase

inhibitor) blocked the increase in mounting induced by T, without affecting E2-stimulated mounts. In complementary studies, the nonsteroidal aromatase inhibitor fadrozole impaired sexual behavior when delivered into the MPOA[470] or the lateral ventricle.[99] Moreover, Clancy et al.[471] implanted E2 into the MPOA of gonadally intact males treated systemically with an aromatase inhibitor. Thus, E2 was available only to the MPOA, although androgens were available throughout the body. Estradiol-treated animals regained about half the numbers of mounts, intromissions, and ejaculations that they had exhibited before surgery, while copulatory behavior of controls remained low. Therefore, E2 in the MPOA combined with systemic androgen is sufficient to maintain at least some copulatory and ejaculatory behavior. Collectively, these results are consistent with the idea that E2 is able to stimulate copulation in males, and that the effects of T require aromatization to E2 within cells of the central nervous system.

The aromatization of T to E2 in the MPOA may also be important for sexual preference in rams. Rams that prefer to mate with other rams have reduced capacity to aromatize T to E2 in the MPOA and anterior hypothalamus, in addition to lower circulating levels of T and E2.[472] High sexually performing rams also had more ERs than did low sexually performing rams.[473]

There have been relatively few experiments testing implants of DHT in the MPOA to activate male sexual behavior. DHT implants in the MPOA and anterior hypothalamus induced copulation in only 33–35% of castrates, a percentage not significantly different from cholesterol-treated controls.[463,468] For the DHT-treated males that copulated to ejaculation, intromission latency and the number of mounts to intromission were significantly elevated compared with precastration levels, although other measures of copulation were normal.[463] Implantation of DHT into the anterior hypothalamus of male hamsters had no detectable effect on copulation.[467] Baum et al.[390] were somewhat more successful in stimulating copulation with DHT implants in the MPOA/anterior hypothalamus of male rats. In this study, castrated males ejaculated on about 35% of the tests prior to implantation, whereas the percentage increased to about 70% after the males received intracranial DHT. Likewise, implants of the anti-androgen flutamide into the MPOA blocked sexual behavior in castrated rats treated systemically with T.[474] Male guinea pigs have been shown to be particularly responsive to intrapreoptic area implants of DHT, with full copulatory behavior restored in virtually all males tested.[475]

Another approach to study the effects of intracranial steroid administration on copulation has been to combine a brain implant with systemic hormone treatment subthreshold for the elicitation of behavior. In one study, MPOA implants of DHT combined with subthreshold systemic DHT treatment in castrated rats promoted ejaculation in 40% of males.[476] When Davis and Barfield[463] gave brain implants of E2 to castrated male rats treated systemically with DHT, 60% copulated to ejaculation. Baum et al.[390] performed the complementary experiment by implanting DHT into the brain of male rats receiving systemic E2. DHT implants in the MPOA/AH were ineffective, but DHT did stimulate mating when implanted in the lateral septum or Me.

Yet another approach is to block either steroid receptors or enzymes that produce E2 or DHT locally. Fadrozole, a nonsteroidal aromatase inhibitor, delivered into either the MPOA[470] or the lateral ventricle,[99] impaired copulation in male rats. In contrast, an implant of E2 in the MPOA partially reversed the impairment by systemic administration of fadrozole.[471] These studies support the importance of E2 in the MPOA for male sexual behavior. However, MPOA androgen also contributes to sexual behavior. Administration of the antiandrogen flutamide into the anterior MPOA impaired copulation, but not sexual motivation (partner preference), whereas flutamide in the posterior MPOA had the reverse effects: impairment of motivation, but not copulatory performance.[477]

Effects of Direct Application of Drugs Affecting Specific Transmitters

The MPOA plays a central role in coordinating many facets of sexual behavior, so it is not surprising that drugs administered into the MPOA have affected numerous behavioral measures. Most effects of locally administered drugs resemble those of the same drug injected systemically. However, there are a few site-specific differences.

DOPAMINE

MPOA DA facilitates copulation, genital reflexes, and sexual motivation. Dopaminergic neurons of the periventricular system lie along the third ventricle and send widely branching axons laterally into the MPOA and anterior hypothalamus (reviewed in Ref. 477a). The classic D_1/D_2 agonist apomorphine, microinjected into the MPOA, facilitated copulation in intact male rats[478] and in long-term castrates,[143] and also increased the numbers of touch-based erections and seminal emissions.[479] Similarly, reverse-dialysis of the DA reuptake inhibitor bupropion into the MPOA increased levels of extracellular DA and increased both touch-based and NCE.[480] Conversely, the D_1/D_2 antagonist *cis*-flupenthixol in the MPOA impaired copulation and genital reflexes, and decreased the number of choices of a female in an X-maze, without affecting running speed or the number of no-choice trials (reviewed in Ref. 3). The decrease in sexual motivation (choice of the female) was relatively modest, probably because the drug was injected

only unilaterally. However, there was spatial specificity with both apomorphine's and *cis*-flupenthixol's effects; microinjections anterior, dorsal, or lateral to the MPOA were ineffective in all experiments. There was also behavioral specificity, in that neither apomorphine nor *cis*-flupenthixol affected eating, drinking, locomotion, or rearing in the home cage, although flupenthixol slightly increased time spent inactive.[481] MPOA microinjections of a different DA antagonist, haloperidol, also resulted in increased intromission latency and decreased ejaculations in a bilevel apparatus, although motoric slowing may have contributed to these deficits.[482] In a more recent study, microinjection of apomorphine into the MPOA of males whose copulatory ability had been severely compromised by large excitotoxic lesions of the amygdala, fully restored their copulatory ability.[355] Trends toward apomorphine-induced increases in intromissions and ejaculations in sham animals were not statistically significant. These data suggest that a major consequence of amygdala lesions is impaired DA activity in the MPOA.

Studies found that 6-OHDA neurotoxic lesions of DA neurons in the MPOA impaired copulation only within the first 24 h after the lesion[483] or if a subthreshold dose of a DA synthesis inhibitor was administered.[484] There was only a 23% depletion of DA, a likely result of the sparse population of DA transporters in the MPOA, which are necessary to transport the toxin into the axon terminals. Thus, increased DA synthesis in the remaining neurons occurred during the first 24 h after the lesion and was able to restore copulation to normal. This effect was specific for DA, since the 6-OHDA was co-administered with desipramine, an NE transporter inhibitor; and NE levels were not affected.

Stimulation of D_1 receptors has consistently facilitated copulation and touch-based erections, whereas D_2 agonists have produced biphasic effects. A low dose of the D_2/D_3 agonist quinelorane, microinjected into the MPOA, decreased the latency to the first genital reflex, without affecting the numbers of erections, anteroflexions, or seminal emissions.[485] Thus, small increases in dopaminergic stimulation may disinhibit reflexes via D_2-like receptors. However, a large dose of quinelorane, or of the D_1 antagonist SCH-23390 decreased erections but increased seminal emissions. Thus, intense stimulation of D_2-like receptors or antagonism of D_1-like receptors appear to facilitate sympathetically controlled seminal emission while inhibiting parasympathetically controlled erections. Conversely, a D_1 full agonist, tetrahydrothienopyridine (THP) increased touch-based erections but inhibited seminal emission.[486] The D_1 partial agonist SKF-38393 was ineffective (unpublished observations). Experiments using low and high doses of apomorphine, together with D_1 and D_2 antagonists, also support the opposing effects of D_1 and D_2 receptors on autonomic function. The low dose of apomorphine (1 μg) increased touch-based erections, but not seminal emissions; this effect was blocked by both D_1 (SCH-23390) and D_2 (raclopride) antagonists, suggesting that both disinhibition by D_2 receptors and facilitation by D_1 receptors contributed to apomorphine's increase.[487] Unexpectedly, a high dose (10 μg) of apomorphine failed to increase erections significantly; however, co-administration of the high dose with a D_2 antagonist unmasked the facilitative effects apparently mediated by D_1 receptors. The high dose of apomorphine, administered alone, did increase seminal emissions, an effect that was blocked by a high dose of the D_2 antagonist, but not by the D_1 antagonist. According to a more recent study, it is the D_3 receptor, a member of the D_2 family, that promotes ejaculation. A D_3 agonist (7-OH-DPAT) microinjected into the MPOA of anesthetized rats elicited rhythmic contractions of the bulbospongiosis muscle, seminal vesicle pressure increases, and/or semen expulsion; this response was mostly abolished by simultaneous MPOA microinjection of a D_3 antagonist (nafadotride).[488]

The association of D_1 receptor activation in the MPOA with erections, and of intense D_2/D_3 stimulation with ejaculation, was supported in copulation tests. The D_1 agonist THP, microinjected into the MPOA, increased copulatory efficiency, resulting in more ejaculations per 30-min test.[486] Conversely, the D_1 antagonist SCH-23390 increased intromission latency but decreased the threshold for ejaculation.[489] It also decreased the choice of the female in an X-maze, without impairing motor activity.[490] A high dose of the D_2/D_3 agonist quinelorane also increased intromission latency and decreased ejaculatory threshold.[490] However, it did not decrease the percentage of X-maze trials on which the male chose the female, but rather increased the latency to reach the female's goal box.[490] This delay was not the result of slowed motor function, but of apparent reluctance to cross the line in front of the female's compartment, beyond which the male would be placed into that compartment. In summary, D_1 and D_2 receptors in the MPOA appear to exert reciprocal effects on copulation and genital reflexes. Activation of D_1 receptors facilitates parasympathetically mediated erections and copulatory performance, whereas activation of D_2 receptors promotes sympathetically mediated ejaculation and the postejaculatory state.

Activation of D_1 receptors also facilitates the experience-induced enhancement of mating in male rats[491] (Figure 49.14). Microinjection of a D_1 antagonist (SCH-23390) into the MPOA before each of seven noncopulatory exposures to an estrous female over the male's cage dose-dependently blocked the facilitative effects of such exposures on a subsequent drug-free mating test, compared to effects of vehicle injections. In addition, there was greater phosphorylation of DARPP-32 (dopamine- and cAMP-regulated phosphoprotein), a downstream marker of D_1 activation, in males that had both chronic

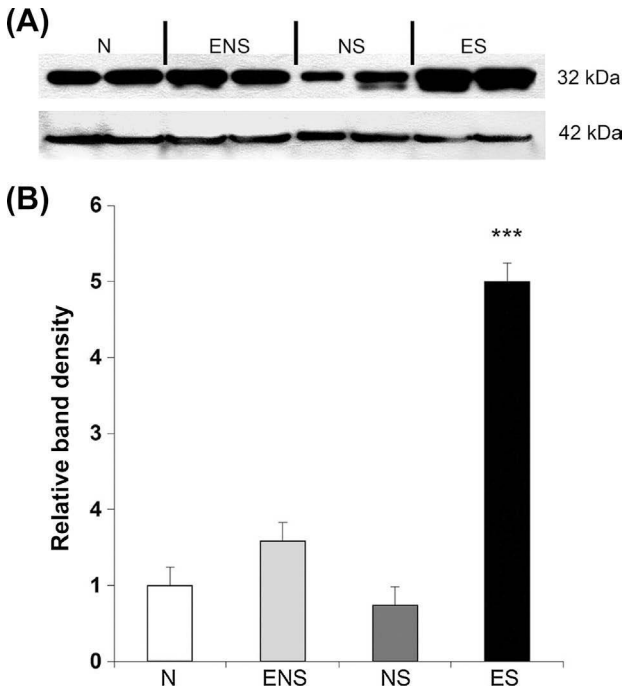

FIGURE 49.14 Protein concentration for phosphorylated dopamine- and cAMP-regulated phosphoprotein (pThr34-DARPP-32) in the medial preoptic area (MPOA) of male rats. (A) Western immunoblot of samples collected from the MPOA of male rats that were either sexually naive and did (NS) or did not (N) mate on the day of euthanasia and sexually experienced rats that did (ES) or did not (ENS) mate on day of euthanasia. The immunoblots depict bands for pThr34-DARPP-32 at 32 kDa and bands for beta-actin at 42 kDa. (B) Graph summarizing relative band densities from the Western immunoblots. Values are expressed as mean ± standard error. ***$p < 0.001$. *Source: Figure is reprinted from Ref. 491, with permission.*

and acute sexual experience compared to naive males and those that had only chronic or only acute mating experience. Therefore, D_1 receptors in the MPOA, possibly acting through a cAMP/PKA intracellular mechanism, mediate the experience-induced enhancement of copulation.

SEROTONIN

5-HT is generally inhibitory to male sexual behavior, and large doses of 5-HT microinjected into the MPOA did impair copulation[202]; furthermore, a 5-HT_{1B} agonist delayed ejaculation.[202] Reverse dialysis of 5-HT into the MPOA impaired ejaculation and also attenuated glutamate release, which normally increases during copulation, with a 300% rise in the 2-min sample during which the male ejaculated.[492] In accord with the facilitative effects of systemically administered 5-HT_{1A} agonists, 8-OH-DPAT microinjected into the MPOA facilitated ejaculation.[201] Administered by reverse dialysis into the MPOA, 8-OH-DPAT also facilitated copulation[203] and increased both DA and 5-HT levels.[493] The facilitative effects of 8-OH-DPAT were partially blocked by the D_2 antagonist raclopride, but not by the 5-HT_{1A} antagonist p-MPPI, suggesting that the elevation of DA levels, resulting in stimulation of D_2 receptors, mediated much of the facilitation.[203]

GAMMA-AMINO BUTYRIC ACID

GABA is a ubiquitous inhibitory neurotransmitter in adult mammals. As expected, the GABAergic drugs muscimol and ethanolamine-O-sulfate, microinjected into the MPOA, decreased the numbers of male rats that mounted, intromitted, or ejaculated, whereas the $GABA_A$ antagonists bicuculline or 3-mercaptopropionic acid (3-MPA) dramatically shortened ejaculation latency and postejaculatory intervals and decreased the numbers of intromissions preceding ejaculation.[494] However, MPOA administration of the same two antagonists failed to restore copulation in satiated males, again suggesting that the postejaculatory interval is governed by mechanisms separate from those that regulate sexual satiety.

