There is a general consensus that the MBH–pituitary unit is sufficient for the control of tonic gonadotropin secretion in all species studied to date. Thus, knife cuts that partially, or completely, disrupt input to the MBH have little or no effect on tonic gonadotropin secretion in intact or OVX rats,[157–159] sheep,[160,161] monkeys,[162] or guinea pigs.[163] Some rats with complete cuts around the MBH show constant diestrous vaginal smears indicating low circulating E_2 and possibly inadequate tonic gonadotropin secretion. In one study,[157] these rats did not respond to OVX with an increase in LH secretion, but in another study[158] they did; in any case, no obvious histological differences in the location of the knife cuts were evident between rats showing constant diestrus and those with similar knife cuts showing constant estrus smears, indicating elevated E_2 secretion.[157] Because episodic LH secretion was also evident after OVX in all these studies, the neural substrates responsible for GnRH pulse generation must reside within the MBH, a conclusion consistent with the location of most electrodes that record bursts of multiunit electrical activity (MUA) that correlate with endogenous LH pulses in several species.[164–168] The conclusion that the MBH–pituitary unit is sufficient for normal episodic LH secretion is consistent with the location of GnRH cell bodies within the MBH in primates, sheep, and guinea pigs, but is at odds with the general consensus that no GnRH cell bodies are found in the MBH of rats.[153] However, a few scattered GnRH cell bodies are observed in the MBH of rats with some antibodies.[169,170] It has also been suggested that a projection from rostral GnRH cell bodies could have been missed by these knife cuts,[171] and may be sufficient to account for the GnRH immunoreactivity observed in the median eminence[159,171–173] and maintenance of episodic LH release after de-afferentation. Evidence that only a few GnRH neurons are sufficient for episodic GnRH secretion supports this possibility. However, the effects of

knife cuts that clearly severed this pathway, along with the other efferents from POA GnRH cells, on LH pulses have not been determined. Thus, this apparent paradox in rodents remains to be completely resolved.

There is less information available on the areas within the MBH that are necessary for tonic GnRH secretion. In guinea pigs, the arcuate nucleus (ARC) appears to be the critical area,[174] while in the rat, lesion data point to the anterior portion of this nucleus as critical for episodic GnRH secretion.[158,159] Interestingly, in at least one rodent study, knife cuts through the anterior arcuate largely disrupted LH pulses, but LH concentrations were still detectable.[159] Since LH pulses were augmented by transplantation of fetal MBH tissue that did not contain GnRH cells,[172] it has been proposed that non-GnRH neurons in this region help drive episodic GnRH release by an action at GnRH terminals in the median eminence.[175] The anterior region of the ARC may also be important in sheep as well, based on the effects of frontal knife cuts in this area to disrupt episodic LH secretion in OVX ewes, although damage to posterior regions of the ARC may have occurred.[160,161] It is interesting to note that these lesion data in rats and sheep are not entirely consistent with the recently proposed role for ARC kisspeptin cells in driving GnRH pulses,[176–179] since these are concentrated in the posterior, not the anterior, ARC. In contrast, lesion data in rhesus monkeys are more consistent with this hypothesis because more posterior portions of the ARC must be lesioned to completely disrupt LH and FSH secretion in OVX females.[180] Thus, another unresolved question is the nature of the neural elements in the rostral ARC that appear to be important for episodic GnRH secretion in rats and possibly sheep.

Many of the studies described here also examined the negative feedback actions of E_2, with the conclusion that complete or anterior knife cuts had no effect on the ability of E_2 to inhibit LH secretion in rats,[181] sheep,[161] and monkeys.[162] They also had no obvious effect on the negative feedback actions of progesterone in rats[182] and sheep.[183] Thus, both these steroids most likely exert their primary negative feedback actions within the MBH–pituitary unit. As noted in this chapter, these observations do not exclude additional sites of E_2 negative feedback outside the MBH, as has been observed in rats[184] and sheep,[185] but just illustrate that these sites are not essential for the normal feedback control of tonic GnRH secretion. Because the primary action of progesterone in most species is to inhibit pulse frequency, it has been inferred that progesterone must act in the MBH, and there is substantial evidence for this in sheep (see the section Neural Circuits Mediating the Negative Feedback Actions of Ovarian Steroids). In contrast, there has been considerable controversy about whether E_2 negative feedback occurs in the MBH or pituitary. This question has been clearly answered in sheep: during the estrous cycle, E_2 inhibits GnRH pulse amplitude (Figure 33.6),[186] probably by actions in the ARC,[185] in addition to direct inhibitory effects at the pituitary. There is also strong evidence in rabbits that E_2 inhibits both GnRH secretion and the pituitary response to GnRH,[76] and it is interesting to note that while E_2 inhibits GnRH pulse amplitude in both sheep and rabbits, it increases pulse frequency in sheep but decreases frequency in rabbits (Figure 33.6). In contrast to rabbits, current data in ferrets indicate that this steroid does not inhibit GnRH secretion.[191] Thus the negative feedback action of E_2 probably occurs at the pituitary in ferrets, although E_2-induced decreases in response to GnRH have been observed in some studies,[192] but not others.[193]

No clear conclusions can be drawn from studies of E_2 negative feedback in monkeys and rats. Early work in rhesus monkeys demonstrated that E_2 completely suppresses

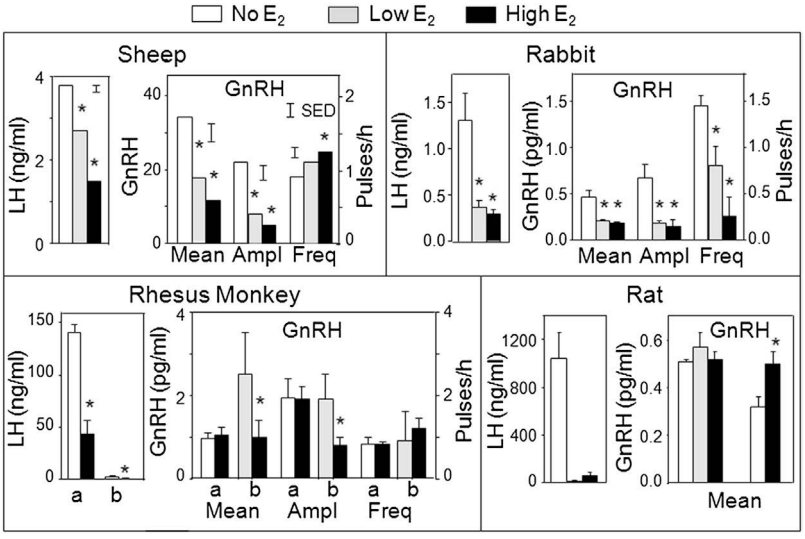

FIGURE 33.6 Negative feedback actions of E_2 on GnRH secretion measured in hypophysial portal blood in sheep,[186] and push–pull perfusions of the median eminence in rabbits,[76] monkeys,[187,188] and rats.[189,190] Mean (±SE) LH (in peripheral samples) and GnRH concentrations and GnRH pulse amplitude and frequency in sheep, rabbits, and monkeys are shown, but GnRH pulse parameters are not available in rats. Variabilities in data from sheep (SED) are presented as the standard error of mean of difference among groups from analysis of variance. Data from two different studies (labeled a[187] and b[188]) in rhesus monkeys are presented to illustrate variability in the effects of E_2. Data from rats compare mean GnRH values at 1300 h from OVX and intact ("low E" on diestrus and "high E" on proestrus) animals (bars on left)[189] and from OVX + E rats (bars on right).[190] Note that for data in sheep, mean GnRH is pg/10 min, while GnRH pulse amplitude is pg/pulse. *$P < 0.05$ versus no E group.

LH pulses maintained in MBH-lesioned animals by exogenous GnRH,[138] but these results do not preclude actions at both the MBH and pituitary. Local administration of E_2 within the MBH decreased gonadotropin secretion,[194–196] but high doses of estradiol benzoate given peripherally did not inhibit GnRH concentrations in cerebrospinal fluid[197] or in samples collected by push–pull perfusion of the median eminence[187] at a time when LH concentrations are clearly suppressed in OVX monkeys (Figure 33.6, study a). In contrast, a similar treatment inhibited GnRH concentrations by about 50% in samples collected from the median eminence of OVX monkeys pretreated with an E_2 implant that produced follicular-phase concentrations of this steroid (Figure 33.6, study b).[188] It should also be noted that all three of these studies used acute injections of estradiol benzoate that produced supraphysiological levels of E_2, so the relevance of the data to the normal negative feedback actions of E_2 is unclear.

The story in the rat is even more perplexing. Studies examining the chronic effects of peripheral implants[131] or intrahypothalamic microimplants[198] of E_2 have demonstrated a suppression of tonic LH secretion and a simultaneous increase in response of the pituitary to exogenous GnRH. The inescapable conclusion of these observations appears to be that these E_2 treatments are inhibiting GnRH secretion. However, when endogenous GnRH is measured in portal blood of rats, inconsistent effects of OVX are observed.[199,200] Furthermore, GnRH concentrations in push–pull perfusions of the median eminence of unanesthetized OVX rats are the same as, or lower than, those in ovary-intact rats (Figure 33.6),[189] and estradiol benzoate increased GnRH levels in morning samples collected by push–pull perfusion of OVX rats (Figure 33.6).[190] Thus, there is strong indirect evidence in the rat that E_2 inhibits GnRH secretion, but direct measurements of GnRH do not support such an action. Recent evidence that E_2 negative feedback occurs via ARC kisspeptin neurons in rats[3] (discussed further here) clearly favors the former conclusion, but no clear explanation for the lack of increased GnRH release in response to OVX has been advanced.

Neural Circuits Mediating the Negative Feedback Actions of Ovarian Steroids

There is now considerable evidence in a number of species that the negative feedback actions of progesterone occur via EOPs. Based on the effects of naloxone and similar EOP receptor antagonists, it is now clear that EOPs hold LH secretion in check during the luteal phase in a number of species. This was first reported in women[201] and has since been demonstrated in monkeys,[1] sheep,[2] and pigs,[202] and during pregnancy in rats.[203] Because the most consistent effect of naloxone is to increase LH pulse frequency in these studies, it was proposed that EOPs mediate progesterone negative feedback in these species. This hypothesis is supported by a number of reports that EOP antagonists have no effect in postmenopausal or oophorectomized women[1] or in long-term OVX sheep[2] or pigs,[202] but increase LH secretion when exogenous progesterone is given to women[204,205] or sheep.[2] In rats, EOP inhibition of LH may occur in the absence of progesterone because some studies reported that naloxone induced small increases in LH pulse amplitude in OVX rats.[206] However, there are also reports that naloxone had no effect in OVX rats,[207–209] and the effects that have been observed are less dramatic than those observed during pregnancy.[203] In contrast to these spontaneous ovulators, naloxone increases LH secretion in OVX rabbits[210] and ferrets,[211] but not in ovary-intact rabbits or estrogen-treated OVX ferrets, although the former studies were done when progesterone was low or absent. There is also one report that naloxone increases LH pulse amplitude in OVX guinea pigs,[212] but the effects of this antagonist have not been examined in ovary-intact guinea pigs. In summary, there is a consensus that EOPs mediate progesterone negative feedback during the luteal phase in those species in which this hypothesis has been tested. It is less clear which EOP is involved, but there is strong evidence that dynorphin plays this role in sheep[2] and some evidence that this is also the case during pregnancy in rats.[213]

While EOPs appear to mediate progesterone negative feedback in many species, their role in the negative feedback action of E_2 appears to be species specific. Thus naloxone increases LH secretion during the late follicular phase of the human menstrual cycle[1] and in oophorectomized women given exogenous estrogen,[205,214] but has no effect during the follicular phase of the monkey menstrual cycle.[215,216] There is one report that naloxone increases the frequency of LH pulses and MUA in OVX+E (ovariectomized E_2-treated) monkeys, but these authors concluded that this effect was not physiologically relevant because of the lack of effects of naloxone in follicular-phase animals.[217] While there is some evidence that EOPs mediate E_2 negative feedback on LH pulse amplitude in sheep, naloxone had equivalent stimulatory effects on GnRH pulse amplitude in OVX and OVX+E ewes.[2] In rats, naloxone increases LH secretion on all days of the estrous cycle[218] and restores episodic LH release in estrogen-treated OVX rats.[206,219] However, this EOP antagonist has equivalent stimulatory effects on GnRH secretion in ovary-intact and OVX rats, indicating that EOPs are unlikely to mediate E_2 negative feedback in this species.[220]

More recent work has focused on the possible role of ARC kisspeptin neurons in mediating the negative feedback actions of E_2.[156,221] These ARC neurons also contain neurokinin B (NKB) and dynorphin and thus are referred to as KNDy cells.[177] The evidence in support of this hypothesis comes largely from reports that E_2 inhibits kisspeptin expression in this region,[155] an effect that has been consistently observed in rats and mice,[3] hamsters,[222] musk shrews,[223] sheep,[2] monkeys,[1] and humans.[224] Since kisspeptin stimulates GnRH release, these inhibitory effects of

E_2 could mediate its negative feedback actions on GnRH. In rats, ablation of the ARC kisspeptin neurons with saporin conjugated to an NK3R agonist prevented the increase in LH concentrations following OVX, but some inhibitory effects of E_2 were still evident.[225] These authors thus concluded that ARC kisspeptin neurons play a major, but not exclusive, role in E_2 negative feedback. However other ARC neurons containing NK3R would also be lesioned by the techniques used and this proposed role for ARC kisspeptin neurons in rodents remains controversial.[3] Finally, it is interesting to note that, at least in sheep, the same population of KNDy neurons may mediate the negative feedback actions of progesterone and estradiol, but do so via different transmitters (dynorphin and kisspeptin, respectively).

Hypothalamic Control of the Gonadotropin Surge

Not surprisingly, given its central role in ovarian function, the mechanisms responsible for the preovulatory surge have been studied extensively, and consequently are better understood than those controlling tonic GnRH secretion. These mechanisms, including species variations in them, have been the focus of several recent reviews,[31,152,155,226] so this discussion will be more of a broad overview of the similarities and differences among species, again focused largely on rodents, sheep, and primates. The most obvious commonality across all these species is the stimulatory effects of E_2 on the pituitary response to GnRH (Figure 33.5). The temporal correlation between these stimulatory effects of E_2 at the pituitary and the time required for the estrogen-induced LH surge argues that these effects play an important role in the positive feedback actions of E_2. It should also be noted that the self-priming actions of GnRH on gonadotropes is estrogen dependent,[124,137] so this can be considered another aspect of E_2 positive feedback at the pituitary.

It is also clear that, in all species in which it has been measured, a GnRH surge accompanies the preovulatory LH surge (Figure 33.7). The strongest case for this is the ewe, in which GnRH can be monitored in hypophysial portal blood collected from unanesthetized animals.[229] GnRH measurements in rats,[189] rabbits,[227] and monkeys[228] have been done using push–pull perfusion of the median eminence. This is a technically challenging procedure, so it is not surprising that there is more variability associated with these estimates. Nevertheless, a significant increase in GnRH secretion coincident with the preovulatory surge has been identified in all four species. A second common feature observed across species, with one notable exception, is a dramatic increase in Fos expression (commonly used as an index of neural activity)

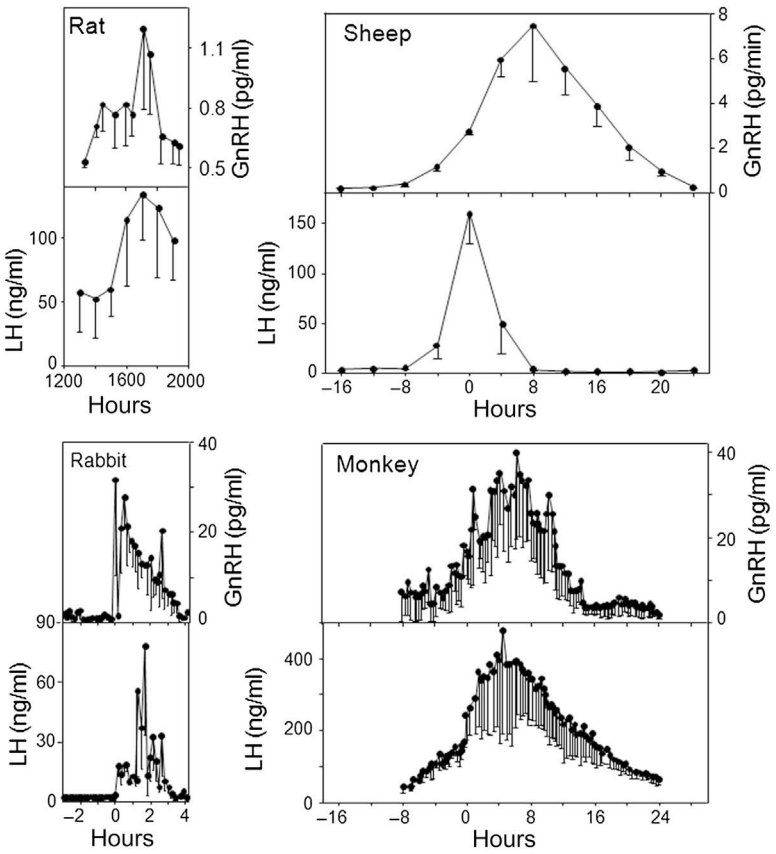

FIGURE 33.7 Endogenous preovulatory LH (in peripheral samples) and GnRH surges measured in hypophysial portal blood in sheep,[2] and push–pull perfusions of the median eminence in rabbits,[227] monkeys,[228] and rats.[189] Note that widths of plots have been adjusted to illustrate differences in the duration of LH and GnRH surges across species. *Redrawn with permission from the Endocrine Society.*

in GnRH neurons at the time of the preovulatory surge. This occurs in mice,[230] rats,[231] hamsters,[232,233] sheep,[234] and reflex ovulators such as the rabbit[235] and ferret,[236,237] with Fos seen throughout the anatomical distribution of GnRH cell bodies, including the MBH in those species in which GnRH neurons are found in this area (sheep, rabbits, and ferrets). The one exception to this pattern is the rhesus monkey,[238] which may relate to the important sites of E_2 positive feedback in this species (see the section Hypothalamic Areas Necessary for the Preovulatory Surge).

Hypothalamic Areas Necessary for the Preovulatory Surge

In contrast to the similarities of E_2 positive feedback at the pituitary among these species, there are significant species differences in the hypothalamic mechanisms underlying the activation of GnRH neurons during the preovulatory surge. The most obvious of these differences is between spontaneous and reflex ovulators. In the latter, which includes a large group of mammals,[6,7] stimulatory input from coitus to GnRH neurons is conveyed by numerous pathways. Thus in rabbits, complete de-afferentation of the hypothalamus is needed to block copulation-induced ovulation.[239] However, there are major differences in neural areas required for the surge even among spontaneous ovulators. The most dramatic of these is between rats and monkeys: in rats, knife cuts (either complete or partial) between the POA and MBH completely block the estrogen-induced LH surge[240] and ovulation (Figure 33.3),[35–37] while in monkeys similar cuts have no effect on menstrual cycles or the ability of estrogen to induce an LH surge.[162] In sheep[160,161] and guinea pigs,[163] the effects of these knife cuts are intermediate between these two extremes in that they do not completely block the estrogen-induced LH surge, but suppress its amplitude (Figure 33.8).

Differences in hypothalamic areas participating in the GnRH surge reflect underlying differences in the sites and mechanisms of E_2 positive feedback among these species. These have been best characterized in the rat,[3,31,152,155,226] in which a set of neurons in a region known as the rostral periventricular area of the third ventricle (RP3V),[226] which includes the anteroventral periventricular area (AVPV), mediate E_2 positive feedback. These neurons may receive neural afferents from the superchiasmatic nucleus (SCN) that gate the GnRH surge to a specific time of day[31]; if E_2 concentrations are elevated, this signal stimulates RP3V neurons, which in turn act on GnRH cell bodies in the POA[231] to trigger the preovulatory GnRH surge.[189] In sheep, there is strong evidence that E_2 acts in the MBH, and more specifically within the ventromedial nucleus (VMH)–ARC region, to induce the GnRH surge.[185] These systems, in turn, activate GnRH neurons in both rostral (POA and anterior hypothalamic area) and caudal (MBH) regions,[234] resulting in a prolonged GnRH surge,[229] which reflects a progressive change from episodic to non-episodic GnRH secretion.[241] In monkeys and humans it is clear that the changes in hypothalamic GnRH release are not required for the estrogen-induced LH surge[128,242] and ovulation,[242,243] because these can be produced in lesioned monkeys and women with Kallman syndrome (who have no GnRH neurons) by treatment with invariant episodic injections of GnRH. However, as reviewed recently,[152] there is also considerable evidence for a preovulatory GnRH surge in monkeys (Figure 33.7), although they are the one species studied in which Fos expression does not increase at the time of the surge.[238] The data in women are more equivocal: indirect indices of GnRH release suggest there is no increase at the time of the LH surge,[244,245] but the preovulatory LH surge is consistently blocked with GnRH receptor antagonists,[246,247] an effect that is unlikely to be due to disruption of the effects of GnRH pulses.[248] In reflex ovulators, it has also been difficult to identify stimulatory effects of E_2 on GnRH release because estrous behavior, which is a prerequisite for coitus, only occurs in E_2-treated females.[6] It is thus not possible to compare the effects of coitus in OVX and OVX+E animals, but there is strong evidence that E_2 is required for the stimulatory actions of NE (see the section Neural Circuits Responsible for the Control of the GnRH Surge by Ovarian Steroids) during the coitus-induced surge in rabbits.[249]

Neural Circuits Responsible for the Control of the GnRH Surge by Ovarian Steroids

The two neural systems implicated in the induction of GnRH surge across several species are: (1) NE, one of the oldest identified; and (2) kisspeptin, one of the newest

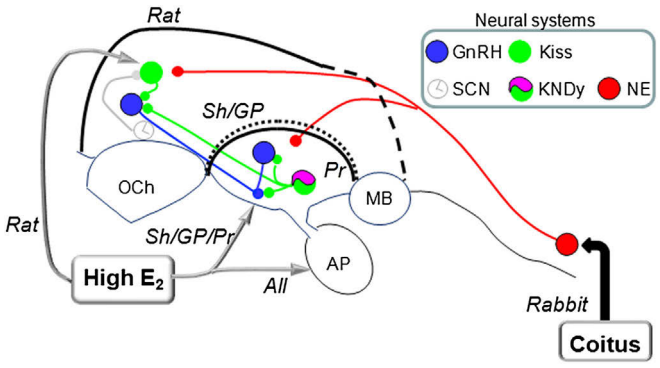

FIGURE 33.8 Schematic of parasagittal section of the hypothalamo–hypophysial unit illustrating the anatomical areas and neural systems participating in the preovulatory GnRH surge and sites of E_2 positive feedback in various species. This figure is reproduced in color in the color plate section. All structures are required in rabbits; in other species, solid lines depict knife cuts that had no effect on the surge. Dotted lines are cuts that only decreased the amplitude of the LH surge, and the dashed line illustrates that NE input is normally required for the surge in rats but can be compensated for under some circumstances. See the text for more details. AP: anterior pituitary; GP: guinea pig; MB: mammillary body; OCh: optic chiasm; Pr: primate; Sh: sheep.

entries into this arena. NE (along with acetylcholine) was initially identified as playing a role in the preovulatory LH surge by classic work in the late 1940s demonstrating that the α-adrenergic receptor antagonist, dibenamine, blocked ovulation in both rabbits[32] and rats[27] (Figure 33.2). Since then, abundant data have accumulated supporting this hypothesis in several species. As reviewed elsewhere,[6,7] the strongest case for a pivotal role for NE comes from work in the rabbit and includes evidence that coitus induces NE release in the median eminence just before GnRH secretion increases (Figure 33.9).[227] This temporal correlation reflects a stimulatory effect of NE on GnRH secretion because: (1) exogenous NE induces LH[250] and GnRH[251] secretion in intact and OVX+E, but not OVX, does[249]; and (2) an α_1-adrenergic antagonist blocks the coitus-induced increase in GnRH secretion.[252] To put this system into its physiological context: tactile stimuli from the vagina and cervix initiate action potentials that travel up the spinal cord to stimulate brainstem NE neurons, probably via a cholinergic pathway.[253] The A1 (medulla oblongata), A2 (nucleus of the solitary tract), and A6 (locus coeruleus) NE cell groups all project to the hypothalamus and are activated by coitus.[253–255] Thus, NE release from their efferents stimulates GnRH release by actions at both GnRH terminals in the median eminence[227,256] and GnRH cell bodies throughout the POA and MBH.[235] There is some evidence that the A1 and A2 groups may stimulate the A6 group and that the latter helps prolong NE release in the hypothalamus.[7,253] Despite this speculation, the mechanisms by which a brief (1–3 min) coital act is transduced into release of NE, and thus GnRH, which lasts for 2–3 h, remain a mystery.

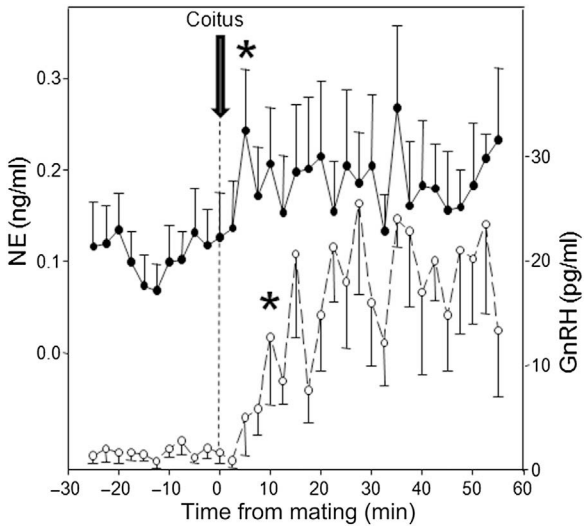

FIGURE 33.9 Effects of coitus (arrow) on mean (±SEM) concentrations of norepinephrine (NE; solid symbols and lines) and GnRH (open symbols and dashed line) measured in push–pull perfusions collected every 2.5 min from the rabbit median eminence ($n = 6$). Data averaged from plots of individual animals.[227] *First statistically significant increase in NE and GnRH over values before mating.

There are very limited data on the role of NE in other reflex ovulators, but there is considerable information on the role of this neurotransmitter in the LH surge in rats, sheep, and monkeys. The only other study in reflex ovulators reported that coitus increased Fos expression in A6 NE neurons but not in the A1 group in ferrets.[257] Interestingly, A2 NE neurons showed increased Fos in response to both coitus and male pheromones, suggesting that they are activated primarily by chemosensory cues. In spontaneous ovulators, NE release (estimated by microdialysis or turnover rate) increases in the POA and median eminence before and during the preovulatory LH surge in rats,[258,259] sheep,[260–262] and monkeys.[263] These species differ in the source of this NE input; both the A2[264–266] and A6[267–269] NE groups appear to be important in rats, whereas the A1[270,271] and A6[263] NE groups have been implicated in sheep and monkeys, respectively. The relative importance of NE to the normal surge also varies among these species (Figure 33.8), with α-adrenergic antagonists completely blocking the surge in rats,[27,259] but having no effect in primates.[41] The sheep appears to fall between these two extremes as phenoxybenzamine, a noradrenergic antagonist, delays or blocks the estrogen-induced surge in some, but not all, ewes, although the inhibition in some animals could reflect nonspecific effects because of the high dose used in this study.[272] It should also be noted that NE is not absolutely required for the LH surge even in rats because chronic disruption of all NE inputs from the brainstem does not block the ability of estrogen to induce surges in this species.[150] Thus it has been proposed that NE acts as a facilitatory agent in rats, increasing the responsiveness of GnRH neurons to other stimulatory inputs that drive the preovulatory GnRH surge.[264] In summary, NE plays an important stimulatory role in the preovulatory GnRH surge, but its importance varies from obligatory in rabbits, to facilitatory in rats (and possibly sheep), to redundant in monkeys.

There is a growing consensus that the rostral kisspeptin population plays a key role in the estrogen-induced LH surge. In rodents this population is concentrated in the RP3V, while in other mammals it is more scattered in the POA. There is very strong evidence that RP3V kisspeptin neurons mediate E_2 positive feedback in rodents,[3] and substantial evidence for a similar role for the POA kisspeptin population in sheep.[2] E_2 also increases kisspeptin expression in this region in guinea pigs[273] and musk shrews,[223] but apparently not in hamsters,[274] and Fos expression increases in these rostral kisspeptin neurons at the time of the surge in all of these species. It is interesting to note, in this regard, that pony mares are the one species in which rostral kisspeptin neurons have not been identified,[275] which may relate to the apparent absence of E_2 positive feedback in this species.[43]

While the proposed functional dichotomy in the roles of rostral (positive feedback) and ARC kisspeptin (negative feedback) populations in the actions of E_2 is largely

supported by data from rodents, it may not be applicable to other species. Specifically, in sheep[2] and guinea pigs[273] there is evidence that the ARC kisspeptin population is involved in both negative and positive feedback actions of E_2; the latter effects would be consistent with the sites of E_2 positive feedback in the MBH in these species (as discussed in this chapter). Whether this reflects subpopulations of ARC kisspeptin neurons dedicated to different effects of this steroid, or different responses of the same neurons to high and low E_2 concentrations, awaits further study, but a recent report in sheep favors the latter.[276] It is also important to note that this model is based on data from a limited number of species (primarily rats, mice, and sheep) so care must be taken in generalizing it to other mammals at this time. In particular, while it is clear that kisspeptin is critical for GnRH secretion in humans[277,278] and that kisspeptin expression in the ARC increases in postmenopausal women,[224] little is known about the physiological roles of kisspeptin in control of the menstrual cycle in monkeys[1] and nothing about its role in the control of the menstrual cycle in women.

While NE and kisspeptin have been implicated in the positive feedback actions of E_2, EOPs appear to mediate the ability of progesterone to block the GnRH surge in rats.[279] In contrast, EOPs play little, or no, role in mediating the ability of progesterone to block the LH surge in monkeys[280] or sheep.[2] These species differences may reflect differences in the role of EOPs in the normal LH surge. In rats, removal of endogenous EOP tone plays an important role in controlling the LH surge,[281] but EOP antagonists do not advance the LH surge in sheep[2] and there is no evidence that EOP withdrawal is important in primates.[280]

In comparing the neural areas and systems contributing to the preovulatory GnRH surge across species, an interesting continuum is evident (Figure 33.8). At one end are the reflex ovulators, exemplified by the rabbit, in which neural signals during coitus stimulate brainstem NE neurons whose input is absolutely essential for the GnRH surge. At the other end are nonhuman primates, in which no neural input (including NE) into the MBH is necessary for the LH surge, and humans in which there is no direct evidence that GnRH secretion increases at the time of the LH surge. Sheep and guinea pigs appear closer to primates than rabbits in this continuum, while rats appear closer to rabbits. In the former species, input from outside the MBH augments the amplitude of the GnRH surge, but is not necessary for it, and the role of NE is questionable. In the rat, both input from the POA and NE stimulation are normally required for the preovulatory LH surge, although compensatory mechanisms can replace NE input if it is chronically depleted. The similarity between rats and rabbits is further emphasized by evidence that rats can become reflex ovulators under some circumstances.[282,283] Interestingly, one of these examples involved disruption of inputs from the SCN to the POA,[283] so conceptually input from the biological clock in the SCN may have replaced the stimulus from coitus in the rat. The NE contribution to the GnRH surge in the rat may also reflect spillover of NE input to the hypothalamus, which is essential for the prolactin surge on proestrus[284] and mediates the coitus-induced increase in prolactin secretion responsible for pseudopregnancy in rats.[285]

Finally, it is interesting to note a similar continuum in the sexual differentiation of the GnRH surge in spontaneous ovulators. All species show a sexual dimorphism in the positive feedback actions of E_2, in that this steroid cannot induce an LH surge in adult males with normal testicular function, although the basis of this sexual dimorphism varies among species. In the rat, the absence of positive feedback is caused by the organizational actions of testosterone during development, which sexually differentiates the surge system so that it cannot respond to E_2 under any circumstances.[286] In contrast, E_2 induced a robust LH surge in male monkeys that were castrated as adults[287] and in hypogonadal men.[288] Moreover, some male monkeys showed apparently normal ovarian cycles when the testes were replaced with an ovary,[289] while similar procedures in rats resulted in constant estrus.[11] From a historical perspective, these observations reinforced knife cut studies that indicated that there were fundamental differences in neural mechanisms controlling the LH surge in primates and rats.[152] Sheep appear to fall between these two extremes because androgen exposure during development masculinizes the LH surge in females treated with an E_2 implant neonatally, but does not do so until later in life in ovary-intact females,[290] possibly because of masculinizing effects of prolonged exposure to E_2 after birth.[291]

PHYSIOLOGICAL DISRUPTIONS OF REPRODUCTIVE FUNCTION

The reproductive system differs from most other systems in the body in that it is not critical for survival of the individual. Thus it can be shut down for prolonged periods under physiological conditions if infertility is eventually advantageous for survival of the species (i.e., the individual survives to breed at a later date). The most common instance of this is the hiatus in reproductive function prior to puberty, but periods of physiological infertility in adults are more often the norm than the exception. Many species show annual periods of fertility and infertility that ensure the young are born into environmental conditions favorable for their survival. Reproductive function can also be suppressed by undernutrition, lactation, stress, and social interactions. This section will focus on comparative aspects of puberty and lactation and more briefly

consider other examples of reversible infertility because these are discussed in detail elsewhere in this book. Aging is also often associated with reproductive failure, but this topic is considered in Chapter 37, and the usefulness of a comparative approach to this topic is unclear because most species do not live long enough in their natural environment for this to be considered a physiological process. Even in humans, the occurrence of menopause is probably a fairly recent phenomenon because females probably did not live past middle age during most of the evolution of our species.

Puberty

In virtually all mammals, there is a hiatus between birth and onset of fertility, which allows the body to develop so it is physically and psychologically capable of rearing offspring. This is obviously important in females, who bear the energetic costs of pregnancy and lactation, but it is also important in males, who participate in rearing offspring in some species and must compete with mature males for access to females in many species. Because onset of fertility is a key event in propagation of the species, it should be expected that evolutionary pressures would result in differences among species and between sexes of the same species.[292] The latter is compounded by the duration of spermatogenesis; for example, although male rats are fertile (sperm in vas deferens) at a later age (55–60 days) than first ovulation in females (35–40 days), the first stages of sperm production must occur within the first week of life in males.

Considerations of the physiology of puberty usually begin with a discussion of its definition. On a superficial level, puberty can simply be considered the time when an individual becomes capable of producing viable offspring, but whether it is defined as a process or a single final event remains an open debate. The latter is often used in females because first ovulation, or first estrus, provides a single time point for the onset of fertility. In contrast, because of the duration of spermatogenesis, puberty in males is more often considered a developmental process. However, even in females it is clear that ovulation is preceded by a sequence of developmental events, in which different elements in this process (i.e., the ability of the follicle to respond to gonadotropins, and the positive feedback actions of E_2) mature at different times during the prepubertal period. This developmental process can be extended backward to consider important events during embryonic development (i.e., the development and migration of GnRH neurons, and the differentiation of gonadotropes), but for the purposes of this discussion, it is useful to focus on the final, rate-limiting steps leading to first ovulation and estrus in females, and initiation of spermatogenesis in males. Finally, it is important to point out that these definitional issues are not just of academic interest. For example, as discussed below, the relative weight one gives to specific developmental events depends on whether one considers menarche or first ovulation the onset of puberty in female primates.

If one focuses on the final step leading to fertility, a common feature emerges among those species that have been studied in detail: in both males and females, an increase in episodic secretion of GnRH is the rate-limiting step for onset of puberty.[293–295] In males, it is clear that such an increase will stimulate the secretion of FSH and LH necessary for testosterone and gamete production by the testes. In females, the situation is a bit more complex because the hypothalamus must be able to respond to the increasing concentrations of E_2 from the preovulatory follicle with a GnRH surge for ovulation to occur. However, the mechanisms responsible for the positive feedback of E_2 usually mature some time before first ovulation so they do not represent the rate-limiting event. One interesting exception to this generalization is monkeys and humans, in whom exogenous E_2 fails to induce an LH surge before the initial increases in GnRH that indirectly result in menarche.[295] However, there is strong evidence that this lack of E_2 positive feedback prior to menarche most likely reflects inadequate stores of LH in the pituitary due to the absence of endogenous GnRH pulses.[296] Moreover, the importance of episodic GnRH secretion to puberty in primates has been clearly demonstrated by the report that administration of exogenous GnRH pulses that mimic follicular-phase levels induced an increase in E_2 concentrations, an LH surge, and ovulation that resulted in a menstrual cycle in juvenile monkeys.[297] These data also support the role for GnRH pulses in providing sufficient pituitary gonadotropin for an LH surge because E_2 administration failed to induce an LH surge 30 days after the exogenous GnRH was discontinued in these prepubertal females. While there is thus general agreement that an increase in episodic GnRH secretion is a key step in initiation of puberty in many species, controversy remains as to the underlying neuroendocrine mechanisms in part because of species differences in them. These controversies can be broken down into three major issues: (1) the role of changes in response to steroid negative feedback; (2) the specific upstream neural (and glial) systems responsible for the increase in GnRH secretion; and (3) the relative roles of peripheral signals and developmental clocks in timing of puberty.

Historically, the first neuroendocrine mechanism for puberty proposed that LH release was suppressed in prepubertal animals by the negative feedback actions of low circulating gonadal steroids, and that at puberty a "resetting of the hypothalamic gonadostat" produced a decrease in sensitivity to this inhibition.[298] This change allowed GnRH secretion to increase until the negative

feedback loop was re-established at a lower set point so that adult concentrations of testosterone or estradiol were required to hold GnRH release in check. This proposal, which became known as the "gonadostat hypothesis," was initially formalized by Ramirez and McCann based on data in rats that doses of estrogen that were ineffective in adults were able to suppress the postcastration rise in gonadotropins in prepubertal animals. This hypothesis was soon extended to humans[299] and subsequently to several other species, including sheep,[300] cows,[301] guinea pigs,[302] and ferrets.[303,304] However, work in rhesus monkeys challenged this hypothesis because gonadotropins were undetectable throughout much of the prepubertal period in gonadectomized males and females, and then increased at about the age that puberty occurs in gonadally intact individuals.[295,305] Similar variations in gonadotropin secretion during development were also observed in agonadal children, so that it was proposed that "steroid-independent" inhibition of GnRH secretion was responsible for the prepubertal hiatus in primates.[295] The resulting debate on the relative importance of steroid-dependent and steroid-independent mechanisms to puberty lasted for over two decades, but has waned recently as workers focused on other issues. Moreover, close examination of the data suggests that both mechanisms contribute in many species, particularly in females (Figure 33.10). Perhaps the best example of this is the female rat, which is more sensitive to the negative feedback of E_2 prior to puberty than in adulthood. However, these inhibitory effects wane only after first ovulation,[306] and a modest steroid-independent increase in LH secretion evident as daily afternoon increments during the week preceding ovulation appears to be the ultimate signal for this seminal event.[307,308] While these data argue against the gonadostat hypothesis, it should be kept in mind that GnRH release is being held in check prior to puberty by E_2 negative feedback so that both steroid-dependent and steroid-independent systems contribute to the physiological concentrations of LH immediately before ovulation. Moreover, the decrease in steroid-dependent inhibition that occurs shortly after first ovulation most likely helps compensate for the negative feedback effects of the increased progesterone secretion occurring at this time,[306] and thus may well be critical for continued fertility. A similar temporal sequence of first steroid-independent and then steroid-dependent increases in GnRH occurs in primates,[295] with the former responsible for menarche, while the latter may be necessary for first ovulation.[309] Interestingly, the reverse sequence occurs in male hamsters, with steroid-dependent changes being responsible for the initial testicular growth up to 8 weeks of age, and a secondary steroid-independent increment apparently driving the sustained growth through 14 weeks.[310] Finally, even in species such as sheep and cows, where a decrease in E_2 negative feedback is the primary signal, steroid-independent increases in LH are evident in OVX animals at similar ages[300,301] and become rate limiting to puberty under conditions of low nutrition.[311,312] Thus, both mechanisms are evident in many species, with their

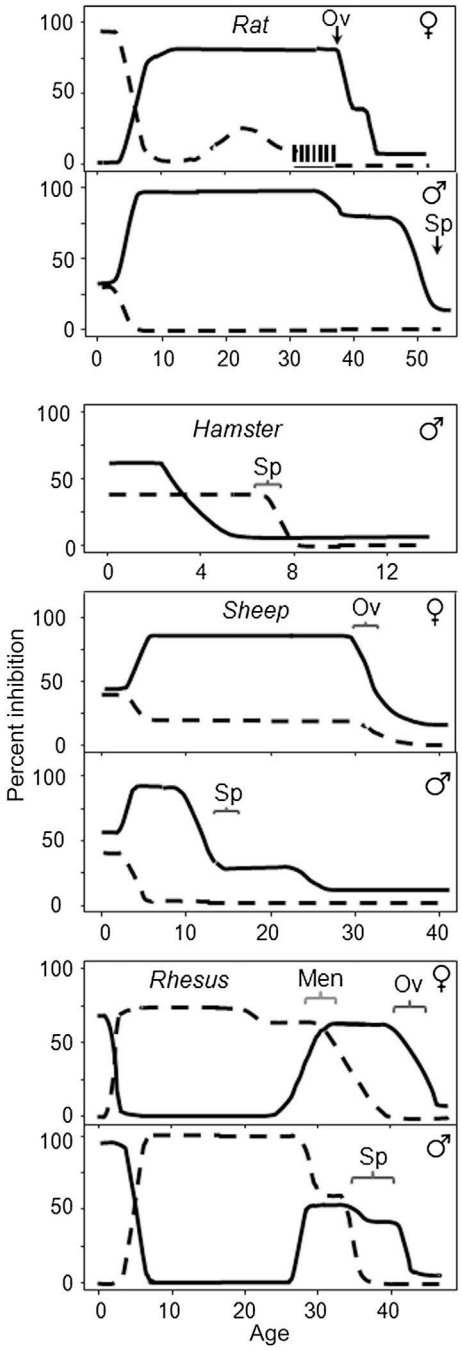

FIGURE 33.10 Schematic illustration of the time course of steroid-dependent (solid lines) and steroid-independent (dashed lines) mechanisms inhibiting LH secretion before and through puberty in female and male rats, sheep, and rhesus monkeys and male hamsters. Time scale is in days for rats, weeks for hamsters and sheep, and months for primates. Men: menarche; Ov: first ovulation; Sp: first appearance of mature sperm in reproductive tract.

relative importance changing with the phase of development and nutritional level. It is interesting to note that there can also be sex differences in the same species in the relative importance of these two mechanisms. For example, in contrast to females, puberty in male rats appears to be solely dependent on steroid-dependent mechanisms,[313] while the converse may be true in mice because LH concentrations increase following OVX, but not after orchidectomy, of prepubertal mice.[314]

There is less information available on the other two major issues under consideration: the neural systems underlying puberty and the ultimate signals that time these events. Until recently, there was no consensus on the important upstream neural systems, and there appeared to be major species differences.[293–295] For example, there is strong evidence that removal of an EOP inhibition of GnRH secretion contributes to puberty in female rats, but EOPs do not hold GnRH secretion in check in prepubertal monkeys, and although EOP receptor antagonists increase LH secretion in prepubertal sheep this EOP break does not decrease as the ewes go through puberty. Another dramatic example is NPY, which may play a stimulatory role during puberty in female rats and monkeys, but removal of its inhibitory actions may contribute to puberty in male monkeys. There is strong evidence for removal of a GABAergic inhibition and increase in stimulatory glutamatergic input in female rats and monkeys, but little direct support for this in other species. This story, of course, changed dramatically with the discovery of kisspeptin, which is now thought to be important for puberty in many species. There is now strong correlative and functional evidence that an increase in kisspeptin is the proximal stimulus driving GnRH secretion at puberty in humans, female monkeys, rats, and mice, and slightly weaker evidence in male monkeys and sheep.[156,293–295,315] In all these species, except mice, kisspeptin neurons in the ARC appear to be important for this process, and NKB produced by these neurons has more recently been implicated.[316–320] In mice, AVPV kisspeptin neurons may be as important as those in the ARC for puberty.[156] It has been argued that kisspeptin's role in puberty may not be regulatory in nature, but simply reflect its role as an essential component of the GnRH pulse generator.[321] In any case, identification of kisspeptin not only has been a major advance but also has moved the focus one step upstream of the GnRH neuron.

Much of the recent work in this field has focused on identifying the ultimate signals that determine at what age puberty occurs. Some of these, such as photoperiod in seasonally breeding animals,[294] are species specific but two potential mechanisms have been proposed to occur in most species[293–295]: (1) peripheral signals, indicating that critical maturational events have occurred and that sufficient energy reserves are available to reproduce; and/or (2) a developmental clock within the central nervous system that controls the timing of expression of a set of genes critical for puberty onset. For obvious reasons, work on the former has concentrated in general on metabolic (e.g., glucose) and related endocrine (e.g., insulin and IGF1) signals and specifically on leptin. In general (see the specific chapters on puberty[293–295] and Chapter 35 for detailed reviews), these studies demonstrated that insufficient concentrations of these signaling molecules delay puberty, but that increases in their concentrations do not immediately precede the onset of puberty. Thus, the consensus is that these indicators of metabolic well-being are permissive for, rather than determinant of, puberty onset.

There has been less work on a possible genetic clock in the central nervous system, although genetically programmed development is common in the reproductive axis since many of its components (e.g., GnRH neurons, gonadotropes, and cellular components of the gonads) develop to maturity before puberty occurs. Moreover, it has been estimated based on studies of dizygotic and monozygotic twins that 50–80% of the variability in age at menarche may be genetic in nature.[322] An interesting theoretical construct and some genes that may be components of this pubertal clock have recently been presented,[323] but human genetic analysis raises a cautionary note (see Chapter 32 for a more detailed discussion). Although linkage studies of rare genetic mutations producing infertility have produced major advances in our understanding of reproductive neuroendocrinology,[277,278,324,325] the genes identified by this method do not appear to contribute to the determination of age at menarche in the general population.[326] Furthermore, more systemic genome-wide association studies of age at menarche have to date only provided a few useful candidate genes for this theoretical puberty clock.[322] This may reflect methodological problems or the complex nature of the events leading up to menarche, which undoubtedly involve many genetic elements.[322] If the cause is methodological, recently developed techniques for high-throughput genomic and proteomic analysis[323] together with more powerful human genetic studies[322] are likely to provide significant progress over the next few years. Finally, it should be kept in mind that these two mechanisms are not mutually exclusive; an interaction of genetic signals, internal signals, and input from the external environment undoubtedly determine onset of puberty in most species.[292]

Lactation

Suppression of ovarian function during lactation occurs in many species, although there are some exceptions (e.g., the marmoset).[327] From an adaptive point of view, this period of infertility ensures that the mother

does not become pregnant during lactation because the latter is one of the most energetically demanding periods in her lifespan. However, postpartum ovulation and estrus occur in quite a few mammals (including rats, rabbits, ferrets, guinea pigs, horses, and kangaroos) so they are often pregnant and lactating at the same time. In some of these cases (e.g., guinea pigs and horses), gestation lasts much longer than lactation so that the latter is completed before the more energetically demanding later stages of pregnancy. In others (e.g., rats and kangaroos), lactation induces delayed implantation so that the later stages of pregnancy do not overlap with lactation. Nevertheless, adverse effects of combining lactation and pregnancy on both the developing fetuses and nursing offspring have been reported.[328] Because there was an excellent comparative consideration of this topic in the previous edition of this book,[327] in this section I will briefly compare the physiology of lactational infertility in a number of species and then describe recent developments in underlying mechanisms, based on data in rats. Readers interested in more in-depth consideration of this issue are referred to the previous edition of this book[327] and some excellent earlier[329,330] and contemporary[331] reviews.

Physiological studies on the mechanisms of lactational infertility have been largely limited to rats, pigs, sheep, cows, nonhuman primates, and humans. It is interesting to note, parenthetically, that rabbits have not been included in this group probably because does nurse their young for only about 3 min at the same time each day and show estrus within 24 h of pup removal.[332] They are thus more useful for studying suckling as a nonphotoperiodic zeitgeber for circadian rhythms[333] in both mothers[334] and pups,[335] than for its effects on fertility. In making comparisons across these other species, there are three potential confounding issues that should be kept in mind. First, rats ovulate immediately postpartum (in conjunction with their postpartum estrus) and, if not mated, become psuedopregnant because of the luteotropic actions of the elevated prolactin concentrations induced by the suckling stimulus.[327] Because any studies during normal lactation in rats are thus confounded by the elevated (compared to other species) circulating progesterone concentrations, many of these have been done in OVX animals. Second, in ewes (and some other seasonal breeders) lactational infertility usually overlaps with seasonal anestrus. Thus studies in this species have to be done in females that are bred out of season so that they lamb in the breeding season, and the significance of lactational anestrus to normal reproductive function is unclear. Third, comparisons of data from cows, which have been studied extensively because of the adverse economic consequences of lactational infertility,[336] with work in other species should keep in mind that dairy cows in particular have been bred to maximize milk yield. Thus the evolutionary (or selection) pressures in rats, sheep, and dairy cows may have been markedly different than those in other species, including primates.

Despite these caveats, some common patterns emerge when lactational infertility is examined across these species. First, in those species not showing postpartum estrus and ovulation, there is an initial period of infertility that is independent of lactation (Figure 33.11). This period, which occurs even if offspring are lost or removed, lasts from 2 weeks to 2 months depending on the species, and reflects the time needed for recovery of the hypothalamo–pituitary unit from the inhibitory effects of the high steroid concentrations of pregnancy and involution of the uterus. As this postpartum recovery progresses the inhibitory actions of lactation become dominant, but these effects can be divided into two phases. During approximately the first half of pregnancy the suckling stimulus itself, directly or indirectly (as discussed further below), inhibits reproductive function; while during the latter stages of lactation, as the suckling stimulus declines and the negative energy balance caused by the demands of the growing infants increases, the latter plays a more important role in suppressing fertility in the mother.

A second common feature is that ovarian inactivity reflects inadequate LH secretion, because FSH returns to normal follicular-phase concentrations shortly after parturition in most species.[327] In contrast, LH concentration

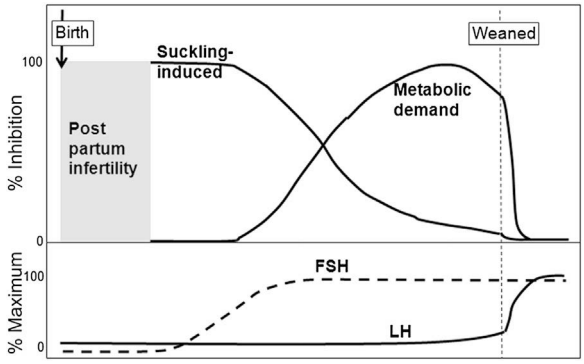

FIGURE 33.11 Schematic representation of systems inhibiting GnRH secretion (top panel) and the time course of FSH and LH concentrations (bottom panel) during lactation. In animals that do not have a postpartum ovulation, reproductive function is initially suppressed after parturition by lactation-independent effects of gestation (shaded bar). When the hypothalamus has recovered from the effects of gestation, GnRH secretion continues to be inhibited primarily by the effects of suckling, which may include both direct neural inhibition and the actions of elevated prolactin. As the offspring grow, the intensity of suckling decreases, but their metabolic demands increase so the latter becomes more important in suppressing GnRH secretion. In general, FSH returns to normal concentrations in the first half of lactation, so that episodic GnRH release and thus LH concentrations limit fertility. Weaning at any time after the postpartum period of infertility will result in a rapid increase in episodic GnRH secretion that soon results in ovulation.

and, more specifically, LH pulse frequency are suppressed throughout lactation and then increase rapidly shortly after weaning (Figure 33.11). As was the case with the prepubertal hiatus, both steroid-independent and steroid-dependent mechanisms contribute to the inhibition of GnRH pulse frequency in rats,[329,337] sheep,[338] cows,[339,340] and primates.[341,342] Nursing women are also more sensitive to the negative feedback actions of estrogen,[327] but steroid-independent inhibition has not been studied in women for obvious ethical reasons. In rats, there is strong evidence that steroid-independent mechanisms predominate in the first half of lactation, while increased response to E_2 negative feedback is critical during the latter stages.[337] This has not been systematically studied in other species, but the time course of LH concentrations in OVX lactating cows[340] and primates[341,342] is consistent with this possibility.

Species differences begin to emerge when the underlying mechanisms of this lactation-induced inhibition of GnRH secretion are examined. The suckling stimulus induces at least four important changes in hypothalamic function: (1) increased oxytocin secretion that is critical for milk ejection but probably plays no role in decreased GnRH release; (2) increased prolactin secretion that results from inhibition of ARC dopaminergic (DA) neural activity and is important for milk synthesis and secretion; (3) altered activity of orexigenic and anorexigenic neurons to increase maternal food intake; and (4) inhibition of GnRH secretion. The latter could reflect a direct effect of a neural signal initiated by suckling but could also be coupled to increased prolactin or changes in the neural circuitry controlling food intake. Hyperprolactinemia is well known to cause hypogonadism, so the possible role of prolactin has been examined in several species using a dopamine agonist (CB-154) to inhibit this hormone in nursing mothers. In OVX nursing rats, CB-154 partially restored LH concentrations in early lactation and completely overcame the inhibitory effects of sucking in the later stages.[343] Thus early in lactation prolactin significantly contributes to suckling-induced inhibition of GnRH and it may be the major inhibitor of GnRH during the second half of lactation in rats. In contrast, similar studies in sheep, cows, and pigs failed to provide any consistent evidence for an important role of hyperprolactinemia in lactational infertility.[327] Blockade of prolactin secretion increased the bursts of MUA coincident with LH pulses in some lactating monkeys, but the effects were inconsistent[344] and a review of the literature in humans concluded that prolactin plays only a minor role in lactational amenorrhea.[327]

Suckling produces a dramatic increase in food intake that correlates with increased activity of orexigenic neurons (NPY and agouti-related protein (AgRP)) and decreased activity of anorexigenic neurons (pro-opiomelanocortin (POMC) and cocaine-and-amphetamine responsive transcript (CART)) in the ARC.[331] Because NPY inhibits, and MSH and CART can stimulate, LH secretion, these changes could contribute to the suckling-induced suppression of GnRH secretion,[345] but recent data discussed later indicate this is unlikely in rats. Instead, these changes in orexigenic and anorexigenic neural activity probably assist the mother in compensating for the increased energy demands of lactation and most likely reflect both a direct neural signal and the abnormally low concentrations of leptin and insulin seen during lactation in rats[346] and cows.[347] In nursing women, leptin concentrations appear to be normal,[327] but increased insulin secretion (based on C-peptide) preceded the resumption of menses.[348] Thus, although hyperprolactinemia appears to be important in rats, neither the increased prolactin concentrations nor changes in the neural circuitry controlling food intake are critical for lactational infertility in other species. Interestingly, another possible mechanism arises from studies of nursing cows that have strongly implicated the formation of a maternal–calf bond, rather than the suckling stimulus per se, as critical for inhibition of GnRH secretion.[349] Whether this occurs in other species in which the mother can identify her own offspring, and the underlying neuroendocrine mechanisms, remain to be determined.

Virtually all work on neuroendocrine mechanisms suppressing GnRH during lactation since the previous edition of this book has been done in the rat, but it has led to an interesting model for the effects of suckling on hypothalamic neural circuits controlling food intake and the inhibition of GnRH secretion.[331] As noted above, suckling produces hyperphagia and there is a corresponding shift in the ARC circuitry critical for metabolic homeostasis (increased NPY and AgRP; decreased POMC and CART).[346,350–352] These ARC circuits are well known to stimulate downstream orexogenic neurons (orexin and MCH) in the lateral hypothalamic area (LHA) and inhibit anorexogenic CRH neurons in the PVN to increase food intake, changes that are also seen in lactation.[330] In addition, suckling induces NPY expression in the dorsomedial hypothalamus (DMH) neurons[352] that also project to the PVN[353] and have been implicated in suckling-induced hyperphagia.[354] The increased NPY in the DMH is partially due to the elevated prolactin concentrations because CB-154 suppressed NPY expression in the DMH, but not to levels seen in nonlactating controls.[355] All these appetite-regulating neurons (in the ARC, LHA, and PVN) also project to GnRH cells in the rat and could therefore directly inhibit GnRH release.[331] Alternatively, suckling may act via kisspeptin because it inhibits both kisspeptin and NKB (but does not affect dynorphin) expression in KNDy neurons.[337,346,356,357] The effects of suckling on kisspeptin expression in the AVPV is less clear; there are reports that *Kiss1* mRNA levels either did not change[357] or decreased[356,357]

during lactation, but the number of kisspeptin-immunoreactivity (kisspeptin-ir) cells in the region increased in lactating rats.[356]

The relative importance of all these changes was clarified by the report that increasing leptin and/or insulin in lactating rats to concentrations seen in normal controls restored expression of ARC NPY, AgRP, and POMC to normal, but had no effect on ARC kisspeptin–NKB or DMH NPY expression.[346] Importantly, these treatments had no effect on the hyperphagia or low-LH concentrations induced by lactation. Thus the ARC metabolic circuitry is likely responding to the increased metabolic demands of lactation, but is not critical for the behavioral and reproductive effects of this condition. Since these ARC systems drive neural activity in the LHA and PVN, it is likely that levels of orexin, MCH, and CRH were also partially or completely normalized, although this has yet to be demonstrated. Instead, the current model proposes that suckling stimulus, conveyed in part by neurons in the lateral parabrachial nucleus and ventrolateral medulla,[358,359] acts to directly stimulate DMH NPY and inhibit ARC KNDy and DA neurons (Figure 33.12). The increased prolactin concentrations, resulting from the latter, likely complements these effects because prolactin increases DMH NPY[355] and inhibits ARC kisspeptin expression,[360] and both these cell populations contain prolactin receptors.[355,361] The increase in DMH NPY then stimulates food intake, and the decreased release of kisspeptin inhibits GnRH secretion. NPY projections from the DMH may also inhibit GnRH secretion, but there is no clear evidence for such an action at this time. Thus, this model proposes that the suckling stimulus and prolactin act in concert to directly and indirectly inhibit kisspeptin, and thus GnRH, release. It is also important to keep in mind that the effects of leptin and/or insulin replacement indicate that the ARC metabolic circuitry is not required for inhibition of GnRH, but do not exclude the possibility that they contribute to this suppression. Given the redundancy in both reproductive and metabolic neuroendocrinology, it seems prudent to suggest that increased input of orexogenic (NPY, AgRP, orexin, and MCH) and decreased input of anorexigenic (MSH and CART) to GnRH neurons work together with the decreased kisspeptin drive to maintain infertility during lactation. Finally, while this is a very attractive model, its applicability to other species that do not show a postpartum ovulation and in which prolactin probably plays a minor role in suppression of reproduction is completely unknown.

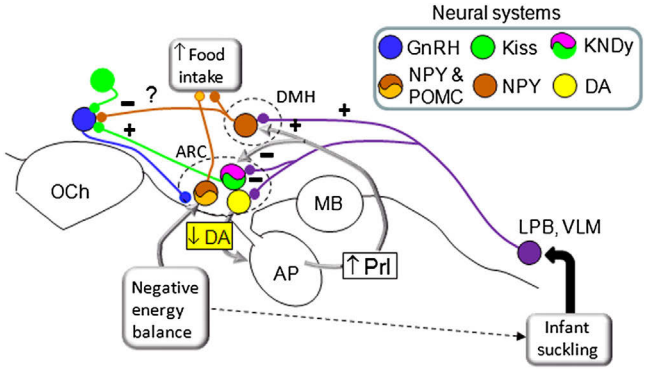

FIGURE 33.12 Neural systems stimulating food intake and inhibiting GnRH secretion during lactation in the rat. This figure is reproduced in color in the color plate section. The suckling stimulus is transmitted to the hypothalamus via neurons in the lateral parabrachial nucleus (LPB) and ventrolateral medulla (VLM), inhibits DA release from tuberoinfundibular dopaminergic (TIDA) neurons and kisspeptin release from KNDy neurons, and stimulates NPY neural activity in the DMH. The fall in DA allows prolactin secretion to increase, which further inhibits KNDy kisspeptin and stimulates NPY from the DMH. The latter increases food intake, while the former inhibits GnRH secretion. At the same time, the negative energy balance in the mother induced by the demands of the offspring acts via the metabolic homeostatic circuitry in the ARC (increased NPY–AgRP and decreased POMC–CART), which also acts to stimulate food intake and may inhibit GnRH secretion. Note that this circuitry is depicted by a single neural element (NPY and POMC) for simplicity. Similarly, orexogenic neurons in the LHA and anorexogenic CRH neurons in the PVN are not illustrated.

Other Instances of Physiological Suppression of Reproduction

As noted earlier, reproduction is also inhibited seasonally and by undernutrition and stress in many species, and is often modified by social interactions and pheromonal systems. Since most of these topics are considered in detail elsewhere in this book, this discussion of them here will be fairly brief with an emphasis on comparative aspects.

Seasonal Breeding

Most species living in temperate zones, and many of those in the equatorial region, have evolved mechanisms that ensure that their young are born at the time of year best suited for their survival. Given its obvious evolutionary significance, it is not surprising that a wide variety of reproductive strategies have been adopted to limit the timing of births, but two of these are fairly common and relevant here: (1) limiting fertility of the adult to a specific time of year; and (2) prolonging pregnancy by inducing a period of embryonic diapause. It is also useful to divide seasonality based on the two major environmental cues a species uses to time reproduction: (1) food availability; or (2) photoperiod. Small mammals with short pregnancies often couple their fertility to food availability because an increase in food will almost always last from fertilization through lactation.[362] There is evidence that some species use a specific plant compound to time reproduction,[363] but in most cases fertility is regulated by metabolic compounds (e.g., glucose availability) and

related hormones (e.g., leptin and insulin), presumably by the same neuroendocrine pathways by which these factors control reproduction in rats and mice. Because these pathways are described in detail in Chapter 35. I will focus the rest of this discussion on photoperiodic control of reproduction.

Animals whose pregnancy lasts several months routinely use photoperiod (hours of light/day) as the environmental cue because it remains exactly the same from year to year, and is thus a reliable predictor of when spring will occur. Moreover, in all mammals (from marsupials on up) that use photoperiod, the pineal hormone, melatonin, is the internal signal that times critical reproductive events. Melatonin is only secreted at night, so the duration of melatonin secretion is a hormonal analog of the external photoperiod. The duration of elevated melatonin then alters secretion of prolactin or GnRH to control embryonic diapause or fertility, respectively. Embryonic diapause usually occurs at the blastocyst stage of development and is characterized by cell cycle arrest.[364,365] The blastocyst then remains in suspended animation until the appropriate signal reinitiates mitosis and implantation soon follows. In species in which photoperiod controls this reinitiation process, a change in prolactin secretion, acting via ovarian hormones, is the primary trigger. Interestingly in all mammals studied to date, long photoperiods (i.e., short-duration melatonin) stimulate prolactin secretion, while short photoperiods inhibit secretion. Thus species have evolved different downstream actions of prolactin depending on whether implantation occurs on long or short days. For example, in mink diapause termination takes place on long days due to a spike in ovarian secretion of progesterone (and an unidentified protein hormone) in response to increasing prolactin.[365,366] The converse occurs in the tammar wallaby; elevated prolactin inhibits progesterone secretion from the ovary so the fall in prolactin produced by short days stimulates progesterone secretion, which terminates diapause so implantation occurs.[364]

In contrast to prolactin, the effects of photoperiod on GnRH secretion depend on whether an animal is a short-day or long-day breeder. Long-day breeders have short pregnancies so GnRH release is high, and breeding occurs during spring and summer, while short-day breeders have pregnancies that last about 5–6 months so elevated GnRH and breeding occur in the fall and early winter. These effects of photoperiod on GnRH release are further complicated by internal timing mechanisms that allow animals to anticipate a coming season (see Chapter 34). In the few mammals that have been extensively investigated (primarily sheep and Siberian and Syrian hamsters), inhibitory photoperiods (regardless of whether they are long or short days) suppress GnRH secretion by both steroid-dependent and steroid-independent systems, although the relative importance of each depends on the species.[367,368] However, the actual neural systems involved vary among these three species. Changes in kisspeptin appear to be important in sheep and Syrian hamsters, but not in Siberian hamsters.[369] Increased RFRP3 (RFamide-related peptide 3) in the DMH has been implicated in stimulating GnRH secretion in both hamster species,[369] but may have inhibitory actions in sheep.[2] Finally, there is strong evidence in sheep that activation of an inhibitory dopaminergic system (A15) that suppresses kisspeptin secretion is critical for seasonal infertility in anestrus,[370] but there is no evidence for an analogous system in hamsters. Thus, each of these seasonal breeders appears to have evolved different hypothalamic mechanisms to control GnRH secretion.

Despite the marked differences in the neural mechanisms by which melatonin controls fertility and embryonic diapause, recent work has uncovered possible convergence in the initial steps by which it acts. Specifically, there is now increasing evidence that long-day melatonin patterns act in the pars tuberalis of sheep and hamsters to stimulate prolactin secretion and alter GnRH release. The pars tuberalis contains the highest concentrations of melatonin receptors in the body, and melatonin is thought to act here to stimulate a prolactin-releasing factor (or "tuberalin"), which may be substance P, that stimulates prolactin secretion from lactotrophs during long days. However, it is unclear at this time if this mechanism applies to the actions of melatonin that control embryonic diapause. Melatonin has also been proposed to control GnRH secretion in hamsters and sheep by stimulating TSH secretion from thyrotrope-type cells in the pars tuberalis. This TSH then diffuses into nearby tissue to alter expression of enzymes that de-iodinate T_4 and produce a local increase in the biologically active T_3 during long days, which is responsible for altering GnRH secretion (to stimulate in long-day, and inhibit in short-day, breeders). The mechanisms by which T_3 produces these effects and whether this model also applies to the control of GnRH by short-day melatonin patterns remain to be determined. Readers interested in a more detailed discussion of melatonin secretion and actions, and the neural pathways controlling GnRH in seasonal breeders, are referred to the Chapter 34.

Stressors

It is clear that many different types of stressors inhibit reproductive function (see Chapter 36), although stimulatory effects are sometime observed.[371] Inhibition of the estrogen-induced LH surge has been observed with some, but not other, stressors, whereas all stressors inhibit tonic LH secretion.[371,372] Because a decrease in episodic LH secretion will indirectly block ovulation (by preventing the necessary increase in E_2 secretion), most workers have focused on stress-induced inhibition of pulsatile LH

secretion. It appears that the inhibitory effects of stressors are usually mediated by central mechanisms rather than by actions of elevated glucocorticoids.[371,372] Thus acute treatments with glucocorticoids have little effect on episodic LH secretion in rats, monkeys, and humans. Cortisol does act at the pituitary to suppress LH pulse amplitude in ewes[373]; this action is not required for the inhibition of episodic LH secretion by endotoxin,[374] but may play an important role in the effects of psychosocial stress.[375,376] Moreover, cortisol clearly suppresses LH pulse frequency during the follicular phase of the ovine estrous cycle,[377] so sheep may be one species in which glucocorticoids have important inhibitory effects on GnRH secretion.

Although central systems mediate the inhibition of GnRH by stressors, a comparative approach to identifying common neuroendocrine mechanisms underlying this inhibition reveals many more differences than similarities. This lack of common mechanisms may be due in part to the different types of stressors used, the most common of which are immunological (endotoxin or cytokines), insulin-induced hypoglycemia, restraint in rats, and psychosocial stress in sheep and monkeys. Although these stressors all increase corticotrophin-releasing hormone (CRH), vasopressin (AVP), adrenocorticotropic hormone, and glucocorticoid secretion, they presumably activate different sensors that impinge on both the hypothalamic–pituitary–adrenal (HPA) and hypothalamic–pituitary–gonadal (HPG) axes via different pathways. For example, hypoglycemia is likely to activate glucose sensors in the hind brain[378] not affected by endotoxin, so it is not surprising that NE input from this region to CRH neurons in the PVN has been implicated in suppression of GnRH by insulin-induced decreases in blood glucose.[372] However, species differences are evident even if one focuses on a specific stressor. For example, there is strong evidence that CRH mediates the inhibitory actions of cytokines in monkeys, but not in rats.[371] However, based on the effects of naloxone, EOPs participate in suppression of LH secretion by a variety of stressors in rats, sheep, monkeys, and humans, the one exception being hypoglycemia in monkeys.[371] There are also significant individual variations in sensitivity to some stressors that can complicate identification of important systems.[379] Finally, as noted in the discussion on lactation, there are also undoubtedly many redundancies in the systems activated by a specific stressor, so workers are unlikely to find one system that is absolutely essential to suppression of GnRH secretion.

Despite the problems inherent in making species comparisons, some useful generalizations can be made on the neuroendocrine inhibition of GnRH secretion by stressors. Given their role in the HPA axis, considerable attention has focused on AVP and CRH. AVP has received less attention and the data are somewhat inconsistent, but it does appear to play some role in the inhibition of GnRH secretion by hypoglycemia and cytokines.[371,372] In contrast, CRH appears to be an important mediator of many stressors. There are, however, two important caveats to this general statement: (1) in ewes, CRH either stimulates[380] or has no effect[381] on LH secretion, so it is unlikely to be important for stressed-induced inhibition of GnRH, possibly because cortisol is more important in this species; and (2) in rats, many stressors act via CRH receptor 2 (CRHR2), not CRHR1, so that urocortins may also be important mediators.[382] Other useful concepts that have recently emerged are the importance of limbic CRH systems and the interaction of CRH with aminergic neurons in the brainstem. Given its role in emotional processing, it is not surprising that neurons containing CRH in various portions of the limbic system have been implicated in the inhibition of GnRH by stressors.[372] There is strong evidence that some of their inhibitory effects occur by activation of NE neurons in the locus coeruleus.[383] Reciprocal connections between CRH neurons in the PVN and serotonergic neurons in the raphe nucleus have also been implicated in the inhibition of menstrual cycles in monkeys by psychosocial stress.[379]

In comparing the inhibition of GnRH secretion by stressors with seasonal and lactational effects, it is interesting to note that while stressors are clearly inhibitory in OVX animals, they are generally more effective in the presence of E_2 and/or progesterone than in their absence.[384–387] These data have usually been interpreted as an action of ovarian steroids to increase the effects of CRH or other mediators of stress, but could equally be viewed as a stressor producing both steroid-independent and steroid-dependent inhibition of GnRH. Recent work in this area has focused on kisspeptin, with the only two papers reporting that endotoxin induced a decrease in *Kiss1* mRNA[388] or protein[389] expression in the ARC. The former observed similar effects of this and other stressors and CRH on *Kiss1* and *Kiss1r* mRNA expression in the ARC and POA. Exogenous kisspeptin did stimulate LH secretion in the presence of endotoxin, but the magnitude of the response was markedly reduced compared to that in controls.[389] Thus the functional significance of the stress-induced decrease in kisspeptin remains to be determined. Finally, as noted above, many effects of stressors in general, and CRH in particular, appear to be mediated by EOP.[371] These data led to the suggestion that some of these actions may be mediated by increased dynorphin release from ARC KNDy neurons.[372] This hypothesis has yet to be tested, but earlier reports that an antagonist to μ-EOP, but not κ-EOP, receptors blocked effects of some stressors argues against it.[390,391]

Nutritional Suppression of Reproduction

Reproductive function is usually suppressed whenever a female is in a condition of negative energy balance to help ensure she survives and can reproduce at a later date. This condition can occur during periods of

high demand such as lactation (see the section Lactation) and intense exercise regimens even though food intake is increased, but the more common cause is inadequate nutrition, particularly in animals living in nonequatorial regions where food scarcity in winter is the norm.[392] Smaller mammals are particularly susceptible to the adverse effects of limited food because they have little energy stored as fat and a high surface-to-volume ratio that dissipates heat rapidly. Thus they must have a higher metabolic rate to maintain normal body temperature and must eat more food per unit body weight than larger animals.[392] Similar logic indicates that growing animals are more susceptible to food restriction than adults, and this is evident by the marked effects of undernutrition on the timing of puberty. While males and females of the same species are generally subject to the same energetic demands, these are usually more likely to produce infertility in females than males. This sexual dimorphism reflects the higher and more long-term energy demands on the mother during both pregnancy and lactation[392]; in contrast, while males may expend considerable energy in competition with other males, this usually lasts for a relative short period and is less energy demanding than pregnancy and lactation.

The effects of nutrition are often evident through their interaction with other factors that control fertility. As already noted, inadequate nutrition will delay puberty, and signals of adequate nutrition such as leptin concentrations are often permissive for puberty onset. Another obvious example is lactation, when the negative energy balance produced by the offspring acts in synergy with the suckling stimulus to suppress GnRH secretion. Moreover, nutrition also plays an important role in seasonal breeding. As discussed earlier, in some species with short pregnancies, fertility is controlled directly by levels of nutrition, which leads to a seasonal pattern because of the seasonal nature of food availability. Even in species that rely on photoperiod as the proximate cue to time fertility, food availability is thought to be the ultimate factor that provided the evolutionary drive that determined when breeding occurs (i.e., it ensures that the young are born when food is plentiful, usually in the spring). Finally, the effects of undernutrition and stress are often confounded. As discussed above, one of the most commonly used experimental stressors is insulin-induced hypoglycemia, which may be inhibiting GnRH secretion via metabolic sensors, rather than stress-sensitive neurons. Conversely, food deprivation is undoubtedly a stressor under most circumstances, so the resulting suppression of fertility may reflect activation of a stress system. It is thus not surprising that there is some convergence of signals generated by food deprivation and stress onto the PVN.

Mammals rely on multiple signals to monitor food availability and energy reserves in order to control fertility, including vagal input from the GI track, and circulating concentrations of metabolic fuels and their associated hormones.[378] There is considerable evidence in rodents that input from the vagus nerve and neural sensors in the lining of the fourth ventricle that detect a fall in glucose or fatty acids converge on the A2 NE neurons (solitary tract nucleus) in the brainstem.[378,393–395] These NE neurons send projections to the PVN, where they stimulate activity of CRH-containing neurons that inhibit GnRH secretion.[396–398] The mechanisms by which leptin, insulin, and other metabolic hormones affect GnRH secretion are a very active area of research. As described in Chapter 35, these hormones likely act via the NPY–AgRP and POMC–CART circuitry in the ARC (and possibly their downstream targets in the LHA and PVN) to influence both food intake and GnRH secretion and leptin-sensitive neurons in the ventral premammillary nucleus to control GnRH release.[399]

Inadequate nutrition inhibits GnRH secretion via both steroid-independent and steroid-dependent mechanisms[400,401] and the A2 NE input to the PVN appears to primarily increase the negative feedback actions of E_2,[394] possibly via changes in expression of ERα.[402] Decreases in kisspeptin also appear to play a central role in mediating the effects of undernutrition, although the relative importance of kisspeptin neurons in the ARC and POA is still under debate (see Chapter 35). Although some ARC kisspeptin cells contain leptin receptors, recent work indicates that the effects of leptin on kisspeptin expression and reproductive function are most likely mediated by leptin actions on other neural systems.[399,403]

Psychosocial and Pheromonal Control of Reproduction

Successful reproductive function requires coordinated complex behavioral interactions between males and females, and there is considerable information on the hormonal control of these behaviors. Conversely, psychosocial interactions can also influence secretion of GnRH (Chapter 36). One clear example of this is the marked difference in testosterone concentrations between dominant and submissive males in a troop of monkeys,[404] although the low testosterone in the latter might be due to stress-induced suppression of GnRH secretion.[405] The best studied example of psychosocial control of reproduction involves communication via pheromones, although these chemical signals can be supplemented by visual and auditory signals under some circumstances.[406] Pheromonal input can be stimulatory or inhibitory; for example, adult male urine will advance puberty onset in rodents, while urine of adult females delays first ovulation.[406] In most cases, the effects of pheromones on reproduction occur via changes

in GnRH secretion, but the ability of novel males to interrupt pregnancy in mice is mediated by inhibition of the prolactin secretion (via increased DA) necessary for maintenance of pregnancy in these rodents.[407]

There have been two important developments in our understanding of how pheromones influence GnRH release in the last decade that relate to the initial and ultimate effects of these chemicals. Historically, based largely on lesion studies in rodents, the vomeronasal organ, rather than the main olfactory epithelia, was thought to be the site where pheromones that affect reproductive function are sensed.[406] A multisynaptic neural pathway originating in this structure that projects to the hypothalamus via the accessory olfactory bulb and medial amygdala conveys pheromonal information to GnRH neurons. However, elegant tract-tracing studies using transgenic mice clearly demonstrated that cells in the main olfactory epithelia, the main olfactory bulb, the olfactory cortex, and the cortical nucleus of the amygdala represent a multisynaptic pathway from the main olfactory epithelia to GnRH neurons.[408,409] Moreover, this olfactory system conveys important pheromonal information to GnRH neurons based on Fos expression and genetic lesions of the main olfactory epithelium[408,409]; Fos data also confirmed a role for the secondary olfactory system.[408] Similar lesion and Fos expression studies in sheep have also implicated the main olfactory system in the ability of male odors to stimulate episodic LH secretion in anestrous females.[410–412] Interestingly, in contrast to just male odors, exposure to male sheep increased LH pulse frequency via both main and accessory olfactory systems in ewes. Thus, the general consensus at this time is that pheromones act via both main and accessory olfactory systems to stimulate episodic GnRH secretion.

Information on the final steps in this pathway comes largely from work in sheep and goats examining the ability of males to stimulate episodic LH release (in sheep)[2,413] and the corresponding bursts in MUA recorded from the ARC (in goats).[166] A series of experiments in OVX goats have demonstrated that brief exposure to male odor induces a single burst of MUA within seconds, suggesting that pheromonal information has direct access (via one of the pathways described above) to the GnRH pulse generator.[166,414] This hypothesis is consistent with evidence that male pheromones stimulate LH pulses in both anestrous and luteal-phase ewes,[415] which indicates that this stimulation is likely independent of the negative feedback actions of ovarian steroids. It is also supported by the recent report that ARC kisspeptin neurons mediate the stimulatory effects of the male in anestrous ewes.[416] Thus it seems likely that, in sheep and goats, stimulatory pheromones exert their effects directly on the GnRH pulse generator in the ARC; whether this also occurs in other species is unclear at this time.

Summary

It is not surprising that different external factors use different neuronal systems to control fertility. However, despite this diversity some common features emerge from this review. First, many of these modulators of reproduction produce their primary effects by controlling episodic GnRH secretion. Thus LH, not FSH, secretion is usually rate limiting for initiation, or reinitiation, of fertility. Second, many of these systems inhibit GnRH secretion via both steroid-independent and steroid-dependent mechanisms (Figure 33.13) similar to those operative in prepubertal animals, although the relative importance of each varies. Whether these mechanisms represent completely independent neural systems, or the same system that functions at a low level in gonadectomized animals and is stimulated by gonadal steroids, remains to be determined. Third, changes in activity of the GnRH pulse generator are responsible for most, if not all, of the actions of the neuroendocrine systems activated by external factors. This is not surprising given the importance of episodic GnRH secretion to control of fertility, but it does identify key neural systems that can be the focus of future research. Finally, changes in kisspeptin have also been implicated as the penultimate neural system driving GnRH secretion. This may reflect the possible role of kisspeptin as the output signal from the GnRH pulse generator (Figure 33.13) or other actions of kisspeptin related to its potential role in the negative and positive feedback actions of ovarian steroids.

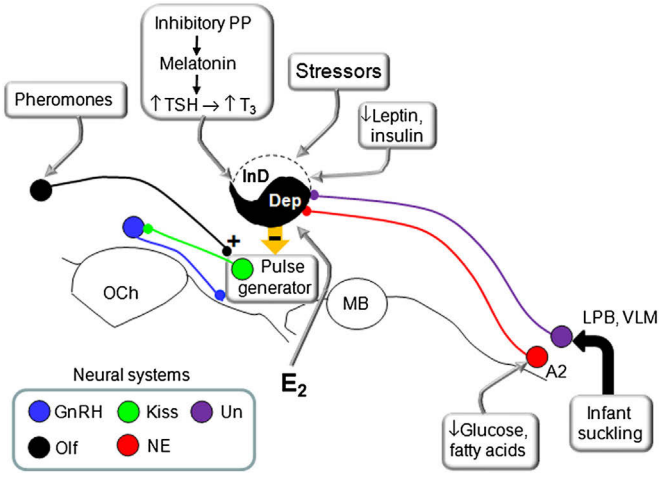

FIGURE 33.13 Schematic of parasagittal section of the hypothalamus illustrating mechanisms by which different external factors alter episodic GnRH secretion. This figure is reproduced in color in the color plate section. Note that neural inputs are conceptual and do not represent monosynaptic pathways. See the text for more details. Dep: steroid-dependent mechanisms; InD: steroid-independent mechanisms; Kiss: kisspeptin; NE: norepinephrine; Olf: olfactory epithelium; Un: unknown neurotransmitter.

CONCLUSION

From a historical perspective, it is clear that comparative studies of the neuroendocrine control of reproductive function played a key role in the development of the concept of tonic and surge secretion of LH. Comparative studies have also led to a better understanding of the multitude of neuroendocrine systems and pathways that can influence GnRH secretion, and some of the fundamental observations were initially made in species not commonly used for experimental work. One is particularly struck by the number of important observations first made in primates that laid the foundation for subsequent work in rats and mice. In addition to the identification of kisspeptin based on genetic studies in humans, these include the initial observation of episodic LH secretion (and the inference that this mode is due to intermittent GnRH release), and the identification of the importance of episodic GnRH secretion to normal LH and FSH secretion and of its electrophysiological correlate (bursts in MUA), all of which came from work in nonhuman primates. It is also important to keep in mind that from the perspective of a true comparative endocrinologist, the number of species in which detailed reproductive neuroendocrine control systems have been identified is small and not very diverse.

With the caveat that we are dealing with a relative small number of species, two general conclusions can be drawn from these species comparisons. First, there are marked species differences in the neural systems controlling the preovulatory LH surge, ranging from reflex ovulators that require an external signal to primates that apparently do not require any change in GnRH secretion for normal ovulation. In contrast, the endocrine signal (a sustained increase in E_2 concentrations) has been relatively conserved during evolution, because it serves to limit the LH surge to the time when a mature ovum is present in the follicle. Given this contrast, it is difficult to envision environmental pressures that led to the diversity of neural mechanisms responsible for the preovulatory GnRH surge. Perhaps as long as the estrogen signal was retained, there was little natural selection pressure to limit development of new neural systems. Second, in contrast to the diversity in neural mechanisms responsible for the LH surge, the neural systems driving episodic GnRH secretion appear to be fairly similar in those species examined to date. Moreover, the GnRH pulse generator is also the common final pathway for control of fertility by a wide variety of external factors (Figure 33.13). This may reflect the importance of episodic GnRH secretion, but not the GnRH surge, to fertility of *both* males and females, in contrast to the LH surge. This common role for the GnRH pulse generator in both sexes may also explain why it was targeted by evolutionary pressures for modification by the external environment.

This overview of the comparative aspects of reproductive neuroendocrinology highlights the importance of this approach to our understanding of basic mechanisms controlling GnRH secretion. Unfortunately, the prospects for future work in this field seem bleak. Over the last decade, the number of detailed reproductive neuroendocrine studies in nonrodent species has dwindled significantly. For example, in light of the historical impact of studies in the rabbit, it is remarkable that there is no information on kisspeptin expression in this species over a decade since the discovery of the reproductive actions of this peptide. Moreover, given the emphasis on genetic manipulations and the growing expense of nonhuman primate work, this trend is likely to accelerate. Thus important comparative issues may not be addressed. For example, although it is clear that both kisspeptin and NKB are critical for normal fertility, their physiological roles in the human, and other primates, menstrual cycle are essential unknown, a gap in our knowledge that is unlikely to be addressed. Recent evidence has also raised the possibility of species differences in the role of KNDy peptides in the control of episodic GnRH secretion between rodents and ruminants.[417,418] It will thus be important to determine which model applies in other species, including primates. One can hope that application of technical developments in genomics, proteomics, and neurobiology to a variety of species in the future can address the current deficit in comparative studies of reproductive neuroendocrine systems.

Acknowledgments

I thank Drs Fred Karsch, Tony Plant, Tony Zeleznik, and Allan Herbison for their thoughtful comments on draft versions of this chapter. The input of Dr Susan Smith was particularly useful to the development of the section on lactation. Supported by grants from the US National Institutes of Health (HD017864 and HD039916), and personal funds to cover the costs of copyright permissions.