OPIOIDS

As with systemic manipulations, studies using microinjections of opiates or opioids into the MPOA suggest that low doses of agonists facilitate, and high doses inhibit, copulation. The lowest doses of the μ agonist morphine and of the κ agonist dynorphin (1–13) decreased the time and numbers of intromissions before ejaculation, and the highest dose of morphine resulted in failure to resume copulation after the second ejaculation.[495] The selective μ agonist morphiceptin delayed the onset of copulation but had no effect on copulatory performance, touch-based erections, sexual motivation, or locomotion.[496] However, the potent μ agonist β-endorphin microinjected into the MPOA both delayed copulation and inhibited its performance.[497] In support of the importance of low levels of endogenous opioids, naloxone in the MPOA prevented induction of sexual reinforcement.[498]

NOREPINEPHRINE

Administration of NE into the MPOA facilitated both sexual arousal and copulatory performance; conversely, the β-noradrenergic antagonist propranolol and the α-antagonist phenoxybenzamine inhibited copulation.[499] The α_2 agonist clonidine, which would have decreased NE release by stimulating autoreceptors, decreased the number of animals that copulated and increased ejaculation latency and interintromission interval; however, intromissions preceding ejaculation decreased.[500] In addition, the α_2 antagonist yohimbine (which would have disinhibited NE release) in the MPOA blocked the inhibitory effects of systemically injected clonidine.[500] Therefore, stimulation of α_2 receptors in the MPOA appears to facilitate copulation.

NITRIC OXIDE

As with systemic manipulations, local increases in NO facilitate some aspects of copulation. Reverse dialysis of its precursor, L-arginine, into the MPOA increased mount rate, whereas the NOS inhibitor L-NMMA decreased that measure.[501] L-NMMA microinjections increased the number of *ex-copula* seminal emissions and decreased the number of inexperienced males that copulated, although it did not affect experienced males.[502] L-NAME microinjections into the MPOA prevented intromissions and ejaculations in sexually naive males and decreased the numbers of intromissions and ejaculations in experienced males.[503] Furthermore, in naive males, L-NAME microinjections before each of seven exposures to an inaccessible female prevented the facilitative effect of those exposures, which was observed in saline-treated males, compared to non-exposed animals.[503]

Nitrergic function in the MPOA is hormonally regulated. Castration of male rats decreased production of cGMP (the most common second messenger of NO) and blocked NMDA-induced increases in plasma GnRH and in cGMP in MPOA slices.[504] Castration also decreased nNOS-IR in the MPN of male hamsters and rats (reviewed in Ref. 3). T replacement for 2, 5, or 10 days in castrated rats resulted in progressive improvement in copulation and increases in NOS-IR; shorter mount latencies were correlated with greater NOS-IR density. Either E or T replacement, but not DHT, was able to restore NOS-IR.[505] However, in DHT-treated castrates (to maintain peripheral structures) reverse dialysis of an nNOS donor (sodium nitroprusside, SNP) increased DA release and restored ejaculation in half of the animals (Figure 49.15).[506] The lack of full restoration suggests that NO in other brain sites also contributes to mating ability or that unilateral reverse dialysis of an NO donor does not provide a sufficient amount of NO for full restoration. Furthermore, ERα knockout mice had less nNOS-IR than wild-type mice or mice lacking AR because of the testicular feminization mutation (*tfm*).[507] Thus, the aromatization of T to E likely mediates the upregulation of NOS-IR. Gonadal steroid receptors are co-localized with nNOS-IR in mice, rats, and hamsters (reviewed in Ref. 3). In contrast to the castration-induced decreases in NOS-IR in the above studies, there is one report of increased NOS-IR and activity after castration and reduction by either T or DHT.[508] The reason for this apparent discrepancy is not clear, but may be related to the more posterior location examined by Singh and colleagues or their use of an antibody that labeled very few cells. In summary, NO in the MPOA enhances copulation and increases GnRH release. T, probably through aromatization to E and activation of ERα, increases production of NOS in the MPN, although apparently not in more posterior areas.

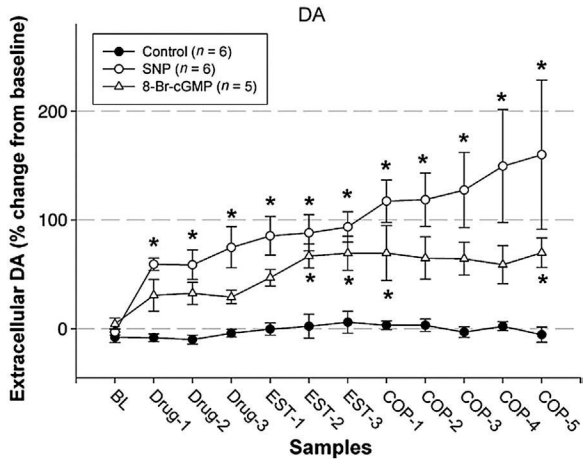

FIGURE 49.15 In DHT-treated castrates (used to maintain peripheral structures), reverse dialysis of an nNOS donor (sodium nitroprusside, SNP) increased dopamine (DA) release and restored ejaculation in half of the animals (not shown). While in 8-Br-cGMP-treated animals, DA levels increased relative to baseline (BL), but reached significance at only the second and the third estrous female samples (EST-2 and EST-3), when the female is presented above the male's cage, as well as at the first and the last copulation samples (COP-1 and COP-5), when males copulated with a sexually receptive female. Values are expressed as mean ± standard error. *$p < 0.05$. *Source: Figure is reprinted from Ref. 506, with permission.*

GLUTAMATE

Microinjection of the N-methyl-D-aspartate (NMDA) receptor antagonist MK-801 into the MPOA of sexually naive male rats prevented copulation, and in sexually experienced males, impaired copulation.[509] Furthermore, in sexually naive males microinjection of MK-801 before each of seven noncopulatory exposures to an estrous female prevented the facilitation of such exposures on a drug-free test on day eight that was observed in saline-treated males, compared to unexposed males. Therefore, endogenous glutamatergic stimulation of NMDA receptors in the MPOA facilitates copulation in both naive and experienced males and is permissive for the sensitization to female cues by repeated exposures to a female in sexually naive males. In tests of genital reflexes in anesthetized male rats, microinjection of glutamate into the MPOA elicited erectile responses[456] and the UG reflex.[458]

ACETYLCHOLINE

The nonspecific ACh agonist carbachol or the muscarinic agonist oxotremorine, microinjected into the MPOA, decreased the numbers of intromissions preceding the first ejaculation.[510] This effect was blocked by the muscarinic antagonist scopolamine, which also decreased the numbers of animals that mounted, intromitted, or ejaculated.[510] Acetylcholinesterase immunoreactivity in the SDA was more dense in male gerbils than in females; castration decreased staining intensity, which was restored by T replacement.[510a] Therefore, ACh in the

MPOA may contribute to the hormonal control of sexual behavior.

PROSTAGLANDIN E_2

Bilateral administration of PGE_2 into the MPOA of castrated male rats, maintained on a subthreshold T replacement regimen, activated copulation within 30 min.[511] Half the animals copulated and 40% copulated to ejaculation. Thus, PGE_2 in the MPOA facilitates copulation, possibly by increasing MPOA temperature (see section on systemic manipulation of PGE_2).

OREXIN/HYPOCRETIN

Orexin/hypocretin neurons, located in the perifornical lateral hypothalamus, are better known for their facilitation of feeding[512] and prolonging wakefulness.[512a] However, microinjection of orexin/hypocretin into the MPOA of male rats also facilitated copulation.[513]

OXYTOCIN

Microinjection of oxytocin into the MPOA facilitates male rat sexual behavior, and an antagonist impairs mating.[514] Furthermore, repeated experiences increase both gene expression and protein levels of oxytocin receptors.[515] Therefore, while oxytocin has been studied primarily in the PVN and mesolimbic system, it also works in the MPOA to promote mating.

Electrophysiological Recordings

Electrophysiological recordings have revealed that different neurons in the MPOA participate in the control of sexual motivation and copulatory performance. Some neurons were activated only before male rats began to copulate, while others were activated only during copulation.[516] Similar results were obtained in monkeys, in which neural activity was highest while the animal was making an operant response (pressing a lever) to bring a female closer; activity decreased slightly during copulation and ceased after ejaculation.[517] In slice preparations from the MPOA of Japanese quail, intra- and extracellular recordings revealed that bath applications of DA inhibited most cells (52–80%) but excited a few (10–24%). These effects were not blocked by either D_1 or D_2 antagonists, but were blocked by α_1 or α_2 antagonists, respectively.[518] The effects were not blocked by dopamine–β-hydroxylase inhibitors, indicating that DA was not being converted to NE to produce the effects. Therefore, in quail DA affects neuronal activity via crosstalk with NE receptors.

Chemical Changes Detected by Microdialysis or from Tissue Punches

There is a close association between extracellular MPOA DA levels and sexual behavior in male rats. DA increased as soon as a receptive female was placed behind a perforated barrier; DA levels remained high, or increased further, when the animals were allowed to copulate (Figure 49.16) (reviewed in Ref. 3). The recent presence of T is required for both copulation and the DA response to the female. All gonadally intact males, as well as two-thirds of animals castrated one week before, showed a precopulatory DA increase and copulated when the barrier was removed.[519] The remaining one-third of the one-week castrates, and all two-week castrates, did not show a DA response to the female and did not copulate. There was behavioral specificity, in that neither voluntary exercise in a running wheel nor presentation of another male behind the barrier elicited a DA increase,[519] and eating a palatable food did not increase the DA metabolite DOPAC in a previous study.[520] Furthermore, probes anterior or lateral to the MPOA did not detect a response to the female. The increase in DA before copulation began provides evidence that the DA increase was not caused by copulation, but was more likely associated with sexual motivation.

In the original studies described above, basal levels of extracellular DA were not measured; thus, it was not clear whether basal levels were also affected by

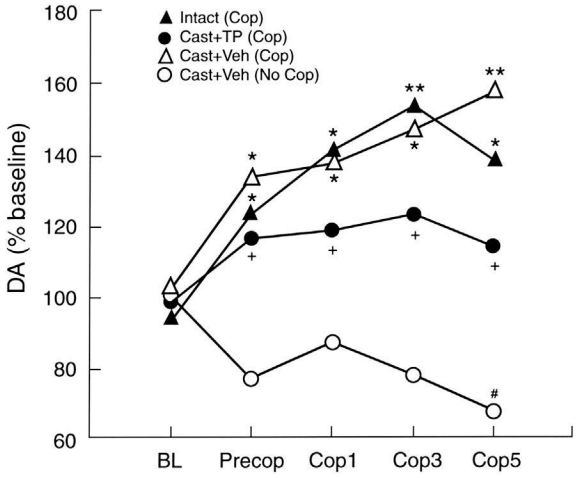

FIGURE 49.16 Extracellular dopamine in the MPOA of male rats during baseline (BL), a precopulatory period (Precop; estrous female behind a perforated barrier), and three 6-min periods after the barrier was removed and the animals were free to copulate (Cop). All gonadally intact males and all castrates treated with testosterone propionate (200 µg/day) showed a significant increase in dopamine during the precopulatory period and during copulation; all of these animals did copulate. A total of nine of 14 oil-treated 1-week castrates also showed the precopulatory dopamine response and copulated after the barrier was removed. The remaining 1-week and all four 2-week oil-treated castrates failed to show the precopulatory dopamine response and failed to copulate; data from these two groups are combined. $^{*}p<0.05$ compared to final baseline for intact males or for 1-week vehicle-treated castrates that copulated. $^{**}p<0.01$ compared to final baseline for intact males or for 1-week vehicle-treated castrates that copulated. $^{+}p<0.05$ compared to baseline for testosterone-treated castrates. $^{\#}p<0.05$ compared to final baseline for vehicle-treated castrates that failed to copulate. *Source: Figure is reprinted from Ref. 519, with permission.*

castration, or only the response to a female. Therefore, the no-net-flux technique was used to measure absolute basal levels in castrates, compared to gonadally intact males.[521] Briefly, different amounts of DA are added to the dialysate; if there is less DA in the brain than in the dialysate, some will diffuse out of the dialysate into the brain, and the loss can be detected.[522] Conversely, if there is less DA in the dialysate, or none, as in standard dialysis, DA will diffuse from the brain into the dialysate, and the gain can be detected. A regression line is drawn, and the point at which it crosses from loss to gain represents the basal extracellular DA level. In castrates the absolute extracellular DA levels were only about one-fifth those of gonadally intact males (0.3 versus 1.3 nM[521]). Therefore, the deficit in castrates was a general one, not limited to the increase in response to a female. However, systemically administered amphetamine elicited greater DA release in castrates than in intact males, and there was more DA in tissue punches from castrates than in those from intact males.[521] Therefore, synthesis and storage of DA were at least as great in castrates as in intact males, but castrates were unable to release their abundant stores.

Further evidence for an association between DA release and the ability of castrates to copulate was provided by a study of restoration of copulation by 2-, 5-, or 10-day regimens of T treatment.[86] No 2-day T-treated castrate showed a DA response to the female and none copulated. Eight of nine 5-day T-treated castrates showed a DA response, and those eight copulated, with five also able to ejaculate. All 10-day T-treated castrates showed a precopulatory DA response, and all copulated. There were numerous correlations between DA release and copulatory measures. Therefore, both loss of copulation following castration and its restoration following T replacement were closely associated with female-elicited DA release in the MPOA.

A major factor regulating DA release in the MPOA is NO. Both basal[523] and copulation-induced[524] DA release were dependent, in part, on NO. Furthermore, NOS-IR in the MPN is positively regulated by T and E[505,507,525–527]; but see Ref. 508. Therefore, T may maintain both basal and female-stimulated DA release by upregulating NOS in the MPOA.