Seasonal Regulation of Reproduction in Mammals

David Hazlerigg

Department of Arctic and Marine Biology, University of Tromsø, Tromsø, Norway

Valerie Simonneaux

Institut des Neurosciences Cellulaires et Intégratives, Strasbourg, France

INTRODUCTION

This chapter deals with the mechanisms by which breeding in mammals is synchronized to environmental seasonality. Seasonality is a fundamental feature of the earthly environment, due to basic geophysical considerations: the Earth's orbit around the Sun, and the 23° tilt in the Earth's axis of rotation relative to its plane of solar orbit (Figure 34.1(A)). These considerations lead to an annual cycle of changing solar light exposure experienced over the entire globe, with an amplitude that varies dramatically based upon latitude: at the poles continuous illumination is replaced by continuous darkness at 6 month intervals, while in the equatorial zones the day length and the zenith of the midday sun vary imperceptibly over the course of the year (Figure 34.1(B)). As a consequence of these differences in the annual cycle of illumination (and hence solar energy supply), the amplitude of annual rhythms of environmental seasonality increases dramatically as one travels away from the equator. Seasonality is also seen within the equatorial zones, related to rainfall patterns, but these occur without the predictable periodicity seen at higher latitudes.

Since the raising of young is the most energetically demanding phase of the life history cycle, and is crucial for evolutionary fitness, mammals have evolved mechanisms to ensure that breeding is timed so that parturition occurs in windows of environmental favorability, typically in the spring and summer months. For short gestation species (for example, rabbits or hamsters), this leads to the breeding season being confined to the spring or summer (so-called "long day breeders"), while longer gestation lengths seen in ungulates are often associated with breeding in the preceding autumn (so-called "short day breeders") (Figure 34.2). Understanding the mechanisms determining the timing of the breeding season was a key motivating factor behind the seminal work of Francis Marshall on reproductive physiology more than a century ago.[3] Regardless of when breeding takes place, mammals rely on a photoperiodic readout system built around pineal production of the indole amine hormone, melatonin. Although a link between the pineal and reproduction in humans was suggested as early as the late nineteenth century from clinical studies linking pineal tumors to precocious puberty,[4] the isolation of melatonin as the principal bioactive output of the pineal gland was not achieved until more than half a century later.[5] Moreover, while melatonin had an unambiguous effect on skin color in amphibians (giving it its name), its role as a calendar signal in mammals was not appreciated until the 1980s, with the synthesis of understanding from experiments in long- and short-day breeding seasonal mammals (revealing clear effects of melatonin on breeding not evident in earlier work in nonphotoperiodic laboratory strains of rat). Progress in the last three decades has been impressive: the pharmacological basis of melatonin receptor signal transduction was established in the 1990s, and the importance of sites of melatonin action in the hypothalamus or in the neighboring pars tuberalis (PT) of the anterior pituitary for seasonal endocrine function also became clear. In the last decade, thyroid hormone metabolism within the mediobasal hypothalamus has emerged as the key gatekeeper for seasonal reproductive activation in mammals as well as in birds. In mammals, melatonin engages with hypothalamic thyroid metabolism via a pathway involving a novel paracrine function of thyrotropin

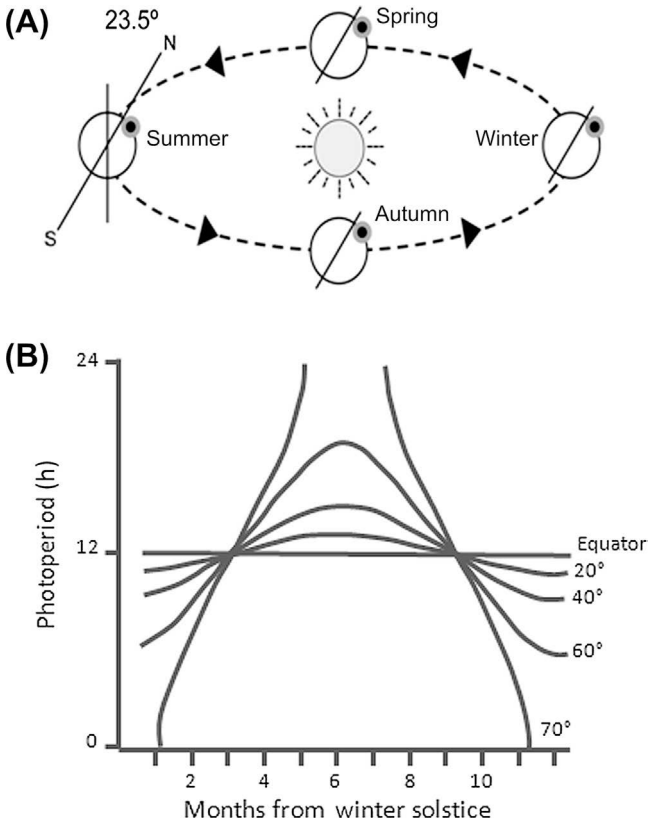

FIGURE 34.1 Geophysical basis of seasonality. (A) The Earth's axis of rotation is tilted at 23° relative to the perpendicular of the plane of rotation around the Sun. The filled point represents a reference location at a high, northern latitude. (B) This gives marked seasonal clines in the amplitude of annual day length variation from an almost constant 12-h day in the equatorial regions to 24 h in the polar regions.

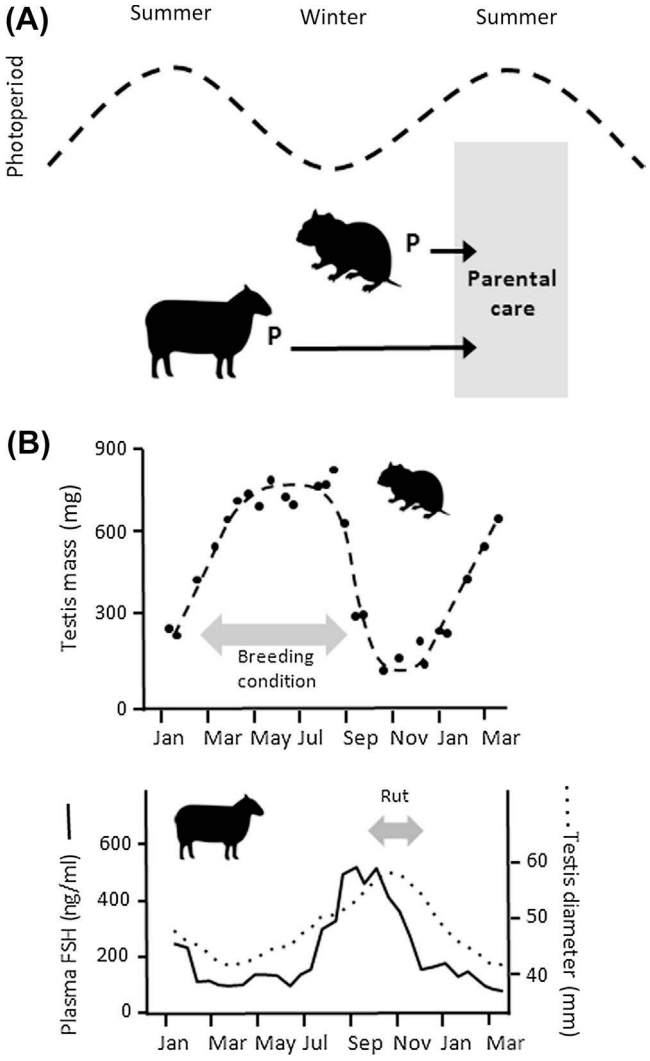

FIGURE 34.2 Timing of the breeding season relative to gestation length. (A) Mammals generally time parturition to coincide with relatively benign spring/summer conditions. This dictates the timing of the breeding season, and hence small rodents with short gestations initiate pregnancy (P) during the summer months, while long gestation ungulates like sheep and deer breed in the preceding autumn. (B) This is reflected in seasonal patterns of testicular growth and regression in male Djungarian hamsters (top panel) and Soay rams (bottom panel) exposed to natural illumination. *Source: Adapted from Refs 1,2.*

(TSH) produced by melatonin-sensitive cells in the PT. Remarkably, this regulatory pathway also operates in birds, although in this vertebrate group photoperiodic input does not rely on melatonin. Current attention now focuses on mechanisms downstream of thyroid metabolism, in particular the role specialized glial cells found around the third ventricle, known as tanycytes, and of hypothalamic neurons expressing kisspeptin (Kp) or argenine-phenylalanine-amide related peptide (RFRP) in mediating changes in gonadotropin-releasing hormone (GnRH) secretion. In this chapter, we discuss the following: the ecological context for seasonal breeding strategies, current knowledge of the mammalian photoperiodic response pathway, and lastly future prospects in this fascinating subject.

ECOLOGICAL CONTEXT FOR SEASONAL BREEDING: ULTIMATE FACTORS AND PROXIMATE CUES

As the driver of seasonal energy availability, the Earth's orbit of the Sun can be seen as the ultimate factor driving the evolution of seasonal breeding strategies. Additionally, this orbit leads to an annual cycle of varying day length (photoperiod), which has become the proximate cue used by seasonal mammals to synchronize breeding to the annual environmental cycle. The exploitation of photoperiod as a cue reflects its invariant cyclical nature (i.e., the hours of daylight on any given date is the same from year to year), which because of its geophysical basis, is reliably predictive. In contrast, other proximate cues such as food availability, temperature, or availability of mates in breeding condition are noisy signals of poor predictive value for forthcoming conditions.

The extent to which breeding is organized to a specific phase of the calendar year may vary in a graded fashion across the latitudinal range occupied by a given species;

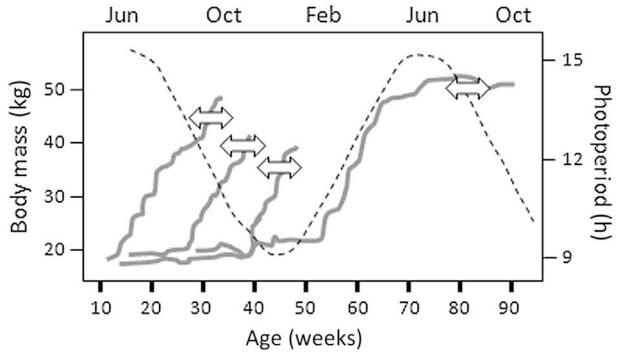

FIGURE 34.3 Nutrition x photoperiod interactions controlling puberty in Suffolk lambs. Shown are the growth trajectories (gray lines) for groups of lambs held on four different feeding regimes. The horizontal double arrows show the timing of puberty in each group. The dashed curve shows the annual photoperiod cycle. Lambs fed from weaning on an ad libitum plane of nutrition grow to about 40 kg by early autumn when they enter puberty. Delaying growth by undernutrition until the autumn or early winter leads to a delayed puberty in the first winter of life, at a reduced body weight compared to ad libitum controls. If, however, growth is delayed by undernutrition until the following spring, then puberty is not attained until the second autumn of life, when body weight is significantly higher than in control lambs. Hence nutrition and photoperiod jointly determine the onset of reproductive maturation in lambs. *Source: Redrawn from Ref. 7.*

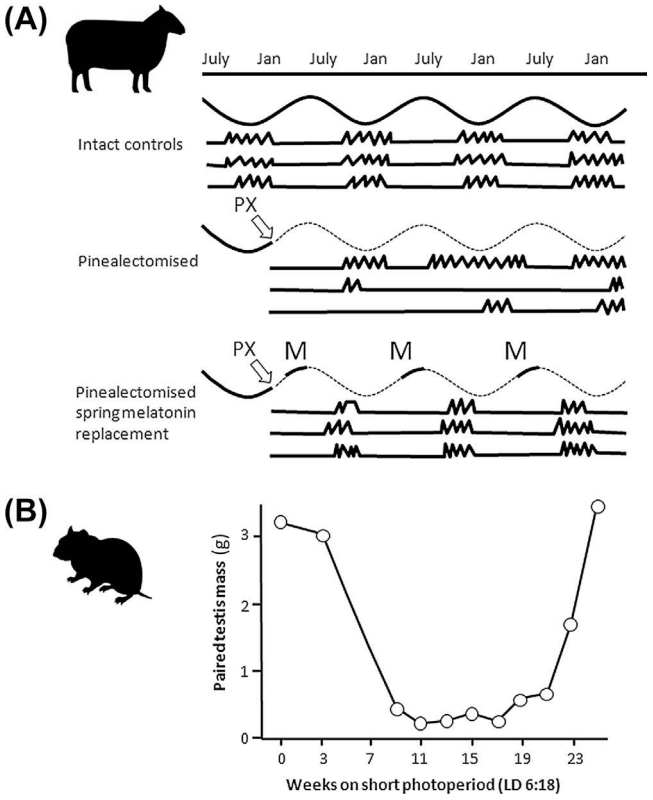

FIGURE 34.4 Innate long-term regulation of reproductive activity in seasonal breeders and the synchronizing effect of melatonin. (A) Ewes exposed to natural cycles of changing day length enter breeding condition synchronously in the autumn-to-winter months. Pinealectomy (PX) removes the endogenous melatonin (M) signal and leads to asynchronous episodes of reproductive activation (squiggles) and quiescence (straight lines). Synchrony can be restored by a subcutaneous infusion of melatonin in a temporal pattern to imitate the endogenous sequence of nocturnal pineal melatonin signals spanning just a quarter of the overall annual cycle. A sequence of infusions imitating the spring-to-summer photoperiod sequence is particularly effective as a circannual synchronizing signal. *(Source: Based on data in Ref. 10.)* (B) Male adult Syrian hamsters exposed to a short photoperiod of 6 h light/18 h darkness for 25 weeks initially undergo testicular regression, reflecting reproductive quiescence. Afterwards, despite continued short day exposure, they display a spontaneous recrudescence of testicular growth and return of reproductive activity. *Source: Redrawn from Ref. 11.*

populations living at higher latitudes showing strong cycles of seasonality consistently synchronized to a specific phase of the calendar year, while lower latitudes favor continuous breeding, with an opportunist element related to prevailing food availability.[6] This pattern suggests that, in the wild, the "decision" to breed is conditional on photoperiod integrated with other proximate cues reflecting energy availability. A nice demonstration of the interaction between photoperiod and nutrition in a laboratory setting can be found in studies by Foster and colleagues of the timing of puberty in sheep[7] (Figure 34.3): for spring-born lambs, puberty onset occurs in the first autumn of life, but this may be delayed by food restriction earlier in life. If release from food restriction occurs soon enough to permit sufficient growth in the first growing season, lambs attain puberty in the first year with a slight delay, and a slightly reduced size, compared to control animals. If, however, feed restriction is extended, delaying growth within the first growing season so that a threshold body size is not achieved in the first autumn of life, puberty is delayed for a full year until the next seasonally permissive window for breeding.

The concept of nutrition × photoperiod interaction is underlined by reproductive behavior in microtine rodents (voles), wherein breeding is highly sensitive to the presence of new growing grasses in the diet.[8] This effect has been proposed to depend on the presence of plant metabolites that act as reproductive stimuli (e.g., Ref. 9), but the precise mechanisms of action of such molecules, and how they interact with the photoperiodic response mechanisms discussed later in this chapter, remains unclear.

Relationship between Photoperiodic Cues and Innate Long-term (Circannual) Timing

A remarkable feature of mammalian seasonal biology is that long-term transitions in seasonal state may proceed independently of changing environmental stimuli. In their most striking manifestation, this property is expressed as so-called "circannual rhythms" of reproduction or energy metabolism in animals held under artificially constant conditions for periods of years (Figure 34.4(A)). The term *circannual* derives from the Latin c., approximately, and *annus*, year, and refers to innate biological rhythmicity with a period length of approximately 1 year. This definition emphasizes the analogy with the more widely studied

"circadian" biology, which concerns innate rhythmicity with a period length of approximately 1 day. Circadian rhythmicity emerges from cellular oscillations in gene transcription and from the existence of pacemaker tissues capable of coordinating circadian rhythms in physiology throughout the organism.[12,13] Efforts to isolate analogous structures responsible for circannual rhythm generation have been less conclusive but suggest that sites within the hypothalamo-pituitary axis may be important.[14] The fundamental origins of circannual rhythm generation have been suggested to derive from cyclical histogenic mechanisms,[15] but the definitive evidence for this is still lacking.

The expression of circannual rhythms necessarily is confined to species whose life history normally encompasses survival through multiple breeding years. In short-lived rodent species, in which adult survival is unlikely to extend into a second winter of life, spontaneous long-term cycling between breeding and nonbreeding condition is not observed. Nonetheless, in these species, too, innate long-term timing mechanisms governing reproductive control are evident and appear to be important for the spontaneous reversion to a spring phenotype (typically including reproductive reactivation, since this group of animals is typically of short gestation length) following prolonged exposure to winter day lengths[11,16,17](Figure 34.4(B)). This phenomenon, which has widely been referred to as *photorefractoriness*, does not involve a loss of capacity to sense day length per se but rather a decoupling between proximal day length–sensing mechanisms and downstream seasonal biology.[18–20] More recent work also demonstrates that the timing and pattern of day-length increase shapes the response to declining day length in Djungarian hamsters (*Phodopus sungorus*).[21] Indeed it has been suggested that the mechanisms underlying photorefractoriness in short-lived species and circannual rhythm expression in long-lived species are probably very similar.[15]

In an ecological context, the spontaneous initiation of long-term changes in reproductive physiology exemplified in Figure 34.4 is generally believed to serve an adaptive function by anticipating forthcoming environmental change. Given that the growth of gonads and of secondary sexual characteristics essential for breeding success may take months to achieve, this interpretation seems justified. Moreover, periods of breeding activity or quiescence may traverse phases of the annual cycle (around the solstices) when rates of seasonal change do not provide a strong seasonal *zeitgeber* (synchronizing cue, from the German *zeit* = time and *geber* = giver), and hence favor internal long-term timers to drive predictive seasonal change. In hibernating species, winter survival may rely on behaviorally driven isolation from external seasonal time cues while sheltering in the hibernaculum, and this would further militate in favor of evolving internal long-term timing mechanisms. While this adaptive reasoning is entirely plausible, formal tests of the evolutionary fitness advantage of innate long-term timing have not been attempted.

Lastly, it should be noted that in equatorial species, it appears that innate long-term timing of seasonal breeding rhythms occurs independently of photoperiodic input, and is instead reliant on rainfall or conspecific social cues for its synchronization.[15]

Photoperiodic History Dependence and Maternal Photoperiodic Programming

Associated with the concept of circannual rhythmicity is the concept of photoperiodic history–dependence (i.e., that the response to exposure to a given day length depends on the prior sequence of day length experienced by the animal). A clear rationale for predicting that photoperiodic sensing will be history dependent is the response required to equinoctial day lengths experienced in the spring and autumn—the former being predictive of summer, the latter of winter. Evidence for history-dependent responses at the level of overt reproductive activation comes from studies in rodents and in ungulates. For example, in the Djungarian hamster, exposure to a 14-h day length will either stimulate reproductive activation or regression depending upon whether prior exposure was to 16-h or 10-h.[22]

The importance of history-dependent photoperiodic programming applies also to postnatal reproductive development in juvenile animals. Photoperiodic information is relayed transplacentally, giving a photoperiodic history reference to determine appropriate photoperiodic responses in the juvenile period[23,24](Figure 34.5). For rodent species in which growth and development proceed rapidly in the first growing season, allowing progeny to breed in the same year in which they are born, the ecological significance of maternal photoperiodic programming is clear: a program of accelerated reproductive development is appropriate for spring-born offspring, while for late summer/autumn-born progeny delaying breeding to the following spring is the only viable strategy.[24] Indeed, laboratory-based studies of photoperiodic programming mechanisms were initially stimulated by field data demonstrating a strong month of birth effect on rate of sexual maturation in montane voles (*Microtus montanus*).[8] The mechanisms behind this transplacental relay of photoperiodic information probably rely on the pineal hormone, melatonin, since pinealectomy or melatonin injections have pronounced effects on photoperiodic programming.[23] Maternal photoperiodic programming effects have also been observed in the sheep, with prolactin secretion in lambs being highly sensitive to photoperiodic experience in utero[7] (Figure 34.5(B)). These programming effects emphasize the profound importance of melatonin for seasonal photoperiodic synchronization in mammals, discussed in detail in the following section.

The mechanisms underlying photoperiodic history dependence may be similar to those involved in circannual rhythm expression, and as such may lie downstream of the proximal day length sensing pathway. Nonetheless

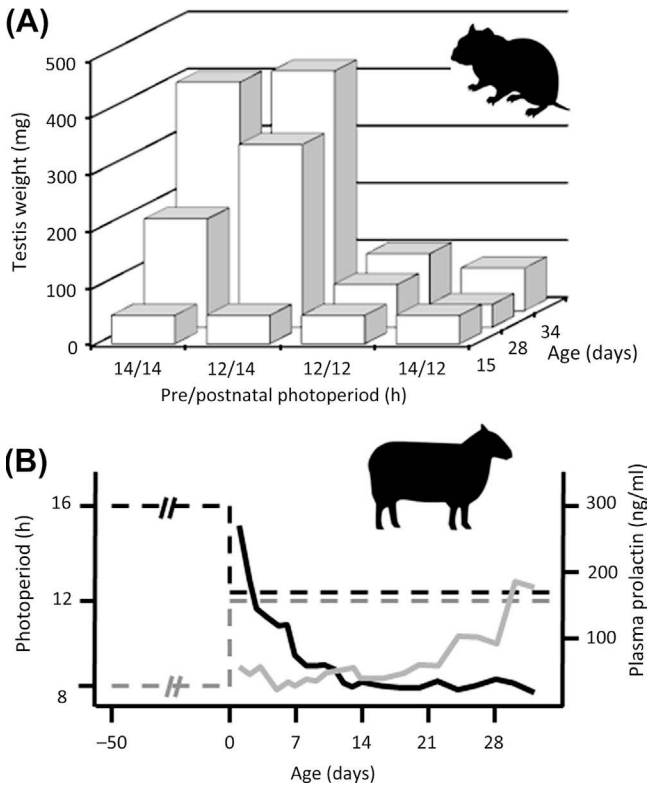

FIGURE 34.5 Maternal photoperiodic programming of reproductive development and endocrine function. (A) In Djungarian hamsters, maternal exposure to different combinations of 12-h and 14-h photoperiods during gestation and postnatally leads to widely different rates of gonadal growth (testis mass at 28 days). Additionally, exposure to a 14-h photoperiod during postnatal life promotes more rapid gonadal development, if the prenatal photoperiod was 12 h rather than 14 h. Hence maternal photoperiodic history programs photosensitivity in the neonate. *(Source: Graph drawn based on data in Ref. 25.)* (B) In Suffolk lambs, prolactin secretion shows a similar history dependence. Exposure to an equinoctial photoperiod for the first 28 days of postnatal life suppresses prolactin secretion in lambs born to mothers held on a 16-h photoperiod, but stimulates it in lambs born to mothers held on an 8-h photoperiod. *Source: Redrawn from Ref. 7.*

perinatal light exposure in rodents has been reported to alter day length responses in the suprachiasmatic nuclei (SCN) and in the pineal gland, both of which constitute important upstream elements in the photoperiodic response pathway, as we will discuss in detail following. Hence history-dependent programming of seasonal light responses probably acts at multiple levels.

ROLE OF THE PINEAL HORMONE MELATONIN IN MAMMALIAN SEASONAL BREEDING

At the end of the nineteenth century, Heubner presented the case of a boy with pineal tumor associated with precocious puberty,[4] suggesting a link between the pineal and reproduction. In 1917 McCord and Allen[26] described the skin-lightening effect of feeding tadpoles a pineal extract. This effect formed the bioassay for the eventual isolation of *N*-acetyl-5-methoxytryptamine some four decades later, and led to the name *melatonin* being coined for this indole amine.[5] Although effects of pineal extracts on reproduction in rats had been described prior to the isolation of melatonin (e.g., Ref. [27]), the pivotal role of melatonin in the regulation of reproductive activity became clear only when studies were performed in seasonally breeding rodents.[28–30] In the male Syrian hamster, pinealectomy or pineal denervation prevented short day–induced gonadal regression, and this effect was reversed by melatonin administration,[29,31,32] suggesting an "antigonadal" role for melatonin. Subsequent experiments in short day breeding ungulates further supported a link between the pineal gland and photoperiodic synchronization, but refuted the antigonadal concept.[33–35]

Although melatonin is synthesized in sites including the retina, Harderian gland, and gut,[36–39] levels of melatonin in the circulation[40] and in the cerebrospinal fluid (CSF)[41] are dependent entirely upon synthesis in the pineal gland. The mammalian pineal gland develops as an evagination of the diencephalic roof. In some species like sheep and humans, the gland forms a solid mass adjacent to the third ventricle, and part of the synthesized melatonin is therefore released into the CSF, giving nighttime CSF concentrations some two orders of magnitude higher than in the peripheral circulation.[41] By contrast, in rodents, the gland consists of a minor part closely related to the third ventricle, whereas the major part has migrated dorsally between the cerebral hemispheres and the cerebellum. As we shall see later, melatonin synthesis in the pineal is tightly temporally controlled, allowing melatonin to uniquely serve as a hormonal representation of time.

Control of Pineal Gland Activity

Pineal melatonin synthesis displays a marked daily rhythm that is restricted to the dark phase of the day.[42,43] The rhythmic synthesis of melatonin depends upon three interdependent factors: the endogenous circadian oscillator located in the SCN, the light/dark cycle that synchronizes the circadian oscillator, and the acute inhibition of melatonin synthesis by light.[44–47] The complex pathway controlling the pineal gland, termed the *retino-hypothalamo-pineal pathway*, ends with dense sympathetic innervation of the pineal parenchyma[48–50] (Figure 34.6). Photic information is conveyed to the SCN principally via the retino-hypothalamic tract, which relies on signals from conventional rod and cone photoreceptors as well as from a specialized subset of retinal ganglion cells, which are intrinsically light sensitive. These ganglion cells express the photopigment melanopsin, which is maximally sensitive to light in the blue region of the spectrum (@ 485 nm), and project to the SCN where they release

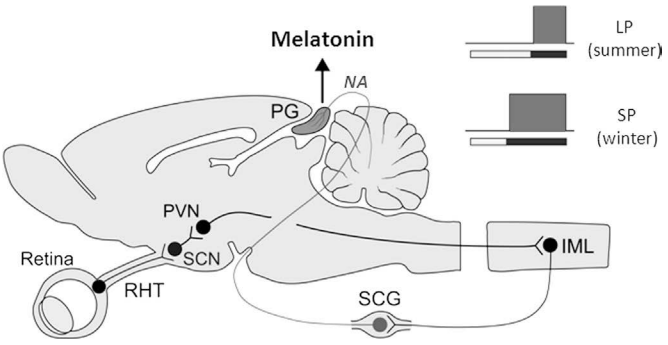

FIGURE 34.6 The photoneuroendocrine system drives the rhythmic release of melatonin. In mammals, light/dark information is perceived by photoreceptors and retinal ganglion cells that project, via the retinohypothalamic tract (RHT), to the suprachiasmatic nuclei of the hypothalamus (SCN), seat of the master circadian clock. In turn, the SCN controls the activity of the pineal gland (PG) via a polysynaptic pathway running via the paraventricular nucleus of the hypothalamus (PVN), the intermediolateral cells of the spinal cord (IML), and the superior cervical ganglia, whence noradrenergic neurons project massively to the pineal gland. The pathway is shown on a schematic parasagittal section of rodent brain. The activity of the SCN restricts noradrenaline (NA) release and, consequently, melatonin synthesis and secretion to the night time. The activity of the SCN is regulated by day length (photoperiod), and as a consequence the duration of the nocturnal melatonin message changes seasonally: during summer, long photoperiods (LP) are associated with short melatonin peaks, whereas during winter, short photoperiods (SP) are associated with longer melatonin peaks. *Source: modified from Ref. 51.*

the neurotransmitters glutamate and pituitary adenylate cyclase activating peptide (PACAP), which mediate light entrainment effects on the SCN circadian pacemaker.[52–54] The molecular clockwork generating and synchronizing the circadian activity within each SCN cell has been well established and relies on a combination of cell autonomous circadian oscillators based on transcriptional negative and positive feedback loops involving a set of clock genes (particularly *Clock*, *Bmal1*, *Per1-3*, *Cry1-2*, *Rev-erbα*, *Rorβ*), as well as extensive coupling between SCN neurons through VIP/PACAP signaling.[55–57] Importantly in the context of seasonality, daily rhythms of clock gene expression in the SCN (Figure 34.7) respond to annual changes in photoperiod,[58–62] with diurnally expressed genes showing extended periods of elevated expression in animals exposed to long photoperiod. This is associated with altered sensitivity to light input, as observed through light-induced c-fos expression, as well as modulation of rhythmic SCN outputs, including vasopressin synthesis[58,63] and electrical activity.[64] In turn, these effects are presumed to modify rhythmical behavior of SCN targets, which include the pineal gland. The hypothalamic paraventricular nuclei act as an essential relay between the SCN and pineal melatonin synthesis, exerting a sustained tonic stimulation of pineal activity during the night, which is inhibited during the day by the SCN-driven release of GABA.[65,66] Hypothalamic timing information is forwarded to the intermediolateral cells of the upper three segments of the spinal cord and the superior

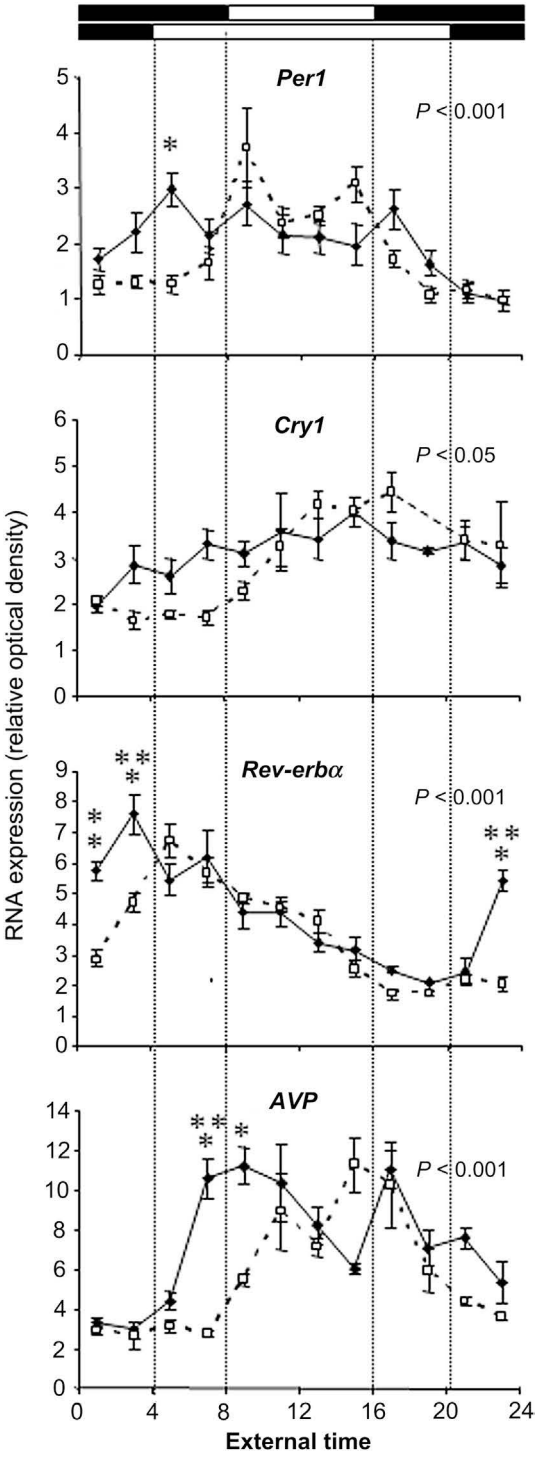

FIGURE 34.7 The SCN encodes photoperiodic variation in day length. Photoperiod modulates rhythmic expression of multiple genes in the Djungarian hamster SCN. The graphs show the 24-h expression profiles of clock and clock-controlled gene mRNA in the hamster SCN. Animals were housed under long photoperiod (filled diamonds, solid line) or short photoperiod (open squares, dotted line) for 8 weeks. Each value is mean ± SEM of four animals. Solid and open bars represent the dark and light periods, respectively. Clock genes: *Per1* = period 1, *Cry1* = cryptochrome 1, *Rev-erbα* = nuclear receptor subfamily 1, group D, member1; clock-controlled gene: *AVP* = argenine vasopressin. *P*-values represent interaction between Photoperiod and External Time (12.00 = mid light phase) for each gene. *Source: Modified from Ref. 58.*

cervical ganglia and finally reaches the pineal gland as a marked nocturnal release of norepinephrine (NE).[67–69] The pineal gland receives other fibers from various origins and containing various neurotransmitters, but NE is by far the most potent and critical neurotransmitter to generate the rhythms in melatonin synthesis.[70]

Melatonin Synthesis Pathway

The effect of NE on the pineal biochemistry has mainly been studied in the rat, but it should be kept in mind that species differences exist in the cellular pathways activated by NE at night. Activation of the pineal β1- and α1-adrenergic receptors induces a large increase in intracellular levels cAMP and Ca^{2+} and a downstream activation of cAMP dependant protein kinase A (PKA), a pivotal cellular event leading to melatonin synthesis at night.[70–73] The multistep enzymatic pathway through which NE controls melatonin synthesis is summarized in Figure 34.8. Melatonin synthesis is initiated from circulating tryptophan taken up from the blood stream and metabolized into 5 hydroxytryptamine (5HT) by the consecutive action of tryptophan hydroxylase and aromatic amino acid decarboxylase, whose activities display negligible daily and seasonal changes. By contrast, the subsequent enzyme, which converts 5HT into *N*-acetylserotonin, arylalkylamine-*N*-acetyltransferase (AANAT), exhibits a dramatic nighttime increase in activity in all species investigated.[43,68,70,74–78] The final step of melatonin synthesis is catalyzed by hydroxyindole-*O*-methyltransferase (HIOMT), the activity of which displays negligible daily variations.[42,79,80]

There was an interval of about 25 years between the discovery of the pivotal role of AANAT in driving the nocturnal increase in melatonin synthesis and the delineation of the molecular pathways underlying this activation.[81–83] Analysis of *Aanat* transcriptional regulation shows remarkable species differences. In rodent species, the *Aanat* gene is not expressed during the daytime; but at the beginning of the night, following NE release and PKA activation, there is a large increase in *Aanat* mRNA levels followed by a synthesis in AANAT protein, the latter being activated by phosphorylation and interaction with the 14-3-3 protein. Contrastingly, in ungulates, primates, and humans, the *Aanat* gene is constitutively expressed throughout day and night, but during the day the AANAT protein is immediately degraded by proteolysis, whereas at night phosphorylation of AANAT leads to its activation and stabilization by interaction with 14-3-3 protein[70,84–86] (Figure 34.9). The two major features of AANAT are its marked activation upon nighttime release of NE and its very short half-life (3–5 min), leading to a rapid decrease upon termination of NE stimulation at the end of the night or following light exposure at night.[47,90,91] As a consequence, AANAT behaves as an ON/OFF signal and should be viewed as the *melatonin rhythm generating enzyme* and the regulator of the nocturnal melatonin

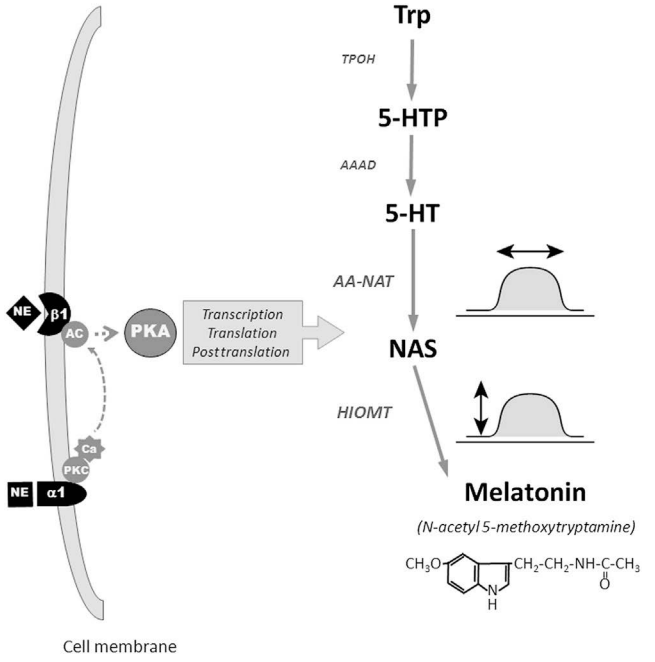

FIGURE 34.8 Biochemical pathway of melatonin synthesis. Melatonin is synthesized from tryptophan, which is metabolized into serotonin (5-HT) by tryptophan hydroxylase (TPOH) and aromatic amino acid decarboxylase (AAAD); serotonin is next acetylated into *N*-acetyl serotonin (NAS), then methylated into melatonin by the consecutive action of the pineal-specific arylalkylamine *N*-acetyl transferase (AA-NAT) and hydroxyindole-*O*-methyltransferase (HIOMT). Norepinephrine (NE) released at night binds to β1- and α1-adrenergic receptors leading to a strong activation of a cAMP-dependent protein kinase A (PKA). PKA acts through multiple biochemical pathways to promote melatonin synthesis. Notably, AANAT enzyme activity is strongly activated at night onset and inhibited at night offset, determining the duration of the nocturnal synthesis of melatonin. Contrastingly, HIOMT activity shows only a weak nocturnal induction but displays photoperiodic changes in activity with higher values in short photoperiod. This may modulate the amplitude of nocturnal melatonin synthesis.

peak duration.[92,93] Although the activity of HIOMT does not show daily variations,[42,79,80] there is a clear photoperiodic/seasonal variation in the enzyme activity being higher in short as compared to long photoperiod.[89,94] This long-term regulation of HIOMT activity may result from extended *Hiomt* (also known as *Asmt*) transcription during long nights combined with high protein stability. Strikingly, in seasonal species like the Djungarian hamster, higher HIOMT activity in short photoperiod is clearly associated with heightened nighttime production of melatonin, leading to the proposal that, during the night, HIOMT is the *melatonin rate limiting enzyme*.[89] Hence, the combination the two melatonin synthesizing enzymes with differing biochemical characteristics, the reactive but unstable AANAT together with the stable HIOMT, shapes the daily and seasonal rhythm in melatonin synthesis (Figure 34.8).

Melatonin is not stored in the pineal cells but directly released by diffusion. In all species investigated, the pineal gland is a highly vascularized organ[95] and has

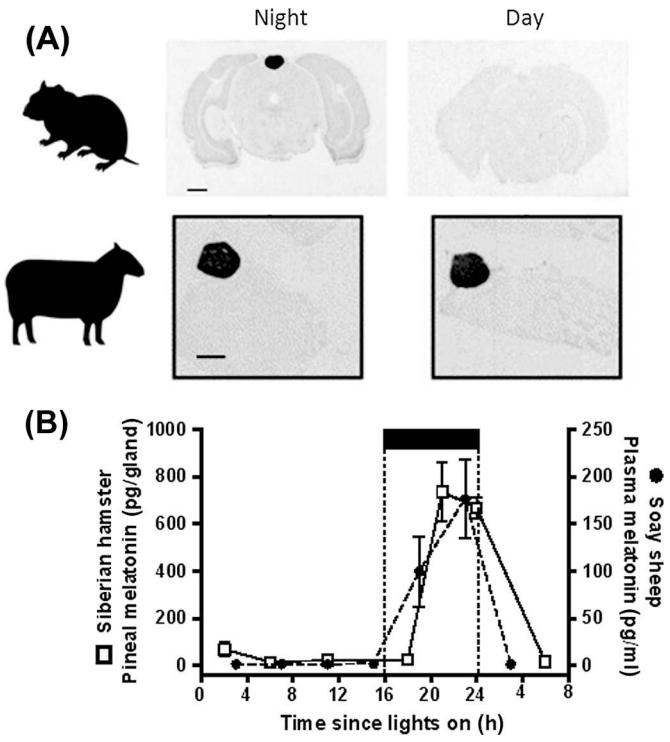

FIGURE 34.9 Regulation of pineal AANAT gene expression in rodents and ungulates. (A) Radioactive in situ hybridizations showing that *Aanat* mRNA levels are markedly increased at night in the rat pineal gland (top panel), *(Source: Adapted from Ref. 87.)* whereas they are constitutively elevated in the sheep pineal gland (bottom panel) *(Source: Adapted from Ref. 88.)*; scale bars are 1 mm and 5 mm, respectively. (B) The differential regulation in *Aanat* gene expression results in an earlier onset of melatonin synthesis and secretion at night onset in ungulates *(Source: Data here from the Soay sheep from Ref. 19.)*, where AANAT activity is regulated posttranslationally, as compared to rodents. *(Source: Data here in the Djungarian hamster, adapted from Ref. 89.)*

a blood flow estimated to be 4 ml/min/g.[96] Circulating melatonin is rapidly degraded by hepatic hydroxylation into 6 hydroxymelatonin and then excreted in the urine mainly as 6 sulfatoxymelatonin, with a half-life of approximately 20 min.[97,98] Any modification in the synthesis pathway is thus immediately translated into similar modification in circulating melatonin. Because the duration of the nocturnal synthesis of melatonin is positively related to the length of the night, the changes in circulating melatonin constitute a strong endocrine representation of the time of the day and time of the year. Notably, the daily profile of circulating melatonin may differ greatly among species, and even among individuals of the same species. For example, in the rat, the plasma melatonin concentration increases from about 10 pg/ml at daytime up to 50–500 pg/ml at nighttime,[70,99–101] whereas in the sheep, the nighttime peak ranges from 100 to 1000 pg/ml.[102] Notably, however, under stable photoperiodic conditions the melatonin pattern is highly reproducible in the same individual.[103,104]

Timed Infusion Experiments Defining Melatonin's Mode of Action

Based on the elucidation of the pattern of synthesis and secretion of melatonin by the pineal gland, several groups undertook experiments aimed at defining how photoperiodic information was encoded in the melatonin signal. The key approach has been to combine pinealectomy (PX) to ablate the endogenous circulating melatonin signal with timed subcutaneous infusion of melatonin to mimic melatonin secretion under different photoperiodic conditions. This has been dubbed the "timed-infusion paradigm."[105] Three basic hypotheses for information coding in the melatonin signal have been considered: (1) that the total amount of melatonin secretion dictated the response (amplitude hypothesis); (2) that the continuous duration of melatonin secretion dictated the response (durational hypothesis), and (3) that the phase relationship between periods of melatonin secretion and an internal circadian clock dictated the response (melatonin sensitivity rhythm hypothesis). Of these, the overwhelming evidence points toward the duration of the interval between the evening onset and dawn offset of melatonin secretion as the key variable through which photoperiod is encoded (Figure 34.10). Maintained presence of melatonin between these two transitions, and absence of melatonin during daylight hours, appear also to be key features.[105–110] There is no absolute requirement for the period of elevated melatonin infusion to synchronize with nighttime in PX hamsters, indicating no requirement for melatonin readout by melatonin-independent aspects of circadian organization.[111] Nonetheless two studies have reported that short breaks in melatonin secretion during the night may not interfere with melatonin signal interpretation.[112,113] While these studies do not refute the basic requirement for maintained presence of melatonin for longer intervals between dusk and dawn, they do hint at a possible melatonin-based oscillator in the readout mechanism; this idea is echoed in subsequent molecular studies on this issue,[62,114] which are discussed below.

As well as defining the signal characteristics of pineal melatonin secretion necessary for photoperiodic synchronization, the timed infusion paradigm has been important for delineating the relationship between this synchronization process and innate long-term/circannual timing. In the sheep, long-term seasonal breeding cycles can be effectively synchronized by melatonin input delivered for only 25% of the year, so that the circannual breeding rhythm effectively free runs for 9 months of the year[10] (Figure 34.4). This approach also highlights the idea that specific phases of the year may be particularly important for photoperiodic

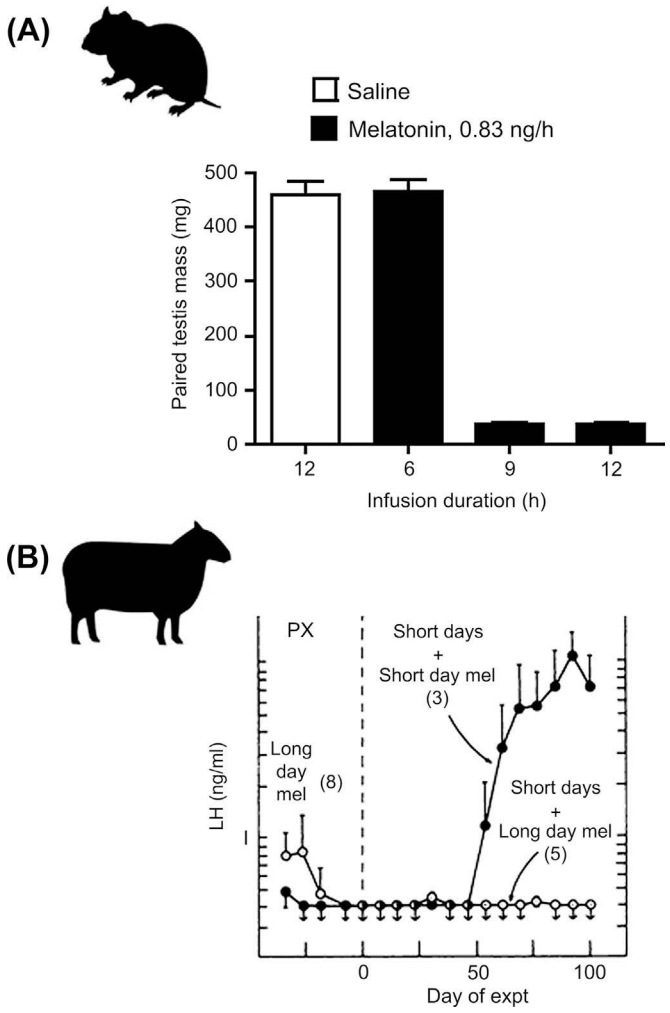

FIGURE 34.10 Timed melatonin infusion experiments demonstrate the importance of melatonin signal duration for photoperiodic responses. (A) Mean paired testis mass measured in long day housed PX male Djungarian hamsters receiving different daily durations of melatonin infusion. *(Source: Adapted from Ref. 106.)* (B) Mean serum LH concentrations in PX and ovariectomized + estradiol-treated ewes treated daily with a short or long melatonin infusion. Prior to day 0, all PX ewes received a long day melatonin infusion; beginning day 0, all ewes were transferred to short days and five ewes continued to receive the long day melatonin pattern (O) while three were switched to a short day melatonin infusion (●). *(Source: Adapted from Ref. 107.)* Note that whereas short day (long duration) melatonin infusions cause gonadal regression in hamsters, they promote reproductive activation in sheep.

synchronization: maintained circannual synchrony is strongest for sheep receiving a melatonin infusion mimicking the increasing day length between the spring equinox and the summer solstice, and weakest for sheep receiving a signal mimicking the declining day length between the autumn equinox and the winter solstice. The concept of photoperiodic/melatonin entrainment of underlying circannual rhythmicity also appears to apply in the European hamster (*Cricetus cricetus*), a long-lived rodent species.[115]

MELATONIN RECEPTORS AND SITES OF ACTION

Consistent with the standard model for pubertal reproductive activation through changes in central sensitivity to gonadal negative feedback signals, as described in Chapter 31, steroid clamping experiments in seasonal sheep demonstrated photoperiodic shifts in the sensitivity of the GnRH pulse generator to gonadal steroids.[116] Gonadal steroid negative feedback effects are strongest with the transition to anestrus and weakest with the onset of the new breeding season. This led to the general inference that seasonal photoperiodic effects of melatonin must be mediated through central, most likely hypothalamic, sites of melatonin action. Early direct evidence for this mode of action came from studies using melatonin-impregnated pellets placed in the hypothalamus of white-footed mice (*Peromyscus leucopus*), resulting in reproductive suppression.[117] The current model outlined below is broadly consistent with a central mode of melatonin action and highlights the role of melatonin sensitive cells not in the hypothalamus, but in the immediately adjacent pituitary stalk, in the cells of the PT.

Binding Studies and Melatonin Receptor Autoradiography

Progress on understanding the sites of melatonin action benefited enormously from the synthesis of an iodinated analog of melatonin, 2-iodomelatonin, which retains biological activity mimicking that of melatonin itself.[118,119] This opened the way for analysis of tissue distribution of melatonin binding sites, their functional characterization, and, ultimately through expression cloning approaches, their molecular characterization.

Using high specific activity radio-iodinated 2-[^{125}I]-iodomelatonin (IMEL) for in vitro autoradiography, it became clear that high affinity melatonin bindings sites were present in the hypothalamus and PT of mammals.[120–123] Considerable species variability in the distribution of brain IMEL binding sites has emerged, with hypothalamic sites including the SCN, dorso- and ventro-medial hypothalamic nuclei, mediobasal hypothalamus, and premamillary arcuate nucleus (ARC) having been recorded in many instances, along with a variety of sites elsewhere in the central nervous system.[121,124,125] Additionally, high levels of melatonin binding sites have been consistently observed in the PT of the pituitary stalk but not in the other portions of the anterior pituitary (i.e., the pars distalis, PD)—a finding seen in all mammals studied to date[122,126–133] with the possible exception of humans[134] (Figure 34.11). In these studies, levels of IMEL binding in the PT consistently exceed those seen in any neighboring brain area.

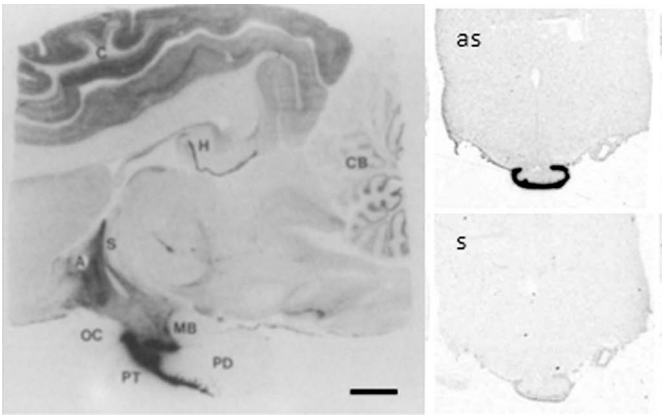

FIGURE 34.11 The pars tuberalis (PT) expresses a high density of melatonin receptors. Staining for melatonin receptor distribution in the sheep brain and pituitary gland. Left panel: autoradiography for high affinity melatonin binding sites in a parasagittal section, using the radioanalog of melatonin 2-[^{125}I]-iodomelatonin (IMEL). Note the intense labeling in the pituitary pars tuberalis (PT), and lower levels of labeling in the hypothalamus (between the optic chiasm (OC) and the mammillary body (MB)), the cortex (C), and the cerebellum (CB). *(Source: Modified from Ref. 135.)* Right panel: In situ hybridization for type 1 melatonin receptor (*Mtnr1a*) RNA expression in coronal sections through the sheep hypothalamus. Note the intense labeling with the antisense (as) probe in the PT region. Scale bar = 5 mm. *Source: Images from Dr Hugues Dardente.*

Pharmacological characterization of the IMEL binding sites in the PT as well as in the hypothalamus indicated that they represented high affinity (Kd in the picomolar range) G protein–coupled receptors (GPCRs).[124] Further characterization of these receptors, principally using cells harvested from ovine PT tissue, revealed distinct pharmacological subtypes and coupling to various signal transduction pathways. Of these, acute inhibitory and chronic sensitizing effects of melatonin on adenylyl cyclase/cAMP signaling have been most extensively characterized,[136–139] while effects on intracellular calcium levels,[136,140] on arachidonic acid,[141] and on phosphoinositide[142] signaling have also been described. Downstream effects on cAMP-dependent protein kinase, and MAPK, as well as on phosphorylation-dependent transcription factors have also been described.[143–145]

Cloning of the G Protein-Coupled Melatonin Receptor Family

The development of IMEL also opened the way for cloning of the melatonin receptor using an expression cloning approach and RNA from *Xenopus laevis* dermal melanophores,[146] and this led to the cloning of mammalian and avian orthologs based on sequence homology.[147,148] Three melatonin receptor subtypes have been characterized and designated (see http://www.iuphar-db.org/) MT1 (previously Mel1a), MT2 (previously Mel1b), and Mel1c. Of these, MT1 and MT2 are present in all vertebrate groups, while Mel1c is found only in nonmammalian vertebrates.[149] Contrastingly, peculiar to mammals is the orphan melatonin-related receptor (GPR50), which does not bind melatonin in in vitro expression assays and remains a puzzle from a functional perspective.[150] Cloning of the genes encoding MT1 and MT2 (designated *Mtnr1a* and *Mtnr1b*, respectively, see http://www.genenames.org/) allowed a further characterization of melatonin receptor localization in the mammalian brain and showed that the previously observed high level of IMEL binding in the PT was attributable to *Mtnr1a* expression (Figure 34.11).

Evidence that G Protein-Coupled Melatonin Receptors Mediate Seasonal Neuroendocrine Synchronization

Several lines point toward the seasonal neuroendocrine actions of melatonin being mediated by GPCRs. Firstly, the affinity and functional sensitivity of MT1 and MT2 receptors are both in the picomolar range and correspond well to the observed day–night variation in plasma or CSF melatonin levels (plasma nighttime maximum @ 100–300 pM; CSF nighttime maximum @ 1 nM in sheep). This contrasts with the various proposed non-GPCR routes of melatonin action that appear reliant on concentrations of melatonin well in excess of the nighttime peak driven by pineal melatonin secretion. These GPCR-independent routes of melatonin action include antioxidant actions,[151] low affinity interactions with a quinone reductase,[152] and the controversial assignment of RORβ as a nuclear melatonin receptor.[153,154]

Secondly data from mice in which the effects of melatonin receptor knockout have been explored also favor a GPCR-mediated route of melatonin action. Laboratory mice do not show overt seasonal photoperiodism, probably because of many generations of inbreeding in animal facilities run on a constant (often 12-h) photoperiod. Nevertheless, they do express melatonin receptors in the hypothalamus and pituitary[155,156] and have proved useful models for understanding initial mechanistic steps in photoperiod sensing. In particular, photoperiod/melatonin effects on pituitary and hypothalamic gene expression seen in seasonal mammals are also seen in mice and appear to depend on presence of the MT1 receptor.[157,158] Knockout of *Mtnr1a* abolishes these transcriptional effects and all IMEL binding in the mouse PT, a result that not only emphasizes the importance of GPCRs for melatonin signaling but also of the MT1 receptor in particular. Intriguingly, in the Djungarian hamster, which shows strong seasonal photoperiodic control of breeding, the MT2 receptor appears not to be expressed, due to in-frame STOP codons in the *Mtnr1b* gene predicted to grossly truncate the translated receptor protein.[159] This

species nonetheless shows high levels of IMEL binding in the PT and appears to use the same downstream pathways to control seasonal phenotype as seen in other mammals. Hence data from both laboratory and natural melatonin receptor knockouts favor the interpretation that the key receptor for seasonal neuroendocrine control is MT1. With the exception of the retina, where both MT1 and MT2 are highly expressed, typically MT1 appears to be the dominantly expressed form based on in situ hybridization or RT-PCR analysis, with MT2 present at significantly lower levels.[160,161] It remains to be seen whether these two receptor isoforms play distinctive functional roles in mammals.

A Link between the Melatonin-Related Receptor/GPR50 and Energy Homeostasis

Recently it was shown by synteny mapping that GPR50 is the mammalian ortholog of MEL1c.[162] Rapid evolutionary divergence from the ancestral MEL1c appears to have occurred with the branching of the mammalian lineage, and in the duck-billed platypus a MEL1c-like MEL1c/GPR50 is found. The underlying causes for this divergence are unclear, but are most simply interpreted as a consequence of a major chromosomal rearrangement, resulting from GPR50 residing near the end of the long arm of the X chromosome in eutherian mammals. X-chromosomal genes are typically associated with sequence instability, and the syntenic neighbors of GPR50 show a similar rapid evolution.[162] Despite this, GPR50 shows highly localized expression in the mammalian brain, consistent with maintained function, and evolutionary sequence analysis suggests that GPR50 has been subject to directional selection in mammals, rather than just neutral drift on an evolutionary pathway to a loss of function.[162]

These reflections get us little closer to establishing a function for GPR50 in mammals or to identifying possible ligands through which it may exert a signaling function. One school of thought, propounded by Jöckers and colleagues,[163] is that GPR50 acts as a dimerization partner for mammalian melatonin receptors, thereby modulating melatonin signal transduction in a ligand-independent manner. A difficulty with this hypothesis is the rather limited anatomical overlap between melatonin receptor and GPR50 expression, the former being concentrated in the PT, the latter showing strongest expression in brain sites in which melatonin receptor expression is weak or absent.[164,165]

In the hypothalamus, GPR50 is expressed in sites that have been linked to energy homeostasis (e.g., dorsomedial hypothalamus and paraventricular hypothalamus),[164] which raises the possibility that this receptor may mediate the well-known seasonal changes in food intake and metabolism.[166] In rodents, GPR50 is also expressed in the ependymal cell layer lining the wall of the third ventricle. In Djungarian hamsters, exposure to short photoperiods leads to a loss of body fat, reproductive switch off, and suppressed GPR50 expression in the mediobasal hypothalamus.[167] Knockout of GPR50 in mice produces a lean phenotype, and entry into torpor in response to food restriction.[168,169] These findings appear to link GPR50 to metabolic regulation, and this is likely to remain the focus in the search for ligands for this orphan receptor.

IDENTIFYING FUNCTIONALLY IMPORTANT SITES OF MELATONIN ACTION

The identification of hypothalamic and pituitary sites of high affinity IMEL binding has informed attempts to identify key sites of melatonin action through site-specific lesioning, microinjection, or microimplant studies.

Pars Tuberalis as a Site of Melatonin Action for Seasonal Control of Prolactin Secretion

The first direct evidence linking the PT to seasonal neuroendocrine control came from studies using the hypothalamo-pituitary disconnection (HPD) technique in sheep, pioneered by Iain Clarke and colleagues.[170] This involves surgically ablating neurosecretory terminals in the median eminence of the hypothalamus, effectively blocking the descending flow of information from hypothalamic hypophysiotropic hormone secreting cells into the anterior pituitary, while leaving the pituitary (including the PT) intact. This produces animals in which normal anterior pituitary hormone regulation is drastically curtailed, with control of the thyroid, somatotropic, gonadal, and glucocorticoid axes largely absent. Remarkably, Lincoln and Clarke[171] demonstrated that seasonal photoperiodic regulation of prolactin secretion persists in HPD rams in a form indistinguishable from that seen in intact animals (Figure 34.12). Importantly, in line with the concept that acute regulation of prolactin does depend on descending hypothalamic signals (for example, TRH or dopamine), the HPD lesion completely abolishes the prolactin response to stress (namely a barking dog). Hence photoperiodically synchronized long-term regulation of prolactin, but not acute, stress-dependent regulation of prolactin persists in HPD rams.

There is no evidence that melatonin receptors are present in anterior pituitary prolactin-secreting cells (lactotrophs), suggesting that another cell type within the isolated anterior pituitary unit relays the photoperiodic information to the lactotrophs. Since melatonin receptor expression is limited to the PT region of the anterior pituitary, the most logical inference is that it is these PT

cells that relay the effects of photoperiod in the HPD ram model. This led to the hypothesis that the PT secretes a molecule, termed by some *tuberalin*,[173,174] that acts in a paracrine manner to control the activity of PD lactotrophs. In vitro coculture experiments with sheep, hamster, or bovine cell/tissue culture preparations provide some evidence for the existence of a PT-derived prolactin releasing factor[175–178] and also for changes in the level of the production of this factor as a function of seasonal state.[177,178] More recently it has been suggested that this factor may be a Substance P/Tachykinin gene product based on transcriptomic and immunohistochemical analysis of the PT, as well as the in vitro Prl releasing activity of this family of peptide signals.[179,180] Additionally one report suggests a link between PT synthesis of endocannabinoids and PD function in rodents.[181]

The concept that the PT acts as a major relay in the pathway linking photoperiod to seasonal physiology was given considerable impetus by experiments demonstrating melatonin-dependent photoperiodic encoding of clock gene expression in PT of rodents and ungulates.[59–62,182–184] Initial reports described an effect of photoperiod on the amplitude of *Per1* gene expression in hamsters, which could be overridden by pinealectomy or melatonin injection. Subsequently, it emerged that melatonin exerted dual evening and morning effects on rhythmical gene expression, the former being exemplified by induction of *Cry1* by melatonin,[62,183,185] while the latter is characterized by *per1* induction due to melatonin withdrawal. Because PER and CRY proteins form transcriptionally repressive complexes,[186] it was proposed that these effects on PT clock gene expression rhythms might constitute a "coincidence timing" mechanism whereby the photoperiodically variable interval (the coincidence) between the onset and offset of the melatonin signal, and hence the presence of PER/CRY protein, allowed decoding of the photoperiodic message as a change in PT transcription.[62] Experiments in sheep using acute day length extension demonstrated that acute melatonin-dependent effects on the CRY-PER coincidence preceded changes in prolactin secretion but left open the downstream mechanisms through which such effects could be coupled.[183]

The principal secretory cells in the PT have been referred to as "PT-specific cells",[173,187] and are characterized by a much lower density of secretory granules than is seen in the classical granular endocrine cells of the anterior pituitary. They nonetheless show cytology consistent with active secretory function.[188] These cells are of particular interest since they appear to be the major melatonin-responsive cell type in the ovine PT.[136] Whether these cells are the origin of a prolactin releasing factor has yet to be demonstrated, but there is increasing evidence that PT-specific cells represent a thyrotropic cell lineage, distinctive from that seen in the PD. In rodents and in ungulates, RNA expression for both the α and β subunits of thyrotropin (αGSU & TSHβ, respectively) are present in PT-specific cells, and undergo photoperiod-dependent changes in expression (Figure 34.13). [158,189–194] Immunoreactivity for the protein products of these genes has also been observed, but generally with a much weaker signal than is seen in PD endocrine thryotrophs, possibly due to the lack of granular storage in PT-specific cells. While there is no evidence linking the thyrotropic aspect of PT-specific cells to prolactin secretion, PT TSH production is now strongly implicated in seasonal reproductive control. Moreover, recent work provides a mechanism linking the effects of melatonin on clock gene expression in the PT to photoperiodic changes in TSH expression.[114,194] These developments are further discussed later in this chapter.

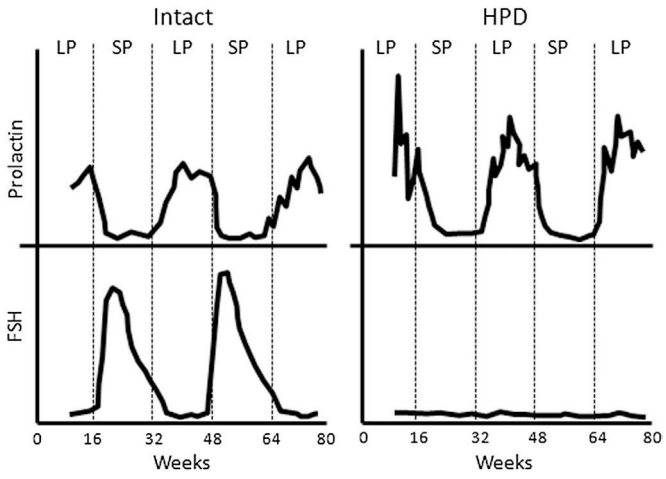

FIGURE 34.12 Persistent photoperiodic control of prolactin secretion in hypothalamo-pituitary disconnected (HPD) Soay rams. Intact and HPD rams were held on alternating photoperiod cycles of 16 weeks 16 h light/day (LP) and 8 h light/day (SP). In intact animals transfer to SP suppresses prolactin secretion and activates FSH secretion. Remarkably, while HPD abolishes control of FSH, the seasonal photoperiodic control of prolactin remains very similar to that seen in intact animals. See text for details. *Source: Based on data in Ref. 172.*

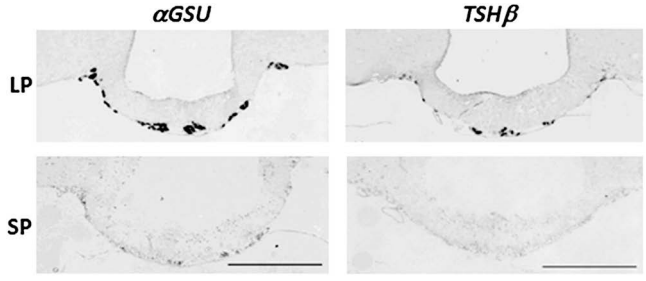

FIGURE 34.13 Photoperiodic variation in α-glycoprotein–subunit (*αGSU*) and thyroid stimulating hormone β–subunit (*TSHβ*) gene expression in the pars tuberalis of the European hamster. Under long photoperiod (LP), high levels of expression of *αGSU* and *TSHβ* mRNA are observed. Under short photoperiod (SP), expression of both genes is dramatically reduced. Scale bar = 200 μm *Source: Adapted from Ref. 189.*

Hypothalamic Lesions and Implants and a "Two Site" Model for Seasonal Reproductive Control

The HPD result linking the PT to prolactin secretion led to what has been described as a "two site" model for seasonal neuroendocrine actions of melatonin.[195] According to this model, while prolactin regulation is PT dependent, the control of seasonal gonadotropin secretion involves an additional site of melatonin action located not in the PT but in the mediobasal hypothalamus. This conclusion is underpinned by a combination of site-specific lesioning and microimplantation studies performed in seasonal hamster species and in sheep. In Syrian hamsters, lesions in the mediobasal hypothalamus region corresponding to IMEL binding sites abolished melatonin-dependent testicular regression.[196,197] In Djungarian hamsters, melatonin infusion in the region of the SCN or SCN lesion altered the testicular response to photoperiod.[198,199] In sheep, melatonin implants placed in the ventromedial hypothalamus or premammillary arcuate regions, but not in PT, effectively abolished photoperiodic synchronization of seasonal breeding, apparently consistent with the presence of IMEL binding sites in these regions.[200–203] These findings have led to the hypothesis that melatonin may act at several, species-dependent hypothalamic sites to exert its effect on the reproductive axis.

The interpretation of microimplant and lesioning experiments outlined herein is hampered by difficulties in excluding actions through the neighboring PT. In the case of melatonin microimplants, Malpaux and colleagues presented evidence based on IMEL implants that drug delivery did not reach the neighboring PT,[204] but given the picomolar affinity of melatonin receptors it is difficult to exclude this possibility beyond doubt. In the case of lesioning experiments, the scenario that lesions simply remove a paracrine target of the PT from the regulatory circuit is difficult to exclude without more concrete data on the pathways involved.

THE PT AND THYROID HORMONE-DEPENDENT CONTROL OF SEASONAL BREEDING

The role of the thyroid gland in the control of seasonal breeding cycles has been suspected since the demonstration that thyroidectomy results in persistent breeding in starlings.[205] Follett and colleagues subsequently observed similar effects in sheep with the spring transition to anestrus, but not the autumn onset of the breeding season, blocked by thyroidectomy.[16] Subsequently, Karsch and colleagues thoroughly characterized the requirement for thyroid hormone in the sheep and demonstrated that the effect of thyroidectomy could be reversed by treatment with thyroxine (T4) in a sensitive window from spring until the mid-summer[206–211] (Figure 34.14). A similar, albeit less detailed, picture has also emerged from studies in seasonal rodent species. In Djungarian hamsters, chemically induced hypothyroidism, achieved by addition of thiourea to the drinking water, advanced the reactivation of the gonadal axis following extended exposure to short photoperiod.[212] Conversely, triiodothyronine (T3) administration blocks seasonal reproductive inhibition and onset of winter physiology in response to short photoperiod in Djungarian (Figure 34.15(B)), and Siberian hamsters.[214–216]

In both rodents and sheep, it has become clear that these effects of thyroid hormone on seasonal breeding rhythms are mediated through sites in the hypothalamus. In the sheep, effects of thyroid hormone microimplants are most effective in the premammillary hypothalamus (PMH), while a lower proportion of implants placed in the ventromedial preoptic area (vmPOA) also were able to induce seasonal anestrus[213,217] (Figure 34.15(A)). In hamsters, mediobasal hypothalamic implants of T3 prevent seasonal anestrus in response to short day exposure[214] (Figure 34.15(B)).

Hypothalamic Deiodinase Mediation of Seasonal Reproductive Role of Thyroid Hormone

A framework for the conceptual synthesis of these findings has emerged with the demonstration that changes in hypothalamic metabolism of thyroid hormone are a primary response to photoperiodic cues in seasonal mammals and birds. The key insight came from a transcriptomic analysis in Japanese quail (*Coturnix japonica*) in a study designed to identify initial hypothalamic changes in gene expression preceding reproductive activation in response to long day exposure.[218] This revealed a rapid induction of type 2 thyroid hormone deiodinase (DIO2) in the first few hours following day length extension. DIO2 is an outer ring thyroid hormone deiodinase, which converts T4 to the more biologically active form T3[219] (Figure 34.16(A)). In the quail, photoperiodic induction of *Dio2* gene expression is associated with a concomitant rise in hypothalamic T3 content, and pharmacological blockade of hypothalamic DIO2 activity by central administration of iopanoic acid prevented photoperiodic activation of the gonadal axis.[218]

Subsequent studies demonstrated that the inductive effect of exposure to long photoperiod on *Dio2* expression also occurred in seasonal rodents[221–226] and in sheep[193] (Figure 34.16(B)). Increased *Dio2* expression was also observed in the median eminence, and in the arcuate or ependymal layer, in goats exposed to artificial long photoperiod.[227] In mammals, this

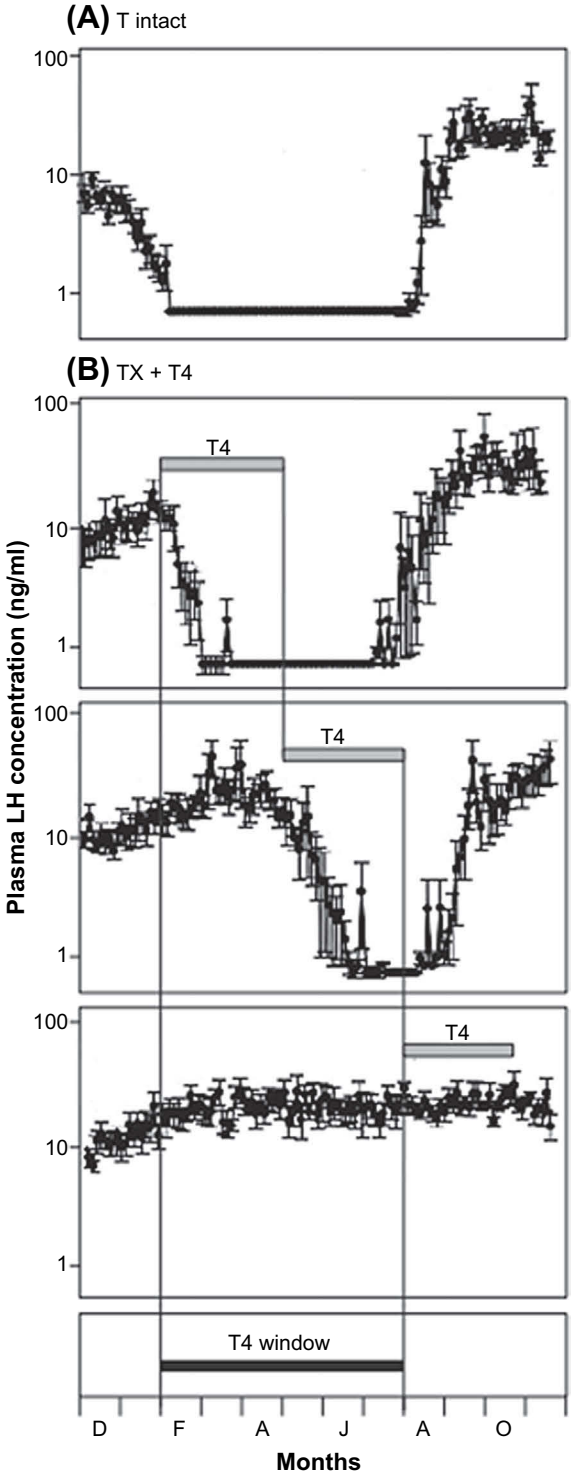

FIGURE 34.14 **The role of thyroid hormone in seasonal breeding cycles in the sheep.** (A) The normal seasonal profile of luteinizing hormone (LH) secretion in estradiol-treated ovariectomized ewes comprises a phase of elevated expression commencing in the autumn and continuing until early the following spring, when a pronounced decline occurs concurrent with the nonbreeding season (N.B. data are plotted on a log scale, and levels during the summer months are below the sensitivity limit of the assay). (B) In thyroidectomized (TX) ewes, thyroxine (T4) replacement permits the seasonal shut down of reproductive function, provided T4 is given in the spring–mid-summer months. Delaying T4 replacement until the late summer–autumn months results in seasonal anoestrous being abolished. Hence a sensitive spring–summer window for T4 actions is defined. *Source: Adapted from Ref. 211.*

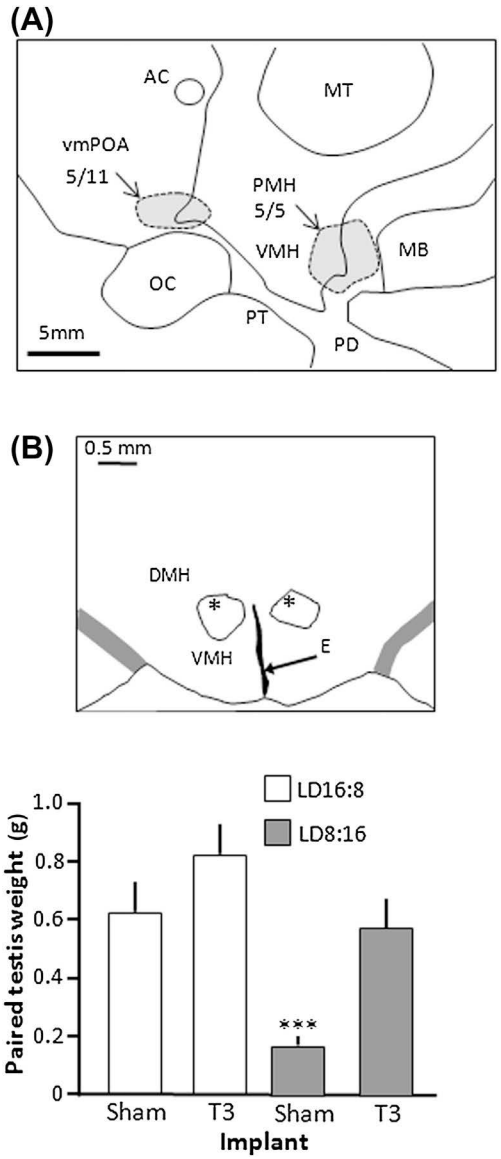

FIGURE 34.15 **Anatomical localization of the seasonal reproductive effects of TH.** (A) In the sheep, T4 microimplants placed in the basal hypothalamus of THX ewes are sufficient to bring about seasonal breeding suppression during the spring. The diagram shows hypothalamic locations in which implants were maximally effective. Abbreviations: AC anterior commissure, MB mammillary body, MT medial thalamus, OC optic chiasm, PD pars distalis, PMH premammillary hypothalamus, PT pars tuberalis, VMH ventromedial hypothalamus, vmPOA ventromedial preoptic area. *(Source: Redrawn from Ref. 213.)* (B) In the Djungarian hamster, T_3-releasing microimplants placed in the mediobasal hypothalamus override the inhibitory effects of short photoperiod on testis size. Asterisks in the upper panel show the approximate location of bilaterally placed microimplants. ***Significantly reduced testis weight compared to LD16:8 sham implant controls ($P<0.001$). *Source: Redrawn from Ref. 214.*

photoperiodic control of *Dio2* appears to be melatonin dependent.[222,223] Furthermore it has become clear that additional genes linked to thyroid hormone metabolism are also photoperiodically regulated. In particular, opposite to *Dio2*, hypothalamic expression of type 3 deiodinase (*Dio3*) appears to be induced by exposure to declining photoperiod[214,220,224,228] (Figure 34.16(B)).

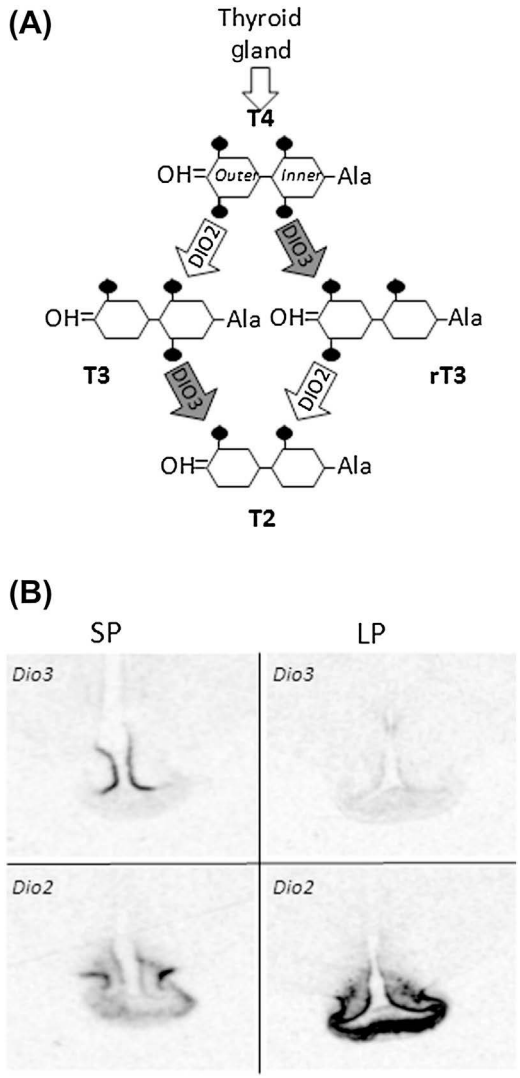

FIGURE 34.16 Thyroid hormone deiodination in the hypothalamus of a seasonal breeder. (A) Enzymatic pathways leading to the conversion of thyroxine (T4) produced by the thyroid gland into either triiodothyronine (T3) by outer ring deiodination catalyzed by type 2 deiodinase (DIO2), or reverse T3 (rT3) by inner ring deiondination catalyzed by type 3 deiodinase (DIO3). The former, activating process leads to increased thyroid hormone actions through nuclear thyroid hormone receptors; the latter is an inactivating process. Further metabolism of T3 or rT3 is possible, leading to diiodothyronine (T2) production, which has no known signaling activity. (B) Reciprocal switching between states of high *Dio2*/low *Dio3* expression and vice versa, through photoperiodic control. Images are autoradiograms of radioactive in situ hybridization histochemistry for *Dio2* or *Dio3* in coronal hypothalamic sections from sheep that were held on either 8 h light/24 h (SP) or 16 h light/24 h (LP) for 4–8 weeks prior to sacrifice. Note strong labeling in the mediobasal hypothalamic area under LP for *Dio2*, but under SP for *Dio3*; note also that *Dio2* labeling extends into surrounding hypothalamic tissue, while *Dio3* labeling is confined to the ependymal zone immediately surrounding the third ventricle. *Source: Adapted from Ref. 220.*

DIO3 is an inner ring deiodinase, converting T4 to reverse T3 (rT3), which appears to be biologically inactive. Recently, monocarboxylate transporter 8 (*Mct8*) gene expression in the Djungarian hamster mediobasal hypothalamus has also been shown to be increased in short photoperiod, similar to *Dio3*[229]; *Mct8* appears to be involved in controlling thyroid hormone uptake into the central nervous system,[230] implying a global photoperiodic regulation of pathways linked to hypothalamic thyroid status.

Although there appear to be differences in the details (for example, in Djungarian hamsters *Dio3* but not *Dio2* is sensitive to short day exposure[214] whereas both genes are photoperiod sensitive in the European hamster, Soay sheep, and the common vole (*Microtus arvalis*)[220,224,225]), the general picture is that long day exposure promotes a euthyroid state in the hypothalamus (increased T4 uptake and conversion to T3), while short day exposure has the opposite effect, promoting local hypothyroidism. Importantly, this general picture is independent of whether species are short or long day breeders. Additionally, innately timed changes in expression of *Dio2* and *Dio3* are associated with the onset of photorefractoriness,[220,229] suggesting that spontaneous long-term changes in hypothalamic thyroid metabolism may generate circannual reproductive rhythms.

The expression of deiodinases and of *Mct8* is highly localized in the hypothalamus, being confined to the ependymal zone surrounding the ventral portion of the third ventricle. The ependymal layer in this region contains a mixture of typically cuboidal ependymal cells and specialized glial cells known as tanycytes.[231] Unlike the cuboidal ependymal cells, tanycytes have cytosolic projections into the parenchyma of the surrounding basal hypothalamus, as well as down into the median eminence. While definitive evidence is lacking, and expression in neighboring glial cells cannot be excluded, the patterns of *Dio2*, *Dio3*, and *Mct8* expression are all consistent with enriched expression in the third ventricle tanycyte cell population. The biological role of tanycytes has been much discussed (see Refs 231–233). They appear critical in the estrous regulation of reproduction in female rodents.[234] In addition to being a specific site of deiodinase expression, tanycyte structure undergoes a marked melatonin-driven remodeling.[235] Thus, these cells are now receiving renewed attention in the context of seasonal reproduction.

Relationship between the PT and Deiodinase Expression in Tanycytes

Recently it has become clear that in mammals, melatonin-dependent production of TSH by the PT mediates photoperiodic regulation of deiodinase expression in the hypothalamic ependymal zone[158,193,236] (Figure 34.17), challenging the two-site model for melatonin's role in seasonal breeding. It has long been known that thyrotropic cells comprise a significant proportion of the endocrine cell population present in the PT, that these cells

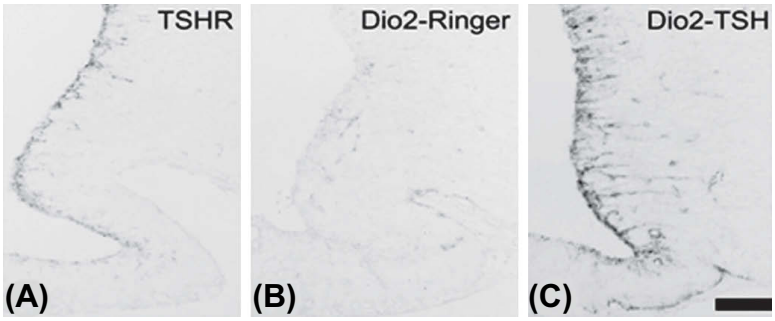

FIGURE 34.17 Central infusion of TSH promotes *Dio2* expression in tanycytes surrounding the base of the third ventricle. In the male Djungarian hamster, tanycytes express TSH receptors (TSHR, left panel) and acute intracerebroventricular infusion of 1 mIU TSH (right panel), but not of Ringer solution (middle panel) induces *Dio2* mRNA expression within 4 h in short day-adapted animals. Scale bar = 100 μM
Source: Adapted from Ref. 237.

express MT1, and that levels of PT TSH expression vary with seasonal state in seasonal rodent species[189,238–240] (Figure 34.13). These cells constitute a distinct population developmentally from those found in the PD and appear not to express receptors for thyrotropin-releasing hormone,[191] placing them outside of the classical thyrotropic regulatory axis.