T's metabolites were differentially effective in restoring basal and female-stimulated DA release in long-term castrates.[98] E restored high basal levels of DA, but not the increase in response to a female. E-treated males all intromitted, but none showed a behavioral ejaculation pattern. Neither DHT nor oil vehicle maintained basal DA levels or a female-stimulated increase, and no DHT- or oil-treated animal copulated. Although DHT was ineffective by itself, when it was administered together with E, the combination effectively restored basal and female-stimulated DA responses, as well as copulation.

Although extracellular DA levels were positively correlated with copulatory measures, tissue (stored) DA levels were negatively associated with copulation.[505] The noncopulating groups (DHT and oil) had higher tissue levels of DA than did the groups that copulated (E, E+DHT, and T). As in the Du et al.[521] study above, DHT- and oil-treated animals could synthesize and store DA, but had difficulty releasing it in basal conditions and also in response to a female. Furthermore, a deficiency in NO may have led to the impaired DA release; DHT- and oil-treated males had less NOS-IR than did the three groups that were able to copulate.[505] A similar finding regarding an apparent DA response to stimuli from a female was recently reported regarding juvenile versus adult male hamsters.[528] Adult hamsters showed an increase in DOPAC in punches from the MPOA in response to presentation of vaginal secretions from an estrous female, suggesting release of DA and subsequent uptake and metabolism, whereas juveniles showed no such response and were unable to copulate.

A major factor regulating the MPOA DA response to a female is input from the Me. Small radiofrequency lesions of this area in highly experienced rats increased both the number of intromissions and the time preceding ejaculation and decreased the number of ejaculations[355] (see the section Amygdala above). These lesions did not affect basal DA levels, but they abolished the DA increase in response to an estrous female (Figure 49.17). Thus, as

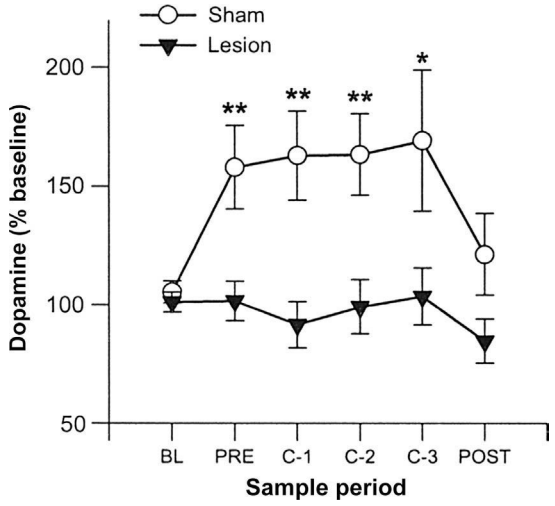

FIGURE 49.17 Levels of dopamine in dialysate from the MPOA of animals with medial amygdala lesions. Levels represent percent changes from baseline (BL) in response to precopulatory exposure to an estrous female (PRE), during copulation (C-1 to C-3), and after copulation (POST). Extracellular levels of dopamine significantly increased during the precopulatory and copulatory stages of testing for animals with sham lesions but not for animals with medial amygdalar lesions. The baseline value used for computation was obtained by dividing the value of the last baseline by the mean of all three baselines. Values are expressed as mean + SEM. *$p < 0.05$; **$p < 0.01$. *Source: Figure is reprinted from Ref. 355, with permission.*

with E2 treatment of castrates,[98] normal basal levels of MPOA DA were compatible with suboptimal copulatory ability. However, an increase in DA before and during copulation appears to contribute to the ability to ejaculate. As noted above, apomorphine microinjected into the MPOA of males with large excitotoxic lesions of the amygdala completely restored their copulatory ability, which had been almost abolished by the lesions.[355] Therefore, input from the Me is important for increasing DA release in the MPOA in response to a female and during copulation, and this is a major way in which the Me facilitates copulatory ability. A recent critical review observed that "there was no delay whatsoever with regard to the initiation of sexual behavior despite the absence of preoptic DA release" in the Dominguez et al.[355] article.[167] They suggested, therefore, that DA has little or nothing to do with sexual motivation. However, the data do show trends that approach statistical significance for both mount latency and intromission latency; the relatively high variability among animals with lesions may have contributed to the lack of statistical significance. Furthermore, there was not an "absence of DA release" but rather a lack of female-stimulated increase in DA; basal DA levels were normal and, as we have suggested, are sufficient for suboptimal copulation. As noted above, DA in the MPOA increased as soon as an estrous female was presented behind a barrier; thus, it was not elicited by copulation per se, and may represent motivation to gain access to the female.[519] In addition, in Japanese quail, as in rats, the presence of a receptive female elicited DA release in the MPOA, but only in males that did copulate (Figure 49.18).[529,530] In males that did copulate, the DA did not fall during the periods between actual mating behaviors, which are only about 4 s long. The authors suggest that the DA release is not simply triggered during actual copulation and occurs only in males that are motivated to copulate. Therefore, the data from both microinjection and microdialysis experiments suggest that MPOA DA does contribute to sexual motivation, copulatory ability, and genital reflexes, although other structures and other neurotransmitters also contribute to these processes.

The olfactory bulbs apparently provide the signal relayed by the amygdala to the MPOA. Male hamsters with sham bulbectomy, or with unilateral bulbectomy contralateral to the MPOA microdialysis site, showed increased extracellular DA in the MPOA when presented with an estrous female.[320] However, bilateral or ipsilateral bulbectomy inhibited the DA response and impaired copulatory behavior, similar to the results of Dominguez et al.[355]

In sexually mature male hamsters, pheromones from estrous females elicited an apparent increase in DA release, inferred from an increase in the DA metabolite DOPAC, in tissue from the MPOA.[528] However, tissue from prepubertal males did not show such an increase.

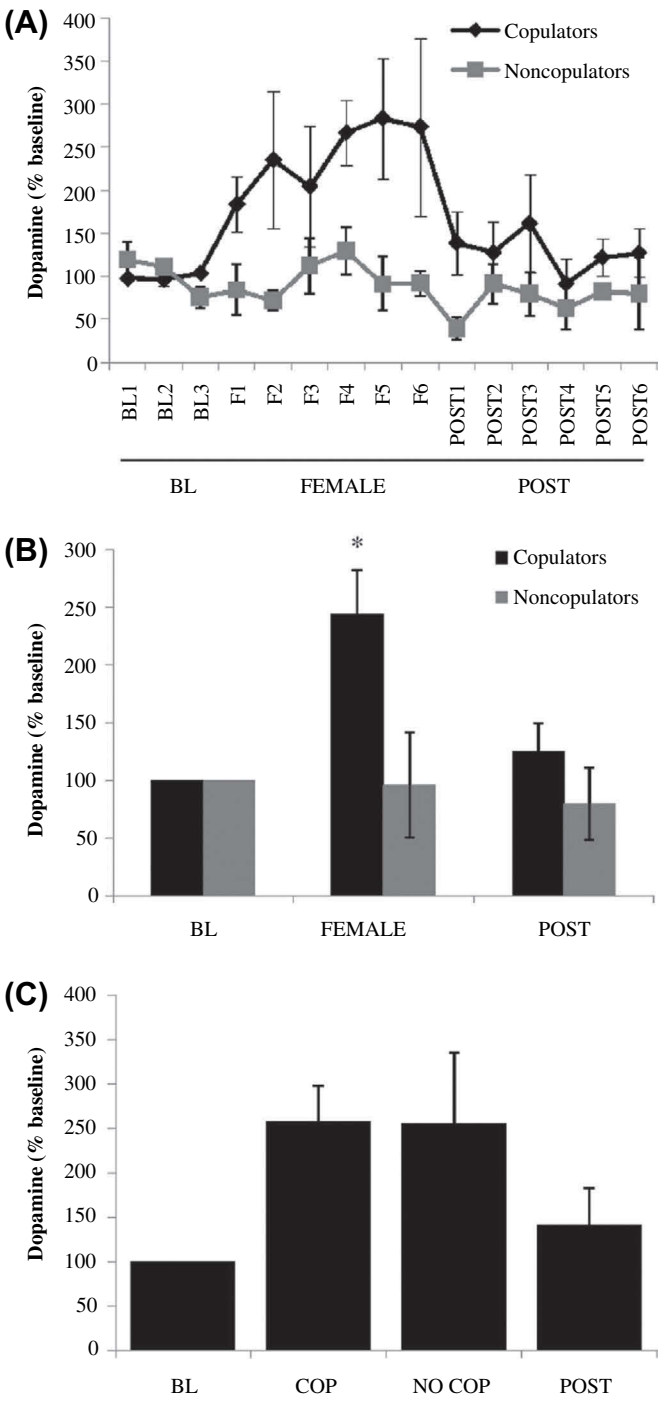

FIGURE 49.18 Extracellular dopamine (DA) in the medial preoptic area (MPOA) of Japanese quail changes in the presence of a female. A and B depict mean change in MPOA DA during baseline (BL), in the presence of a female (FEMALE), and after the female was removed (POST). Panel C depicts mean change in MPOA DA during copulation (COP) and no copulation (NO COP), within the same birds. In males that did copulate, the DA did not fall during the periods between actual mating behaviors. Samples were collected at 6-min intervals. Values are % baseline and expressed as mean ± SEM. *$p < 0.05$. *Source: Figure is reprinted from Ref. 529 with permission.*

Therefore, the neural processing of sexually relevant chemosensory stimuli matures during puberty.

The 5-HT metabolite 5-hydroxyindole acetic acid (5-HIAA) increased in dialysates from the POA of male rats that had ejaculated,[531] and 5-HT itself was increased in tissue punches from the POA following ejaculation.[532] These authors suggested that postejaculatory 5-HT increases in the POA contributed to postejaculatory quiescence. However, a more recent study, based on analysis of 5-HT itself, concluded that MPOA and, more laterally, POA 5-HT levels were constant throughout copulation and the postejaculatory interval.[533] However, 5-HT was increased in the anterior lateral hypothalamic area (LHA) at the time of ejaculation. The increase in 5-HIAA observed by Refs 534 and 531 may have resulted from diffusion from the adjacent LHA. Therefore, it seems unlikely that 5-HT in the MPOA contributes to postejaculatory quiescence.

Expression of c-fos *and/or Other Immediate–Early Genes*

In keeping with the pivotol role of the MPOA in the control of male sexual behavior, numerous studies in a variety of species have documented Fos induction in the MPOA with sexual activity. Fos is expressed in the MPOA following copulation in male rats, gerbils, mice, and hamsters (reviewed in Ref. 3). In particular, neuronal activation in the MPOA appears to be selective for sexual activity, because mating, but not aggressive behavior, increased Fos-IR in the MPOA of male hamsters.[535] Sexual experience may also prime MPOA neurons to be more responsive to sexual stimuli. The number of Fos-IR neurons in the MPN following one ejaculation was greater in sexually experienced male rats compared to naive males, even though experienced males required fewer intromissions to reach ejaculation.[536] Likewise, chemosensory cues were more effective in stimulating Fos expression in MPOA of sexually experienced male hamsters.[335]

Fos is expressed in androgen receptor-containing neurons of the MPOA in rats,[373] but Fos does not co-localize with aromatase in quail MPOA.[537] Using retrograde tract-tracing, Fos-positive neurons were demonstrated in Me and CTF that project to the MPOA.[373] Heeb and Yahr[538] reported similar findings in male gerbils. Moreover, mating-induced Fos expression in the MPOA requires afferent input from both Me and CTF, because combined ipsilateral lesions of Me and CTF blocked copulation-induced Fos in the MPN, though single lesions did not affect Fos.[337] In turn, Fos-positive neurons in the MPOA send their projections to the PAG.[539]

Fos may be expressed in the MPOA in response to female odors alone, although there is less consensus on this point. Sexually experienced male rats exposed to estrous-female bedding showed an increase in Fos-IR in the MPOA.[340,369] Likewise, chemosensory cues from females activated Fos in the MPOA of male hamsters,[371,540] macaques,[409] gerbils,[374] and aromatase-knockout mice.[382] Similar results were obtained using fMRI in marmosets[541] or with brain temperature recordings in male rats.[542] In addition, electrical stimulation of the vomeronasal organ activated Fos in the MPOA of male hamsters.[543] Finally, exposure to sexual conditioned stimuli increased Fos-IR in the MPOA of male Japanese quail; neural activation was higher in subjects exposed sequentially to the CS and copulation than in subjects exposed to copulation or the CS alone.[13] However, other investigators did not report an MPOA Fos response to female odors in rats,[337,421] mice,[338] hamsters,[333] or ferrets.[344] It may be that certain subregions of the MPOA are activated selectively by ejaculation while others respond preferentially to chemosensory cues. In this regard, chemosensory cues selectively activated the medial and lateral sexually dimorphic areas of the male gerbil,[374] as well as the magnocellular subdivision of the MPOA in hamsters.[371,540] However, ejaculation activated Fos within the medial preoptic nucleus of both hamsters[540] and rats.[421] In a similar manner, the posterodorsal preoptic nucleus (PdPN) in gerbils expressed Fos only after ejaculation.[374] Whether chemosensory cues inducing Fos in MPOA are mediated by the main or accessory olfactory systems remains unclear.[334,335]

The neurochemical identity of Fos-positive neurons has only recently been studied. In male gerbils, approximately half of the Fos-positive cells in the medial sexually dimorphic area and PdPN are GABAergic.[380] Nearly 25% of cells in the medial sexually dimorphic area are glutamatergic, but PdPN neurons do not express glutamate. In male rats, galanin neurons in the MPOA are activated selectively by ejaculation.[380a] Administration of a DA D_1 antagonist before copulation decreased ejaculation-induced Fos,[536] suggesting that at least some of the copulation-induced Fos-IR may result from stimulation of D_1 receptors.