Interest in PT-derived TSH as a regulator of seasonal reproductive physiology was reinvigorated with the finding that expression of TSH receptor (TSHR) RNA in the basal hypothalamus shows a remarkable overlap with that for *Dio2*/*Dio3*.[158,193,224,236] Exposure to long photoperiod causes a rapid induction of *Tshβ* RNA expression in the PT in sheep,[193] hamster[189] (see Figure 34.13), and in melatonin-proficient lines of mice.[158] Since *TSHβ* subunit expression is rate limiting for synthesis of TSH,[241] these observations suggested that PT TSH might act in a paracrine manner on neighboring ependymal cells to control deiodinase expression. Direct evidence for this interpretation is provided by the demonstration that central TSH infusion induces *Dio2* expression in SP-acclimated sheep[193] and hamster[237] (Figure 34.17), and by the finding that *Tshr* knockout blocks photoperiodic induction of *Dio2* in melatonin-competent mice.[158]

Remarkably, PT-derived TSH appears to be the key relay between photoperiod and deiodinases in birds as well as mammals, despite melatonin apparently not being required for seasonal control of reproduction in birds.[236,242] Rather, deep brain photoreceptors, with opsin-like sensitivity characteristics located in paraventricular sites within the diencephalon, are proposed to project to the avian PT and control its function.[243,244]

Follow-up studies addressing the issue of how melatonin regulates TSH production in the PT highlight the role of the transcriptional coactivator, eyes absent 3 (EYA3), as an upstream signal controlling *Tshβ* transcription.[114,180,194] EYA3 acts in concert with other members of a network of transcription factors, coactivators, and corepressors associated with eye, pituitary, and limb development.[245] In the PT, EYA3 potentiates the transcriptional activating effects of thyrotroph embryonic factor (TEF) to drive *Tshβ* expression. *Eya3* transcription is under circadian control, with a phase of peak expression occurring approximately 12 h after melatonin onset in the evening. Additionally, the amplitude of peak *Eya3* expression is directly repressed by melatonin.[114,194] These two effects appear to combine to give day length dependent *Eya3* expression in the PT, with long days/short melatonin signals favoring increased *Eya3* expression due to absence of melatonin at the phase of peak *Eya3* expression some 12 h after dark onset (Figure 34.18). This in turn leads to photoperiodic control of *TSHβ* expression[114,194] (Figure 34.18). Promoter analysis of the *Eya3* gene shows that it is under circadian control through E-box response elements, suggesting that *Eya3* regulation is the key link between the effects of melatonin on circadian clock gene expression discussed above and seasonal photoperiodic readout in the PT.[62,114,180,194]

Recent data from sheep indicate that the innately timed return to breeding condition with extended exposure to long photoperiod (i.e., long day photorefractoriness), involves parallel declines in brain deiodinase and PT *TSHβ* gene expression.[220,222] This spontaneous decline may account for the limited time window during which a T4 implant can elicit termination of the breeding season on TX ewes[211] (Figure 34.14). Conversely, in the sheep, the spontaneous return to anestrus after extended short photoperiod exposure (i.e., short day photorefractoriness) involves changes in deiodinase expression, without any measurable effect on PT *TSHβ* expression,[220] and earlier reports in hamsters indicate that short day photorefractoriness develops without observable increases in *Dio2* expression.[222] These findings suggest that long-term timing of seasonal breeding is generated at more than one site in the neuroendocrine system, but leave open the fundamental question of how these long-term timing effects are generated.

HYPOTHALAMIC NEURAL PATHWAYS INVOLVED IN NEUROENDOCRINE CONTROL OF SEASONAL BREEDING—THE ROLE OF RF-AMIDE SIGNALING PATHWAYS

GnRH neurons in the rostral hypothalamus (preoptic area and organum vasculosum of lamina terminalis) represent the final common pathway in the neural

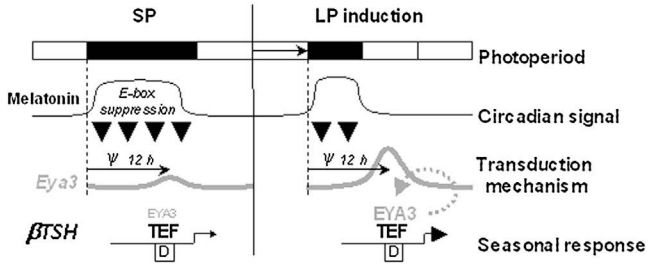

FIGURE 34.18 Model for photoperiodic control of Eya3 and TSHβ expression in the pars tuberalis. The model proposes that melatonin exerts a direct suppressive effect on *Eya3* expression and an indirect effect via circadian gene oscillations in the pars tuberalis. The phase of the circadian rhythm of *Eya3* expression *relative* to the rhythmical presence of melatonin (Ψ) is critical for determining whether a strong peak of *Eya3* expression occurs. Independent of day length, *Eya3* peaks some 12h after dark (melatonin onset). This means that under short days (SP, left panel), the peak occurs during the night, while the melatonin level is high and exerting a suppressive effect, and so the peak is small. Contrastingly, under long days (LP, right panel), the *Eya3* peak occurs the following morning when the melatonin level is minimal, and so the peak is large. This classic "external coincidence timer" mechanism limits EYA3/TEF synergism and hence elevated levels of *TSHβ* expression to long days, controlling the onset of a summer phenotype. *Source: Modified from Ref. 114.*

regulation of the hypothalamo-pituitary-gonadal axis (see Chapter 11). GnRH neurons project to the median eminence where they release GnRH into the portal blood to stimulate the synthesis and release of the pituitary gonadotropins luteinizing (LH) and follicle-stimulating (FSH) hormones, which, in turn, control gonadal growth and activity. Early experiments have demonstrated that in most species the number of GnRH neurons and the content of GnRH immunoreactivity do not change during seasonal reproductive quiescence, despite a marked decrease in gonadotropin secretion and gonadal activity.[246] Rather, the release of GnRH in the portal blood shows remarkable photoperiodic variation, indicating that melatonin acts to control the neurosecretory activity of GnRH neurons.[247,248] As discussed in Chapter 27, a marked increase in sensitivity to the negative feedback effects of gonadal steroids appears to be a key feature of seasonal reproductive quiescence in sheep. A similar photoperiod-controlled change in response to testosterone negative feedback has been observed in male hamsters.[249] This implies that the key downstream consequence of inhibitory photoperiod is a potentiation of steroid negative feedback effects on GnRH neurons in seasonal breeders. Since there is no evidence that GnRH neurons are directly sensitive to sex steroid feedback,[250,251] current attention focuses on interneuronal pathways linking melatonin and sex steroid sensitivity to the GnRH pulse generator.

In the sheep, evidence implicates the A15 group of dopaminergic (DA) neurons in the inhibition of GnRH secretion during seasonal anestrus, and these DA neurons are activated by estrogen indicating that they may mediate estrogen negative feedback[252] (see Chapter 27). Consistent with this hypothesis, short photoperiod- or melatonin-induced reproductive activation is associated with a decline in tyroxine hydroxylase (the rate limiting enzyme in DA synthesis) activity in the DA terminals of the median eminence.[253] Although other studies support a putative role of DA in the photoperiodic control of reproduction in horses,[254,255] at the present time, there is no evidence linking DA signaling to photoperiodic shifts in gonadotropin secretion in seasonal rodents, and recent attention has instead focused on the RF-amide (arginine-phenylalanine-amide) family of peptides. In particular, Kp and RF-amide related peptide-3 (RFRP-3) have emerged as potent regulators of GnRH neuronal activity.

Kisspeptin in the Arcuate Nucleus is a Gate-Keeper of Seasonal Reproduction

The *Kiss1* gene[256] gives rise to a Kp precursor peptide that may be cleaved to give fragments ranging in size from 10 to 54 amino acids (Kp10 and Kp54, respectively), with similar N-terminal decapeptide characteristics. These act as ligands for the G protein–coupled Kiss1 receptor (Kiss1r, previously known as GPR54). In 2003, it was shown that loss of function mutations of the *Kiss1r* in humans and mice prevent pubertal development and cause infertility.[257–259] This remarkable finding spurred great interest in the role of Kp in reproductive function.[260] In mammals, low doses of central Kp10 or Kp54 have a powerful stimulatory effect on GnRH neuron activity, gonadotropin secretion, and sex steroid production. Kp neurons are found mainly in two hypothalamic areas in rodents, the ARC and a more rostral area, the anteroventral periventricular nucleus (AVPV), while in the sheep they are found within the ARC as well as in the preoptic area.[192,261,262] In rodents, the AVPV Kp neuronal population is much larger in females than in males, in line with the pivotal role of AVPV Kp in the control of the preovulatory LH surge.[263,264] ARC Kp neurons also co-express neurokinin B and dynorphin, and are now therefore referred to as KNDy neurons.[265] Kp neurons project to areas where GnRH neurons are located, and over 90% of GnRH neurons express Kiss1r.[266,267] Additionally, Kp fibers extend toward the median eminence where the peptide acts on GnRH nerve terminals to regulate GnRH release.[268] Strikingly, Kp neurons are the main target for the positive (in AVPV/preoptic area) and negative (in ARC) central feedback effects of sex steroids, underlying their pivotal role in the tightly controlled positive/negative feedback loops of the reproductive axis.[262,269–271]

The pivotal role of Kp in the control of pubertal reproductive activation suggested that Kp neurons might also be involved in seasonal reproductive

control. Consistent with this hypothesis, seasonal mammals exhibit significant photoperiodic variation in Kp expression, albeit with marked differences between species.[272] In the Syrian hamster, Kp expression increases in the long day breeding season, both in the AVPV and the ARC, and this appears to be a melatonin-dependent response[262,271] (Figure 34.19(A)). Chronic administration of Kp, either centrally or peripherally, fully reactivates the reproductive activity of male Syrian hamsters exposed to short photoperiod,[271,274] implying a key role for seasonal changes in Kp expression for control of the reproductive axis (Figure 34.19(A), lower panel). A similar picture has emerged from studies in the short day breeding sheep: Kp expression is increased within the caudal part of the ARC upon exposure to short photoperiod[192,261,275] (Figure 34.19(B)), and Kp infusion drives reproductive activation in ewes kept in photo-inhibitory conditions[273,276] (Figure 34.19(B)). Melatonin, however, does not act directly on Kp neurons because, in the Syrian hamster, the ARC region lacks IMEL binding sites,[121,122,277] and in the sheep, Kp neurons are devoid of melatonin receptors.[278]

While the data in Syrian hamsters and sheep both suggest that ARC changes in Kp expression mediate changes in seasonal reproductive activation, the picture is complicated somewhat by data showing that, in the Djungarian hamster, long photoperiod suppresses ARC Kp expression.[279,280] Potentially this discrepancy might be due to superimposed effects of testosterone negative feedback on Kp expression in these reproductively active hamsters. In the short photoperiod–adapted Syrian and Djungarian male hamsters, increasing circulating testosterone levels by chronic implants induces a marked inhibition of Kp expression in the ARC but a stimulation of expression in the AVPV.[262,271,280] In the sheep, the estrogen-sensitive DA neurons project to the Kp neurons to inhibit their activity in anestrus.[281] The effects of steroid feedback on Kp expression are complex, and the resulting levels of Kp may be different among species. Additionally, metabolic parameters, notably leptin, also influence Kp expression,[282–285] adding another level of complexity in the seasonal context. Clearly further work is required to resolve the complex interplay between these factors and photoperiodic modulation of Kp signaling networks.

RFRP Neurons in the Mediobasal Hypothalamus May Mediate Melatonin Action on Seasonal Reproduction

Other peptides of the RF-amide family, characterized by a common C-terminal LPXRFamide (X = L or Q) motif were shown to regulate reproductive activity in birds and mammals (for reviews, see Refs 286–288). In the quail, one such peptide acts directly at the pituitary to inhibit gonadotropin release and is accordingly named gonadotropin-inhibitory hormone (GnIH).[289] Additionally, GnIH expression in the avian paraventricular hypothalamus is increased by a direct activation of Mel1c receptors.[290] In mammals, the *RF-amide related peptide* gene (*Rfrp*), the mammalian ortholog of *GnIH*, is expressed in neurons located in the mediobasal hypothalamus, and it encodes a precursor that produces two peptides, RFRP-1 and RFRP-3.[291,292]

RFRP neurons project to multiple brain regions including the preoptic area, the ARC, the lateral septum, the anterior hypothalamus, and the bed nucleus of the stria terminalis. Notably, RFRP-immunoreactive fibers make apparent contacts with 20–40% of GnRH neurons in rodents and sheep[292–295] and a subpopulation of Kp neurons,[296] suggesting that RFRPs act centrally to control the reproductive axis. The first functional studies in mammals reported that central or peripheral administration of RFRP-3 reduces LH secretion in male and female rats and ewes.[292,297–299]

Several studies have explored photoperiodic regulation of RFRP expression in mammals. In the Syrian hamsters, levels of *Rfrp* mRNA and RFRP are markedly downregulated in short as compared to long day conditions with no significant daily variation in both photoperiods[300] (Figure 34.20(A)). A similar short day inhibition of RFRP expression was observed in the Djungarian[295,300] and European hamsters,[288] the jerboa,[302] and, to a lesser extent, in the sheep,[261,303] suggesting common regulatory mechanisms. In male Syrian and Djungarian hamsters, the short day inhibition of RFRP expression is driven by melatonin and independent of the photoperiodic variation in the circulating levels of sex steroids.[295,300]

The role of RFRP in reproductive regulation in mammals seems to vary with species, and with annual phase of the breeding season. In short day breeding sheep, RFRP peptides have been described as having an opposed role to that of Kp, suppressing gonadotropic activity in the summer,[298,304] although a recent study could not replicate this observation.[305] Contrastingly, RFRP-3 activates the gonadotropic axis in male Syrian and Djungarian hamsters. In the Syrian hamster, central injection of RFRP-3 in long photoperiod–acclimated animals activates GnRH neurons and increases gonadotropin and testosterone secretion[301] (Figure 34.20(B)). In the same species, a 5-week central infusion of a low dose of RFRP-3 was able to restore testicular function to levels comparable to those observed in long day–acclimated hamsters.[301] Importantly, this RFRP-3-induced reactivation of reproductive function was associated with a significant increase in *Kiss1* expression the ARC. In the male Djungarian hamster, central infusion of RFRP-3 increases LH secretion in short day conditions, whereas it is inhibitory in long day conditions.[295] Of note, however, another study reported that RFRP-3 administration in ovariectomized female

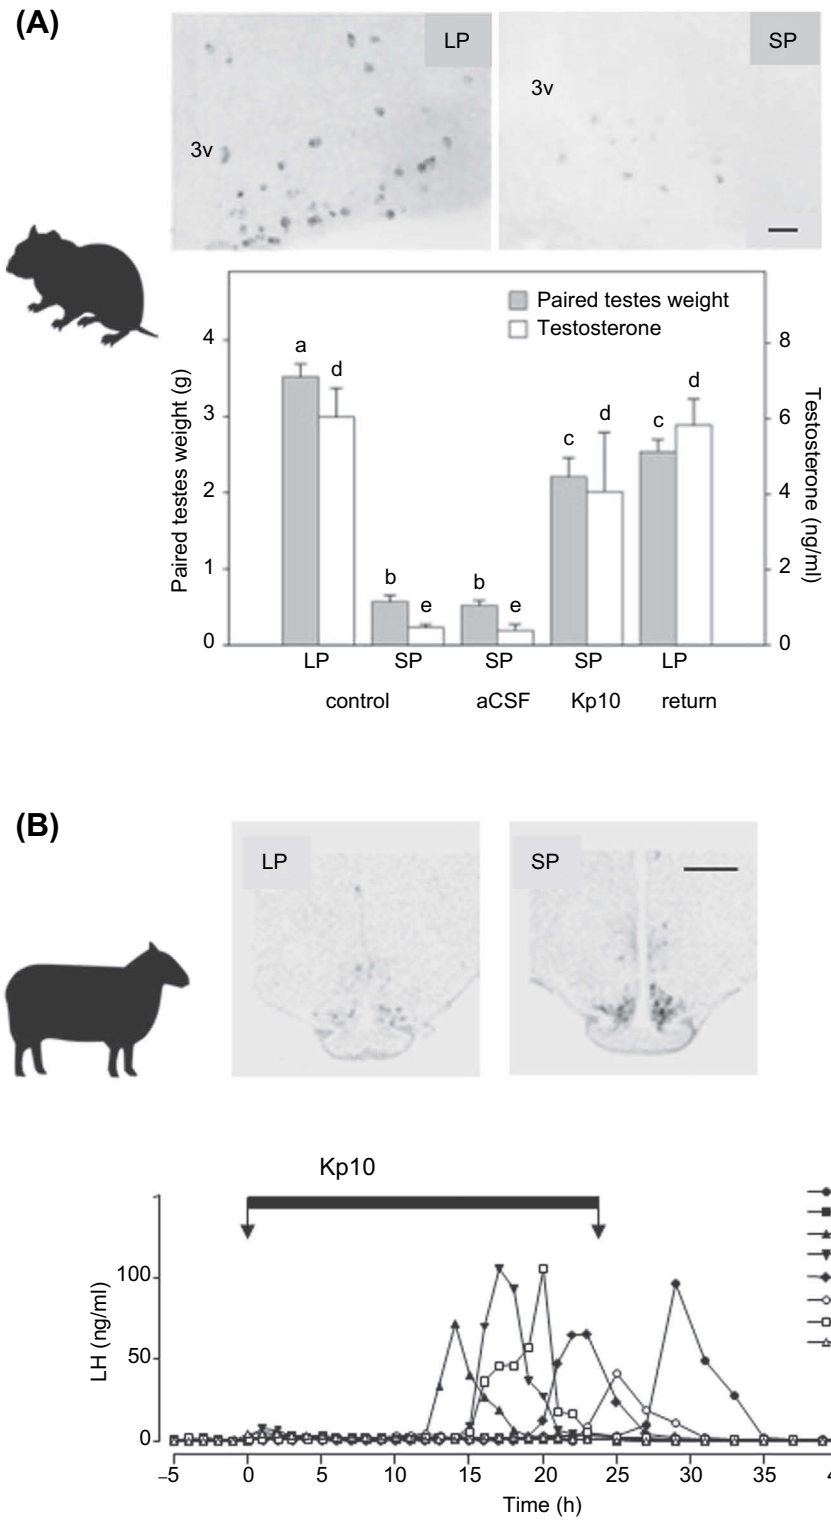

FIGURE 34.19 Kisspeptin (Kp) plays a key role in photoperiodic regulation of reproduction. (A) In the male Syrian hamster; *Upper panel*, the number of *Kiss1* mRNA–expressing neurons in the ARC is significantly increased in long photoperiod (LP) exposed sexually active animals as compared to short photoperiod (SP) adapted animals; scale bar = 100 µM; *(Source: Modified from Ref. 262.) Lower panel*, chronic (4 weeks) intracerebroventricular infusion of Kisspeptin 10 (Kp10, 1 mM, 0.25 µl/h) partially restores testicular function in short photoperiod (SP)–adapted male Syrian hamsters. Note that Kp10-induced testicular activity is similar to that reached in hamsters returned to LP for 4 weeks (LP return) (control = non-infused animals; aCSF = animals infused with artificial CSF). Bars with differing letters differ significantly ($p < 0.05$); *(Source: Adapted from Ref. 271.)* (B) In the sheep; *Upper panel*, autoradiographs showing elevated *Kiss-1* expression at the level of the arcuate nucleus of female Soay sheep kept under short photoperiod compared to ewes on long photoperiod (SP/LP, respectively); Scale bar = 1 mm; *(Source: Adapted from Ref. 192.) Lower panel*, patterns of secretion of luteinizing hormone (LH) in individual anestrous ewes infused with Kp10 (15.2 nmol/h) for 24 h (infusion period is represented by the black bars and arrows). Surges of LH secretion (in response to an increase in estradiol secretion stimulated by a rise in tonic LH) occurred between 19 and 34 h after the start of the infusion of Kp10 *Source: Adapted from Ref. 273.*

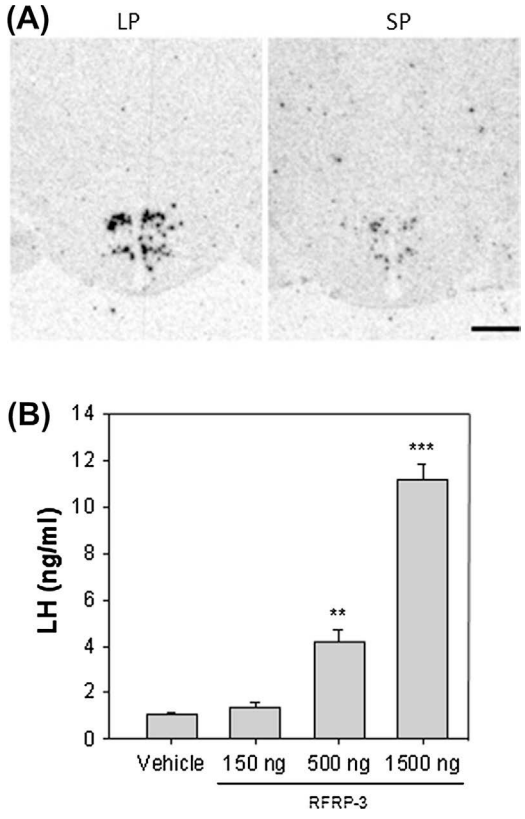

FIGURE 34.20 Photoperiodic regulation and role of RFRP 3 in the male Syrian hamster. (A) Autoradiographs showing that Rfrp mRNA levels in the dorsomedial/ventromedial hypothalamus are markedly reduced in short photoperiod (SP) as compared to long photoperiod (LP) conditions; Scale bar = 1 mm; (*Source: Adapted from Ref. 300.*) (B) Acute intracerebroventricular administration of RFRP 3 induces a dose-dependent increase in LH secretion within 30 min. Data are mean ± SEM ($n = 7$ per group) of circulating LH value examined 30 min after the central injection (***, $P < 0.001$) *Source: Adapted from Ref. 301.*

Syrian hamsters reduces LH secretion.[292] Taken together, these findings indicate that while short photoperiod exposure inhibits RFRP expression in the mediobasal hypothalamus of various seasonal breeders, the downstream consequences are species and possibly gender specific. This divergence of action possibly reflects differences in pharmacology and cellular sites of action.

Thyrotropin-Dependent Control of Hypothalamic RF-Amide Expression and Reproduction

Recent data indicate that photoperiodic, melatonin-dependent changes in both RFRP and Kp expression are downstream consequences of changes in PT TSH signaling and regulation of deiodinase expression.[237] In short day–acclimated, sexually inactive, male Syrian and Djungarian hamsters, chronic central infusion of TSH fully reactivates their reproductive function. This effect occurs in parallel with an increased expression of *Dio2* in the ependymal zone and a restoration of RFRP expression to long day levels. Interestingly, in both species, the expression of Kp is also restored, although not completely to a long day pattern.[237] These observations implicate RFRP neurons in the downstream hypothalamic response to melatonin-driven changes in TSH/T3. Given that RFRP-3 stimulates reproductive activity in the male Syrian and Djungarian hamsters,[295,301] but has the opposite effect in sheep,[298,304] it is tempting to speculate that the divergent downstream consequences of melatonin-sensitive deiodinase gene expression may be accounted for by species-dependent actions of RFRP-3 on the gonadotropic axis.

HYPOTHESES LINKING HYPOTHALAMIC T3 CONTENT TO HYPOTHALAMIC NEURAL CHANGES DRIVING SEASONAL BREEDING: A PIVOTAL ROLE FOR TANYCYTES?

Two basic conclusions emerge from the foregoing discussion: (1) Deiodinase-dependent changes in hypothalamic thyroid hormone metabolism, which determine T3 levels in the hypothalamus, are crucial for the expression of seasonal changes in reproductive activation in mammals, and (2) RF-amide based neural circuits are seasonally regulated modulators of reproductive activation, providing the interface between gonadal steroid feedback and GnRH pulse generator activity. These appear to be the major upstream and downstream elements for inclusion in the current working model, and from this the question emerges of how T3 availability influences RF-amide–dependent GnRH release (Figure 34.21). Several hypothetical mechanisms may now be considered.

Hypothesis 1: T3 Produced by Tanycytes Influences Hypothalamic Neuronal Excitability

Coppola and colleagues[306] have argued that mitochondrial activity is critical for sustained neuronal activity in hypothalamic NPY/AGRP neurons involved in energy sensing, and that T3 made available by surrounding glial cells (including tanycytes) supports mitochondrial activity by stimulating mitochondrial gene expression (especially uncoupling protein 2). Tanycyte expression of *Dio2* might mediate this effect and favor increased neuronal excitability under long photoperiod. Since tanycytes project widely into the parenchyma, encompassing the ARC, the ventromedial hypothalamus and the median eminence, this mechanism may extend to a wider variety of cell types than that specifically considered by Coppola et al., and could conceivably impact on the behavior of Kp/RFRP neurons linked to seasonal reproductive control.

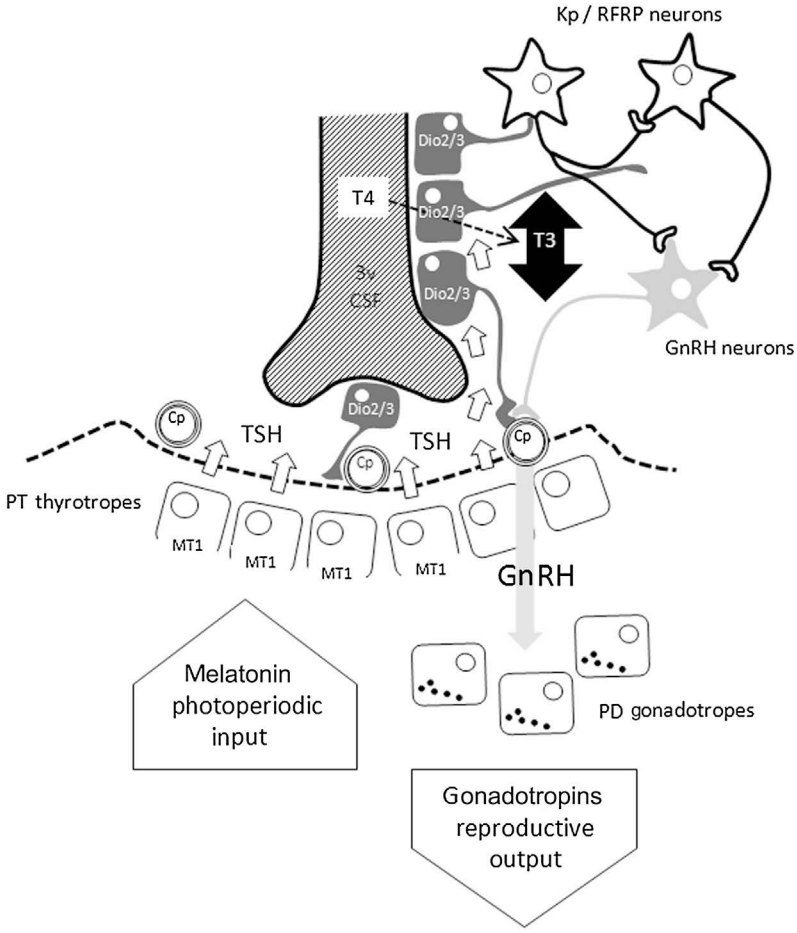

FIGURE 34.21 Working model for the pituitary/hypothalamic network regulating seasonal reproduction in mammals. Photoperiodic input is relayed to the PT via pineal production of melatonin and expression of type 1 melatonin receptors (MT1) in PT cells. Dependent on the duration of the nocturnal melatonin signal, these cells produce high or low levels of TSH, which act on tanycytes surrounding the base of the third ventricle (3v). High levels of TSH promote high levels of *Dio2* expression in tanycytes, while low levels favor *Dio3* expression. These enzymes determine the levels of T3 in the mediobasal hypothalamus. T4 is presumed to reach the ependymal region via the CSF, although supply via brain capillaries (Cp) is not excluded. The resultant photoperiodic modulation of hypothalamic T3 levels in turn affects the activity of the neuropeptidergic neurons governing pulsatile GnRH release. This may include effects of T3 on GnRH nerve terminals, or indirect effects via RF-amide neurons expressing Kp/RFRP. Resultant changes in pulsatile GnRH in turn govern pars distalis (PD) gonadotropin secretion and hence reproductive output.

Hypothesis 2: Tanycytes Modulate Energy Sensing

Central, hypothalamic actions of T3 may be important for the control of thermoregulation.[307] AMPK is a sensor of energy stress, whose activation through AMP accumulation/ATP depletion (the AMP:ATP ratio[308]), slows cell metabolism and lipid biosynthetic pathways. In the hypothalamus, AMPK-dependent changes in lipids are believed to influence neuronal excitability, possibly through effects on ion channel activity or intracellular calcium levels.[309] Hypothalamic T3 downregulates AMPK signaling in hypothalamic energy circuits, and this increases sympathetic thermogenic drive to brown adipose tissue. Interestingly, T3 implants block the capacity to lower body temperature and enter torpor in short day–acclimated Djungarian hamster.[216] Given that the capacity to enter torpor is highly dependent on metabolic status, a strong hypothesis is that this effect of T3 implants is mediated through a shift in AMPK-dependent energy sensing in the hypothalamus. By extension, seasonal shifts in T3-dependent modulation of AMPK sensing could alter the activity of neurons controlling GnRH pulse generator activity.

There is also evidence that tanycytes themselves act as hypothalamic energy sensors, a function consistent with their anatomy and morphology. Recent studies show that tanycytes respond to glucose by an increase in intracellular Ca^{2+} and ATP release.[310,311] Interestingly, a recent study reported that chronic TSH infusion in short day–adapted Djungarian hamster restored the long day phenotype of body weight together with that of reproduction.[237] At this time, the relationship between these energy sensing mechanisms, and photoperiodic influences of TSH and T3 metabolism, remain unclear, but this is likely to remain an active line of enquiry in the next few years.

Hypothesis 3: Tanycytes Support Hypothalamic Neurogenesis

Recent studies suggest the presence of a neurogenic stem cell niche in the basal hypothalamus, and that tanycytes in this niche are neural stem cells.[312,313] Pharmacological[314] or radiological[312] insults to cell division in the tanycyte-containing ependymal layer at the base of the third ventricle produce long-term, persistent changes in appetite and energy balance in mice, suggesting that

neurogenesis is required for maintenance of hypothalamic function. Cell division in this region yields progeny neurons that migrate into neighboring arcuate regions and acquire peptidergic phenotypes (e.g., AGRP+) consistent with their incorporation into circuits involved in metabolic regulation.[312,313] Accordingly, the possibility that neurogenesis-dependent changes in hypothalamic neural circuitry form the basis for long-term cycles of seasonal physiology merits attention.[15] At the time of writing, however, no specific link between the proposed hypothalamic stem cell niche and seasonal physiology has been made, despite several correlative reports of changes in hypothalamic cell proliferation related to seasonal status.[315–319] Given that T3 levels have been linked to neurogenic processes in other brain regions, also involving tanycytes (e.g., Ref. 320), it is tempting to suggest that seasonal changes in T3 availability may drive stem cell–dependent cycles of neural change linked to reproduction.

These three hypotheses for the downstream consequences of seasonal changes in tanycyte function/hypothalamic T3 metabolism are by no means mutually exclusive, and an attractive scenario is that distinct mechanisms operate to bring about rapid "activational" change at one phase of the circannual cycle, while others mediate long-term "preparative" change with delayed consequences months into the future.

CONCLUSION

The establishment of hypothalamic processing of thyroid hormone as the major pathway through which photoperiod synchronizes seasonal cycles of breeding represents a major advance in the last decade. This pathway appears to be conserved across mammals, regardless of the timing of their breeding season, and to rely on melatonin actions through the PT. This pathway does not exclude other routes of melatonin action, but given the explanatory power of the TSH-deiodinase model, we suspect that elucidation of additional pathways will lead to refinement rather than paradigm shifting. This is not to say that there are not a good deal of important unanswered questions in this field; rather, the current model brings several longstanding issues back to the forefront of research interest and should help to formulate new hypotheses. We still do not understand how widely species-divergent phasing of the breeding season emerges from basically conserved regulation of hypothalamic thyroid availability, but the complexity of RF-amide effects in seasonal breeders indicates that downstream signaling networks will be crucial to resolving this conundrum. The fundamental nature of innate long-term timing of seasonal breeding cycles, and other circannual physiology, is another mystery for which the current model suggests new hypotheses, with the role of hypothalamic tanycytes now under the spotlight. Another prospect is extension of progress in laboratory animal models to consider mechanisms in more ecological settings. The interaction between photoperiod and other cues to time seasonal reproduction in mammals, and the influence of ecology on genetic variation in seasonal timing mechanisms, have become very timely problems because of their topicality in relation to climate change. We can now turn to these issues because modern genomic tools will bring molecular physiologists and ecological geneticists together in an unprecedented manner.

Physiological Mechanisms for the Metabolic Control of Reproduction

Manuel Tena-Sempere

Department of Cell Biology, Physiology and Immunology, University of Córdoba, Córdoba, Spain, CIBER Fisiopatología de la Obesidad y Nutrición, Instituto de Salud Carlos III, Spain, Instituto Maimónides de Investigaciones Biomédicas (IMIBIC)/Hospital Universitario Reina Sofia, Córdoba, Spain

INTRODUCTION

Reproduction, as the biological process whereby organisms produce new organisms of the same kind, is essential for the survival and perpetuation of any given species. Accordingly, reproductive maturation and function are subjected to precise regulatory mechanisms, which impinge at different levels of the hypothalamic–pituitary–gonadal (HPG) axis. As described elsewhere in this book, this neurohormonal system is primarily composed of the hypothalamic factor, gonadotropin-releasing hormone (GnRH); the pituitary gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH); and gonadal hormones of a steroid and peptidergic nature. These factors are connected by feedforward and feedback regulatory loops, which are organized at early developmental periods and are responsible for the dynamic regulation of the reproductive system during the life span.[1]

The function of the HPG axis is tightly connected to the mechanisms governing other key body systems.[1] Yet, in contrast to other relevant biological functions, such as brain activity and metabolism, pubertal maturation and fertility are dispensable at the individual level. Hence, numerous conditions that disturb organism homeostasis, including different forms of nutritional stress, can result in reproductive perturbations that, depending on the time of presentation, manifest in either the lack of proper pubertal maturation or the loss of reproductive capacity in the adult.[1] The mechanisms for such a *collateral* regulation of the reproductive system are likely multifaceted, but a nidus for this control is located at central levels of the HPG axis, and comprises direct or indirect modification of GnRH neuronal function.[1–5]

It is now well known that the reproductive axis in general and GnRH neuronal function in particular are highly sensitive to the magnitude of body energy reserves and to the modulatory actions of several nutritional and metabolic factors.[1–7] This connection between body weight, as an index of energy reserves, and fertility was probably inferred on the basis of intuitive knowledge as early as the Paleolithic Age, when fecundity icons, globally referred to now as *Venus figurines*, were often represented as overweight women. However, it was not until the 1960s and 1970s that this relationship became formulated on a scientific basis.[6,8] Although the pioneering studies in experimental animals by Kennedy and Mitra set the grounds for this formulation,[9] it was the work in humans of Rose E. Frisch and colleagues, using first epidemiological data and later results from clinical experimentation, that crystallized these concepts into the so-called critical fat mass hypothesis.[10,11] This hypothesis was the first to point out the need to reach a certain threshold of body (fat) mass in order to complete pubertal development and/or sustain an appropriate reproductive function in adulthood. This hypothesis, which stated that body fatness is a better predictor than chronological age for the timing of puberty, provided the biological basis for the switch-off of the reproductive axis in adverse metabolic conditions. Since reproduction, and especially pregnancy and lactation, involve a substantial metabolic drain on the female,[12] suppression of puberty and fertility could be considered a failsafe mechanism to ensure the proper supply of energy substrates to life-sustaining body systems and processes in situations of limited energy resources.

http://dx.doi.org/10.1016/B978-0-12-397175-3.00035-1

Admittedly, the Frisch hypothesis had several limitations and was the center of numerous criticisms and strong debate among both clinical and basic scientists.[13–15] It was initially pointed out that weight and height, as used by Frisch and colleagues, were not fully reliable as proxy indices of body fatness. It was also suggested that the numerous exceptions to the fixed threshold dictated by body weight and adipose content, as well as the concurrence of numerous co-variables (e.g., in conditions of very low body weight), which may explain alterations of puberty and fertility per se, rendered this formulation of limited value.[16] It can be added that the work of Frisch did not consider the potential effects of very early metabolic influences, later shown to affect pubertal timing,[17] and did not address the impact of alterations at the other end of the spectrum of metabolic disorders, such as obesity. In fact, obesity and related alterations have warranted considerable contemporary attention because of their epidemic proportions and discernible effects on human puberty and fertility, as revealed by recent studies.[18–21]

Another aspect that was not sufficiently considered in the above studies was the impact of metabolic cues in male reproduction. Indeed, although this was initially neglected, it has been now documented that, through common and specific regulatory pathways, male puberty and reproductive capacity in adulthood are also sensitive to the influence of metabolic signals.[22] The teleological reasons of such a connection may appear less obvious, since male reproduction does not apparently face similar metabolic demands as in the female. Notwithstanding, in numerous species, key aspects of reproductive performance in the male, such as territoriality and dominance, are closely linked to, and dependent on, adequate energy conditions.[4] Yet, it is also obvious that there is a marked sexual dimorphism in some aspects of the metabolic control of reproduction.

In any event, despite its limitations, the work of Frisch and colleagues, together with the previous observations of Kennedy and Mitra on the roles of body weight and food intake in puberty initiation in rats,[9] highlighted the connection between body energy reserves and reproductive function. It thus paved the way for the identification of factors involved in such an integrative control and of their potential pathophysiological implications. These later developments are illustrated by recent milestones in the area of reproductive biology, such as the discovery in the mid-1990s of the adipose hormone leptin and the clinical consequences, in terms of puberty onset and fertility, of human mutations in the genes encoding this ligand or its receptor.[23,24] More recently, a compelling candidate for a major central target or sensor of key metabolic signals governing the HPG axis has emerged in the form of the hypothalamic peptides, kisspeptins,[25] as a result of the discovery that loss-of-function mutations of their receptor (*KISS1*-derived peptide receptor, KISS1R, aka GPR54) were associated with hypogonadotropic hypogonadism and delayed or absent puberty in humans.[26,27]

In this chapter, we will review the main mechanisms whereby body energy stores and the metabolic state of the organism participate in the dynamic control of reproductive maturation and function. Because an extensive description of the interactions of metabolism and reproduction is available in the third edition of this book (at http://www.sciencedirect.com/science/article/pii/B978012515400050052X), this chapter will focus on recent work examining the biological effects on the reproductive axis of three key peripheral hormones and their central regulatory sensors, targeting directly or indirectly GnRH neuronal function. However, it is important to note that signals other than peripheral hormones are also involved in conveying metabolic information to the reproductive axis. For instance, direct nutrient sensing by specific cellular populations of the brain is known to also play an important role in the metabolic control of reproduction,[25] and ependymocytes lining the wall of cerebral ventricles in the hindbrain have been proposed as glucose sensors regulating the activity of GnRH neurons in the rat.[28] Likewise, catecholaminergic neurons located in the lower brainstem that project to the paraventricular nucleus (PVN) have been shown to sense and mediate the inhibition of the HPG axis induced by conditions of lipid deprivation.[29]

In this chapter, major attention will be paid to the mechanisms for the metabolic control of reproduction in females, yet comments on the metabolic regulation of male reproduction will be included where appropriate. Mention will also be made at the end of the chapter of the reproductive effects of some metabolic factors outside of the brain. In line with the theme of this book, emphasis will be placed on the review of physiological mechanisms, although some brief comments on pathophysiological implications will be also included when considered relevant. For further details on the adverse consequences of bidirectional metabolic–reproductive interactions, see Chapter 29.

METABOLIC HORMONES REGULATE REPRODUCTION: ROLES OF LEPTIN, INSULIN, AND GHRELIN

Since the formulation of the Frisch hypothesis, much effort has been devoted to deepen our understanding of the mechanisms responsible for the metabolic control of puberty onset and gonadotropin secretion in the adult, which has increased considerably in recent years. This has been mainly due to the discovery of several

neuroendocrine pathways whereby different peripheral hormones inform the reproductive centers of the brain about key parameters of the metabolic status of the body, such as the amount of energy (fat) reserves. In fact, it is well established that numerous hormones play important roles in transmitting metabolic information to the reproductive centers in both physiological and pathological conditions. For the sake of concision, I will mostly focus in this section on the physiological actions of the *classical* metabolic hormones, leptin, ghrelin, and insulin, in the control of the HPG axis; a synoptic overview of these regulatory effects is provided in Figure 35.1.

Leptin

Among the numerous endocrine regulators involved in the integrative control of reproduction and metabolism, leptin, a hormone identified in 1994 as a major secretory product of the white adipose tissue,[23] is universally recognized as an essential neuroendocrine integrator linking the magnitude of body fat stores with several neuroendocrine axes, including that regulating the reproductive system.[6,7,12,30] Leptin is secreted by the white adipose tissue in proportion to the size of body fat stores and acts as an anorexigenic and thermogenic factor at the hypothalamic level, thus contributing to dynamically adjusting energy requirements, fat reserves, and food intake.[12,30] Regarding reproductive control, numerous studies have settled the concept that leptin plays a central role in the metabolic control of puberty and fertility.[6,7,12,30,31] Accordingly, conditions of leptin insufficiency are often coupled to a delay or absence of puberty onset and perturbed fertility,[32] as observed in various animal models (e.g., the leptin-deficient ob/ob mouse, the leptin receptor–deficient db/db mouse, and the genetically obese Zucker fa/fa rat) as well as in human pathologies associated with low or null leptin levels.