Effects of Intracerebral Grafts

Sexual arousal and copulatory ability decline with advancing age in males of many species. Injection of suspensions of fetal MPOA neurons into the MPOA of 19- to 24-month-old rats improved their copulatory behavior between 21 and 45 days after implantation.[544] The improvements lasted until the end of the experiment 4.5 months later. Grafts from cerebral cortex to MPOA or from MPOA to the ventromedial hypothalamus (VMH) were ineffective. Two hormonal measures, serum T and the postcastration increase in luteinizing hormone, were also increased by the grafts. Therefore, some age-related declines in copulatory ability, sexual motivation, and neuroendocrine function may result at least partially from dysfunction in the MPOA.

Activation of Neurotransmitter Receptors

Endocytosis of μ opioid receptors in the MPOA was observed within 30 min of copulation and was still evident 6 h later.[41] The opioid antagonist naloxone prevented receptor internalization. Microinjections of a μ agonist produced similar endocytosis, and mating resulted in increased Fos-IR in neurons that contained μ receptors. However, naloxone pretreatment did not prevent the Fos response in μ receptor-containing neurons, suggesting that the Fos response did not result directly from μ activation during mating.

Summary of MPOA Functional Roles

The MPOA receives both chemosensory and genitosensory input, as well as information from other sensory modalities. Reciprocal connections with the sources of the sensory input allow hormone-concentrating neurons to bias the sensory input to favor sexually relevant information. Output from the MPOA to other hypothalamic, midbrain, and brainstem nuclei that control somatomotor patterns and genital reflexes contribute to the initiation and orchestration of complex, interactive copulatory behaviors.

Mesocorticolimbic DA Tract

Cell bodies in the ventral tegmental area (VTA) give rise to axons of the mesocorticolimbic DA tract that innervate the nucleus accumbens (Acb), prefrontal cortex, and ventral forebrain areas.[545] This system is critical for appetitive behavior and reinforcement and is activated before and/or during a variety of motivated behaviors, including eating, drinking, sexual activity, drug self-administration, and intracranial self-stimulation.[546,547] It is not clear whether this system is more important for reward processes,[548] behavioral activation,[549–551] "wanting" (as opposed to "liking"[552]), or incentive learning.[553,554] However, it is clearly essential for appetitive behavior. The mesocorticolimbic tract is activated both before and during copulation in male rats. DA released in the Acb is important for the activation of numerous motivated behaviors, including sexual behavior, but appears to have little influence on specifically sexual motivation or on copulation per se. Because most research on this system has focused on the Acb and VTA, this review will also concentrate on these areas.

Effects of Electrolytic or Cell Body Lesions or of Electrical Stimulation

Few recent studies have tested the effects of lesions of the Acb or VTA on sexual behavior. In general, elements of the mesocorticolimbic DA tract appear to be important for sexual arousal in response to remote cues from females, but play a relatively less critical role in copulatory performance per se. Lesions of the VTA and the adjacent interpeduncular nucleus increased the postejaculatory interval, but did not affect other copulatory measures.[555] Likewise, male rats with DA-depleting lesions of the Acb had a lower incidence of NCE, fewer erections, and longer latency to display erection; radiofrequency lesions of the Acb also increased the latency to the first NCE.[556] Nonetheless, copulation was normal in both groups of lesioned rats. Using excitotoxic lesions of the Acb, Kippin et al.[557] observed a reduction in NCE, as well as intromission and ejaculation. However, lesioned male rats maintained a normal preference for receptive females.

Electrical stimulation of the VTA decreased the latencies to mount, intromit, and ejaculate[558,559] and increased the number of ejaculations in a 30-min test.[559] This facilitation was specific to the Acb, as stimulation of the caudate putamen inhibited sexual behavior.[560] Stimulation of the Acb did not reverse sexual satiety.[560] These results are consistent with a general activating effect of the mesocorticolimbic tract.

Effects of Castration or of Direct Applications of Hormones

Although the Acb and VTA are logical sites for gonadal steroid hormones to stimulate sexual motivation, there are relatively few data to support this hypothesis. Intracerebral implants of T into the VTA of castrated male house mice did not restore mounting, ultrasonic vocalizations, urine marking, or attraction to female urine.[561] However, the combined application of T to the MPOA and VTA was more effective than implants in the MPOA alone. T may also be reinforcing, independent of its effects on sexual motivation. Male rats formed a conditioned place preference for intra-Acb injections of T,[562] and T-induced conditioned place preference was blocked by intra-accumbens injections of a DA antagonist.[563] This effect appears to be due to androgenic metabolites of T acting on the shell of the Acb, because intracerebral implants of DHT into the Acb shell also induced conditioned place preference.[564]

The mechanisms through which steroid hormones may act on the mesolimbic DA system are unclear. There are contradictory reports on the effects of castration on Acb DA levels. In male rats, castration depressed DA concentrations in the Acb, and this effect was reversed by replacement with T, E2, or DHT.[565,566] However, Hernandez et al.[567] found that amphetamine released more DA in dialysates from prepubertally castrated males, suggesting that there may be more DA stored in tissue. Likewise, the presence of steroid receptor-containing neurons in the Acb or VTA remains controversial. Early studies reported no binding of hormones to classic steroid receptors in the VTA, though low levels of binding were found in the Acb.[568,569] A more recent study found

small patches of AR neurons in the VTA that were also immunoreactive for tyrosine hydroxylase, the rate-limiting enzyme for catecholamine synthesis.[570] Despite the scarcity of AR and ER in the mesolimbic DA system, there is the additional possibility that gonadal steroids may act on Acb and VTA via nongenomic receptors.

Expression of c-fos *or Other Immediate–Early Genes or Receptor Activation*

Mating stimulated Fos in the Acb of male rats.[337,339] Moreover, sexual experience enhanced Fos-IR in the Acb induced by an estrous female, particularly in the Acb shell.[12] Fos was expressed in the Acb in response to female odors, but was also conditioned to a nonsexual odor paired with mating.[354] Conditioned odor cues also stimulated Fos-IR in the VTA.[571] Increased Fos-IR in the VTA of male rats that were exposed to sex-related cues or that copulated was found in both dopaminergic (tyrosine hydroxylase-IR) and nondopaminergic neurons.[572] Both types of stimuli also activated neurons in the Acb core and shell. In addition, μ opioid receptors in the VTA were internalized following both sex-related cues and copulation. The authors suggested that μ receptors on GABAergic neurons in the VTA release dopaminergic neurons from tonic inhibition. Tail pinch, an arousing stimulus that can promote copulation in olfactory bulbectomized males[326] or castrates maintained on subnormal T replacement[229] (reviewed above), also increased Fos-IR in the VTA as well as the MPOA, BST, paraventricular nucleus (PVN), Me, and several sites not usually associated with copulation. However, Fos expression in the Acb in response to sexual activity may be limited to rats. In hamsters and gerbils, no mating-induced increase in Acb Fos-IR was observed.[374,379]

Effects of Direct Applications of Drugs Affecting Specific Transmitters

DOPAMINE

Stimulation of impulse-regulating autoreceptors in the VTA with apomorphine delayed the onset of copulation and slowed its rate.[573] Similar microinjections slowed the speed of running in all four arms of an X-maze and increased the number of trials on which the male failed to leave the start area; however, neither the percentage of trials on which the male chose the female's goal box nor *ex-copula* genital reflexes were altered.[574] Thus, inhibiting mesocorticolimbic DA activity decreased behavioral activation but had no effect on specifically sexual motivation or on genital reflexes.

Application of drugs to the Acb also affected primarily activity measures. The onset of copulation was speeded by amphetamine and delayed by *cis*-flupenthixol or the DA neurotoxin 6-OHDA (reviewed in Ref. 353). Amphetamine also increased responding for a secondary reinforcer that had been paired with copulation.[353] The D_2/D_3 agonist quinelorane increased the number of trials on which the male failed to leave the start area but did not affect the percentage of trials on which he chose the female's goal box or his copulatory behavior when he reached the female.[490] It is not clear whether quinelorane's effects resulted from stimulation of terminal autoreceptors or postsynaptic receptors. However, drug injections into either the VTA or the Acb have affected general activation, with little influence on specifically sexual motivation or on copulatory measures.

OTHER NEUROTRANSMITTERS

A cholecystokinin A (CCK_A) antagonist, microinjected into the posteromedian Acb, attenuated the facilitation that resulted from electrical stimulation of the VTA, as did either a CCK_A or CCK_B antagonist into the anterolateral Acb.[559] CCK is located in dopaminergic terminals in the posteromedian Acb, but is in nondopaminergic terminals in the anterolateral portion.[575] These data suggest that CCK potentiates the facilitative effects of mesocorticolimbic DA activity.

5-HT microinjected into the Acb inhibited ejaculation (increased mounts, intromissions, and time preceding ejaculation); the 5-HT_{1A} agonist 8-OH-DPAT decreased those same measures.[576] Injection of these compounds into the dorsal striatum was without effect. The authors suggested that 8-OH-DPAT's effects may have resulted from antagonism of 5-HT_2 receptors.

Microinjection of the opioid antagonist naloxone into the VTA decreased anticipatory level changing in a bilevel apparatus but had no effect on sexual performance; β-endorphin had no effect.[233] Microinjections of the neuropeptide oxytocin into the VTA induced penile erections; this effect was inhibited by administration of an oxytocin receptor antagonist or DA receptor antagonist.[577] In addition, oxytocin-induced erections correlated with increased dopaminergic activity in the Acb and PVN.[577]

Chemical Changes Detected by Microdialysis or Voltammetry

Exposure of a male rat to the odor of an estrous female, but not of a nonestrous female, increased extracellular DA in the Acb.[534,578–580] DA levels also increased during copulation.[534,580,581] The DA response to the female's odor occurred on the first exposure to the odor[580] and was attenuated by systemically injected naloxone, which may have blocked the disinhibition of DA neurons by endogenous opioids.[582]

Finer temporal analysis, using in vivo voltammetry[583,584] or microdialysis with capillary chromatography,[585] revealed that Acb DA rose in response to the presentation of the female, increased further during

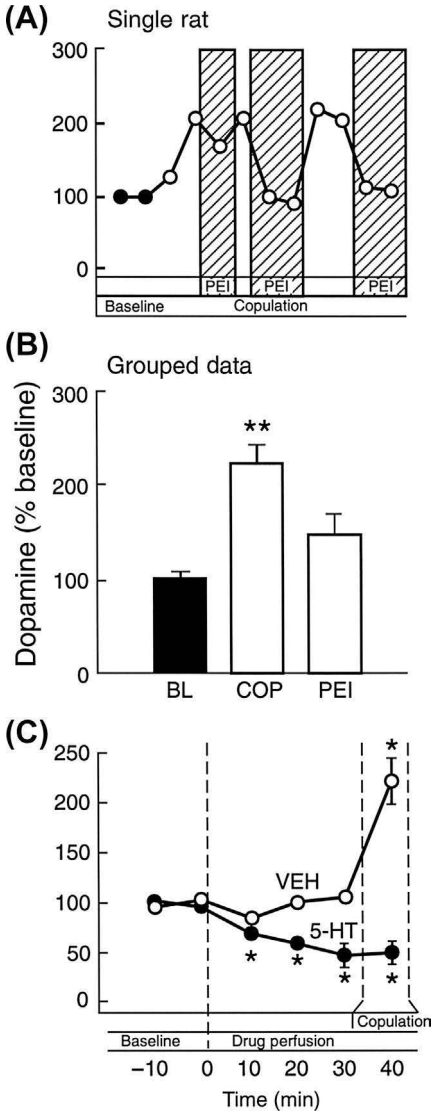

FIGURE 49.19 Levels of dopamine in microdialysate collected from the nucleus accumbens (Acb) of male rats during sexual behavior sessions. (A) Representative example of temporal changes in a single rat. (B) Mean change in DA levels (+SE) for a group of six rats. Samples were collected at 3-min intervals during three ejaculatory series and are designated precopulatory baseline (BL), copulation (COP) or postejaculatory interval (PEI). Dopamine content was significantly greater in samples collected during copulation, compared with samples collected under baseline and postejaculatory conditions (**$p < 0.01$). (C) Temporal change in dopamine concentration of the dialysates collected from the Acb before and during 40 min of 5-HT perfusion into the LHA of six male rats. Samples were collected at 10-min intervals. An estrous female was introduced to the male, and copulation was allowed during collection of the final sample during 5-HT perfusion. A significant decrease in dopamine occurred throughout the entire 5-HT perfusion period. This treatment blocked the increase in Acb DA seen in control animals during copulation.*$p < 0.05$, perfusion times versus time 0 (baseline). *Source: Figure is from Ref. 585, with permission.*

copulation, fell following each ejaculation, and increased again when the male resumed copulation (Figure 49.19). Reverse dialysis of 5-HT into the LHA decreased basal DA in the Acb and prevented the DA response to the female.[585] Because 5-HT is increased in the LHA with ejaculation,[533] one factor contributing to the postejaculatory interval may be decreased Acb DA, as a result of 5-HT release in the LHA.

Sexually satiated male rats, presented with a novel estrous female behind a barrier, showed a slight increase in extracellular DA in the Acb; DA rose significantly when the barrier was removed and the animals copulated.[586] Furthermore, sensitization to the motor-activating effects of amphetamine, following repeated systemic injections of amphetamine, also increased the DA response to a female.[147] Therefore, there is cross-sensitization between a psychostimulant drug and a natural motivated behavior. On the other hand, prenatal stress decreased the number of rats that were able to copulate, but did not affect the DA response to an inaccessible female or DA levels during copulation.[587]

Nigrostriatal DA Tract

The nigrostriatal tract arises from the substantia nigra of the midbrain (A9 cell group) and innervates the dorsal striatum (caudate putamen). Nigrostriatal activity enhances the readiness to respond to external stimuli.[588] Loss of nigrostriatal neurons in Parkinson's disease leads to difficulty in initiating movements and to slowing of movements. Nigrostriatal neurons respond rapidly to any sudden stimulus, but do not contribute to specific information about those stimuli.[589]

Effects of Electrolytic or Cell Body Lesions

Bilateral lesions of the substantia nigra slowed copulation and decreased the number of ejaculations.[555] These data support the proposal that nigrostriatal activity contributes to the somatomotor patterns of copulation.