Although an important role of leptin in the control of puberty was established soon after its identification in the mid-1990s, the precise nature of leptin effects on pubertal timing and subsequent fertility was initially the subject of considerable debate. Thus, early pharmacological studies in rodents suggested that leptin administration might actually induce or advance the onset of female puberty, therefore implying a net stimulatory action.[33,34] This possibility was relevant not only from a physiologic standpoint but also from a therapeutic perspective. Since leptin was considered for treatment of forms of morbid obesity of early origin, especially

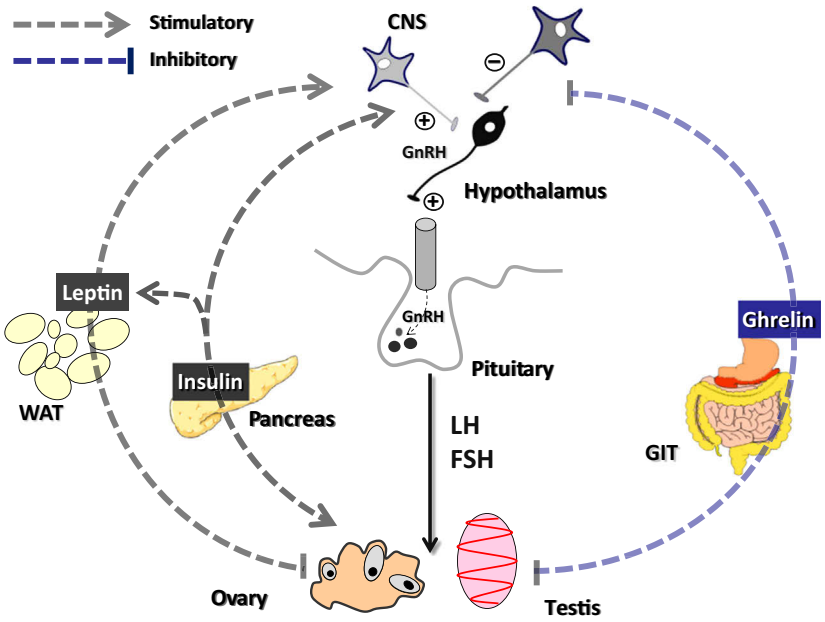

FIGURE 35.1 Schematic presentation of the regulatory roles of key hormonal signals, originating from different metabolic tissues, involved in the integrative control of food intake, energy balance, and reproductive function, including puberty. Paradigmatic examples of hormones with proven roles in the integrative control of food intake and the reproductive axis are presented, including factors from the adipose tissue (leptin: an inhibitory signal for food intake and a stimulatory or permissive signal for puberty and reproduction), pancreas (insulin; the same profile as leptin in terms of actions on food intake and reproduction), and gastrointestinal tract (ghrelin: a stimulatory signal for food intake and an inhibitory signal for the reproductive axis). These peripheral signals do not primarily target GnRH neurons, but rather operate via neuronal afferents that are either stimulatory (light gray) or inhibitory (dark gray). In addition to actions at central levels, inhibitory and stimulatory actions of these metabolic hormones directly at the pituitary (not depicted) and the gonads have been described. CNS: central nervous system; WAT: white adipose tissue; GIT: gastrointestinal tract.

in leptin-null individuals, any potential action of leptin to trigger precocious puberty could be considered an important adverse side effect and factor limiting the use of leptin in the management of childhood obesity. However, detailed studies of leptin administration in humans and rodents with leptin deficiency clearly documented that, while leptin is indispensable for puberty to proceed, leptin alone cannot trigger early puberty, therefore supporting a major permissive role for this hormone in the metabolic gating of pubertal maturation.[24,31,32,35–37] This implies that threshold leptin levels are mandatory, but not sufficient per se, to attain normal pubertal development and to maintain reproductive function in adulthood. Admittedly, this permissive function has been better characterized in females, whereas the role of leptin in male puberty and reproductive function remains less clear. In fact, circulating leptin has been shown to rise during the pubertal transition in girls,[38] while puberty onset in boys and male monkeys does not seem to correlate with a similar increase in leptin levels.[38,39] Moreover, high leptin levels, such as those seen in morbidly obese men, are frequently associated with hypogonadism,[40] yet the mechanism for such a paradoxical suppression of gonadal function in conditions of severe hyperleptinemia may involve central leptin resistance as well as direct inhibitory effects at the testicular level[40]; the latter will be discussed in more detail in the section Reproductive Effects of Metabolic Hormones Outside the Brain: Pituitary and Gonadal Actions of this chapter. In any event, conditions of leptin deficiency, such as those seen in ob/ob mice, are associated with detectable reproductive deficits in males,[4] whereas supraphysiological leptin replacement has been shown to increase testosterone and (modestly) gonadotropin secretion during short-term fasting in men,[41] thus suggesting that threshold leptin levels may be also needed to maintain proper reproductive function in males.

In spite of the compelling experimental and clinical data linking leptin and reproduction, recent findings suggest that particular aspects of the metabolic control of the gonadotropic axis may not involve a major role of leptin. For instance, apparent normalization of mean leptin concentrations in conditions of negative energy balance, such as short-term fasting, did not restore gonadotropin levels in female rats[42]; similar observations also have been reported in sheep, in which restoration of LH levels following exit of food restriction conditions took place in the absence of detectable changes of circulating leptin.[43] While leptin replacement in the above rat studies might not have reached optimal physiological levels, these observations represent a call of caution that warrants further analysis. In the same line, a recent preliminary report indicated that reducing glucocorticoid excess, which in general drives an inhibitory signal to the HPG axis, by means of genetic elimination of its hypothalamic stimulus, the corticotropin-releasing hormone (CRH), substantially ameliorates the reproductive phenotype of the ob/ob mouse, despite its persistent leptin deficiency.[44] Finally, it must be emphasized that the role and physiological relevance of leptin in the regulation of puberty, a period when full activation of the HPG axis takes place, versus fertility, in which leptin would operate as a signal for the maintenance of the capacity to reproduce during adulthood, might be different, so that the findings in one period may not be directly applicable to the other.

Insulin

Another peripheral hormone with a major role in the regulation of reproduction is the pancreatic hormone, insulin.[8] The key function of insulin as an essential metabolic regulator has long been universally recognized, and detailed recapitulation of its metabolic features clearly exceeds the aims and scope of this chapter. Notwithstanding, it is important to note for the purpose of this review that insulin operates as a major regulator of leptin synthesis, and, thus, their levels (and biological actions) are often tightly linked. In line with this contention, insulin has been proposed to also play a role as modulator of the HPG axis with predominant stimulatory actions, as clearly illustrated by the fact that conditions of low or null insulin levels, such as uncontrolled diabetes, are commonly associated with suppressed gonadotropin levels and various forms of reproductive failure.[8] Yet the reproductive *dimension* of insulin action remains less well characterized than that of leptin, despite the available evidence suggesting a relevant physiological role for insulin signaling in the regulation of the HPG axis.

In good agreement with the stimulatory/permissive role of insulin in the control of reproduction, a mouse line engineered to lack insulin receptors selectively in neurons has been shown to suffer not only hyperphagic obesity but also hypogonadism due to GnRH deficiency.[45] These features are remarkably similar to those seen in mouse models of leptin or leptin receptor deficiency. In addition, high peripheral insulin levels, achieved by hyperinsulinemic clamps, were able to significantly increase LH secretion, regardless of the actual glucose levels, therefore suggesting a primary role of changes in insulin concentrations in this phenomenon.[46] In line with these rodent studies, recent analyses during the menstrual cycle in healthy women have demonstrated that a rise of insulin concentrations peripherally can evoke a significant increase in the frequency of LH pulses.[47] Altogether, these findings support a stimulatory role of insulin in the control of the gonadotropic axis. As a call of caution, however, it remains possible that some of the positive effects of insulin on the reproductive system may stem from its ability to stimulate leptin secretion. In

addition, the physiological roles of insulin in the control of key reproductive events, such as puberty onset or the preovulatory surge of gonadotropin, remain ill-defined and warrant further experimentation.

Ghrelin

During the last decade, compelling evidence has been presented supporting an essential role of ghrelin in the control of food intake and energy balance, ghrelin being mainly produced in the stomach to act as the (only known circulating) orexigenic factor.[48] The metabolic dimension of ghrelin is reinforced by the demonstration of its proven role in glucose homeostasis and insulin secretion,[49,50] its central effects on energy expenditure and nutrient partitioning, and its interactions with key signals in energy homeostasis, such as leptin.[51] To further reinforce the metabolic relevance of ghrelin, its circulating levels are in most cases negatively correlated with the body mass index,[49] and hence ghrelin has been proposed to operate as a long-term signal for energy insufficiency, with reciprocal interactions (in a yin-and-yang manner) with leptin, as a signal of energy abundance.[51] In good agreement, ghrelin has been documented to play a regulatory role in the control of the HPG axis, with a predominant inhibitory action that is opposite to the permissive and stimulatory effects of leptin.

In line with its function as a signal of energy insufficiency, experimental studies conducted mainly in rodents have demonstrated a modulatory role of ghrelin in puberty onset, with predominant inhibitory actions; thus, acute elevation of ghrelin concentrations suppressed circulating gonadotropin levels, and chronically elevated ghrelin levels delayed different indices of pubertal maturation.[22,52–54] Interestingly, studies of the rat suggested that females are less sensitive than males to the inhibitory effects of ghrelin on pubertal maturation.[55] In any event, administration of high doses of ghrelin to female rats during puberty was able to delay this process, based on external (i.e., vaginal opening) and ovarian signs of puberty.[32] The fact that male rodents appear to be more sensitive than females to the inhibitory actions of ghrelin on puberty is opposite to the reported effects of leptin, as females seem to be more sensitive to the regulatory actions of leptin on puberty onset.[6] Whether, as described for the rat, human puberty is sensitive to the effects of ghrelin is yet to be defined. In this regard, a progressive decline in the circulating levels of ghrelin during puberty in humans has been demonstrated.[56] Hence, it is tempting to hypothesize that if ghrelin operates as an inhibitory signal for the onset of puberty in humans, such a decrease in its plasma levels may play a permissive role in pubertal onset.

Compelling experimental evidence indicates that ghrelin is also an inhibitory signal for the gonadotropic system in adulthood. In brief, studies conducted in several species have documented that, after its systemic or intracerebral administration, ghrelin can induce significant inhibition of LH, and to a much lesser extent FSH, secretion. While these studies were initially conducted in rodents, the ability of ghrelin to suppress the gonadotropic axis has since been confirmed in sheep, nonhuman primates (ovariectomized rhesus monkeys), and humans.[53,57–64] In rats, the inhibitory actions of ghrelin on LH secretion have been observed in males and females, after both acute and repeated injection.[53–55,57,58] In good agreement, central administration of ghrelin has been shown to induce a significant reduction of ovarian steroids, estrogen and progesterone, in cyclic female rats,[65] while chronic administration of ghrelin to adult male rats during undernutrition (hence already displaying an elevation of endogenous ghrelin levels) evoked a marked drop in serum LH and testosterone levels.[66] Likewise, in the intact sheep and gonadectomized monkey, ghrelin has been shown to suppress different aspects of the pulsatile secretion of LH.[59,60] Finally, ghrelin infusions have been reported to partially inhibit spontaneous LH pulsatility in healthy men,[61,62] and negative correlations between ghrelin concentrations and LH, FSH, testosterone, and estradiol levels have been detected in young men suffering beta thalassemia, a condition linked to perturbations of puberty and gonadotropic function.[67] On the other hand, another study did not detect significant changes in circulating LH levels following an injection of a single bolus of ghrelin in healthy cyclic women[68]; this might suggest a sexual dimorphism in the sensitivity to the suppressing effects of ghrelin on the gonadotropic axis, with adult males being more sensitive than females, in line with data from pubertal studies.

Other Peripheral Hormones

Despite the prominent roles of leptin, insulin, and ghrelin in transmitting metabolic information to the HPG axis, as described in this chapter, the available evidence strongly suggests that other peripheral hormones, with important roles in the control of metabolism, may also participate in the regulation of various facets of reproductive maturation and function. However, the physiological significance of these additional regulatory axes (whose existence, in some cases, was not documented until very recently) remains to be assessed. As a paradigmatic example, the bone product, osteocalcin, which is known to play an important role in metabolic homeostasis by virtue of its ability to regulate insulin sensitivity and circulating glucose levels,[69,70] recently has been shown to directly regulate testicular function,[71] therefore suggesting the existence of a previously unsuspected hormonal bone–gonadal axis that may contribute to link the metabolic status and the function of the HPG axis. In

the same vein, adipokines other than leptin have been implicated in the control of the HPG axis. Although, for the sake of concision, the experimental data supporting a role of those adipose-born cytokines in the regulation of the reproductive system are not thoroughly reviewed in this chapter, it is worth mentioning that adiponectin, whose levels fluctuate in a reciprocal manner with leptin, has been shown to suppress GnRH secretion by GT1–7 cells[72,73] and to inhibit basal LH secretion and GnRH-induced LH release at the pituitary–gonadotrope level.[74,75] Similarly, other gut-derived hormones may cooperate with ghrelin in the central control of the HPG axis. Thus, glucagon-like peptide 1 (GLP-1), whose roles as an incretin factor and major regulator of postprandial insulin secretion and glucose homeostasis are unanimously recognized,[76] has been shown to stimulate GnRH secretion by GT1–7 cells and to modestly increase LH levels after central administration.[77] Yet, the physiological and pathophysiological relevance of those regulatory functions on the elements of the HPG axis awaits further investigation. Likewise, the role of circulating growth factors, such as insulin-like growth factor I (IGF-I), in the control of the reproductive axis, and particularly of GnRH neurons, has been well documented (for further details, see the section Metabolic Targeting of GnRH Neurons: Direct Actions and Indirect Pathways).

In the same vein, gonadal hormones, such as 17β-estradiol, which play an essential role in the control of GnRH neuronal function, are also known to serve important roles in the control of metabolism and energy homeostasis.[78] Thus, ovariectomy causes an important increase in body weight in laboratory rodents, and loss of estrogens also may underlie the body weight alterations (mainly weight gain) frequently observed after menopause.[78] While such metabolic effects of estrogen have been long recognized, the neuroendocrine basis for these actions remains poorly characterized. Yet, recent studies have helped to dissect some of the central components for the joint metabolic and reproductive effects of estrogens, which seem to operate in the arcuate nucleus (ARC) to suppress feeding and conduct negative feedback, while actions in the ventromedial hypothalamus (VMH) appear to mediate at least part of the effects of estrogen on thermogenesis and ovulation.[79] Thus, elimination of estrogen receptor alpha (ERα) signaling in steroidogenic factor 1 (SF1) neurons in the VMH has been shown to induce obesity, hypometabolism, and anovulation, while ablation of ERα in proopiomelanocortin (POMC) neurons in the arcuate caused hyperphagia, perturbation of negative feedback of gonadotropins, and infertility.[79] Further details on the nature of the neuronal populations mediating the reproductive and metabolic effects of estrogens are provided in the sections Other Products of KISS1 Neurons in the Metabolic Control of Reproduction: Role of KNDy Neuropeptides and Other Central Transmitters in the Metabolic Control of Reproduction of this chapter.

METABOLIC TARGETING OF GnRH NEURONS: DIRECT ACTIONS AND INDIRECT PATHWAYS

As reviewed in the previous section, peripheral hormones modulate the maturation and function of the HPG axis. While compelling experimental data have documented the ability of these signals to act at levels of the reproductive axis other than the brain (for further details, see the section Reproductive Effects of Metabolic Hormones Outside the Brain: Pituitary and Gonadal Actions), it is now recognized that a substantial component of their reproductive effects occurs at central levels, specifically via modulation of GnRH neuronal functions, as the major output pathway for the upstream regulatory elements of the gonadal axis. This has been clearly illustrated by functional genomic analyses showing that neuronal elimination of the receptors for insulin or leptin impairs puberty onset and fertility,[45,80] and by data documenting the ability of leptin, insulin, and ghrelin to modulate GnRH secretion by hypothalamic explants ex vivo or primary cell cultures in vitro.[7,8,81] There has been, however, a significant debate on whether the actions of such metabolic hormones are exerted directly on GnRH neurons or, rather, primarily operate through intermediary neuronal pathways. Such a precedent for an indirect control of GnRH neuronal activity has been long recognized. Thus, despite their central role in the control of the gonadotropic system, it has been known for years that GnRH neurons are devoid of receptors for some of their major regulators, such as ERα, which is responsible for the feedback effects of estradiol,[82] therefore suggesting that such an *indirect* sensing is commonplace for this neuronal population.[83]

In fact, elegant studies using Cre–LoxP approaches support the contention of a predominantly indirect mode of action of leptin and insulin in the control of GnRH function. Thus, studies from Anderson and colleagues showed that while neuron-specific knockout (KO) of leptin receptors prevented normal puberty onset and caused infertility in male and female mice, selective elimination of leptin receptor expression from GnRH neurons was compatible with normal puberty onset in females and preserved fertility.[80] This phenomenon is in good agreement with the observation that intracerebral injection of leptin caused robust expression of signal transducer and activator of transcription 3 (STAT3) in specific hypothalamic areas linked to the generation of the preovulatory surge of gonadotropins, such as the anteroventral periventricular (AVPV) nucleus, but not in GnRH neurons.[80] Moreover, GnRH neurons appear to

be devoid of functional leptin receptors in physiological conditions, according to brain expression studies in rodents and primates.[84,85]

Similarly, Wolfe and coworkers recently demonstrated that selective ablation of insulin receptors from GnRH neurons failed to induce any detectable alteration in the timing of puberty or adult reproductive function in male and female mice.[86] Again, this is in contrast to the overt reproductive phenotype of neuron-specific insulin receptor-null mice, which displayed central hypogonadotropic hypogonadism.[45] Although results from congenital KO should be interpreted with caution because of the possibility of developmental compensatory mechanisms, these findings suggest that direct leptin or insulin signaling in GnRH neurons is dispensable for the development and maintenance of normal reproductive function, at least in rodents. These results thus point out the existence of indirect pathways, sensitive to these key metabolic hormones, which would operate as conduits for the transmission of such metabolic information to GnRH neurons.

Nonetheless, evidence for the direct effects of key metabolic hormones, such as leptin and insulin, on GnRH neurons has been obtained from studies using primary hypothalamic cultures and different GnRH neuronal cell lines. Thus, analyses in the immortalized GnRH-secreting cell line, GT1–7, revealed that these cells express functional leptin receptors and respond to low doses of leptin with increases in GnRH release.[87] In the same vein, the clonal GnRH neuronal cell line, GnV3 (conditionally immortalized GnRH cells), was shown to express the insulin receptor and to respond to insulin stimulation with increases in *GnRH* mRNA expression,[88] a phenomenon that also has been documented in GnRH-expressing GnRH-secreting neuronal 11 (GN11) cells.[89] Furthermore, detailed molecular studies have documented the involvement in this phenomenon of signaling cascades known to mediate insulin effects in peripheral metabolic tissues, such as the mitogen-activated protein kinase extracellular-regulated kinase (Erk) 1/2.[87] It is emphasized, however, that the relevance of these observations is hampered by the fact that the immortalized cell lines used in the above studies might not be representative of truly physiological conditions. In fact, data using functional genomics have challenged the concept of direct GnRH effects of leptin and insulin (as discussed here). The possibility of compensatory mechanisms in models of congenital KO of specific receptors, however, does not allow one to completely rule out that some direct effects of these signals in GnRH neurons might occur under certain conditions. On the other hand, GnRH neurons seem to be sensitive to the direct regulatory actions of other metabolic and growth factors involved in the control of puberty, such as IGF-I, since selective elimination of IGF-I receptors from GnRH neurons resulted in delayed puberty onset in male and female mice.[86]

In contrast to leptin and insulin, the mechanisms whereby ghrelin participates in the central control of the gonadotropic axis remain only superficially studied. Pharmacological analyses have suggested that the inhibitory effects of ghrelin on the this axis occur, at least partially, at the hypothalamic level, since ghrelin has been shown to inhibit GnRH secretion by hypothalamic fragments from female rats challenged with the hormone ex vivo,[53] and systemic administration of ghrelin caused a reduction in GnRH pulse frequency by hypothalamic explants from immature and young adult male rats in vitro.[90] Whether this central action of ghrelin is conducted directly on GnRH neurons or via indirect pathways is yet to be fully defined. Circumstantial evidence suggests an indirect mode of action of ghrelin, since its inhibitory effects on LH secretion in the monkey were inhibited by a nonselective antagonist of CRH,[91] which is a suppressor of the HPG axis. In addition, ghrelin was able to inhibit at least part of the effects of potent stimulators of gonadotropin secretion acting at central levels, such as naloxone in humans and kisspeptin in rats.[54,62] The latter, however, is compatible with a direct action of ghrelin on GnRH neurons to suppress their responsiveness to kisspeptins. For further details on the roles of kisspeptins and the neurons that synthesize these peptides in the metabolic control of the reproductive axis, see the section KISS1 Neurons as Central Relays of Metabolic Information: Expression and Functional Studies.

KISS1 NEURONS AS CENTRAL RELAYS OF METABOLIC INFORMATION: EXPRESSION AND FUNCTIONAL STUDIES

The recognition of the existence of indirect pathways responsible for transmitting metabolic information to GnRH neurons set the scene for the identification of the afferent neuronal circuits responsible for such a function. In this context, considerable efforts have been devoted in recent years to elucidate the putative roles of kisspeptins, the products of the *Kiss1* gene, in the metabolic control of puberty and fertility.[1,2] Kisspeptins are a family of structurally related peptides of the Arg–Phe (RF)-amide superfamily that act via the surface receptor, KISS1R (aka GPR54).[1] Different molecular forms of kisspeptins, varying in amino acid length, have been reported, which include kisspeptin 54 and kisspeptin 10; the latter is the shortest peptide fragment with the capacity to fully activate KISS1R. In terms of nomenclature, we will adhere to recent proposals,[1,92] whereby *Kiss1* and kisspeptins will be used to name the gene–mRNA and proteins, respectively, while the term "KISS1 system" will be employed to globally refer to the ligand-receptor system.

As summarized in Chapter 11 on GnRH neuronal network, during the last few years, neurons producing kisspeptins (referred hereafter as "KISS1 neurons") in the basal forebrain have been recognized as master elements of the reproductive brain, which operate as essential conduits for transmitting the regulatory actions of numerous modulators of the HPG axis, from gonadal steroids to photoperiodic cues.[1,83,93] As reviewed in this section, a number of expression and functional studies conducted in different (mainly rodent) species during recent years have documented that the hypothalamic KISS1 system is sensitive to different forms of metabolic stress known to perturb puberty and gonadotropin secretion.[2,94] These observations, together with the fact that exogenous administration of kisspeptin, as a means to replace its defective endogenous levels, can ameliorate the reproductive deficits seen in those conditions, support a major role of kisspeptin signaling in the metabolic control of reproduction.[2,94] However, recent evidence suggests also that the participation of KISS1 pathways in this phenomenon is probably not as straightforward as initially anticipated, and apparently discrepant findings on the contribution of KISS1 circuits in mediating the effects of key metabolic hormones, such as leptin, have been reported in the last few years. The latter will be critically discussed in the section Leptin Signaling and KISS1 Neurons: Direct, Indirect, or Independent Effects?

Expression Studies

Studies conducted initially in this area were mainly focused on the analysis of changes in *Kiss1* expression in models of negative energy balance, which are linked to different degrees of reproductive suppression. Thus, pubertal male and females rats under short-term fasting were shown to display a significant decrease in the hypothalamic expression of *Kiss1* mRNA, which was coupled to a significant drop of serum LH levels.[95] Similar observations were later reported in adult female rats[96,97] and adult male mice.[98] Suppression of the hypothalamic expression of *Kiss1* has also been described in other models of metabolic stress coupled to negative energy balance and impaired reproductive function, such as uncontrolled experimental diabetes; for example, male and female rats injected with streptozotocin suffered central hypogonadism associated with a marked reduction in hypothalamic *Kiss1* mRNA expression levels.[99,100]

Although these expression studies documented the sensitivity of the hypothalamic KISS1 system to changes in body energy stores and metabolic cues, several aspects of this regulation remained initially uncharacterized. For instance, it is well known that there are two distinct kisspeptin neuronal populations, located in the ARC and the AVPV, which in rodents respond differentially to key reproductive modulators, such as sex steroids; for further details, see Refs 1,83 and Chapter 11 on the GnRH neuronal network and Chapter 26 on control of the ovarian cycle of the rat and mouse. However, the relative sensitivity of the two populations of KISS1 neurons to metabolic regulation is yet to be fully elucidated. In this context, female rats submitted to persistent underfeeding during the pubertal transition display a significant suppression of *Kiss1* mRNA expression in the ARC.[101] Similarly, leptin-deficient ob/ob male mice also demonstrated a decrease in *Kiss1* mRNA levels in the ARC.[102] On the other hand, adult OVX female rats replaced with estrogen and submitted to short-term fasting had reduced *Kiss1* mRNA levels at the AVPV,[103] whereas 50% caloric restriction of adult female rats resulted in a drop of *Kiss1* mRNA levels in both the ARC and the AVPV.[42] An analogous decrease in *Kiss1* mRNA levels in the AVPV has been reported in rats during lactation,[104] another condition of negative energy balance. Finally, dietary restriction in sheep induced a profound inhibition of *Kiss1* mRNA expression in the ARC and preoptic area (POA)[105]; the latter is rostral to the hypothalamus and, as the AVPV, has been reported to hold KISS1 neurons that might be involved in positive feedback and the control of ovulation.[106] These observations suggest that KISS1 neurons in both the ARC and AVPV (or equivalent rostral areas in other species) are subjected to metabolic regulation, although their relative sensitivity to conditions of metabolic stress may differ from each other.

It is also interesting to note that, while most of the analysis on the influence of metabolic signals on the KISS1 system has focused on changes in hypothalamic mRNA levels, whether such changes translate into alterations of kisspeptin content or, eventually, kisspeptin release remains ill defined. As illustrated in Figure 35.2(A), immunohistochemical (IHC) studies in pubertal female rats have described that short-term fasting induces a significant decrease of kisspeptin immunoreactivity (IR) and the number of kisspeptin-positive neurons in the ARC.[2] In the same vein, prolonged conditions of negative energy balance, such as lactation, also have been shown to induce a drop in kisspeptin IR in the ARC.[104] Indeed, the ARC population of KISS1 neurons is also sensitive to other forms of stress, as documented by the decrease in the number of kisspeptin IR cells detected in adult male rats submitted to an acute inflammatory challenge by administration of bacterial lipopolysaccharide (LPS).[107] In any event, some studies have failed to detect an overt decrease in kisspeptin IR in adult female rats after a 48-h period of food deprivation,[2] although this study was conducted in gonadal-intact animals, and compensatory changes in kisspeptin expression might have occurred following fasting-induced changes in the endogenous sex steroid milieu.[2] Furthermore, the lack of direct assessment of kisspeptin release may render IHC

data of limited value, since low kisspeptin IR may be compatible with either enhanced kisspeptin release (and hence signaling) or low synthesis and reduced release (and hence signaling).[104]

Of important note, most of the expression analyses addressing the metabolic regulation of the hypothalamic KISS1 system have been conducted in models of negative energy balance (see this chapter), in order to examine the principle that KISS1 neurons are sensitive to metabolic signals. In contrast, a very limited number of studies have produced data on the impact of situations of persistent overweight and obesity on the hypothalamic expression of *Kiss1*. These analyses, however, are of considerable interest because of the escalating prevalence of obesity and its potential reproductive comorbidities, which include perturbed pubertal timing and subfertility.[18–21] In this context, initial studies in long-term diet-induced obese male mice of the C57 black 6 strain documented that these animals had largely preserved hypothalamic *Kiss1* mRNA expression, despite very low levels of circulating testosterone.[98] Although *Kiss1* mRNA levels in this study were assessed in whole hypothalamic fragments, *Kiss1* expression was likely located in the ARC because male rodents have a prominent ARC KISS1 population but rather few KISS1 neurons in the AVPV.[83] While this finding might suggest a lack of impact of obesity on the hypothalamic KISS1 system, it must be considered that the severely decreased testosterone levels observed in these diet-induced obese mice should have evoked an increase in the hypothalamic expression of *Kiss1* mRNA,[83] which actually did not take place. Hence, these observations strongly suggested that obesity is associated with the impairment of KISS1 neurons to respond appropriately to major regulators, such as sex steroids.[98]

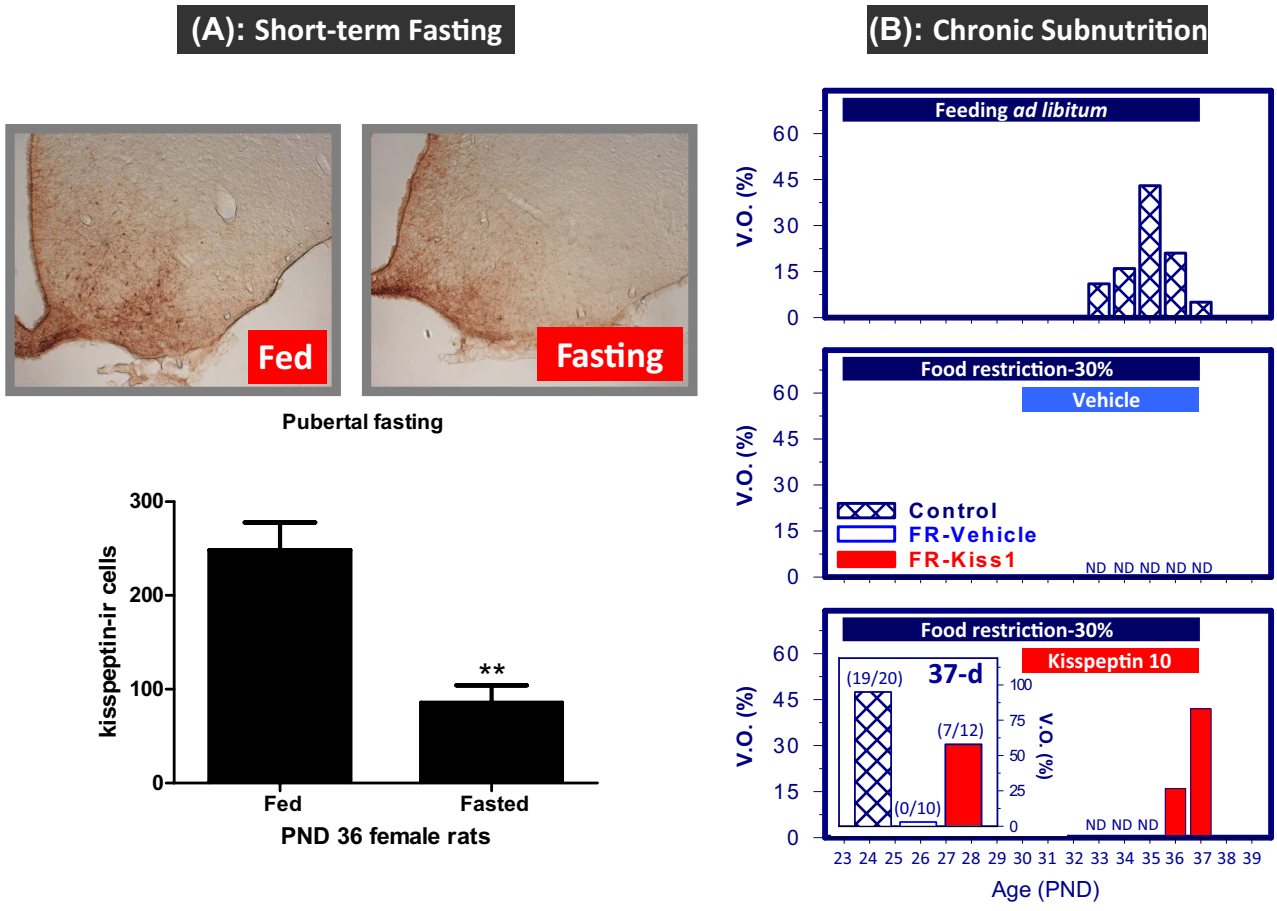

FIGURE 35.2 **Impact of conditions of metabolic stress on the hypothalamic KISS1 system and its functional consequences in pubertal female rats.** In the *left panels* (A), the suppressive effect of short-term fasting on the number of kisspeptin-immunoreactive neurons in the ARC is shown. In the *right panels* (B), the consequences of kisspeptin replacement in terms of pubertal onset in a model of chronic subnutrition (FR: a 30% reduction in daily food ration) during puberty is illustrated. This protocol of partial food deprivation caused a 30% decrease in body weight (BW) gain and prevented vaginal opening (VO), an external sign of puberty. However, repeated intracerebral injections of kisspeptin 10, in the face of a persistent reduction in BW, was sufficient to rescue VO in >60% of the animals; see the accumulated percentage of VO in the experimental groups on PND37 in the inset of the lower graph of Panel (B). In addition, potent gonadotropic and estrogenic responses were evoked by kisspeptin 10 in all treated females (data not shown). PND: postnatal day (age); ND: not detectable; d: day. *Source: Taken from Refs 4,81, with modifications.*

In the same vein, a more recent study has shown that persistent obesity in DBA/2J mice, a mouse strain prone to obesity-induced infertility, caused a marked reduction of *Kiss1* mRNA levels in the ARC and AVPV, as well as in the number of KISS1 neurons in the AVPV.[108] These observations would suggest that conditions of persistent overweight can suppress the hypothalamic KISS1 system, as we have also very recently observed in adult male rats subjected to various obesogenic insults (Sanchez-Garrido & Tena-Sempere, submitted).

Of note, the impact of obesity on the hypothalamic KISS1 system is likely complex and does not always involve clear-cut inhibitory effects. For instance, male rats transiently exposed to a high-fat diet displayed an elevation of hypothalamic *Kiss1* mRNA levels.[96] Similarly, immature female rats fed on a high-fat diet during the pubertal transition displayed an advancement in the age of vaginal opening coupled to an increase in *Kiss1* mRNA expression in the ARC and medial POA.[109] Moreover, recent studies addressing the effects of early postnatal overfeeding in female rats described a potential correlation between early-onset overweight, advanced pubertal maturation, and increased *Kiss1* mRNA levels in the hypothalamus, as well as possibly increased numbers of kisspeptin fibers in the AVPV.[110] Admittedly, however, the latter observations regarding *Kiss1* mRNA levels or kisspeptin projections have not been fully replicated by other studies.[111,112] Altogether, the above data from different models of overweight/obesity in rodents strongly suggest that, depending on the age, duration, and/or degree of obesity, stimulatory or inhibitory responses in terms of *Kiss1* expression and gonadotropic function can take place. However, the mechanisms for such a switch in the responses of the KISS1 system, and to what extent these are similar to or distinct from those affecting the HPG axis in conditions of energy insufficiency, remain to be defined.

Functional Analyses

The capacity of extreme metabolic conditions to affect the expression of *Kiss1*/kisspeptin in discrete hypothalamic areas would anticipate that functional changes in the endogenous kisspeptin tone occur in those conditions, which would be responsible, at least in part, for the associated reproductive arrest. However, direct assessment of actual changes in kisspeptin release in situations of metabolic stress has not been conducted. Instead, proof-of-principle studies have been used to evaluate whether pharmacological administration of kisspeptin, as a means to prevent the expected reduction of endogenous levels in situations of energy insufficiency, could rescue different reproductive parameters in those situations. This might provide indirect evidence for a role of kisspeptin signaling in the metabolic control of the HPG axis. Yet, it must be noted that such proof-of-principle analyses have been mostly conducted in rather extreme metabolic conditions and used protocols of central administration of high doses of kisspeptin, which might have caused an elevation of the endogenous kisspeptin tone over the expected physiological levels. Hence, results must be interpreted with caution.

Despite these potential reservations, various pharmacological studies have shown that by enhancing the endogenous kisspeptin drive in conditions of energy insufficiency and metabolic stress, without any other neuroendocrine manipulation, several indices of pubertal and reproductive failure can be rescued. For instance, as shown in Figure 35.2(B), repeated intracerebral injections of kisspeptin 10 to immature female rats, submitted to a protocol of chronic subnutrition after weaning that caused pubertal arrest, was sufficient to induce vaginal opening in a significant proportion of cases, together with robust gonadotropic and estrogenic responses (not shown in Figure 35.2(B)), that overrode the prevailing suppression of circulating levels of gonadotropins due to malnutrition.[95] Similarly, repeated administration of kisspeptin 10 to hypogonadotropic diabetic male rats ameliorated testicular and prostate weights, and normalized circulating LH and testosterone levels, while central injection of kisspeptin 10 to uncontrolled diabetic female rats was able to reverse their hypogonadotropic state.[99,100] In the same vein, a recent study has documented that 11-h infusions of kisspeptin 10 are able to potently stimulate LH and testosterone secretion in men with hypogonadism associated with type 2 diabetes.[113] Of note, in the studies in models of metabolic stress discussed here, the rescue of reproductive indices was achieved in spite of the apparent lack of direct effects of kisspeptin on metabolic parameters, such as body weight or circulating glucose levels—observations that reinforce the primary role of kisspeptin signaling as the central effector for the metabolic regulation of the reproductive axis.

Interestingly, assessment of acute gonadotropin responses to kisspeptin administration has revealed additional changes in the functionality of the KISS1 system in different conditions of metabolic stress. For instance, LH secretion following bolus injection of kisspeptin 10 to fasted male and female rats was not only preserved but even enhanced, despite the lowering of basal gonadotropins levels due to food deprivation.[95,114] Furthermore, a higher responsiveness to kisspeptin 10 in vitro, in terms of GnRH secretion, has been detected in hypothalamic explants from fasted rats,[95] and the duration of LH responses to the continuous infusion of kisspeptin 10 in vivo was prolonged in female rats subjected to chronic subnutrition.[115] All in all, these findings are suggestive of a state of hyperresponsiveness to kisspeptin in situations of negative energy balance.

A plausible mechanism for this phenomenon is that conditions of negative energy balance, which are associated with a putative decrease of the endogenous kisspeptin tone (see the section Expression Studies), would induce a compensatory state of augmented responsiveness via an increase in the expression of KISS1R. In fact, protracted fasting in pubertal rats evoked an increase in their hypothalamic *Kiss1r* mRNA levels.[95] However, it is emphasized that shorter periods of fasting in adult mice have been shown to reduce *Kiss1r* mRNA expression.[98] It should also be noted that some of the changes discussed here in responses to kisspeptin administration may derive from a greater accumulation of GnRH and/or gonadotropin stores due to continued synthesis of peptide–protein in an absence or reduction in release due to the prevailing state of negative energy balance. Overall, the available evidence strongly suggests that metabolic signals not only modulate *Kiss1*–kisspeptin expression in the hypothalamus but also can influence GnRH–gonadotropin responsiveness to the stimulatory effects of kisspeptins. The nature of such regulatory actions, however, may vary among species, since it has been reported that, contrary to rodents, fasting decreases testosterone responses to kisspeptin stimulation in the monkey.[116]

LEPTIN SIGNALING AND KISS1 NEURONS: DIRECT, INDIRECT, OR INDEPENDENT EFFECTS?

The demonstration of the impact of various conditions of metabolic stress on KISS1 neurons led to specific analyses aimed at the identification of the putative signals responsible for the metabolic control of this system. Because of leptin's paramount physiological relevance in the metabolic gating of puberty and fertility (see the section Leptin), considerable efforts in this area have been devoted to assessing the specific roles of this hormone in the control of the KISS1 system as a putative pathway to transmit its stimulatory and facilitatory effects on GnRH neuron activity.[6,7,12,117] Indeed, in the last few years, convincing evidence has been presented to document the capacity of leptin to modulate *Kiss1* expression. Yet, it is noted that most of the studies reported to date have involved the use of rather extreme models of leptin deficiency or, in some cases, immortalized cell lines. Moreover, the use of high doses of leptin, as a proof-of-principle approach, may limit the physiological relevance of some of the reported stimulatory effects of leptin on the KISS1 system under certain conditions, such as the exit from situations of negative energy balance.[42] While these features do not invalidate the majority of the experimental studies on this topic reported so far, they bring a call of caution when directly extrapolating some of the experimental observations to physiological conditions.

Studies in gonadectomized ob/ob mice were the first to establish that conditions of leptin deficiency induce a marked suppression of *Kiss1* mRNA levels in the ARC, while leptin administration to these animals enhanced *Kiss1* mRNA expression in this nucleus.[102] Similarly, central infusion of leptin to male rats with uncontrolled diabetes was able to normalize hypothalamic *Kiss1* gene expression, along with the restoration of LH and testosterone levels, in this model of hypogonadotropic hypogonadism associated with marked hypoleptinemia and hypoinsulinemia.[99] In line with these in vivo findings, leptin has been shown to increase *Kiss1* gene expression in the murine hypothalamic cell line N6,[98] as well as in primary cultures of human fetal GnRH-secreting neuroblasts.[118]

In line with the ability of leptin to modulate hypothalamic *Kiss1* expression, initial studies in ob/ob mice demonstrated the expression of the gene encoding leptin receptors in a significant proportion (>40%) of KISS1 neurons in the ARC.[102] Of note, however, a later study, using a transgenic mouse line that allows green fluorescent protein tagging and identification of KISS1 neurons in vivo, reported that just a modest fraction of KISS1 neurons express functional leptin receptors, as evidenced by the fact that only a subset of <15% of ARC KISS1 neurons (and none of the AVPV KISS1 neurons) appeared to display conventional phosphorylated STAT3 (pSTAT3) responses to leptin treatment,[119] pSTAT3 being the major transduction signal for leptin actions in the brain.[120] The later findings are consistent with a predominant indirect mode of action of leptin on KISS1 neurons, as proposed recently (discussed in this chapter).

Analogous findings, supporting a role of leptin in the control of the KISS1 system, have been reported in other species. For instance, studies in sheep have demonstrated the expression of the leptin receptor gene in both ARC and POA KISS1 neurons, and leptin has been shown to enhance *Kiss1* mRNA expression in those hypothalamic nuclei.[105] Likewise, a recent study reported that in the guinea pig, ARC KISS1 neurons, which express leptin receptors, are depolarized by leptin via activation of transient receptor potential channels.[121] As a whole, these observations, coming from different species and experimental models, do support the existence of a leptin–kisspeptin connection, whereby leptin actions could be signaled onto GnRH neurons via modulation of KISS1 afferents, thereby allowing proper maturation and function of the HPG axis in conditions of energy (and, hence, leptin) abundance.

Despite the solid evidence summarized here, the concept that leptin acts directly on KISS1 neurons has been challenged recently by two independent studies. First, using a Cre–LoxP strategy, the Elias team has published

that congenital elimination of leptin receptors selectively from *Kiss1*-expressing cells does not prevent pubertal maturation or attainment of fertility.[122] It must be noted, however, that congenital ablation of leptin receptors from KISS1 neurons might have induced developmental compensatory changes that could reduce or eliminate the phenotypic impact of such ablation. Second, a recent independent study, mapping the distribution of leptin receptors in different hypothalamic areas in the mouse and sheep, could not find evidence for their expression in KISS1 neurons except for a small population in the ARC.[123] It must be noted, however, that in this study the number of kisspeptin-positive cells in the ARC was surprisingly low, and therefore this population may have been underestimated and hence, also, the degree of co-expression of kisspeptin and leptin receptors.[123] Interestingly, the latter work identified a previously unknown population of neurons expressing leptin receptors, located in the ARC and AVPV, in the close vicinity of KISS1 neurons.[123] These newly identified leptin receptor-expressing neurons may participate in transmitting leptin effects to KISS1 neuronal populations. All in all, the combination of such expression and functional genomic studies strongly suggests that a substantial component of the effects of leptin on the hypothalamic expression of *Kiss1*/kisspeptin may be conducted indirectly and transmitted via intermediate pathways of as-yet-unknown nature.[123] The physiological significance of such an intricate, indirect mode of regulation of KISS1–GnRH neurons by leptin, and its importance relative to direct KISS1 regulatory effects of leptin in various species, including humans, is yet to be elucidated. It must be kept in mind, though, that species differences might exist regarding the mode of action of leptin on KISS1 neurons, as indirectly suggested by the apparent differences reported in the fraction of KISS1 neurons expressing leptin receptors in the mouse,[119] guinea pig,[121] and sheep.[105]

Notwithstanding the presumed important roles of KISS1 neurons in transmitting metabolic information in general, and leptin effects in particular, to GnRH neurons, there is solid experimental evidence that the reproductive actions of leptin are, in part, conveyed via primary actions at hypothalamic areas that do not apparently contain KISS1 neurons. This raises the possibility of the existence of kisspeptin-independent pathways for transmitting leptin-metabolic effects to the GnRH neuronal network.[5] A paradigmatic example in this sense is the ventral premammillary nucleus (PMV). In fact, this nucleus had been suggested as an important center for the transmission of different environmental cues to the reproductive axis years before the identification of the roles of leptin and kisspeptins were established.[4] Recently, the PMV has been pointed out as a primary target area for the effects of leptin on puberty and fertility.[122,124] Thus, a subset of neurons in the PMV has been shown to express leptin receptors and is excited following leptin stimulation. In addition, bilateral excitotoxic lesions of the PMV lowered LH and estradiol levels, and prevented the positive effects of leptin on the gonadotropic axis in fasted animals. It must be noted, however, that since only a fraction of PMV neurons expresses leptin receptors, it is possible that part of the reproductive phenotypes of these excitotoxic lesions may stem from the damage of leptin-independent pathways. In any event, selective re-expression of leptin receptors in the PMV of leptin receptor-deficient mice was able to induce puberty and improve fertility, specifically in female mice.[4,5] Of note, a similar procedure for leptin receptor rescue of the PMV in male mice was ineffective in terms of recovery of puberty onset,[122] an observation that suggests important sex differences in the role of PMV circuits in mediating the reproductive actions of leptin.