Chemical Changes Detected by Microdialysis or Voltammetry

DA was released in the dorsal striatum only during copulation, in contrast to the DA release in the Acb and MPOA.[578] Therefore, nigrostriatal DA appears to be more important for motor activation than for sexual motivation.

Expression of c-fos *and/or Other Immediate–Early Genes*

Copulation elicited no increase in Fos-IR in the dorsal striatum, in contrast to the significant increases in the Acb, MPOA, BST, and piriform cortex.[339]

Paraventricular Nucleus of the Hypothalamus

The paraventricular nucleus (PVN) of the hypothalamus consists of a magnocellular division, which releases

oxytocin and vasopressin from the posterior pituitary, and a parvocellular division, which projects to several brain areas and the spinal cord (reviewed in Ref. 590). Axons projecting to the spinal cord contain oxytocin, vasopressin, somatostatin, DA, or other, undetermined neurotransmitters. The parvocellular division receives monoaminergic input from noradrenergic and serotonergic brainstem nuclei, as well as from periventricular DA neurons. The PVN is an important integrative site for autonomic and neuroendocrine functions. It is important for both NCE and seminal emission, but provides less critical contributions to touch-based erections and copulation. Oxytocinergic neurons projecting to several areas of the brain and spinal cord mediate much of the PVN's influence, and DA, glutamate, hexarelin analog peptides, and NO provide excitatory drive to those oxytocinergic efferents. GABA and opioid peptides and opiate drugs inhibit these neurons.

Effects of Electrolytic or Cell Body Lesions

Excitotoxic lesions of the parvocellular PVN decreased NCE but did not affect copulation.[591] Similar parvocellular lesions also failed to affect copulation but did decrease the amount of semen ejaculated and also decreased the number of oxytocin IR fibers in the lumbosacral spinal cord.[592] Larger lesions encompassing both the parvo- and magnocellular divisions inhibited both noncontact and touch-based erections and, in copulation tests, decreased intromission ratio and increased ejaculation latency.[591] On the other hand, electrolytic lesions of the PVN only decreased the latency to the first touch-based erection (i.e., facilitated erection).[197] Therefore, the PVN appears to contribute to both NCE and seminal emission, but PVN lesions have inconsistent effects on touch-based erections and copulation.

Lesions of the lateral parvocellular portion of the PVN destroyed the neurophysin-containing axons to the sexually dimorphic spinal nucleus of the bulbocavernosus (SNB).[593] Neurophysin is used as a marker for oxytocin and vasopressin. Neurophysin-containing terminals appeared to be in contact with somas and dendrites of the SNB. Thus, PVN is apparently the source of oxytocinergic neurons to the SNB, which promote seminal emission and ejaculation.

Effects of Direct Applications of Drugs Affecting Specific Transmitters

DOPAMINE AND OXYTOCIN

Microinjections of the DA agonist apomorphine,[594] the D_2 agonist quinpirole, or oxytocin[595] into the PVN elicited drug-induced erections, which were blocked by an oxytocin antagonist microinjected ICV.[596] PVN microinjections of apomorphine[479] or the D_2/D_3 agonist quinelorane[597] also increased touch-based erections and *ex-copula* seminal emissions. In addition, apomorphine in the PVN elicited increases in intracavernous pressure in anesthetized rats, a response that was enhanced by systemic administration of the monoamine oxidase B inhibitor, selegiline.[598] An oxytocin antagonist administered ICV, but not into the PVN, inhibited NCE,[599] suggesting that axons from the PVN, terminating perhaps in the hippocampus,[600] facilitate NCE. A more recent

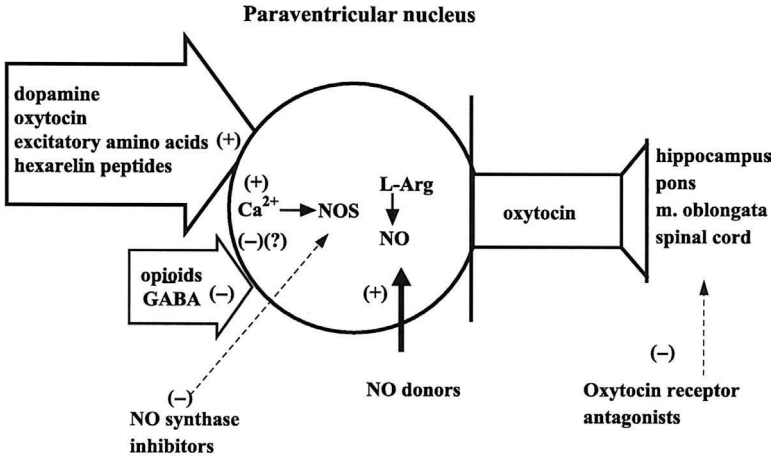

FIGURE 49.20 A schematic representation of oxytocinergic neurons originating in the paraventricular nucleus (PVN) of the hypothalamus and projecting to extrahypothalamic brain areas and the spinal cord involved in sexual activity. Activation of these neurons by dopamine, excitatory amino acids, oxytocin itself, and hexarelin analog peptides facilitates penile erection and sexual activity. The direct or indirect activation of these neurons and the facilitative effects on erection and sexual activity induced by the above substances can be reduced or abolished by the stimulation of opioid and GABAergic receptors. These oxytocinergic neurons are activated by the activation of NOS, present in their cell bodies. Endogenous NO, formed by stimulation of dopamine, excitatory amino acid, or oxytocin receptors; or exogenous NO, derived from NO donors delivered to the PVN, activates oxytocinergic neurons by a yet-unidentified mechanism. This causes the release of oxytocin in brain areas distant from the PVN, as well as the spinal cord, inducing penile erection. Similar mechanisms operate during noncontact erections and copulation. *Source: Figure reproduced from Ref. 602, with permission.*

article suggests that stimulation of D2 receptors in the PVN increases Ca^{2+} influx into oxytocin neurons, leading to production of NO and the resultant release of oxytocin in extra-hypothalamic sites and spinal cord, which increases penile erection and yawning.[601] In summary, DA, acting via D_2 receptors, apparently increases oxytocin release, which in turn promotes drug-induced and NCE (Figure 49.20) (reviewed in Refs 602,603).

NITRIC OXIDE

PVN administration of the NOS inhibitor N(G)-nitro-L-arginine methyl ester (L-NAME) decreased NCE and impaired copulation in male rats.[604] Another NOS inhibitor, N(G)-monomethyl L-arginine (L-NMMA), reverse-dialyzed into the PVN, decreased touch-based erections, whereas the NO precursor L-arginine increased erections; however, copulation was not affected by either drug.[605] These authors noted that similar administration of L-NMMA into the MPOA did decrease the rate of mounting in copulation tests.[501] Therefore, manipulations of NO in the PVN have had inconsistent effects on copulation, but NO antagonists have consistently inhibited noncontact and touch-based erections.

AMINO ACIDS

The glutamate agonist N-methyl-D-aspartate (NMDA), microinjected into the PVN, elicited erections; this effect was blocked by the NMDA antagonist MK-801 (dizocilpine) and by the NOS antagonist L-NAME.[606] Therefore, glutamate, by opening calcium channels associated with NMDA receptors, may lead to calcium activation of calcium-calmodulin kinase (CAM kinase), which in turn activates NOS. Conversely, microinjections of the $GABA_A$ agonist muscimol into the PVN inhibited erections elicited by apomorphine, oxytocin, or NMDA.[607] The $GABA_B$ agonist baclofen was ineffective. Extracellular levels of glutamate and aspartic acid in the PVN increased during exposure to a receptive female and increased further during copulation.[608] Furthermore, microinjection of an NMDA receptor antagonist (MK-801) into the PVN inhibited both NCE and copulation; an AMPA receptor antagonist (CNQX) also impaired copulation, but to a lesser extent.[608]

ADRENOCORTICOTROPIC HORMONE

Microinjected into the periventricular hypothalamus, including the PVN, ACTH elicited erections.[281] Similar injections into the POA, caudate nucleus, or hippocampus were ineffective.

OPIATES

Morphine, administered unilaterally into the PVN before introduction of an inaccessible estrous female, prevented NCE, as well as the increases in production of NO (see the section Chemical Changes Detected by Microdialysis below) observed with control injections.[609]

HEXARELIN ANALOG PEPTIDES

Hexarelin analog peptides, microinjected into the PVN, elicited erections, probably by stimulating specific receptors on oxytocinergic cell bodies, which increase Ca^{2+} influx and activate NOS (reviewed in Ref. 602).

Chemical Changes Detected by Microdialysis

An increase in NO, inferred from increases in NO_2 and NO_3, was detected in microdialysate from the PVN during both NCE and copulation.[604] This increase was blocked by ICV injection of hemoglobin, an NO scavenger, but not by injections into the PVN; PVN injections of hemoglobin also failed to inhibit NCE.[604] Therefore, NO appears to work intracellularly in the PVN, but to have additional effects in other areas that are important for erections. PVN microinjections of morphine inhibited both copulation and the copulation-induced increase in NO.[609] L-arginine, reverse-dialyzed into the PVN, increased both NO production and touch-based erections, and L-NMMA had the opposite effects.[605] Both NO production and NCE were increased by apomorphine or the D_2 agonist LY-171555, but not by the D_1 agonist SKF-38393.[610] The increase in NO production was blocked by a D_2 antagonist (L-sulpiride) but not by a D_1 antagonist (SCH-23390). However, the increase in erections was blocked by both antagonists, suggesting that both D_1 and D_2 receptors contribute to erectile function. On the other hand, a later study failed to find an inhibitory effect of a D_1 or D_2 antagonist, or of an oxytocin antagonist, administered into the PVN, on NCE or on the production of NO in the PVN, although an NMDA antagonist reduced both.[611] Furthermore, the NMDA microinjections that elicited erections (see above) also increased NO in the PVN.[606]

Microinjection of omega-conotoxin, a potent inhibitor of N-type voltage-activated calcium channels, prevented apomorphine- and oxytocin-induced erections and NO production.[612] Exogenous provision of NO by the NO donors sodium nitroprusside or hydroxylamine overcame the effects of the omega-conotoxin, bypassing the need for activation of N-type channels that were indirectly activated by apomorphine and oxytocin. Omega-conotoxin also failed to block NMDA facilitation of NO production and erections, because NMDA stimulates ligand-activated calcium channels, not voltage-gated channels. Consistent with the facilitative effects of the DA agonist apomorphine and of D_2 agonists, increases in DA release in the PVN were observed during NCE and, to an even greater extent, with copulation.[613]

Presence of Steroid Receptors

The lateral parvocellular subdivision of the PVN projects to the L5-L6 region of the spinal cord; 30% of

those neurons concentrated E2, and almost half of the E2-concentrating neurons projected to the lumbar spinal cord.[614] Therefore, some of the effects of steroids on the SNB may be indirect, mediated by steroid-sensitive afferents.

Expression of c-fos *and/or Other Immediate–Early Genes*

Intromission and ejaculation increased Fos-IR in the parvocellular regions of the PVN, with ejaculation eliciting 2.5 times as many Fos-IR neurons.[615] Ejaculation also elicited more Fos-IR neurons in the magnocellular division than did intromission, although overall numbers were lower than in the parvocellular regions. Half the Fos-IR neurons contained oxytocin, even in noncopulating males. Indeed, copulation did not affect the percentage of double-labeled cells, except in the caudalmost PVN, where one-third of the lateral parvocellular neurons were double-labeled following ejaculation, but no cells were double-labeled in noncopulating animals. However, use of a more selective antibody for Fos, as opposed to Fos plus Fos-related antigens (Fras), revealed no double labeling of Fos and oxytocin following ejaculation in male rats (L. Coolen, personal communication). In gerbils neither exposure to an arena previously associated with copulation, nor copulation itself, increased PVN Fos expression.[374] On the other hand, in a more recent report, copulation did increase the number of neurons double-labeled for oxytocin and Fos-IR.[616] Exposure to an anesthetized female also increased Fos-IR in oxytocin-containing cells in sexually experienced males, but not in naive males. Perhaps variability in Fos-IR in non-oxytocin cells contributed to a lack of statistical significance in the earlier studies that found no Fos increases.

Expression of mRNA or Immunocytochemistry for Neuropeptides

Sexually impotent male rats had less expression of oxytocin mRNA in the PVN, and greater expression of mRNA for proenkephalin and prodynorphin, than did sexually competent males.[617] This finding fits well with the observation that morphine in the PVN inhibited NO production and copulation.[609] In addition, NOS is co-localized with oxytocin in the PVN.[618] Activation of these neurons facilitates *ex-copula* erections and may also contribute to copulation. The oxytocin is released in the hippocampus, where it promotes erections,[600] and in the spinal cord, where it promotes seminal emission.[592]

Efferent Projections

Axons project from the PVN to the nucleus paragigantocellularis (nPGi),[619] a major source of inhibition of genital reflexes and copulation (see the section Nucleus Paragigantocellularis of the Medulla later in the chapter). Axon terminals formed close appositions to serotonergic neurons that projected to the lumbosacral spinal cord and indirectly to the corpus cavernosum. Thus, the PVN is positioned to exert control over inhibitory serotonergic projections to the spinal areas that control erection.