Taken together, the observations discussed here would suggest the existence of KISS1-independent circuits for the transmission of leptin effects onto GnRH neurons. Importantly, this evidence does not refute a critical role of kisspeptins in the metabolic control of reproduction, nor does it rule out the possibility of interactions between these alternative circuits and KISS1 pathways. In fact, neuroanatomical data suggest that neurons from the PMV innervate kisspeptin and GnRH neurons, and very recent data have documented that lesions of the PMV disrupt the expression patterns of *Kiss1* and *GnRH* mRNA during the preovulatory period in female rats[125]; therefore, it is highly plausible that leptin-sensitive pathways originating from the PMV may impinge onto KISS1 circuits for transmitting part of the reproductive actions of leptin. A schematic representation of the potential pathways whereby leptin transmits its regulatory effects onto GnRH neurons, via KISS1 by direct or indirect actions or via KISS1-independent actions, is provided in Figure 35.3.

Of note, the ability of leptin to modulate the hypothalamic KISS1 system (as well as other related pathways) is likely not restricted to the adult age, but rather also operates at earlier developmental stages. Thus, studies using models of postnatal under- and overnutrition in female rats indirectly suggested that leptin might also be an important regulator of *Kiss1* and kisspeptin expression during puberty. In rats subjected to underfeeding while nursing, which were leaner and had delayed vaginal opening, a close correlation between low circulating leptin levels at puberty and reduced hypothalamic expression of *Kiss1* mRNA and kisspeptin-positive neurons has been reported.[110] Such an association between early undernutrition, delayed puberty, and suppression of the hypothalamic KISS1 system has been independently confirmed recently in mice[112]; admittedly, however, actual leptin levels were not measured in the later study. Conversely, heavier female rats (due to

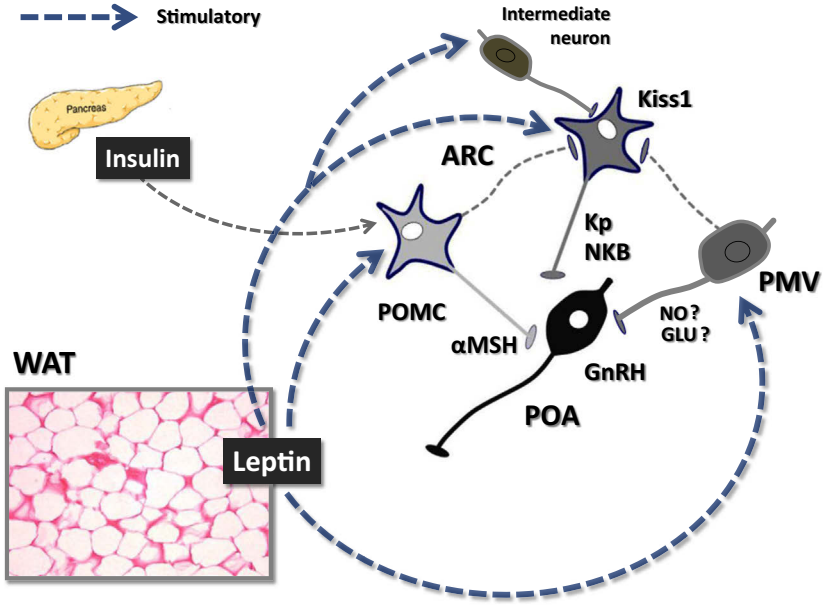

FIGURE 35.3 Potential mechanisms for transmitting leptin actions onto GnRH neurons, as deduced from expression and functional analyses in rodents and other mammals. Since GnRH neurons are devoid of leptin receptors, the actions of the adipose hormone must be conveyed via afferents that are sensitive to leptin effects. These may include (1) POMC neurons, which seem to play a key role in the joint transmission of leptin and insulin effects to GnRH neurons; (2) kisspeptin (Kiss1) neurons, which are sensitive to changes in leptin inputs and operate as major regulators of GnRH neurons; and (3) other neuronal populations, including intermediate neurons (of as-yet-unknown nature), in the vicinity of Kiss1 or GnRH neurons, and neurons in the ventral premammillary nucleus (PMV). Note that fragmentary neuroanatomical and functional data suggest the existence of potential connections between some of these neuronal populations (indicated by dotted-line projections). Such connections may help to explain the fact that leptin appears to operate predominantly in an indirect manner on some of those neuronal subsets (such as Kiss1 neurons). Some of the putative transmitters for these neuronal circuits are depicted. In any event, it is noted that other neuronal populations in the ARC, such as neuropeptide Y (NPY) and agouti-related peptide (AgRP) neurons, are known to be sensitive to leptin effects and have been reported to interplay with POMC, GnRH, and (probably) Kiss1 neurons. However, their roles in transmitting leptin actions to Kiss1 and GnRH neurons need further clarification and, for sake of simplicity, are not depicted in this figure. Likewise, other circuits (such as those originating from the lateral hypothalamus) are not represented either. POA: preoptic area; PMV: ventral premammillary nucleus; Kp: kisspeptins; NKB: neurokinin B; αMSH: alpha melanocyte stimulating hormone; NO: nitric oxide; GLU: glutamate; WAT: white adipose tissue.

postnatal overnutrition) showed earlier entry into puberty and displayed higher serum leptin concentrations and *Kiss1* mRNA levels at the hypothalamus.[110] Whether this phenomenon derives from nutritional or leptin changes at early postnatal periods and/or during puberty is yet to be defined.

As a final note to this section, it is emphasized that, in addition to leptin, KISS1 neurons appear to be directly or indirectly sensitive to other major peripheral regulators of the HPG axis, including ghrelin, insulin, and IGF-I. Thus, ghrelin has been reported to suppress *Kiss1* gene expression in discrete hypothalamic (mainly preoptic) areas, an effect that was associated with a significant decline in LH pulse frequency.[126] However, it is not known whether this action is conducted directly on KISS1 neurons or via intermediate afferents. On the other hand, a recent study has documented that congenital elimination of insulin receptors from KISS1 neurons causes a (modest) delay in the timing of puberty in both male and female mice, suggesting a direct action of insulin in the modulation of the hypothalamic KISS1 system.[127] Yet, selective deletion of insulin receptors from KISS1 cells was compatible with preserved fertility, suggesting a dispensable role of direct insulin signaling in the modulation of adult KISS1 neuronal function and reproductive capacity.[127] In addition, IGF-I has been reported to increase *Kiss1* mRNA expression at the AVPV in prepubertal female rats.[128] Yet, blockade of IGF-I receptors did not alter *Kiss1* mRNA levels in this periventricular hypothalamic area in adult female rats.[129]

OTHER PRODUCTS OF KISS1 NEURONS IN THE METABOLIC CONTROL OF REPRODUCTION: THE ROLE OF KNDy NEUROPEPTIDES

In the last few years, it has been recognized that a notable subset of KISS1 neurons in the ARC co-express at least two relevant transmitters involved in the control of the gonadotropic axis, neurokinin B (NKB) and dynorphin (DYN)[1,130]; hence, the term KNDy has been coined to name this neuronal population to recognize such neuropeptide diversity.[130] It must be emphasized, however, that the percentage of ARC KISS1 neurons that co-express NKB and/or DYN seems to vary depending on the species and sex[131];

hence, it is highly plausible that ARC KISS1 neurons that are not KNDy neurons exist. In any event, the relevance of these kisspeptin co-transmitters is emphasized not only by their conserved co-localization in various species, including rodents and primates, but also by the striking reproductive phenotypes of humans with inactivating mutations of the genes encoding NKB (*TAC3*) or its receptor, NK3R (*TAC3R*), which suffer hypogonadotropic hypogonadism.[132–134] Furthermore, stimulatory actions of the NKB agonist, senktide, on LH secretion have been documented in different species,[135–138] while DYN is a well-known inhibitor of GnRH–gonadotropin secretion (see Figure 35.4). All in all, integration of the available neuroanatomical, pharmacological, and genomic data has led to the hypothesis that KNDy neurons in the ARC are key elements in the generation of GnRH pulses, by virtue of their ability to drive a potent stimulatory output signal (kisspeptin) to GnRH neurons, under the reciprocal modulation of NKB (predominantly stimulatory) and DYN (inhibitory).[94,139] Admittedly, however, important functional aspects of this network are yet to be elucidated and notable species differences in the physiological relevance of KNDy neurons in the control of GnRH neurons may exist. For further details on the roles of KNDy peptides in the central control of GnRH neurons, see Chapters 11, 26–28, on the GnRH neuronal network, control of the ovarian cycle of sheep, control of the menstrual cycle, and control of the ovarian cycle of the rat, respectively.

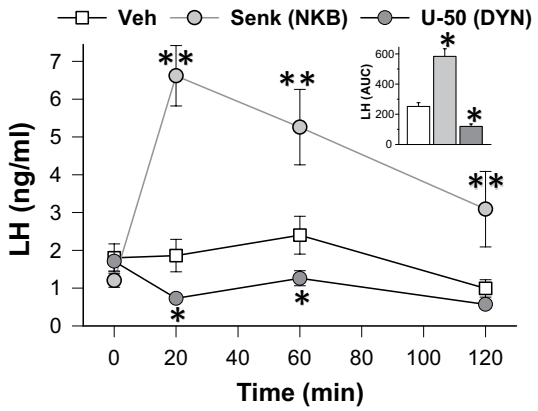

FIGURE 35.4 Effects of intracerebroventricular injection of the agonists of NKB (senktide; 600 pmol/rat) and dynorphin (U-50; 1 nmol/rat) on LH secretion. Adult female rats, subjected to a standard protocol of ovariectomy and physiological estradiol replacement (as described in Ref. 139), were used in these experiments. Saline-injected females (0.9% saline) served as controls. Blood samples were taken before (0 min) and at 20, 60, and 120 min after compound administration. In addition to time-course profiles, the integral secretory responses to the agonists or vehicle were calculated using the trapezoidal rule and depicted in the inset. These hormonal responses illustrate the opposite effects of NKB (stimulatory) and DYN (inhibitory) on GnRH neurons, as indirectly estimated by its surrogate marker, LH secretion. Statistically significant differences are denoted by * ($P < 0.05$) and ** ($P < 0.01$). *Source: Taken from Ref. 139, with modifications, and from our unpublished data.*

In the context of the metabolic regulation of the reproductive axis, recent studies in models of metabolic stress in pubertal animals have demonstrated that, as is the case for KISS1, the hypothalamic NKB system is sensitive to conditions of negative energy balance, so that short-term fasting not only suppressed *Kiss1* mRNA expression in the ARC and AVPV, but also inhibited the hypothalamic expression of the genes encoding NKB and its receptor in pubertal female rats.[140] Importantly, the delay of puberty caused by undernutrition was partially prevented by administration of an NKB agonist (see Figure 35.5), thus supporting the notion that NKB signaling may cooperate with kisspeptins in the metabolic control of puberty.[140] This idea fits well with the proposed model whereby NKB would participate in the central regulation of GnRH secretion by enhancing kisspeptin output to GnRH neurons.[94] As further proof for the sensitivity of NKB pathways to metabolic regulation during puberty, it has been recently demonstrated that feeding on a high-fat diet to female rats from weaning caused precocious puberty onset and increased expression of the gene encoding NKB, as well as *Kiss1*, in the ARC.[109] The role of NKB signaling in the metabolic control of adult reproductive function remains less well characterized, yet certain conditions of negative energy balance and metabolic stress, such as lactation, have been shown to cause a decrease of NKB mRNA and peptide content in the ARC in rats.[42] In addition, the function, if any, of DYN in the metabolic control of puberty and fertility is yet to be elucidated.

Notably, KNDy neurons in the ARC seem to play an important role in the integration of the reproductive and metabolic effects of sex steroids. This has been very recently illustrated by the work of Rance and coworkers, who used a toxic ablation approach to evaluate the consequences of elimination of ARC KNDy neurons on the effects of estrogen upon the negative feedback control of gonadotropin secretion.[141] Ablation of this neuronal population not only altered negative-feedback responses to estrogen withdrawal and replacement, but also abolished the effects of gonadectomy and estrogen supplementation on body weight. This observation would suggest that the integrity of ARC KNDy pathways is indispensable for the conduction of the anorexigenic action of estradiol and would play an important role in energy homeostasis. However, the nature of the KNDy neuropeptide(s) responsible for such a function is yet to be elucidated.

OTHER CENTRAL TRANSMITTERS IN THE METABOLIC CONTROL OF REPRODUCTION

While the recognition of the essential roles of kisspeptins (and related neuropeptides) in the central control of the HPG axis has driven considerable attention to the

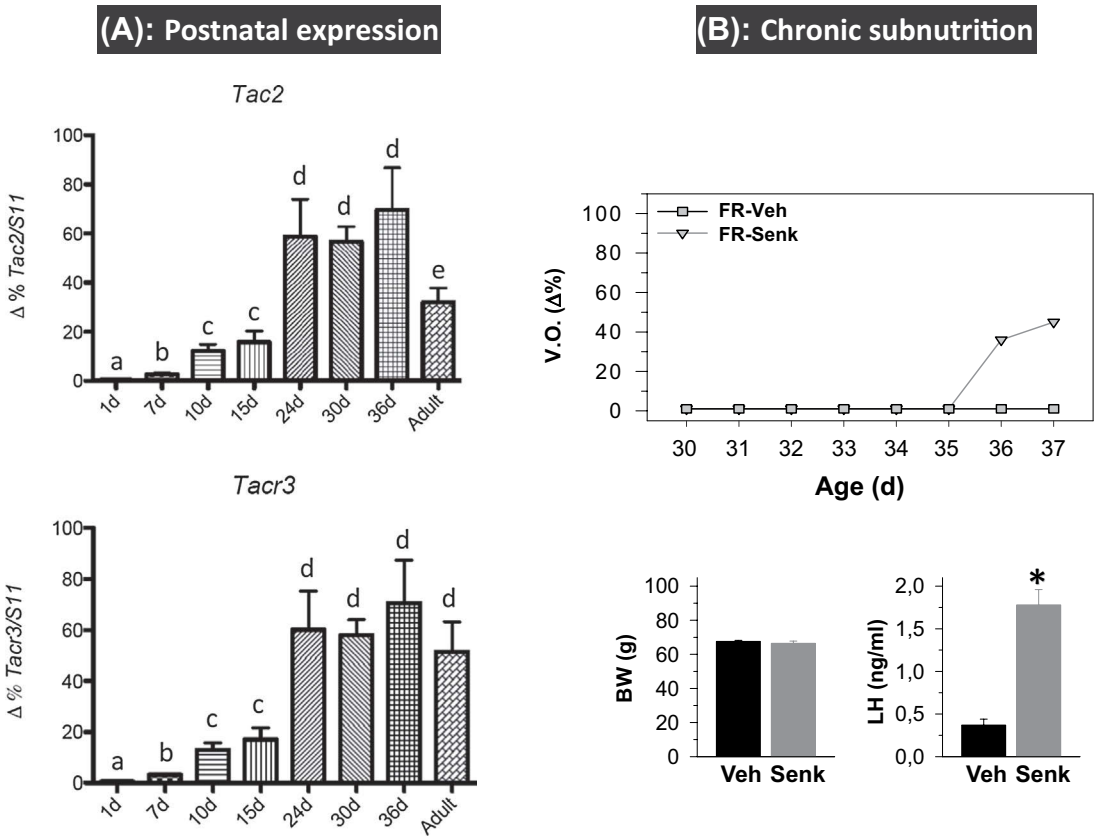

FIGURE 35.5 Characterization of the putative roles of NKB in the control of puberty onset in female rats. The *left panels* (A) show hypothalamic expression levels of the genes encoding NKB (*Tac2*) and its receptor (*Tacr3*) along postnatal maturation and during the pubertal transition. These data illustrate a significant increase in the expression of both hypothalamic genes during the transition between the infantile (<PND21) and juvenile (>PND21) stages. The *right panels* (B) illustrate the effects of repeated central injections of the NKB agonist, senktide, on puberty onset and LH responses in female rats subjected to chronic subnutrition (FR: reduction of 30% in the daily food ration) during the pubertal transition. This regimen of feeding restriction, which induced a drop of ~30% in body weight (BW), was sufficient to cause pubertal arrest, as manifested by lack of vaginal opening (VO) and lowering of basal LH levels in vehicle-treated animals. In this model, repeated central injections of senktide did not change BW but was able to rescue VO in >50% of animals and to induce potent LH responses. Comparison with data from Figure 35.2(B) demonstrate that such effects are remarkably similar to those evoked by kisspeptin replacement in food-restricted pubertal female rats and, together with other results summarized in the section Other Products of KISS1 Neurons in the Metabolic Control of Reproduction: Role of KNDy Neuropeptides, indirectly suggest that NKB cooperates with kisspeptins in the metabolic control of puberty onset. S11: ribosomal protein S11, used as internal control for qPCR assays; PND: postnatal day (age). *Source: Taken from Ref. 140 with modifications.*

analysis of the potential contribution of KISS1 neurons to the metabolic control of puberty and reproduction (see the sections KISS1 Neurons as Central Relays of Metabolic Information: Expression and Functional Studies and Leptin Signaling and KISS1 Neurons: Direct, Indirect, or Independent Effects?), it is clear that other central pathways and transmitters are also involved in this function. In fact, analysis of the available literature strongly suggests that numerous circuits and signals interplay in the dynamic and integrative control of energy homeostasis and reproduction, thus producing a certain degree of redundancy that ensures the best possible adjustment between energy status and reproductive maturation and competence.[4] This redundancy may explain the lack of overt reproductive phenotypes in some models of genetic manipulation of key elements of these regulatory networks, especially when these involve congenital alterations that may trigger developmental compensation. In this section, we provide an account of some of the major transmitters, other than kisspeptins, that have been implicated in the metabolic control of puberty and fertility. Characterization of these central pathways is essential to obtain a complete view on how peripheral metabolic signals impinge on the reproductive brain and ultimately modulate GnRH neuronal function.

As a means of introduction to this section, it is noted that many of the neuropeptides involved in the metabolic control of the HPG axis reviewed herein play an essential role in the central circuits responsible for the regulation of food intake and energy homeostasis.[2] This is well exemplified by the key function of the populations of POMC-cocaine- and amphetamine-regulated transcript (CART) and neuropeptide Y (NPY)– agouti-related peptide (AgRP) neurons (see the sections POMC and CART Neurons and NPY

and AgRP Neurons) that conduct anorexigenic (appetite-suppressing) and orexigenic (appetite-promoting) actions, respectively.[142] These neuronal populations, located in the ARC, are direct primary targets of peripheral metabolic signals, such as leptin, insulin, and ghrelin, and reciprocally interact to transmit to (and modulate) neurons located in other hypothalamic nuclei, which are ultimately responsible to induce either hunger or satiety.[143] In the same vein, the contribution of other hypothalamic areas, such as the ventromedial nucleus or the lateral hypothalamic area (LHA) (the latter is the source of very potent orexigenic signals, such as melanin-concentrating hormone (MCH) and orexins; see the section LHA: MCH and Orexin Neurons), in the control of feeding is well defined.[142] As described in this chapter, these neuronal populations engage also with the central circuits that ultimately regulate GnRH neurosecretory activity and, hence, qualify as potential integrators for the joint control of metabolism, energy homeostasis, and reproductive function. A summary of the major neuropeptide systems reviewed in this section is provided in Table 35.1.

POMC and CART Neurons

Neurons in the ARC expressing the *POMC* gene are well-known first-order neurons (i.e., those primarily sensing peripheral signals to transmit information to other neuronal populations) in the central control of body weight and energy homeostasis,[144] which are sensitive to the regulatory actions of key metabolic hormones, such as leptin, insulin, and ghrelin. In addition, experimental evidence has documented a potential role of this neuronal population in the metabolic control of the reproductive axis, although elucidation of its precise function in this area has been confounded by the divergent roles of the major POMC products, β-endorphin and alpha-melanocyte stimulating hormone (αMSH), in the control of the gonadotropic axis, as well as potential species differences.[144] On the former, β-endorphin has been reported to inhibit GnRH neurons in different experimental conditions,[145,146] whereas αMSH appears to exert predominantly stimulatory effects, although inhibitory actions also have been reported.[4,144] POMC neuronal terminals appear to form synapses with GnRH neurons.

Interestingly, several transgenic models have been generated that allow delineation of the potential role of POMC neurons in the control of the HPG axis. Thus, mice with genetic inactivation of the *POMC* gene or the genes encoding melanocortin receptors 3 and 4 (*Mc3r* and *Mc4r*, respectively), as major receptors for the central effects of αMSH, develop a metabolic (obese) phenotype and subfertility at adult age.[4,147,148] However, the possibility that perturbation of fertility may derive from persistent obesity in those models cannot be excluded. Interestingly, deletion of leptin receptors from POMC neurons failed to cause any reproductive deficit, which would argue against a major role of this neuronal population in transmitting the reproductive effects of leptin.[149] However, the combined elimination of leptin and insulin receptors from these cells induced follicular abnormalities in the ovary, irregularities of the estrous cycle, and late-onset impairment of fertility in female mice.[150] In double-KO males, subfertility was also detected, despite the fact that testicular weights in adulthood were increased, as were also LH levels.[150] A similar finding was also made in double-mutant female mice, which had elevated LH concentrations. One possible explanation for these observations is that the lack of insulin and leptin receptors in POMC neurons decreased β-endorphin output to GnRH neurons, which would cause hyperstimulation of the gonadotropic axis leading to late-onset partial gonadal failure,[144] a possibility that is yet to be fully tested. All in all, these findings would suggest a role of POMC neurons in conveying the combined effects of leptin and insulin to GnRH neurons. Yet the contribution of the metabolic alterations seen in the double-KO model lacking leptin and insulin receptors in POMC neurons to the reproductive phenotype described here cannot be excluded.[4] To our knowledge, the putative role of POMC neurons in transmitting ghrelin effects to the reproductive brain has not been addressed to date.

POMC and KISS1 neurons have been shown to make mutual contacts in the ovine brain, and an agonist of αMSH enhanced *Kiss1* mRNA levels in the POA of sheep, whereas it decreased *Kiss1* expression in the ARC.[151] In addition, in mice, a subset of KISS1 neurons in AVPV express MC4R.[119] Conversely, kisspeptin has been shown to inhibit *POMC* gene expression at the ARC of sheep,[105] while it directly activates ARC POMC neurons in mice.[152] These observations suggest the potential for interplay between POMC and KISS1 pathways in the metabolic control of GnRH neurons. As an additional note, it is emphasized that ARC POMC neurons also express CART, which may also participate in the control of GnRH neurons.[144] In fact, CART fibers have been found in close apposition to GnRH neurons in rats, and a recent report has described that CART can induce depolarization responses, with a modest increase in the firing rate, in approximately 25% of GnRH neurons in mice.[153] Interestingly, the origins of CART afferents to GnRH neurons seem to be diverse and include not only ARC neurons but also neurons from the PMV.[154]

NPY and AgRP Neurons

The population of neurons in the ARC co-expressing NPY and the functional antagonist of melanocortin receptors, AgRP, reciprocally interact with POMC neurons to modulate food intake and energy homeostasis.[4]

TABLE 35.1 Overview of Different Neuropeptides, with Major Roles in the Control of Food Intake and Energy Homeostasis, Which Participate in the Central Control of GnRH Neurons and the HPG Axis

	Site of Neuronal Cell Body	Hormone Regulators	Response to ↓ Energy and ↓ Leptin	Projections	Effects on Food Intake	Effects on LH Levels	Comments
KNDy peptides NKB Dynorphin	ARC	Leptin	↓	KISS1 (auto) GnRH	↑ (DYN)	↑ (NKB) ↓ (DYN)	Important in KP output and GnRH pulsatility
PMV neurons NO/Glu	PMV	Leptin	↓	KISS1 GnRH		↑	Key for transmission of leptin effects

Nesfatin neurons Nesfatin 1	LHA DMH PVN		↓		↓	↑	Critical in puberty onset Receptor(s) unknown

ARC: arcuate nucleus; PMV: ventral premammillary nucleus; LHA: lateral hypothalamic area; DMH: Dorsomedial hypothalamus; SCN: suprachiasmatic nucleus; PVN: paraventricular nucleus; KP: kisspeptin; NKB: neurokinin B; DYN: dynorphin; POMC: proopiomelanocortin; MSH: melanocyte-stimulating hormone; CART: cocaine- and amphetamine-regulated transcript; NPY: neuropeptide Y; AgRP: agouti-related peptide; MCH: melanin-concentrating hormone; NMU–NMS: neuromedin-U and -S; AVP: arginine–vasopressin; NO: nitric oxide; Glu: glutamate. For further information, see the text. Items without conclusive information are marked as an empty box.

**Alarin is an alternatively spliced form of GALP that shares with it a five-amino-acid stretch at the N-terminus.*

Considering their proven sensitivity to key peripheral metabolic regulators, such as leptin and ghrelin, and the existence of appositions of NPY fibers on GnRH neurons,[155] NPY–AgRP neurons seem to be ideally suited for participating in the metabolic control of reproduction. However, the precise nature and specific mechanisms for this function remain contentious, given the diversity of biological effects, signals, and receptors involved.

The participation of NPY in the central control of GnRH neurons has been well documented, yet both stimulatory and inhibitory actions of this neuropeptide on GnRH–gonadotropin secretion have been reported depending on the pattern of administration, developmental stage, sex steroid milieu, and receptor subtype activated.[8,156] This has been nicely illustrated by electrophysiological studies that documented that while porcine NPY (as an agonist of Y1, Y2, and Y5 receptors) inhibited the firing of 45% of GnRH neurons in mice, a combined agonist to Y1, Y4, and Y5 receptors excited as much as 56% of GnRH neurons.[153] Of note, chronic infusions of NPY have been shown to invariably inhibit the gonadotropic axis,[8] a phenomenon that is compatible with a putative role of NPY in the suppression of the GnRH system in adverse metabolic conditions, such as fasting or subnutrition, in which NPY expression increases. Overall, this inhibitory action seems to be conducted via Y1 (but not Y5) receptors, based on pharmacological and functional genomic studies using the Y1 KO mouse.[157–159] In these studies, deletion of this receptor rendered the mice refractory to the inhibitory effects of caloric restriction on the timing of puberty. Such a predominant inhibitory role of Y1 signaling has been recently confirmed by electrophysiological recordings in mouse brain slices ex vivo[153] and pubertal data from Y1 KO mice.[158] Conversely, predominant stimulatory responses to NPY have been associated with preferential activation of Y4 receptors.[153] Yet, the molecular basis for the observed switch between stimulatory and inhibitory effects of NPY is yet to be fully elucidated.

As was described here for POMC neurons, fragmentary evidence suggests the potential interplay between NPY and KISS1 circuits in the central control of the HPG axis. Thus, studies in sheep recently have documented reciprocal innervations between these two populations.[105] In addition, NPY-null mice have been shown to have lower levels of *Kiss1* mRNA in the hypothalamus and failed to display the expected suppression of *Kiss1* mRNA expression associated with fasting,[98] findings that are suggestive of a stimulatory role of NPY signaling in the control of *Kiss1* expression in vivo. This contention is further supported by a demonstration of stimulatory effects of NPY on *Kiss1* RNA levels in the hypothalamic cell line, N6, in vitro.[98] In turn, sheep studies have shown that kisspeptin increased *Npy* gene expression in the ARC,[105] while in the murine NPY-secreting cell, embryonic mouse hypothalamus cell line 38, kisspeptin was able to increase *Npy* mRNA levels and NPY secretion in vitro.[160] Of note, such a reciprocal stimulatory interaction between NPY and kisspeptin is somewhat counterintuitive, given the fact that conditions of negative energy balance, linked to suppressed *Kiss1* expression, are associated with an increase in the endogenous tone of NPY. In fact, since leptin has been shown to suppress the expression of NPY at specific neuronal populations in the ARC,[161] NPY is not likely to operate as a mediator for the stimulatory effects of leptin on KISS1 neurons but, rather, is likely to act as independent modulator. In any event, it is also known that under certain physiological and experimental conditions, NPY may drive a stimulatory signal to the GnRH system,[162] an effect that may be eventually mediated via kisspeptin afferents.

NPY neurons in the ARC also express AgRP, a functional antagonist of melanocortin receptors, and the inhibitory transmitter, gamma-aminobutyric acid, both of which also may participate in the regulation of GnRH neurons. In line with its expected role as antagonist of αMSH actions, AgRP has been shown to induce inhibitory responses, in terms of LH secretion, in female rats and monkeys.[163,164] Yet, stimulatory effects of AgRP on GnRH and gonadotropin secretion have been reported in male rats.[165] This complexity is further illustrated by recent electrophysiological studies in female mice that demonstrated the ability of AgRP to induce inhibitory or stimulatory responses in subsets of GnRH neurons ex vivo.[153] Of note, a recent report showed that ablation of AgRP neurons in leptin-deficient mice was sufficient to restore metabolic homeostasis and fertility[166]; the latter finding suggests that elimination of a single inhibitory signal—namely, AgRP—activated by the lack of leptin would be sufficient to rescue the reproductive deficit induced by the absence of the adipose hormone. Yet, it remains possible that, at least partially, the foregoing phenomenon may derive from elimination of NPY inputs from the same ARC neurons. To our knowledge, the potential interplay between AgRP and kisspeptin signaling in the control of the reproductive axis has not been documented to date.

PMV Neurons

As described in this chapter, the PMV has now been recognized as a key center for transmitting metabolic information, mainly via leptin signaling, to GnRH neurons. Experimental evidence supporting such a role has been summarized in the section Leptin Signaling and KISS1 Neurons: Direct, Indirect, or Independent Effects? It is emphasized, however, that the pathways and transmitters utilized by PMV neurons to modulate GnRH

secretion have not been totally elucidated; yet evidence has been presented that a subset of PMV neurons, which express functional leptin receptors and innervate GnRH neurons and terminals, co-express the neurotransmitters glutamate and nitric oxide, which may operate as effector signals.[122,167,168] It is noted, though, that PMV neurons are a mixed population and some of the projections to GnRH might not be subjected to leptin–metabolic regulation.[4] It is equally noticeable that some PMV neurons seem to innervate KISS1 neurons, so that their regulatory actions on GnRH neurons might use an intermediate kisspeptin pathway.[4]

GALP Neurons

Another transmitter putatively involved in the central control of metabolism and reproduction is galanin-like peptide (GALP). Within the central nervous system, this neuropeptide is almost exclusively restricted to the ARC, where its expression is inhibited by conditions of metabolic stress and negative energy balance, such as fasting and experimental diabetes, and stimulated by key metabolic hormones, such as insulin and leptin.[3,169,170] In addition, intracerebral injections of GALP have been shown to induce LH secretory responses in a variety of species, including the rat, mouse, and macaque.[169–171] Furthermore, GALP administration was able to rescue puberty onset in food-restricted female rats,[172] as well as to normalize reproductive function in uncontrolled diabetic rats.[173] On this basis, GALP has been suggested to act as a transmitter of metabolic information to GnRH neurons.[169,170] This action might involve its capacity to modulate *Kiss1* expression in the ARC, since central injection of GALP to food-restricted rats, which displayed the expected decrease in *Kiss1* mRNA expression, was sufficient to normalize *Kiss1* mRNA levels.[172] Yet the effect of GALP might not be directly conducted in KISS1 neurons, as intracerebral infusion of GALP apparently failed to induce c-FOS in this neuronal population.[172] The physiological relevance of GALP in the metabolic control of puberty and fertility has been partially questioned by the lack of overt reproductive phenotypes of mouse models with genetic inactivation of either GALP or its major receptors, GALP receptors 2 and 1 (GALR2 and GALR1, respectively).[174,175] Notwithstanding, developmental compensatory events might have taken place in those models of congenital elimination of some elements of the GALP signaling cascade, so that other pathways, including KISS1, may overcome the lack of GALP effects. Hence, although dispensable for the central control of the HPG axis, it remains fully possible that GALP significantly contributes, in cooperation with other pathways, in the metabolic regulation of puberty and reproduction in the adult. Of note, a novel peptide product encoded by a splice variant of *Galp* mRNA, termed alarin, recently has been shown to stimulate feeding and to increase LH secretion by promoting GnRH release,[176] and hence may contribute to the joint control of energy homeostasis and gonadotropic function by GALP-expressing neurons.

LHA: MCH and Orexin Neurons

The LHA is known to play important roles in the control of energy homeostasis and to participate in the neuroendocrine control of reproduction; hence, circuits from the LHA would be well suited for the integrative control of metabolism and fertility.[177] Among the various signals arising from the LHA, two groups of orexigenic neuropeptides, namely, MCH and the orexins—of which two major forms, OXA and OXB, exist—have drawn considerable attention as potential metabolic-reproductive integrators. Concerning MCH, electrophysiological studies demonstrated the ability of this neuropeptide to potently suppress the electrical activity of a subpopulation of septal GnRH neurons in mice,[178] a species where neuroanatomical analyses have shown MCH-positive fibers in the vicinity of GnRH neurons.[178] Moreover, MCH is able to block the excitatory effects of kisspeptin on the septal population of GnRH neurons ex vivo,[178] yet other interactions between the MCH and KISS1 systems (e.g., at the transcriptional level) have not been reported to date. In any event, the available data would support a role of MCH circuits in the integrative control of energy balance and reproduction.

Orexins were first identified as feeding-promoting neuropeptides.[177] In addition, orexins are also known to participate in the central control of a wide array of biological functions, including the regulation of the sleep–wake cycle and arousal states,[179] as well as in the control of various neuroendocrine systems, including the HPG axis.[177] Regarding the latter, hypothalamic GnRH neurons have been shown to express the orexin receptor (OX1R) and to receive direct contacts from orexin fibers.[180,181] In addition, OXA was reported to stimulate GnRH release from rat hypothalamic explants.[182] However, the net effects of orexins on LH secretion appear to be region specific; for example, OXA stimulates gonadotropin release by acting on the hypothalamic POA but suppresses LH by acting in the ARC.[181] These actions of OXA are also dependent on the prevailing sex steroid background. Thus, central injection of OXA stimulated LH release in steroid-primed ovariectomized rats but decreased LH secretion in the absence of ovarian steroids.[183,184] In addition, OXA has been reported to inhibit GnRH-induced LH release by dispersed pituitary cells.[182] All in all, while the above data support a function of orexin pathways in the central control of the gonadotropic axis, the actual physiological relevance of orexins in its regulation by metabolic cues is yet to be fully elucidated.

RF-Amide Related Peptides: RFRP3 and 26/43RFa

RF-amide peptides form a large family of ligands, displaying a distinctive Arg–Phe–NH_2 motif in their carboxyl terminus, which was initially discovered in invertebrates. In mammals, five major groups of RF-amide peptides have been described: kisspeptins, RF-releasing peptides 1 and 3 (RFRP1 and RFRP3, respectively), neuropeptides FF and AF, prolactin-releasing peptide, and the 26/43RFa peptides. Among these, RFRP3, the mammalian ortholog of the avian gonadotropin-inhibitory hormone (GnIH), has drawn considerable interest, as it has been shown to function as a putative inhibitory signal for the HPG axis in different mammalian species,[185–188] acting probably at both central (likely on GnRH neurons) and pituitary levels; further details on the physiological roles of the RFRP3–GnIH system can be found in Chapter 11 on the GnRH neuronal network. Indeed, the fact that both kisspeptin and RFRP3 belong to the superfamily of RF-amide peptides but conduct opposite actions on the HPG axis has led to the proposal that the reciprocal interplay between these two structurally related neuropeptides is essential for the control of reproductive function.[189] While the physiological relevance of such a balance is yet to be fully defined, it is interesting to note that RFRP3 may participate also in the regulation of energy balance, because of its ability to stimulate food intake,[190] and that this action is opposite to that of kisspeptin, which according to some reports inhibits feeding[152]; however, the latter has not been confirmed by independent studies.[95,191] This metabolic dimension of RFRP3 is suggestive of a putative role of this transmitter in linking energy balance and reproduction. To add further strength to this possibility, electrophysiological studies have demonstrated the ability of RFRP3 to blunt the excitatory effects of kisspeptin on POMC neurons.[152]

Of note, the role of RF-amide peptides, other than RFRP3 (and kisspeptins), in the integrative control of metabolism and reproduction has also been addressed, even though the available information is still scarce. In this regard, the additional members of the mammalian RF-amide superfamily, 26RFa and 43RFa, which are orexigenic neuropeptides, have been shown to regulate gonadotropin secretion at hypothalamic and pituitary levels,[192,193] yet their potential interplay with other central transmitters involved in the control of metabolism and reproduction has not been explored to date. In addition, another mammalian RF-amide peptide, the prolactin (PRL)-releasing peptide, has been shown to stimulate LH secretion in female rats,[194] and to cooperate with leptin to suppress body weight and food intake.[195] However, the physiological relevance of this PRL-releasing peptide in the metabolic control of reproduction has not been explored.

Neuronal Efferents from the SCN

The suprachiasmatic nucleus (SCN) plays an essential role in the control of biological rhythms. Because these rhythms are tightly connected with both the function of the HPG axis and metabolic homeostasis, several studies have addressed the reproductive roles of transmitters coming from the SCN. The biological profiles of such transmitters, with proven roles in the control of rhythms and energy balance, make them optimal candidates for linking the seasonal and photoperiodic control of metabolism, puberty, and fertility. This is the case for neuromedin-U (NMU) and neuromedin-S (NMS), which are SCN-enriched peptides with the abilities to suppress food intake and to modulate gonadotropin secretion, acting at central levels, in various physiological conditions.[196,197] Similarly, prokineticin-2 (PK2), which is abundantly expressed in the SCN, has been shown to suppress food intake,[198] to regulate energy balance,[199] and to stimulate LH secretion (author's unpublished data); to what extent these functions are connected and contribute to the metabolic regulation of the HPG axis is unknown. On the other hand, the SCN has been shown to target KISS1 neurons in Syrian hamsters via afferents expressing vasopressin (AVP), a transmitter that seems to play an important role in the generation of the preovulatory surge of gonadotropins in this species.[200] Since AVP has been linked to the control of feeding behaviors and since conditions of negative energy balance (such as 48 h fasting) induced a significant suppression of AVP content in discrete hypothalamic nuclei,[201] it is possible that AVP may provide an additional link between energy status and some important aspects of the function of the HPG axis, such as the preovulatory surge of gonadotropins.

Other Central Pathways: Nesfatin 1 and SF1 Neurons

Other central transmitters also participate in the integrative control of energy homeostasis, metabolism, and the reproductive axis. This is likely the case for nesfatin 1, one of the peptide products of the gene nucleobindin 2 (*Nucb2*) that acts as an anorectic signal in the hypothalamus.[202,203] The relevance of the metabolic function of this peptide is suggested by its expression in hypothalamic areas with key roles in the control of food intake, such as the ARC, the PVN, and the LHA.[203] Very recently, nesfatin 1 has been shown to participate also in the control of female puberty in the rat. Thus, hypothalamic NUCB2–nesfatin 1 expression was reported to increase during the pubertal transition, while conditions of negative energy balance known to perturb puberty, such as chronic subnutrition or short-term fasting, decreased hypothalamic *Nucb2* mRNA and protein levels in pubertal females.[204] In addition, central injection of pmol doses of nesfatin 1 evoked significant

increases of serum LH levels in peripubertal female rats.[204] Conversely, suppression of the endogenous tone of nesfatin 1 in the hypothalamus during the pubertal transition, using an antisense morfolino oligonucleotide (as-MON) against NUCB2, delayed the timing of puberty and lowered LH levels and ovarian weights. Interestingly, studies in adult female rats did not detect gonadotropin responses to central injection of nesfatin 1 at doses that were effective in peripubertal rats, nor did infusion of as-MON against NUCB2 affect spontaneous preovulatory surges of LH and FSH.[204] However, recent preliminary data indicate that, at higher doses, nesfatin 1 can stimulate LH secretion in adult male rats[205] as well as in adult mice (Navarro, Ruiz-Pino, & Tena-Sempere, unpublished observations). Altogether, these features qualify nesfatin 1 as a putative effector for the metabolic regulation of puberty and gonadotropic function.[203] In keeping with this view, preliminary data from my laboratory suggest that blockade of endogenous nesfatin 1 tone, by the use of as-MON against NUCB2, induces a suppression of *Kiss1* gene expression in the ARC and AVPV in pubertal female rats, whereas absence of KISS1R signaling (i.e., in *Kiss1r*-null mice) blocked LH responses to nesfatin 1 (Navarro, Ruiz-Pino, & Tena-Sempere, unpublished observations). The latter suggests a putative interplay between nesfatin 1 and kisspeptin pathways in the central control of the HPG axis, which may be relevant for its modulation by metabolic cues.

Neuronal circuits from the VMH are likely to operate also as a connection center linking energy status and reproduction. In this area, neurons expressing SF1, which are the predominant population in the VMH, seem to be involved in this joint control.[144] SF1 neurons are essential for energy homeostasis, as revealed by the generation of brain-specific SF1 KO mice, which develop obesity due to dearrangement of the VMH.[206] In addition, neurons from VMH have been shown to project to GnRH neurons, and SF1-null female mice display impaired fertility due to inappropriate gonadotropic secretion.[207] The metabolic and reproductive phenotypes of SF1 KOs are roughly similar to those of mice with selective, congenital elimination of ERα from SF1-expressing cells.[79] These findings indirectly suggest a role of estrogen signaling in SF1 neurons at the VMH in the integrative control of energy balance and reproduction. The effectors of SF1 neuronal actions in the regulation of reproduction and their eventual interplay with other central transmitters involved in the metabolic control of the HPG axis are yet to be elucidated.