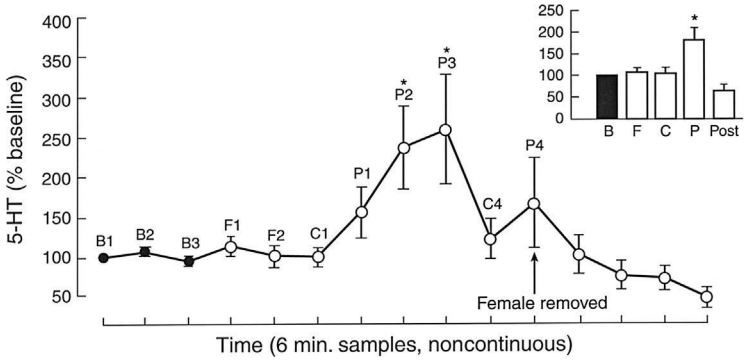

FIGURE 49.21 Temporal changes in extracellular serotonin (5-HT) collected from the lateral hypothalamic area (LHA) of male rats before and during copulation. Each data point is the mean (± SE) for 6-min dialysate samples collected during baseline (B), in the presence of an estrous female (F), during copulation (C), during the postejaculatory interval (P), and after the female was removed (expressed as a % of mean baseline levels). A total of four samples were analyzed after the female was removed, at 30-min intervals. 5-HT levels increased during the second (P2) and third (P3) postejaculatory intervals, compared to final baseline (B3), female behind barrier (F2), and first copulation period (C1). 5-HT during P3 was also higher than during the fourth copulation interval (C4). Samples collected during the second and third copulation series were not analyzed, because most males ejaculated before a full 6-min sample could be collected. The summary graph (inset) represents the mean (± SE) for data from the 15 sample periods collapsed into five groups, based on behavioral condition. Samples collected during the postejaculatory intervals showed higher 5-HT levels compared to all other conditions. Basal extracellular concentrations of 5-HT in the LHA were calculated to be 1.6 ± 0.1 nM. *Source: Figure from Ref. 533, with permission.*

Lateral Hypothalamus

Reciprocal connections of the MPOA with downstream structures pass through the lateral hypothalamus (LH) as part of the medial forebrain bundle,[425] and LH lesions that sever these connections are as effective as MPOA lesions in abolishing copulation. However, LH cell bodies may also influence copulation.

Effects of Direct Applications of Drugs

Microinjection into the anterior LH (LHA) of a selective 5-HT reuptake inhibitor (SSRI) delayed the onset of copulation and delayed ejaculation after the animals did begin to copulate.[533] Thus, the impairment by SSRIs of sexual motivation and ejaculation (reviewed in Ref. 186) may be mediated, in part, by increased 5-HT in the LH.

Changes Detected by Microdialysis

5-HT is released in the LHA at the time of ejaculation, and an SSRI microinjected into the LHA delayed the onset of copulation and delayed ejaculation after the male did begin to copulate (see Figure 49.21).[533] Reverse dialysis of 5-HT into the LHA decreased basal DA levels in the Acb and prevented the usual DA increase during copulation.[585] Because DA release in the Acb contributes to numerous motivated behaviors, the inhibition induced by 5-HT in the LHA may at least partially explain the diminished sexual motivation associated with clinical use of SSRI antidepressants (reviewed in Ref. 186).

Orexin/Hypocretin Neurons

Exposure to a receptive female or copulation increased the number of orexin/hypocretin (orx/hcrt) neurons, located in the perifornical lateral hypothalamus, that were Fos-IR, compared to exposure to another male or placement into an empty cage, respectively.[620] 5-HT inhibits orx/hcrt neurons, which would otherwise excite VTA mesolimbic DA neurons (Figure 49.22).[620] Orx/hcrt neurons are decreased in number by castration and restored by estradiol.[620] Therefore, one means by which SSRIs inhibit mating is via inhibition of orx/hcrt neurons in the LHA that would otherwise activate the mesolimbic system. However, another study reported that specific lesions of orexin/hypocretin neurons did not affect copulation in experienced males and actually shortened the latency to mount in naive males; they also decreased anxiety-like behavior in an elevated plus maze, suggesting that the shortened latencies may have been due to reduced anxiety in the naive males.[621] The reason for the apparent discrepancy between the two studies is not clear.

Ventromedial Hypothalamus

The ventromedial hypothalamus (VMH) is recognized primarily for its role in the control of female rat sexual behavior. (see Chapter 50.) However, the VMH may also modify male sexual behavior. Like the MPOA, the VMH has abundant receptors for androgens and estrogens[411,622] and receives genitosensory input through midbrain projections,[417] as well as chemosensory stimuli via projections from the Me.[402,623,624]

Effects of Electrolytic or Cell Body Lesions

Lesions of VMH often enhance aspects of male sexual activity, suggesting that VMH may tonically inhibit masculine sexual behavior. In this regard, small electrolytic lesions of the VMH in castrated male rats treated with exogenous T reduced the latency to express copulatory behavior.[625] However, in male hamsters, VMH lesions increased ultrasonic vocalizations, but did not alter copulation.[626]

Effects of Hormonal Manipulations

Both ARs and ERs are present in the VMH of male rats[411] and hamsters.[622] Nonetheless, intracerebral implants of T into the VMH in castrated male rats or mice failed to stimulate copulation or ultrasonic vocalizations.[627,628] However, T in the VMH restored partner preference in male rats,[627] and increased urine marking in male mice,[628] suggesting that the VMH contributes to hormone-sensitive

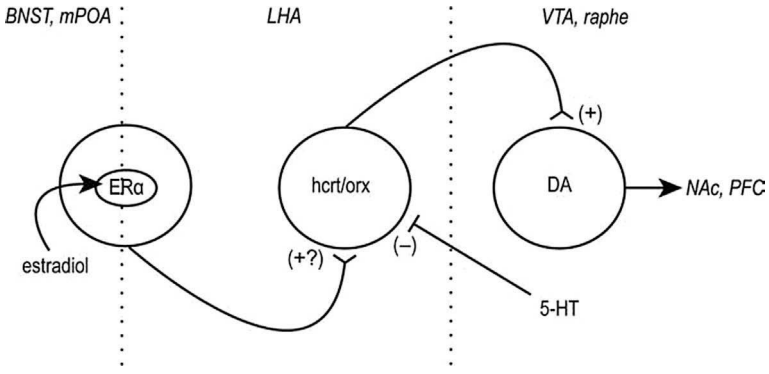

FIGURE 49.22 A model for regulation of hypocretin/orexin (hcrt/orx) by gonadal steroids and ventral tegmental area (VTA) dopamine (DA). Estradiol, synthesized from gonadal testosterone by aromatase, acts on ERα-containing neurons in the bed nucleus of the stria terminalis (BNST), the medial preoptic area (MPOA), and lateral hypothalamic area (LHA). These structures project to hypothalamic hcrt/orx neurons. Excitatory projections from these structures may influence hcrt/orx neuronal and gene expression activity in a steroid-sensitive manner. Hcrt/orx projections to VTA enhance midbrain DA neuronal activity during male sexual behavior. This effect may be blocked by intra-LHA infusions of 5-HT that inhibit hcrt/orx activity, impairing sexual behavior and NAc DA release. *Source: Figure is reprinted from Ref. 620, with permission.*

sexual motivation. Conversely, intracerebral implants of the AR antagonist hydroxyflutamide into the VMH of castrated male rats with T replacement blocked both sexual motivation and sexual behavior.[474] Therefore, it appears that the VMH transduces androgen stimuli important for sexual motivation and copulation. The inhibitory effects of hydroxyflutamide in the VMH stand in contrast to the facilitative effects of VMH lesions described above. It may be that AR-containing neurons inhibit other VMH neurons, or may themselves be inhibited during mating, thereby facilitating male copulatory behavior. Androgen-responsive neurons in the VMH may also affect sexual activity through projections to other sites, including the midbrain.[629]

Expression of c-fos *or Other Immediate–Early Genes*

Mating induced Fos-IR in the VMH in male rats[630] and gerbils.[374] In rats, bedding from estrous females failed to increase Fos-IR in the VMH, suggesting that mating is required to activate Fos expression.[369] However, Fos expression was unaffected by pelvic nerve hemisection in gonadectomized male rats primed with E and progesterone.[631] This suggests that Fos expression in the VMH of males is more dependent on chemosensory input or genitosensory input carried through other pathways, such as the pudendal nerve. By contrast, copulatory activity was not required for the increase in Fos expression in male gerbils.[374]

In contrast to the mating-induced Fos induction observed in the VMH of male rats and gerbils, mating may inhibit neural activity in the VMH of other species. Mating did not increase Fos-IR in the VMH of male musk shrews, although Fos-IR was significantly increased in the VMH of females.[632] Similar results were observed in male hamsters,[540] mice,[338] and ferrets.[344] In male macaques, mating actually elicited less Fos-IR in the VMH than did exposure to an inaccessible female.[409] or exposure to an arena previously associated with copulation.[374]

Midbrain Periaqueductal Gray

In the context of sexual behavior, the midbrain periaqueductal gray (PAG) is primarily associated with vocalization and with lordosis in females. Nonetheless, the PAG has steroid receptors[633] and extensive reciprocal connections with the MPOA (Ref. 424; reviewed in Ref. 3).

Effects of Electrolytic or Cell Body Lesions

The effects of PAG lesions in male rodents are similar to the effects of VMH lesions. That is, lesions of the PAG stimulate sexual activity in male rats.[555] Electrical stimulation of caudal PAG in male guinea pigs produced vocalizations related to sexual behavior.[634] However, combined unilateral lesions of the ventrolateral PAG and the contralateral sexually dimorphic area of the MPOA in male gerbils did not affect mating.[635]

Steroid Receptors and Connections

The caudal two-thirds of the PAG contains a large population of ERα and AR receptors.[636] In the middle third of the PAG, steroid-sensitive neurons were distributed primarily in the dorsomedial and lateral PAG; in caudal PAG, immunoreactive cells were located primarily in the dorsal half. Afferents from the MPOA terminated in close apposition to ERα-IR and AR-IR neurons in the PAG, and between 17% and 54% of PAG neurons that projected to the nucleus paragigantocellularis (nPGi; see the following section) were also immunoreactive for ERα or AR.[633] These data suggest the existence of a hormone-sensitive output pathway for male sexual behavior that extends from the MPOA through the PAG to the nPGi. Similarly, in rhesus monkeys, the PAG projects to the nucleus retroambiguous, a premotor area in the medulla.[637]

MAJOR MOTOR OUTPUTS

Ventral Premammillary Nucleus

The ventral premammillary nucleus receives input from the MPOA, the VMH, and the posterodorsal part of the Me.[623] ARs are located in this nucleus in rats[411] and Syrian hamsters.[393] Fos-IR was increased in this nucleus in male rats following copulation,[630] and Fos-IR neurons also contained AR.[373] Female-soiled bedding elicited Fos-IR in the ventral premammillary nucleus of mice, although no increase was observed in the VMH, posterodorsal medial amygdala, or posteromedial cortical amygdala of these animals; gerbils did not show increased Fos-IR following either copulation

Nucleus Paragigantocellularis of the Medulla

Spinal mechanisms that control erection are under tonic inhibitory control. In rats,[19,638,639] mice,[20] and dogs[640] spinal transection results in an increase in the number or intensity of erections or UG reflexes or a decrease in the amount of stimulation required to elicit such responses. There is increasing evidence that a major source of that inhibition is the nucleus paragigantocellularis (nPGi) of the medulla, located in the ventrolateral medulla. Excitotoxic lesions of the nPGi facilitated copulation in male rats, indicating that resident neurons, not fibers of passage, mediated the effects.[641] Furthermore serotonergic lesions of the periaqueductal gray, which decreased 5-HT in the nPGi, also facilitated copulation.[642]

Effects of Electrolytic or Cell Body Lesions

Bilateral electrolytic lesions of the nPGi in sexually naive male rats increased the number of animals that ejaculated on their first exposure to an estrous female.[643] In the males that did ejaculate, nPGi lesions decreased the time and the numbers of mounts and intromissions preceding ejaculation and increased copulatory efficiency. In sexually experienced males, nPGi lesions increased the latency to sexual satiety and increased the number of ejaculations preceding satiety.[643] Similar lesions decreased the latency to the onset of touch-based penile reflexes and increased the number of anteroflexions.[644,645] External anal reflexes were unaffected by nPGi lesions. Instead, anal reflexes were facilitated by nucleus raphe obscurus lesions, which had no effect on erection, indicating a differential control of sexual and defecatory function.[645] Lesions of the nPGi also allowed the UG reflex to be elicited without spinal transection.[646] Indeed, nPGi lesions were as effective as spinal transection in disinhibiting the UG reflex, suggesting that the nPGi is a major source of the tonic inhibition.

Effects of Electrical Stimulation

Electrical stimulation of the nPGi of male rats has been demonstrated to activate and inhibit pudendal motoneurons.[647] It elicited field potentials in the lumbosacral cord in regions containing spinal cord neurons projecting to motoneurons of the pudendal nerve.[648] Sympathetic fibers in the pudendal nerve were specifically activated by nPGi stimulation.[649] Spinal reflex activation of pudendal neurons by stimulation of the dorsal nerve of the penis was inhibited by nPGi stimulation.[650]

Immunocytochemistry

Anatomical tracing studies demonstrated that neurons in the nPGi project directly to pudendal motoneurons in the dorsolateral and dorsomedial nuclei, sympathetic and parasympathetic preganglionic neurons in the T13-L2 and L6-S1 segments, respectively, and to the interneuronal regions of the medial gray lumbosacral cord.[644,651] A majority (78%) of nPGi neurons projecting to the lumbosacral spinal cord contain 5-HT.[196] These serotonergic neurons receive a direct projection from the PVN.[619] Animals pretreated with the serotonergic neurotoxin 5,7 dihydroxytryptamine demonstrated a decreased descending inhibition in UG reflex tests, and application of 5-HT to the spinal cord suppressed the UG reflex in spinalized rats.[458] Therefore, serotonergic input could mediate the tonic inhibition of genital reflexes.

Other Brain Areas

In a classic study, electrical stimulation of the cingulate gyrus, the medial dorsal nucleus of the thalamus, the periventricular region, and the VTA elicited erections in conscious monkeys.[652] Stimulation of the hippocampus in anesthetized rats also elicited erections.[653] The hippocampus receives excitatory oxytocinergic inputs from the PVN,[603] as well as serotonergic input from the raphe nuclei.[218,654]

Lesions of the lateral septum decreased the numbers of mounts and intromissions.[655] However, the AR antagonist hydroxyflutamide, implanted in the lateral septum of male rats, failed to prevent the T-induced restoration of copulation in castrated male rats, although similar implants into the MPOA did prevent such restoration.[391] Thus, the lateral septum may facilitate copulation, but ARs in that area appear not to contribute to its effects. Microinjection of vasopressin into the lateral septum of monogamous male prairie voles promoted pair bonding, and either a vasopressin or an oxytocin antagonist in the lateral septum blocked pair bonding elicited by either mating or microinjection of vasopressin.[656]

Lesions of the caudal zona incerta, in the subthalamic region, abolished copulation in male rats, without affecting the preference for a receptive female.[657] Thus, the zona incerta appears to be an important node in the circuit that controls copulation; however, little is known of its specific contributions.

Several cortical regions were activated during positron emission tomography (PET) scans when men were shown sexually explicit films, compared to neutral or humorous films.[80] These areas included the inferior temporal cortex, a visual association area; the right insula and right inferior frontal cortex, paralimbic areas that associate highly processed sensory information with emotional states; and the left anterior cingulate cortex, which is associated with autonomic and neuroendocrine states. Plasma T levels were correlated positively with activity in some of these areas.

Spinal Cord

The spinal cord contains the autonomic and somatic nuclei that control the hemodynamic and striated muscle effectors of erection, ejaculation, and detumescence and that provide initial processing of somatic and visceral information from the genital region. Both descending axons from the brain and local reflex loops are important for these processes (see Ref. 38 for review).

Effects of Lesions or Transections

There is convincing evidence of descending inhibition from supraspinal sources, which can be eliminated by transection of the spinal cord. Spinal cord transection releases the UG reflex from descending inhibition, allowing it to be elicited by urethral stimulation.[22] Early postnatal spinal cord transection also accelerates the developmental expression of touch-based erections in

male rats from about 38 to about 28 days of age, without altering androgen titers or their morphological correlates. Spinal cord transection also reversed the inhibition of penile reflexes resulting from dorsal penile nerve transection,[639] application of a topical anesthetic to the glans penis,[658] or excision of the penile sheath, which removes the tonic stimulation necessary for penile reflexes in neurally intact rats.[659]

Effects of Direct Application of Drugs Selective for a Neurotransmitter

The need for caution in interpreting the effects of spinal transection is emphasized by a study in which spinal anesthesia was induced in rats at the thoracic level via an intrathecal cannula.[660] After induction of spinal block, supine males exhibited the abbreviated erection latencies characteristic of spinally transected males, but unlike transected males, they had fewer and weaker erections. The reduction in erection latency may truly be due to the removal of inhibitory influences from the brain, but the decreased number and intensity of erections in spinally blocked males implies interference with excitatory influences from the brain. The increase in touch-based erections after surgical transection may therefore be secondary to neural reorganization within the cord, rather than a direct effect of removing supraspinal inhibition.

SEROTONIN

The UG reflex typically cannot be elicited unless the spinal cord is transected,[22] the nPGi is ablated,[644] or the MPOA is stimulated.[458] However, either intrathecal or ICV administration of the 5-HT neurotoxin 5,7-DHT allowed the UG reflex to be elicited without spinal transection, nPGi ablation, or MPOA stimulation.[458] This suggests that descending serotonergic axons are responsible for a major part of the central inhibition of this reflex. As noted above, a majority (78% ipsilateral) of the axons from the nPGi contain 5-HT.[644] Intrathecal administration of 5-HT abolished the UG reflex, and the 5-HT antagonist methysergide prevented the 5-HT-induced blockade of the reflex.[644] In addition, lesions of the median raphe nuclei (a major source of serotonergic neurons) significantly increased the numbers of anteroflexions (penile body erections) and cups (intense glans erections) in tests of touch-based erections.[197]

Intrathecal administration of either 5-HT or thyrotropin releasing hormone (TRH) resulted in only slight increases in mount and intromission latencies. However, co-administration of 5-HT and TRH caused a marked increase in mount and intromission latencies.[661] However, in a test of touch-based penile reflexes, intrathecal administration of TRH alone decreased the proportion of responders, decreased the numbers of reflexes, and increased their latencies.[662] TRH and 5-HT are co-localized in some bulbospinal neurons.[663] Furthermore, methiothepin, a relatively nonspecific 5-HT antagonist, partially blocked some of the inhibitory effects of TRH.[664] Therefore, either 5-HT or TRH may inhibit copulation and genital reflexes, but their effects may be enhanced by co-administration or endogenous co-release.

In contrast to the demonstrated inhibitory effects of 5-HT on genital reflexes, stimulation of one receptor subtype, the 5-HT_{2C} receptor, appears to facilitate erectile function (see the section Effects of Systematically or Intracerebroventricularly Administered Drugs) Consistent with such a facilitative effect, a systemically administered 5-HT_{2C} agonist (mCPP) facilitated erections in monkeys and rats (reviewed in Ref. 3). In anesthetized animals, the reflex response of the cavernous nerve to stimulation of the dorsal penile nerve is facilitated after the complete section of the spinal cord at the thoracic level and after systemic injection of mCPP.[214]

Intrathecal administration of 8-OH-DPAT decreased the percentage of male rats displaying touch-based erections and seminal emissions.[665] This is in dramatic contrast to the facilitative effects of intrathecally administered 8-OH-DPAT on copulation, and especially ejaculatory threshold. In the copulation tests, 8-OH-DPAT decreased ejaculation latency, intercopulatory interval, and the number of intromissions preceding ejaculation.[665] The basis for the apparent discrepancy between *in-copula* and *ex-copula* measures is not clear. However, a similar discrepancy was observed with intrathecal apomorphine (see below).

GAMMA-AMINO BUTYRIC ACID

In the lower spinal cord, GABA inhibits sexual reflexes. Intrathecal injection of the $GABA_B$ agonist baclofen into the lumbosacral (L5-S1) spinal cord decreased the number of touch-based erections and increased the latency to the first glans erection. The highest dose completely blocked penile responses.[666] However, none of the doses used prevented males from copulating to ejaculation. *In-copula* ejaculation shortly before the reflex test facilitated the onset of touch-based erections in saline controls and also blocked the inhibitory effects of the lower two doses of baclofen, but not the highest dose. Therefore, as in the experiment using 8-OH-DPAT,[665] different neural mechanisms appear to control copulation and *ex-copula* reflexes. In contrast to the inhibitory effects of intrathecal baclofen on *ex-copula* reflexes, the $GABA_A$ agonist THIP produced only slight inhibitory effects at the highest dose. Therefore, stimulation of spinal $GABA_B$, but not $GABA_A$, receptors inhibits *ex-copula* reflexes.

DOPAMINE

Intrathecal infusion of lisuride, a nonspecific monoamine agonist, into the region of the rostral lumbar spinal cord of male rats produced the same effects on copulation as seen following systemic injection, namely,

decreased time and number of intromissions preceding ejaculation.[667] Therefore, stimulation of some type(s) of monoamine receptors appears to facilitate ejaculation, perhaps by increasing sensitivity to peripheral stimulation. Furthermore, intrathecal administration of the catecholamine neurotoxin 6-OHDA increased postejaculatory intervals of male rats and rendered the animals more sensitive to androgen deprivation.[668]

Intrathecal administration of the DA agonist apomorphine also decreased the number of intromissions preceding ejaculation, suggesting that stimulation of spinal cord DA receptors facilitated ejaculation.[668a] However, intrathecal apomorphine also increased the interintromission interval, the ejaculation latency, and the postejaculatory interval. In touch-based reflex tests, the highest dose of intrathecal apomorphine decreased the numbers of touch-based erections and anteroflexions but did not affect seminal emissions.[668a] These data stand in contrast to the effects of systemic injection of apomorphine, which facilitated erections at low doses, inhibited erections at high doses, and facilitated seminal emissions at both low and high doses.[148] However, in anesthetized rats, intracavernous pressure was increased by apomorphine administered intrathecally.[669] The explanation for the different results from these studies is unclear.

NOREPINEPHRINE

Intrathecal administration of NE increased the frequency of pelvic thrusting during intromission, whereas intrathecal administration of both the α_2 agonist clonidine and the β agonist isoproterenol decreased the frequency of thrusting.[670] It is likely that clonidine's inhibitory effect resulted from stimulation of α_2 autoreceptors, thereby decreasing NE release. These results are consistent with the findings that α_1 receptors probably mediate NE's facilitative effects on copulation.

OXYTOCIN

Administration of oxytocin at the lumbosacral, but not the thoracolumbar, level increased intracavernous pressure in dose-dependent fashion.[669] The proerectile effects of intrathecal oxytocin were blocked by an oxytocin antagonist, pelvic nerve section, and a nicotinic antagonist, which blocked transmission between the pre- and postganglionic parasympathetic nerves. An oxytocin agonist also produced proerectile effects. Intrathecal administration of a NO inhibitor blocked the pro-erectile effects of intrathecally delivered oxytocin, indicating that the effects of oxytocin in the spinal cord are mediated through NO interneurons. Vasopressin, a nonapeptide that differs from oxytocin by only one amino acid, was ineffective, as were lumbosacral saline and systemic oxytocin. Blockade of striated muscle activation failed to inhibit oxytocin's facilitative effects, suggesting that oxytocin's effects were mediated by the parasympathetic nervous system, and not by striated penile muscles. These data provide compelling evidence for the proerectile role of oxytocin-containing fibers descending from the PVN to the lumbosacral cord.

OPIATES

Intrathecally administered naloxone decreased the number of intromissions preceding ejaculation, whereas morphine administered in a similar manner increased the number of intromissions.[671] These treatments had no other effects on copulation. The authors suggested that naloxone and morphine influenced the strength of the sensory signal from each intromission.

NITRIC OXIDE

As noted in the section on MPOA stimulation, intrathecal administration of an NO donor, a cGMP analog, or the phosphodiesterase-V inhibitor sildenafil enhanced the increase in intracavernous pressure elicited by electrical stimulation of the MPOA; the NOS inhibitor L-NAME reduced the response.[457] None of these treatments affected blood pressure or intracavernous responses to cavernous nerve stimulation. The authors concluded that central NO/cGMP can affect erectile capacity.

Chemical Changes Detected by Analysis of Cerebrospinal Fluid

The concentration of GABA in cerebrospinal fluid of male rats increased by more than 1000% following ejaculation; concentrations of aspartate and glutamate increased by about 200%.[672] Therefore, the concentration of a major inhibitory neurotransmitter increased markedly during the absolute refractory interval.

Presence of Steroid Receptors

AR-IR was found in three areas of the male rat lumbosacral spinal cord: the spinal nucleus of the bulbocavernosus (SNB), dorsolateral nucleus (DLN), and retrodorsolateral nucleus (RDLN).[673] Virtually no AR-IR was seen in long-term castrated males or males with the Tfm mutation, which renders the AR inactive. Furthermore, unilateral capsules filled with T and placed next to the bulbospongiosus muscle, increased the dendritic arborization of SNB neurons of castrated male rats. In contrast, testosterone administered to the spinal cord of castrated rats was ineffective.[674] Thus, despite the presence of AR in the pudendal motoneurons, the trophic effect of androgens is mediated by actions on the target muscle.

Gréco et al.[675] also found dense labeling for AR in the L5-S1 segments of the spinal cord, especially in the dorsal part of Lamina X. Furthermore, mating-induced Fos-IR was predominantly located in AR-IR neurons.

Therefore, the lumbosacral neurons that are activated by mating are androgen sensitive.

Immunocytochemistry

The 5-HT_{2C} receptor at the spinal level appears to facilitate erectile function. Consistent with such a facilitative effect, 5-HT_{2C} receptor immunoreactivity was found on motoneurons of the sacral parasympathetic nucleus, the dorsal gray commissure, and the motoneurons of the ventral horn.[676] Furthermore, 5-HT_{2C} receptor immunoreactivity was exhibited by all neurons retrogradely labeled from the corpus cavernosum to the sacral parasympathetic nucleus and the dorsal gray commissure of L5-L6, and in ventral horn motoneurons retrogradely labeled from the ischiocavernosus and bulbospongiosus muscles. Therefore, the neurons that are known to promote erection possess 5-HT_{2C} receptors.

Immunocytochemical studies revealed that dopaminergic fibers and terminals exist in virtually all laminae throughout the spinal cord.[677] D_2 receptors identified by immunohistochemical and in situ hybridization techniques were noted in the parasympathetic area of the lumbosacral spinal cord and found to be particularly abundant in the dorsomedial and dorsolateral motoneurons innervating the bulbospongiosus and ischiocavernosus muscles.[678]

Neurons and fibers immunoreactive for α_{2a} and α_{2c} adrenoceptor subtypes were identified in the intermediolateral cell column, the dorsal gray commissure, and the ventral horn of the T12-L2 and L5-S1 spinal cord. The dorsal horn displayed only α_{2a}-IR fibers. Pseudorabies virus-infected neurons in the autonomic nuclei were immunoreactive for both α_{2a} and α_{2c} adrenoceptor subtypes and closely apposed by α_{2a} and α_{2c} immunoreactive fibers.[679] These results suggest an intraspinal modulation of the noradrenergic and adrenergic control of the autonomic outflow to the penis by pre- and postsynaptic α_2 adrenoceptors.

Oxytocinergic axons from the PVN densely innervate clusters of sympathetic preganglionic neurons in the intermediolateral cell column of the thoracolumbar spinal cord.[680,681] There is also immunoreactivity for oxytocin in the sacral parasympathetic nucleus of the rat spinal cord, the dorsal horn, and the dorsal gray commissure. Oxytocin fibers make synaptic contacts on preganglionic neurons in the sacral parasympathetic nucleus.[681] Oxytocin receptor binding was found in the superficial dorsal horn, sacral parasympathetic nucleus, and dorsal gray commissure of the male rat lumbosacral spinal cord.[682]

A coital reflex observed in rats that were spinally transected at the T6 level includes rhythmic muscular activation and expulsion of semen from the urethra.[683,684] The reflex could be elicited multiple times by penile stimulation, but the muscle after-discharges and the penile movements decreased after the first reflex, and the reflex was exhausted after six or seven occurrences. The authors noted that copulating male rats also become sexually exhausted after about seven ejaculations. The spinal generator of ejaculation includes neurons in segments L3 and L4 of the lumbar spinal cord that contain both galanin and CCK[685] and project to the SPFp of the thalamus.[43] These lumbar spinothalamic (LSt) neurons are thought to relay somatosensory information concerning ejaculation from the genitals to the brain. Galanin and CCK immunoreactive neurons showed increased Fos expression only in males that had ejaculated one or two times and not in animals that only mounted or intromitted (except for a few Fos-IR neurons in one male that only intromitted).[43] Furthermore, lesions of galanin-containing neurons in L3 and L4 severely impaired ejaculatory ability of male rats.[43] Therefore, these neurons not only relay ejaculation-specific sensory information to the brain, but also contribute to the execution of the behavior. Lesions of these neurons resulted in a loss of the ejaculatory reflex in spinally transected rats.[686] Thus a spinal generator of ejaculation, which includes the LSt neurons, is normally under inhibitory control from higher neural areas.

CIRCUITRY AND ANATOMICAL INTERCONNECTIONS

Thus far, we have considered separately the functions and connections of different brain nuclei in the control of male sexual behavior. However, it is probably more accurate to view each region of the brain as belonging to one or more functional circuits that converge on the MPOA. In terms of afferent input, MPOA receives chemosensory cues from the vomeronasal organ and olfactory mucosa, somatosensory stimuli from the genitals, as well as direct and indirect hormonal input via steroid receptor-containing neurons. There are also excitatory and disinhibitory pathways from the MPOA to the midbrain and brainstem, from which neurons descend to the spinal cord nuclei to regulate genital reflexes and copulatory motor patterns.

A great deal of research is directed at understanding the signals and pathways through which individual sensory and endocrine stimuli influence mating behavior. However, sensory and humoral cues are seldom presented in isolation. Instead, an organism in a natural setting is confronted with multiple signals from its internal and external environment that together are interwoven to yield an experience richer than the sum of the individual modalities.[687]

To understand complex motivated behaviors, we must determine how different cues are weighed,

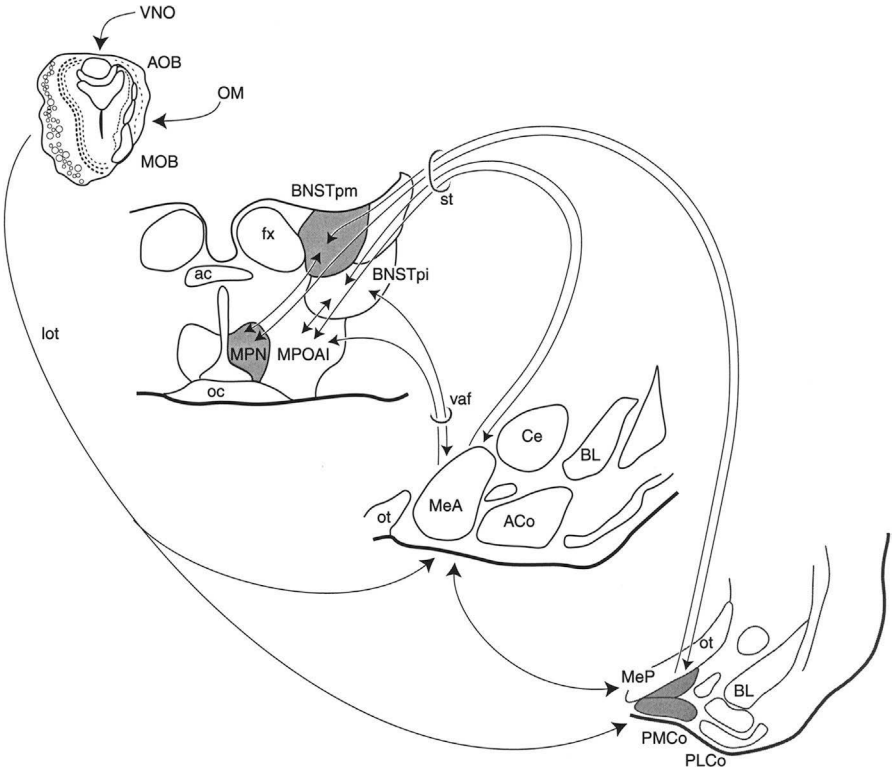

FIGURE 49.23 Schematic diagram of principal limbic nuclei and connections in hamster brain that transmit chemosensory and hormonal cues to control male sexual behavior. Shading indicates areas with abundant steroid receptor-containing neurons. ac, anterior commissure; ACo, anterior cortical amygdaloid nucleus; AOB, accessory olfactory bulb; BL, basolateral amygdaloid nucleus; BNST, bed nucleus of the stria terminalis; BNSTpi, posterointermediate subdivision of BNST; BNSTpm, posteromedial subdivision of BNST; Ce, central amygdaloid nucleus; fx, fornix; lot, lateral olfactory tract; Me, medial amygdaloid nucleus; MeA, anterior subdivision; MeP, posterior subdivision; MOB, main olfactory bulb; MPN, medial preoptic nucleus; MPOAl, lateral subdivision of the medial preoptic area; oc, optic chiasm; OM, olfactory mucosa; ot, optic tract; PLCo, posterolateral cortical amygdaloid nucleus; PMCo, posteromedial cortical amygdaloid nucleus; st, stria terminalis; vaf, ventral amygdalofugal pathway; VNO, vomeronasal organ. *Source: Reprinted from Ref. 688, with permission.*

prioritized, and integrated. The specific signals to guide sexual activity are tailored to the biology of the species. Although rodents rely principally on chemosensory stimuli to initiate behavior, other species use visual, auditory, or somatosensory stimuli, or a combination of sensory cues. Nonetheless, multimodal integration of sensory and humoral signals is ubiquitous, and further studies may uncover common mechanisms that guide the behavior of diverse species.

The Chemosensory Circuits

Lesions along the chemosensory circuit that eliminate mating have established the importance of the Me, BST, and MPOA in male sexual behavior (Figure 49.23). Our understanding of this circuit is enhanced through the use of Fos to identify activated neurons, including steroid-responsive neurons. However, the activity of the chemosensory circuit is also modified by hormonal stimuli. Me, BST, and MPOA each contain large numbers of steroid receptor-containing neurons, and intracerebral implants of T in either Me or MPOA enhance sexual activity above castrate levels.[393,467] These effects are mediated by aromatization to E, for implants of DHT in either area are without effect.[386,689] Steroid implants not only facilitate male copulatory behavior, they also enhance the response to odor cues. Specifically, male mice with intracerebral implants in the MPOA will make ultrasonic vocalizations to female urine.[561] Likewise, intracerebral T implants in Me or BST/MPOA of male hamsters stimulate anogenital investigation.[393] Together, these studies suggest that steroid action along the chemosensory pathway facilitates sexual behavior and responsiveness to sexually relevant chemosensory stimuli.

The challenge is to understand how steroid hormones interact with chemosensory cues to regulate male sexual behavior. Cottingham and Pfaff[394] have proposed that steroids act as a gating mechanism to permit or enhance transmission of chemosensory cues through steroid-sensitive brain nuclei. At the cellular level, castration may reduce synaptic efficiency in the transmission of odor cues by inhibiting release of neurotransmitters and/or suppressing postsynaptic receptors. Gonadal steroids also promote growth and branching of neurons. Although these effects are most dramatic during development, steroids also stimulate neuronal growth in the adult, as detailed by Garcia-Segura et al.[690] In the male Syrian hamster, castration reduced the mean somal area, highest dendritic branch, and percentage of neurons in Me with tertiary branches.[691] There is also potential for steroid effects on synaptic connections. Changes in connectivity can take place rapidly, in the absence of substantial alterations in gross neuronal structure. This has been best studied in females, where synapses in the arcuate nucleus of the hypothalamus are remodeled over the course of the four-day estrous cycle.[692] In the male, loss of synaptic connections after castration could have a major impact on transmission of chemosensory cues

through Me, BST, and MPOA. It is likely that both structural and neurochemical mechanisms contribute to the decline in sexual behavior after castration.

Somatosensory Input from the Genitals

The dorsal nerve of the penis (DNP), a branch of the pudendal nerve, carries sensory input from the penile skin, prepuce, and glans penis.[347] It is the major source of afferent input from the penis, although the cavernous nerve also contributes input from deeper structures.[347] The afferents terminate primarily in the medial portions of the dorsal horn and in the medial central gray matter (dorsal gray commissure) of the lumbosacral spinal cord. Sensory information is relayed to supraspinal sites via both spinothalamic and spinoreticular pathways. The spinothalamic pathways primarily convey the fastest fibers related to the encapsulated nerve endings of the penis. They travel in the dorsal columns and consist primarily of fast myelinated fibers. These fibers terminate in the posterolateral nucleus of the thalamus, and input is subsequently relayed to the medial thalamus. Spinoreticular fibers tend to be slower than the spinothalamic fibers. They travel in the contralateral (and to a lesser extent ipsilateral) lateral spinal columns and terminate in the brainstem reticular formation.

Electrical stimulation of the DNP elicited activity in the nPGi, the PVN, the MPOA, and the cortex.[693,694] The CTF of male rats and SPFp of rats, gerbils, and hamsters show increased Fos-IR following copulation and also project to the MPOA (reviewed in Ref. 3). Finally, a combined anterograde and retrograde tracer study revealed that axons from the L3 and L4 segments of the lumbar spinal cord terminated in close proximity to neurons that projected to the MPOA or BSTpm.[695]

Studies in humans have examined cortical evoked potentials following electrical stimulation of the dorsal nerve of the penis/clitoris (a division of the pudendal nerve). Evoked potentials were recorded bilaterally from cortical areas, with the highest amplitude in the midline (Cz-2) over the sensory cortex.[696] This distribution is consistent with pudendal representation deep in the midline interhemispheric fissure in humans[696a] and cats.[697] The amplitudes of cortical evoked responses were larger in men than in women[693] although slightly shorter in latency in women.[698] The smaller size in women may be related to fewer fibers innervating the clitoris relative to the penis or to the greater accessibility of stimulation of the male dorsal nerve.

An Ejaculation-Related Circuit

As noted above, a spinal ejaculation generator that includes LSt neurons and projects to the SPFp is under supraspinal inhibitory control. Ejaculation, but not copulation without ejaculation, elicited small clusters of Fos-IR in the MePD, the BSTpm, posterodorsal preoptic nucleus (PdPN), and the SPFp of rats, hamsters, and gerbils (reviewed in Ref. 3). Using anterograde and retrograde tracing techniques, it has been demonstrated that neurons in each of these areas expressing ejaculation-induced Fos are reciprocally connected with the MPOA (Figure 49.24).[538,624] In addition, combined unilateral lesions of MePD and SPFp in rats[337] and lesions of the SPFp in gerbils[358] resulted in decreased mating-induced Fos expression in the MPOA, demonstrating that these inputs contribute to the neural activation of the MPOA.

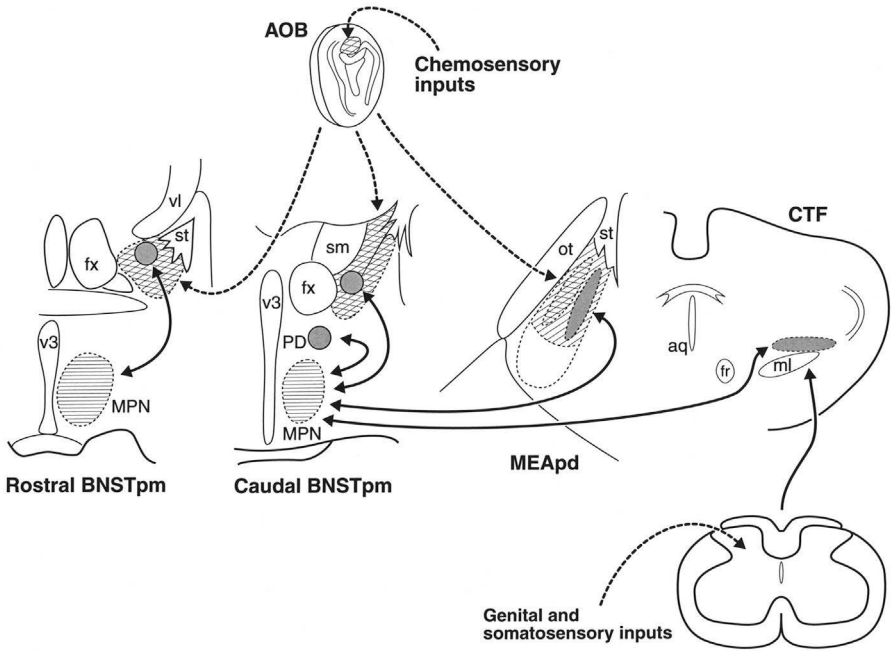

FIGURE 49.24 Schematic overview of neural activation in circuits underlying male sexual behavior. Areas where Fos is induced following chemosensory cues or chemosensory investigation are illustrated by diagonal stripes from upper left to lower right. Areas where Fos is induced primarily following ejaculation are illustrated in dark shading. Areas where Fos is induced by all consummatory elements of behavior are illustrated by diagonal stripes from lower left to upper right.