MOLECULAR MEDIATORS FOR THE CENTRAL CONTROL OF THE HPG AXIS BY METABOLIC SIGNALS

Besides the elucidation of the entire repertoire of peripheral hormones and central transmitters involved in the metabolic control of puberty onset and fertility, considerable attention has been devoted recently to the identification of the molecular mediators linking these sets of peripheral and central signals. These include cellular metabolic gauges that participate in the control of the HPG axis and its regulation by peripheral hormones and metabolic cues, and other molecular cascades that mediate the regulatory effects of different signals (hormones and neuropeptides), which act on key neuronal populations governing the reproductive axis. Altogether, progress in this area has allowed the characterization of the putative roles of several cellular energy sensors, intracellular kinases, ion channels, and transcription factors as mediators for the metabolic control of the major hypothalamic networks governing the reproductive axis. To illustrate the progress in this area, some examples, such as the mammalian target of rapamycin (mTOR), the adenosine monophosphate (AMP)-activated protein kinase (AMPK), the cAMP responsive element-binding protein 1 (CREB1)-regulated transcription coactivator-1 (CRTC1; also termed transducer of regulated CREB1, or TORC1), phosphatidyl-inositol-3 kinase (PI3K), and adenosine triphosphate–sensitive potassium (K-(ATP)) channels, are described in this section.

mTOR has been shown to operate as a cellular metabolic gauge,[208–212] and it seems to mediate some of the effects of leptin in the central control of food intake.[213,214] Experimental evidence obtained in rats strongly suggests that mTOR is also involved in conveying aspects of the regulatory effects of leptin on the reproductive brain, at least in part due to its ability to regulate *Kiss1* expression. Thus, activation of mTOR by central injection of L-leucine, which is one of the major elicitors of mTOR activity, partially reversed the state of hypogonadotropism induced by chronic subnutrition and the resulting low leptin levels.[101] Conversely, persistent blockade of central mTOR signaling delayed the onset of puberty and reduced LH levels; yet this was not caused by a primary effect at GnRH neurons, since they retained their responsiveness to key activators of the gonadotropic axis, such as kisspeptins, which was preserved following mTOR blockade. Importantly, central inhibition of mTOR signaling prevented the positive effects of leptin on puberty onset in a model of caloric restriction.[101] The effects of mTOR inhibition are probably related to a substantial suppression of *Kiss1* mRNA levels in key hypothalamic centers, such as the ARC and, to a lesser extent, the AVPV.[101] Altogether, these observations suggest that leptin may conduct at least part of its regulatory effects on the KISS1 system via the mTOR pathway, which would thereby participate in the metabolic control of puberty onset and fertility (see Figure 35.6). Importantly, these regulatory actions of mTOR do not necessarily occur within KISS1 cells but may take place in intermediate neuronal pathways. In fact, preliminary

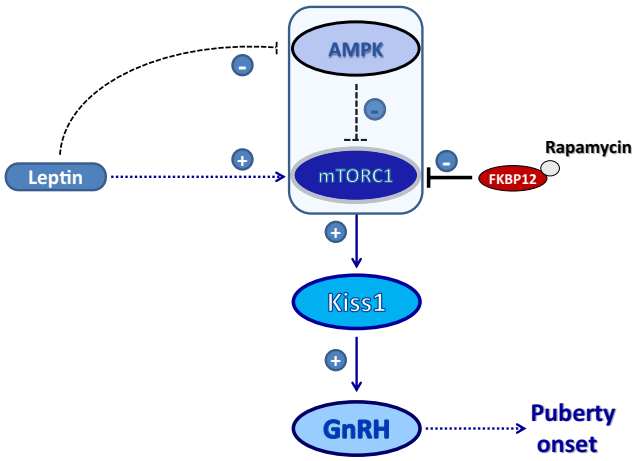

FIGURE 35.6 Tentative model for the potential role of brain mammalian target of rapamycin (mTOR) signaling in the metabolic control of puberty. Leptin, as a key peripheral metabolic signal, is known to modulate hypothalamic mTOR signaling, which mediates part of its regulatory actions in energy homeostasis. In the same vein, experimental evidence suggests that central mTOR may participate in conveying at least part of the actions of leptin on the reproductive brain. This action is likely to involve the regulatory effect of mTOR on *Kiss1* expression, as a major regulatory afferent to GnRH neurons, since blockade of brain mTOR activity not only delayed puberty but also suppressed *Kiss1* mRNA levels in key hypothalamic nuclei, such as the ARC. All in all, the pharmacological and expression data gathered to date strongly suggest that rapamycin-sensitive mTORC1 signaling may operate, in conjunction with other energetic sensors such as AMPK, as a transmitting hub that provides a putative molecular link between peripheral signals and central neuropeptide effectors in the metabolic control of the HPG axis. For further details, see the text. *Source: Taken from Ref. 87, with modifications.*

evidence suggests that a key downstream element of the mTOR cascade, phosphor S6, is not present in KISS1 neurons, therefore suggesting an indirect mode of action of mTOR signaling in the control of the KISS1 system.[108] Of note, mTOR has been suggested to mediate the central metabolic effects of other key hormones, such as ghrelin.[215] Whether the ability of ghrelin to modulate central mTOR signaling is important for its effects on the HPG axis warrants specific investigation.

Another brain fuel-sensing mechanism that might also participate in the central control of the HPG axis is the one involving AMPK, a member of the metabolite-sensing protein kinase family.[216,217] AMPK detects changes in the AMP:ATP ratio and hence in the cellular metabolic state. Thus, in conditions of energy deficit, when ATP is consumed and excess AMP accumulates in the cell, AMPK becomes activated, thus causing the phosphorylation and inactivation of diverse ATP-consuming metabolic cascades. As described for the mTOR pathway, brain AMPK signaling has been suggested to play a pivotal role as a regulator of energy balance and food intake. Activation of AMPK stimulates appetite,[218,219] and leptin has been shown to suppress hypothalamic AMPK activity, whereas ghrelin stimulates it.[220] Interestingly, AMPK and mTOR are mutually regulated (e.g., AMPK inactivates mTOR in different cell systems),[210,221] and hence these two metabolic cell sensors have been proposed to reciprocally cooperate in the central control of energy homeostasis.[213] In this context, it is tempting to hypothesize that this interaction also applies to the metabolic regulation of the HPG axis. While this is yet to be fully proven, indirect evidence would support this possibility, as AMPK activation inhibited GnRH secretion in murine GT1–7 cells in vitro and altered estrous cyclicity, resulting in a modest but detectable change of the interval between consecutive estrous stages in rats.[73,222] In the same vein, our preliminary data suggest that activation of central AMPK signaling delays puberty onset and partially inhibits hypothalamic *Kiss1* expression in the ARC (Roa, Ruiz-Pino, & Tena-Sempere, unpublished observations). All in all, these observations are compatible with a predominant inhibitory role of AMPK pathways in the central control of reproduction, which is in line with its proposed role as a sensor of energy insufficiency and a functional antagonist of mTOR.

Another putative molecular mediator for the metabolic control of the reproductive axis is CRTC1. Evidence for the metabolic and reproductive roles of this transcription factor was provided in 2008, when the phenotypes of CRTC1-null mice were described. These animals were shown to display hyperphagic obesity and infertility.[223] The underlying mechanisms proposed for such a combined alteration of energy homeostasis and reproduction seem to involve the impairment of leptin's capacity to stimulate the expression of the genes encoding CART (which operates as an anorexigenic neuropeptide) and kisspeptins. Leptin has been reported to dephosphorylate and activate CRTC1, which in turn stimulates the recruitment of CRTC1 to *Kiss1* gene promoter. In addition, dephosphorylation of CRTC1 enhanced *Kiss1* gene expression in GT1–7 cells, and CRTC1 overexpression increased *Kiss1* promoter activity.[223] While these observations suggest that CRTC1 may be a molecular node for the integration of metabolic information, and specifically leptin signaling, in KISS1 neurons, this possibility is at odds with the proposed indirect mode of action of leptin on KISS1 pathways (see the section Leptin Signaling and KISS1 Neurons: Direct, Indirect, or Independent Effects?). Moreover, it is noted that an independent report was unable to replicate the consequences of functional inactivation of CRTC1 on mouse fertility.[224] These recent observations therefore warrant the reevaluation of the actual physiological roles of CRTC1 in mediating leptin effects on the HPG axis. Similarly, whether CRTC1 may participate in the central transmission of the reproductive effects of metabolic hormones other than leptin is yet to be defined.

The roles of PI3K have also been evaluated as a potential conduit for the metabolic regulation of the HPG axis. PI3K signaling participates in transmitting the biological effects of leptin and insulin in peripheral metabolic tissues and the brain. An excellent review of the major features of this signaling cascade and its role in metabolism can be found elsewhere.[3] As described in other sections of this chapter, some elements closely related with the PI3K signaling pathway, including ERα, the IGF-I receptor, insulin and leptin receptors, and mTOR, have key roles in the metabolic control of the reproductive brain.[3] Hence, the involvement of PI3K in this function has been addressed by the generation of genetically modified mouse models with selective deletion of key regulatory–adapter or catalytic subunits of PI3K, such as Class-IA, in specific neuronal populations. These studies have revealed that selective elimination of PI3K signaling in POMC or AgRP neurons did not cause an overt reproductive phenotype, therefore arguing against a major, indispensable role of this signaling molecule in mediating reproductive regulatory actions in these neuronal populations. Nonetheless, genetic disruption of PI3K signaling in cells expressing leptin receptors has been shown to prevent leptin effects on key cellular functions in POMC and AgRP neurons in the ARC,[225] as well as in the PMV.[226] Whether PI3K signaling plays a role in the regulation of other neuronal populations, such as KISS1 neurons, which also are sensitive to sex steroid modulation, is yet to be defined.

Because of the known functional properties of leptin receptors in different metabolic tissues, the role of leptin-induced STAT3 signaling in the central control of the HPG axis has been studied.[4] By the use of genetically modified mouse models, it has been demonstrated that, while elimination of STAT3 signaling from the brain results in lack of pubertal maturation and infertility, selective ablation of STAT3 from neurons expressing leptin receptors is compatible with the proper development of reproductive organs and cyclic ovarian function in mice.[227] This suggests that STAT3-independent pathways are activated by leptin in the brain to conduct (at least part of) their effects on the reproductive axis. In addition, these findings point out also that brain STAT3 signaling, activated by factors other than leptin, does participate in the control of puberty and fertility.[4] The nature of such putative regulators of STAT3 is yet to be deciphered.

Finally, the specific role of the K-(ATP) channel, as a mediator of glucose sensing and several neuronal actions of insulin and leptin, in the control of GnRH and LH secretion has been studied by a combination of pharmacological and genomic approaches.[228,229] In this sense, it has been hypothesized that low glucose availability would lead to activation of K-(ATP) channels and, hence, suppressed activity of key neuronal populations governing the HPG axis.[229] In fact, GnRH neurons have been shown to express the K-(ATP) channel subunits, and the blocker of this channel, tolbutamide, depolarized (activated) GnRH neurons and induced GnRH and LH secretion,[228,229] suggesting the potential involvement of K-(ATP) channels in the metabolic control of the HPG axis and its suppression in conditions of low glucose levels. Alternatively, it has also been proposed that low leptin and/or insulin levels in adverse metabolic conditions may lead to reduced K-(ATP) channel activation and, hence, increased activity of key inhibitory afferents of GnRH neurons, such as POMC neurons, which abundantly express this channel.[230] However, fasting-induced inhibition of LH release has been shown to occur in K-(ATP) channel deficient mice, suggesting that this is not an obligatory element for mediating the effects of negative energy balance on GnRH–LH secretion.[229]

REPRODUCTIVE EFFECTS OF METABOLIC HORMONES OUTSIDE THE BRAIN: PITUITARY AND GONADAL ACTIONS

As described in this chapter, a substantial component of the regulatory mechanisms that link metabolism and reproduction takes place at central (mainly hypothalamic) levels by targeting ultimately the GnRH system. However, compelling experimental evidence has demonstrated that metabolic hormones influencing reproductive function, such as leptin, insulin, and ghrelin, also produce biological actions at levels of the HPG axis other than the brain. Because of the focus of this book section, exhaustive review of such *peripheral* actions is clearly beyond the scope of this chapter and can be found elsewhere.[7,22,231] Notwithstanding, some comments on these effects at other levels of the HPG axis will be included in this chapter section in order to illustrate the complexity and diversity of the mechanisms underlying the metabolic–reproductive interactions.

Leptin, insulin, and ghrelin have been reported to act directly at the pituitary, and their actions at this level include the capacity of the three hormones to modulate gonadotrope function and to regulate LH secretion and/or responsiveness to GnRH.[7,8,22] The relative importance of such direct pituitary effects for the metabolic actions of these hormones had been partially neglected, but very recent reports on the impact of selective deletion of leptin receptors in pituitary somatotropes strongly suggest that pituitary cell types, such as GH-secreting cells, can act as metabolic sensors[232]; whether the same applies to gonadotropes is yet to be evaluated. In any event, leptin has been shown to stimulate gonadotropin secretion acting directly at the pituitary level,[233] but the magnitude

of these responses is rather marginal and their metabolic relevance unclear. Likewise, insulin has been reported to directly stimulate LH secretion at the pituitary; this stimulatory effect may be associated with the state of LH hypersecretion seen in patients with polycystic ovarian syndrome (PCOS).[234] The pathophysiological relevance of the direct gonadotropic effects of insulin has been unveiled recently by functional genomics studies showing that selective elimination of insulin receptors from pituitary gonadotropes prevents obesity-induced infertility in female mice.[235] Nonetheless, it is also noted that, in contrast to findings in diet-induced obese mice, pituitary-specific insulin receptor elimination did not cause any detectable alterations of the reproductive axis in basal (lean) conditions.[235] This observation suggests that the physiological relevance of the direct pituitary effects of insulin on gonadotropes, apart from extreme metabolic conditions of obesity, might be modest.

Ghrelin also has been shown to act directly at the pituitary to modulate gonadotropin secretion.[236] The actions of ghrelin at the pituitary appear to involve both stimulatory and inhibitory effects. Thus, ghrelin has been shown to partially suppress GnRH-induced LH secretion by rat pituitaries in vitro. However, direct stimulatory effects of ghrelin on basal LH and FSH secretion by pituitary tissue have been also described in the rat in different physiologic conditions, such as at the various stages of the ovarian cycle and during puberty.[58,236] Such stimulatory action seems to be at odds with the predominant inhibitory effect of systemic ghrelin in the control of gonadotropin secretion. One possibility to reconcile these data is that the above stimulatory effects might derive from the actions of locally produced ghrelin, since gonadotropin stimulation appears to require high ghrelin concentrations,[236] and expression of ghrelin has been reported in the pituitary.[237] However, metabolic regulation of the expression of such pituitary-born ghrelin, and its physiological relevance in linking the energy status and reproduction, are yet to be defined.

Both direct stimulatory and inhibitory actions of leptin and insulin on different aspects of gonadal function have been reported.[7,234,238] Of interest, rodent studies have documented leptin concentrations in the range of those of obese patients can directly inhibit testicular and ovarian steroidogenesis[239,240]; this action was initially considered paradoxical, given the net stimulatory and permissive effect of the adipose hormone in the control of the HPG axis.[238] In any event, such direct inhibitory actions of leptin on some aspects of gonadal function, such as sex steroid secretion, may contribute to the state of hypogonadism commonly associated with conditions of persistent hyperleptinemia, such as morbid obesity.[7] Similarly, as discussed in more detail in Chapter 29 on pathophysiology of the menstrual cycle, hyperinsulinemia has been proposed as a direct contributing factor for ovarian dysfunction and elevated androgens in patients with PCOS.

In the same vein, expression of ghrelin and its canonical receptor, the GHS-R type 1a, has been reported in the testis and the ovary of numerous species, and different studies have documented the ability of ghrelin to directly act at the testicular or ovarian levels to modulate gonadal function.[22] Thus, ghrelin has been shown to inhibit human choriogonadotropin (hCG)-stimulated testosterone secretion by testicular tissue ex vivo, and to partially suppress the expression of genes encoding key steroidogenic factors, such as steroidogenic acute regulatory (StAR) protein, cytochrome P450 side chain cleavage (P450scc), 3β-hydroxy steroid dehydrogenase (3β-HSD), and testis-specific 17β-HSD type III.[241] In line with such putative inhibitory action, ghrelin expression in Leydig cells has been shown to inversely correlate with testosterone levels in men,[242] and ghrelin was reported to suppress the proliferative activity of immature Leydig cells in rat testis.[243] In the case of the ovary, several studies have documented the ability of ghrelin to decrease estradiol and progesterone secretion by cultured human or porcine granulosa–lutein cells.[244–246] In addition, ghrelin may influence additional relevant ovarian functions, including peptide hormone secretion, proliferative activity, and/or apoptosis.[247–249] Notably, other factors with key roles in metabolism and body weight homeostasis, such as resistin, adiponectin, orexin, and nesfatin 1, just to mention some relevant examples, are also expressed and/or act directly in the gonads.[7,250–253] In any event, the pathophysiological relevance of such gonadal expression and actions remains ill defined.

CONCLUSION

In recent decades, a wealth of epidemiological, clinical, and experimental data has substantiated the close connection, long anticipated on the basis of intuitive knowledge, between metabolism, body energy stores, and different aspects of reproductive maturation and function. This association manifests in a wide spectrum of conditions, and has not only important physiological implications but also considerable pathophysiological interest. Indeed, the escalating incidence of human disease or conditions resulting in metabolic disorders, ranging from anorexia to morbid obesity and diabetes, is likely to become (if it is not already) a major threat for human reproductive health. In turn, prevalent reproductive disorders, including PCOS and alterations of puberty, also have a discernible impact on body weight and metabolism, and could hence contribute to the deterioration of the metabolic health of human populations. This evidence has made it mandatory to gain a deeper understanding of the physiological mechanisms

whereby metabolism and reproduction are reciprocally connected.

These efforts have allowed the characterization of the reproductive effects of a large number of peripheral hormones with key roles in the control of metabolism and body weight homeostasis, including leptin, insulin, and ghrelin. Admittedly, this trio is likely to play a major role in transmitting metabolic information to the different levels of the HPG axis. Notwithstanding, it is highly probable on the basis of the available data that additional factors, with important roles in the control of metabolism, also participate in the regulation of various facets of reproductive maturation and function, thereby defining novel regulatory axes whose existence was not documented until very recently.

In the same vein, additional efforts are anticipated in the characterization of the central pathways responsible for transmitting metabolic information to GnRH neurons. The recognition of the inability of GnRH neurons to directly sense changes in key metabolic hormones, such as leptin and insulin, has led to the analysis of different neuropeptide pathways putatively involved in transmitting metabolic information to this neuronal population. In this context, the emergence of kisspeptin as a major regulator of GnRH secretion drew considerable attention to the possibility that specific populations of KISS1 neurons in discrete hypothalamic areas would operate as sensors and transmitters of metabolic cues to GnRH neurons.[1] While the influence of various metabolic hormones, such as leptin and ghrelin, and different conditions of metabolic stress, ranging from short-term fasting to chronic obesity, on the expression and function of the hypothalamic KISS1 system has been thoroughly documented in the last few years, recent evidence has challenged the view that (at least some of) these actions are directly conducted on KISS1 neurons. These studies thus suggest the presence of intermediate afferents responsible for the central transmission of metabolic information to KISS1 neurons, whose nature is yet to be elucidated. It is emphasized, though, that most of the efforts on this front have so far been restricted to the analysis of the actions of leptin, using mainly congenital genetically modified mouse models. Hence, further studies addressing the mode of actions of other peripheral regulators and the generation of even more sophisticated models, such as cell-specific, inducible KO mouse lines, in addition to comparative studies in other species, are needed to fully characterize this phenomenon. In addition, the relative importance of KISS1-dependent versus KISS1-independent circuits in the metabolic control of GnRH neurons needs to be defined. In parallel, it is foreseen that our knowledge of the entire repertoire of central transmitters involved in the metabolic control of reproduction will enlarge in the coming years. This information will also be valuable from a pharmacological perspective, as it will allow us to better characterize the spectrum of biological actions of a number of neuropeptides with potential as therapeutic targets.

The mechanisms whereby metabolic information is integrated within the reproductive circuits have been partially elucidated recently, but our understanding of the precise molecular pathways involved is still incomplete. The mTOR–AMPK duo is likely to play an important role in the central control of energy homeostasis and reproduction, but understanding of the function of AMPK signaling in this context is still incomplete, and the neuroanatomical circuits in which mTOR and/or AMPK are operating are not fully clarified. In the same vein, while the roles of PI3K in mediating the central effects of leptin in the control of body weight and metabolism have been examined by the use of genetically modified mouse models, whether (and, if so, where) PI3K signaling participates in mediating leptin effects on the reproductive brain is yet to be elucidated. Furthermore, the male-biased role of PI3K in the control of GnRH function is intriguing, and its basis and functional implications warrant further investigation. Similarly, whether STAT3 has any role in mediating the reproductive actions of leptin in physiological conditions, as well as the putative function of the transcription factor CRTC1, need further analysis and clarification. Likewise, the molecular mechanisms and primary sites of action of other key metabolic regulators of the reproductive brain, such as insulin and ghrelin, remain ill-defined and will probably attract considerable attention in the future.

In the context of metabolic–reproductive interactions, the effects and mechanisms of action of gonadal steroids on the systems controlling energy balance and food intake have not been completely characterized and will require attention in the future.[78] In this sense, although sex steroids are well-known modifiers of metabolism and body weight, the molecular basis for such a function is, to a large extent, unknown. Anyhow, important progress has taken place recently in the dissection of the primary sites of action of estrogen in the central control of energy homeostasis and reproduction. This work not only confirms the importance of central estrogen signaling in the control of feeding and energy expenditure, a phenomenon with potential implications in menopause-associated metabolic changes, but also demonstrates that distinct neuronal populations play different roles in the integrated control of different aspects of metabolic and reproductive homeostasis. The latter paves the way for the identification of the neurotransmitters and targets involved in such functions.

Finally, while many of the studies addressing the interplay between metabolic signals and the reproductive axis have been conducted using models of negative energy balance, which mimic conditions such as strenuous exercise or anorexia, the impact of obesity, as a highly

prevalent disorder at the other extreme of metabolic disorders, on key aspects of reproductive maturation and function is not so well characterized. Although significant progress has taken place recently on this front (e.g., the characterization of the impact of diet-induced obesity on the hypothalamic KISS1 system), important aspects of this phenomenon remain superficially addressed and warrant further investigation. For instance, whether leptin or insulin resistance to the reproductive actions of these hormones develops centrally in conditions of obesity and, if so, which neuronal circuits are affected are yet to be established. Similarly, the impacts of early metabolic challenges, including obesity, not only on metabolic health but also on key aspects of reproductive function later in life need better characterization. Efforts in these and related areas also will help to better define the pathophysiological basis of common reproductive disorders, such as PCOS.

CHAPTER

36

Stress and the Reproductive System

Xiao-Feng Li, Kevin T. O'Byrne

Academic Department of Anatomy and Human Sciences/Division of Women's Health, School of Medicine, King's College London, Guy's Campus, London, UK

INTRODUCTION

The concept of the *milieu intérieur* was introduced by Claude Bernard in the mid-1800s to describe the principle of dynamic internal physiological equilibrium to sustain the organism in an external environment typified by variability.[1] This is the underlying principle of what would later be called homeostasis, a term introduced by Walter Cannon in the 1930s. He used the physics terminology of strain and stress to describe the homeostatic mechanisms to maintain steady-state conditions. Cannon also incorporated the autonomic nervous system into his model, appreciated psychological impacts, and introduced the term "fight or flight" to describe an animal's response to threats. Hans Selye popularized the term stress (or stressor) for the causative agent in the stress response and critically emphasized that activation of the hypothalamic-pituitary-adrenal (HPA) axis and the sympathoadrenal system is central to the normal physiological response following exposure of an animal to stressors that threaten homeostasis. Indeed, the increase in circulating levels of the glucocorticoids (cortisol or corticosterone) is the benchmark of the stress response.

Selye's doctrine of nonspecificity of stress responses has been challenged. It is now appreciated through the work of Pacák, Palkovits, and many others, who built on earlier descriptions by Cannon, that there is marked heterogeneity of neuroendocrine responses to various stressors with the existence of stressor-specific pathways, neural circuits, and neurochemical signatures.[2] McEwen introduced the term *allostasis*, an extension of the principle of homeostasis, which conceptualizes change in physiological and behavioral systems to attain new set-points that are outside the nonstressed homeostatic range as a stabilizing and adaptive response for survival in the presence of extenuating perturbations. Once these challenges to the system have passed, there is a return to steady baseline levels. Although the allostatic state has a protective function, especially in the short term, if imbalance continues for prolonged periods or additional unpredictable stressors are superimposed, then allostatic overload exceeding the capacity of the individual to cope may occur and pathologies can develop.[3–5]

Stressors have been variously categorized. Perhaps insensibly, for the purpose of this review they are defined as physiological or psychological. Physiological stressors may be metabolic, such as hypoglycemia and fasting, hemorrhagic, thermal, or immunological, to mention but a few. Psychological stressors, on the other hand, encapsulate an element of emotional and cognitive evaluation of the perturbation; common examples include restraint, novelty, noise, and unpredictable and uncontrollable environments. Due to the marked heterogeneity of myriad stressors, overlap in this and other categorizations are common and should be anticipated. For example, it is difficult to separate the physiological and psychological components of food withdrawal or restraint. Furthermore, it is not uncommon, experimentally, to use various stressors in combination to replicate more "natural" scenarios or environmental conditions.

Cameron's laboratory developed a nonhuman primate model of stress-induced amenorrhea, in which cynomolgus macaques are exposed to a combination of mild psychosocial and metabolic stressors (change in social environment plus reduced caloric intake, either with or without exercise)[6] to recapitulate the clinical description of the stressors (psychosocial and metabolic) experienced by women presenting with functional hypothalamic amenorrhea.[7,8] The phenomena of summation and synergism of stressors, including subthreshold stressors, on the reproductive system are implicit[6,9] and could potentially go unrecognized in many experimental settings. Additionally, the impact of environmental factors, often beyond the experimenter's control, such as life history, shipment of animals, or construction work in or nearby animal facilities[10] may also go unrecognized and compromise experimental results.

Knobil and Neill's Physiology of Reproduction, Fourth Edition
http://dx.doi.org/10.1016/B978-0-12-397175-3.00036-3

In addition to activation of the HPA and sympathetic–adrenomedullary axes, there is a broad spectrum of behavioral responses to stress, including a component of the classical fight-or-flight response. Behavioral responses may be stressor specific. The presence of a predator may cause increased vigilance and freezing behavior to aid survival. Illness or immunological challenge following cytokine or endotoxin administration can result in decreased locomotive activity, exploration, appetite and feeding, and sexual behavior, which enable the animal to cope with the stress of infection and aid recovery. The high-energy demands of stress can also result in a shutdown of key physiological processes that are not required for immediate survival, such as reproduction, which is the focus of this review.

The impact of stress on the gonadotropin-releasing hormone (GnRH) pulse generator, the central regulator of the reproductive system, is reviewed in this chapter, along with a detailed description of mechanisms of action, neural circuits, and neurochemical mediators of different types of stressors, including immunological, metabolic, and psychological stressors. The involvement of the recently discovered kisspeptin signaling system in stress-induced suppression of the GnRH pulse generator is also discussed. Finally, the impact of stress on the ovarian cycle and the preovulatory gonadotropin surge is reviewed. Initially, a brief review of the stress system, including the HPA axis, is necessary as a background for understanding its interaction with the reproductive neuroendocrine axis.

THE HYPOTHALAMIC-PITUITARY-ADRENAL AXIS

Primary Hypothalamic Hormones

The neuroendocrine activation of the HPA axis by stressors involves the secretion of two neuropeptides, corticotropin-releasing factor (CRF) and arginine vasopressin (AVP), from hypophysiotrophic neurons in the parvocellular division of the paraventricular nucleus (PVN) into the hypophysial portal blood, which act in a synergistic fashion on the pituitary corticotrophs to increase pro-opiomelanocortin transcription and adrenocorticotrophic hormone (ACTH) release into the circulation; in turn, this stimulates the secretion of cortisol or corticosterone from the adrenal cortex. The increase in circulating levels of glucocorticoids is key to maintaining carbohydrate reserves, as well as mediating a number of other physiological responses, the actions of which are essential for survival. Such physiological responses include increasing cardiovascular tone, muscle catabolism, and gluconeogenesis in the liver, while at the same time shutting down nonessential physiological activities.

Corticotropin-Releasing Factor

Stressors of various types have been shown to induce *c-fos* and CRF gene expression in parvocellular neurons of the PVN.[11,12] Additionally, stressors result in rapidly increasing levels of CRF in hypophysial portal blood of several species, including rats and sheep.[13,14] Increased levels of CRF in the cerebrospinal fluid of monkeys is evident following acute immunological stress,[15] and persistent elevated levels are found in adult monkeys exposed to early-life adversity[16] and in humans who suffered childhood trauma, (particularly emotional neglect).[17] The histocompatible rat strains Fischer and Lewis provide a comparative model of HPA function, in which the Fischer rats are more reactive to environmental challenges[18] and the Lewis rats are hyporesponsive to myriad stressors, with a significantly lower expression of CRF mRNA in the PVN and lower ACTH and corticosterone release.[19] The administration of type 1 CRF receptor (CRF-R1) antagonists or immunoneutralization of endogenous CRF in a variety of species attenuates or blocks the ACTH and glucocorticoid response to diverse stressors.[1,14,20] Similarly, CRF knockout mice have lower basal corticosterone levels and markedly attenuated, but not completely absent, ACTH and corticosterone response to various stressors, including restraint, hemorrhage, and insulin-induced hypoglycemia.[21,22] Although CRF is the most potent activator of the pituitary-adrenal axis[23] and essential for the normal pituitary and adrenal responses to stressors, other neuropeptides, in particular AVP, are implicated. Additionally, CRF is highly expressed in other brain regions, including the amygdala, bed nucleus of the stria terminalis (BNST), and locus ceruleus, where it increases in response to stress.[24,25]

Arginine Vasopressin

AVP was the first identified secretagogue of ACTH. Although it has an intrinsic capacity to stimulate ACTH secretion, its primary function appears to potentiate the stimulatory effects of CRF,[26] particularly under circumstances demanding sustained activation of the HPA axis.[27] However, it cannot compensate for the loss of CRF in maintaining the normal response to stress. AVP is colocalized with CRF in the parvocellular PVN neurons. Its role in HPA axis activation and the stress response is suggested by increased AVP mRNA levels in the parvocellular neurons[28] and its co-release with CRF[13] into the hypophysial portal blood in response to stress. The synergistic effects of AVP on ACTH release are mediated through the vasopressin V_{1b} receptor on pituitary corticotrophs.[29]

Urocortins

The urocortins (UCN1, 2, and 3) are derived from a common ancestral gene to CRF. They have moderate

sequence homology with one another and with CRF, and they are more potent than CRF in activating CRF receptors, particularly the type 2 receptor (CRF-R2).[30] UCN1 is highly expressed in the Edinger-Westphal nucleus and supraoptic nucleus, but very low levels are seen in the PVN.[31] However, UCN1 participation in stress-related mechanisms is probably derived principally from projections to the PVN and autonomic centers in the brainstem.[31,32] In contrast, UCN2 is highly expressed in the PVN, supraoptic nucleus, BNST, and locus ceruleus[33] and UNC3 is highly expressed in the PVN, BNST, medial preoptic area, and medial amygdala nucleus[34,35]; sites critical not only for stress activation but also control of the reproductive axis.

Administration of UCN1 potently activates the HPA axis, stimulating ACTH and glucocorticoid release in rats and sheep[30,36] and ACTH from rat pituitary cells,[30] which is to be expected from its ability to activate CRF-R1, the receptor subtype expressed by corticotrophs. Nevertheless, UCN-deficient mice exhibit normal basal and stress-induced ACTH and corticosterone release.[37] In contrast to UCN1, systemic administration of UCN2 or UCN3, which are highly selective ligands for CRF-R2, failed to stimulate ACTH or corticosterone release[35] commensurate with an absence of this receptor type in the pituitary corticotrophs.[38] However, unlike central activation of CRF-R1 following intracerebroventricular administration of CRF or UCN, which consistently stimulates ACTH and corticosterone release, central activation of CRF-R2 with UCN2 or UCN3 have yielded inconsistent results, with either no effect[39] or stimulation of ACTH and corticosterone.[34,40] Moreover, intracerebroventricular administration of selective CRF-R2 antagonists has consistently failed to block stress-induced corticosterone release in the rat.[41,42] Additionally, UCN2 or UCN3 null mice show normal stress-induced corticosterone release and negative feedback regulation of the HPA axis, as evidenced by normal poststress recovery of corticosterone levels.[33,43] These data might suggest that CRF-R2 ligands are seemingly unlikely physiologic regulators of the HPA axis. However, CRF-R2 is known to modulate the stress response.

In contrast to CRF-R1 knockout mice, CRF-R2 mutants are hyperresponsive to stress, displaying a more rapid and robust rise in ACTH and corticosterone.[44,45] Additionally, the stress-induced rise in corticosterone is prolonged, suggesting a role for CRF-R2 in the recovery phase of the stress response.[45] A corollary to the postulated hormonal stress adaptive function of CRF-R2 is the enhanced behavioral stress-coping phenotype of the CRF-R2 null mouse.[44,45] Interestingly, CRF-R2 and UCN2 null mice exhibit an altered circadian rhythm in circulating levels of ACTH and corticosterone, with an accentuated rise associated with the awakening response at the light/dark transition.[33] Because the peak and nadir of circadian glucocorticoid release reflects changes in the amplitude of the ultradian pulses, with the largest pulses extant at the awakening transition,[46,47] it is conceivable that the CRF-R2 selective ligand UCN2 may modulate glucocorticoid pulse amplitude. Moreover, UCN2 null mice showed increased AVP expression in hypothalamic PVN magnocellular neurons, which might contribute to the increased peak circadian ACTH and corticosterone levels in these animals.[33] These data raise the possibility that the urocortins, or other CRF-R2 agonists, might modulate circadian HPA axis activity, which could potentially impact on stress responsivity.

Neural Systems Mediating Stress Responses

The HPA axis is governed by a diverse set of neurocircuits that relay stressful information to the PVN, which in turn drives the pituitary-adrenal axis culminating in the release of glucocorticoids. Glucocorticoid receptors are widely distributed in the brain. In addition to the PVN, high levels are expressed in limbic brain areas, including the hippocampus, medial prefrontal cortex, and amygdala, amongst other areas, which are implicated in glucocorticoid regulation of the HPA axis and behavioral responses to stress.[48] Similar to the PVN, administration of glucocorticoids into the hippocampus or medial prefrontal cortex reduces basal and psychological stress-induced glucocorticoid release.[49] Conversely, destruction of the hippocampus or the medial prefrontal cortex exaggerates the glucocorticoid response to stressors in rats[50] and nonhuman primates.[51] Additionally, the forebrain glucocorticoid receptor knockout (FBGRKO) mouse, which has an absence of glucocorticoid receptors in the prefrontal cortex and hippocampus, but retains their presence in the PVN and amygdala, shows a prolonged corticosterone response to acute psychological but not physiological stressors.[52] The stress-inhibitory influences of the medial prefrontal cortex and hippocampus, which are largely psychogenic in nature, are not conveyed by direct pathways to the PVN, but rather indirectly, principally converging onto a common relay in the BNST, which provides an inhibitory gamma-aminobutyric acid (GABA)ergic innervation to HPA effector neurons in the PVN.[53] Thus, the BNST may prove to be a key integrative center for these convergent inputs to restrain psychological stress-induced activation of the HPA axis.

In addition to the negative feedback regulation of the HPA axis, glucocorticoid feed-forward mechanisms act via the amygdala to activate the HPA axis, causing sensitization toward stressors. The central and medial amygdalar nuclei in particular contribute the major amygdalar projections to cortical, hypothalamic, and brainstem regions that regulate autonomic, behavioral, and stress responses[54,55] and play a key role in HPA axis

activation. Lesions of these amygdalar nuclei reduce glucocorticoid secretion in response to stress,[55,56] while their stimulation induces glucocorticoid secretion.[57] Glucocorticoid and mineralocorticoid receptors are expressed in the central and medial amygdalar nuclei.[57] Exposure to stress increases CRF release in the central nucleus of sheep, which depends on glucocorticoid receptor activation.[58] Whether this increase in CRF is from CRF neurons intrinsic to the central amygdala or terminal projections from outside the nucleus, such as the PVN, is not known.[58] Although glucocorticoid infusion into the central amygdalar nucleus does not acutely affect HPA axis activation, selective glucocorticoid receptor deletion in this nucleus reduced CRF expression in the central nucleus and the HPA axis response to stress in mice.[59] Moreover, chronic exposure to glucocorticoids or stress upregulates CRF expression in the central amygdalar nucleus.[60] Continuous overexpression of CRF in this nucleus using a lentiviral vector caused upregulation of CRF and AVP in the PVN and decreased glucocorticoid negative feedback.[61] The central amygdalar nucleus also shows enhanced activation by acute stressors following chronic stress exposure, which suggests that it plays a key role in maintenance of stress responsiveness and stress sensitization.[62] In contrast, the medial amygdalar nucleus may be involved in acute (but not chronic) stress activation of the HPA axis.[63] Additionally, the central and medial amygdalar nuclei respond to distinct stress modalities, with the medial nucleus activated by psychological stressors, including restraint, predator exposure, and social interaction,[50] and the central nucleus preferentially responding to physiological stressors, such as hemorrhage and immunological challenge.[64] In common with the medial prefrontal cortex and hippocampus, the amygdala sends limited direct projections to the parvocellular division of the PVN, with the majority involving subcortical relays including the BNST, medial preoptic area, dorsomedial hypothalamus, and brainstem.[57,65,66] The BNST is of particular significance because it not only receives inputs from inhibitory and stimulatory limbic forebrain regions, but also most hypothalamic and brainstem structures involved in stress-induced control of the HPA axis,[67] which implicates the BNST as an even broader integrative center for regulation of the stress response.

Activation of the brainstem noradrenergic and serotonergic neural systems in the locus ceruleus and raphae nucleus, respectively, along with other brainstem structures, further contribute to regulation of the stress response. The locus ceruleus, containing the principal noradrenergic population in the brain, provides a fountain of innervation to a large portion of the neuroaxis and is implicated in myriad behavioral and physiological functions, including enhanced cognition and memory, vigilance, emotional arousal, and adaptive responses to stress. A wide variety of stressful stimuli activate the locus ceruleus[68–70] and stimulation of this structure elicits HPA axis activation and anxiogenic behaviors.[71] There are extensive reciprocal connections between the noradrenergic neurons of the locus ceruleus and CRF neurons of the PVN, BNST, and central amygdalar nucleus, respectively, providing a neural substrate for feed-forward mechanisms.[70,72] Indeed, functional magnetic resonance imaging in humans has shown that stress-induced noradrenergic activity, a sequelae of locus ceruleus activation, prompts large-scale neural network reconfiguration and enhanced functional connectivity, thus facilitating information exchange between brain regions involved in autonomic-neuroendocrine (e.g. elevated heart rate and cortisol) control and vigilant attention (the latter being a component of the fear reaction in the stress response).[73] There is also extensive literature documenting the importance of serotonergic control of the HPA axis. Serotonergic inputs to the PVN stimulate the HPA axis through both direct and indirect pathways from the raphe nuclei, and lesions of the raphe decrease the HPA axis response to stress.[74,75] Restraint stress increases serotonin (5-hydroxytryptamine, 5-HT) levels in the raphe nuclei and 5-HT_{2A} receptor antagonism attenuates the ACTH response.[74]

In summary, the maintenance of homeostasis in the presence of stress requires a complex range of mechanisms; amongst the most salient is the integrated activation of CRF systems in several key brain areas, including the hypothalamus, BNST, and amygdala, which act with brainstem locus ceruleus noradrenergic and raphe serotonergic systems to coordinate the neuroendocrine and cognitive limbs of the stress response.

Modulation of Stress Responses

Glucocorticoids play a key role in regulating the magnitude and duration of HPA axis activation through myriad negative feedback mechanisms at the level of the pituitary, hypothalamus, and extrahypothalamic sites to restore homeostasis or engage allostasis to minimize the deleterious effects of their long-term exposure. In addition to the classical genomic negative feedback effects of glucocorticoids at the level of the PVN, there is a glucocorticoid-induced fast feedback inhibition of parvocellular CRF neuronal activity that is mediated by nongenomic mechanisms.[76] This rapid feedback mechanism may serve to prevent excessive depletion of hypothalamic and pituitary hormone stores, allowing for repeated stress responses.[77]

Changes in the function of the 5-HT reuptake transporter (SERT), which is critical to the control of 5-HT activity, are also associated with altered stress responsivity. The HPA axis and its feedback regulation are impaired in the SERT knockout mouse, which might account for their increased sensitivity to stress.[78] These

knockout animals are also anxiogenic.[78] Several polymorphisms and mutations have been found in the SERT promoter and coding regions,[79] such as polymorphism in the 5-HT transporter-linked promoter region (5-HTTLPR), which influences the transcription rate of the gene encoding SERT, with the short allele being transcriptionally less efficient than the long allele.[80] Human studies have shown that individuals carrying two copies of the short allele are more vulnerable to stressful events, displaying increased cortisol release in response to psychosocial stress and enhanced vulnerability to psychiatric disease.[81] A similar phenotype is evident in rhesus monkeys with the short/long allele 5-HTTLPR genotype.[82,83]

The HPA axis and its key corticolimbic regulators are particularly sensitive to the developmental programming effects of early life stress, resulting in HPA axis hyperactivity and vulnerability to cardiovascular, metabolic, immunological, neuroendocrine, and psychological disorders in adulthood. Although most attention has focused on the prenatal and early postnatal periods, adolescence (particularly puberty) is a critical developmental period that is also vulnerable to environmental perturbation, resulting in predisposition to psychopathologies and HPA axis hyperactivity later in life.[84–86] Diverse and complex epigenetic mechanisms and genetic liability underlie individual differences in vulnerability and resistance to the developmental programming-induced changes in the stress response. The seminal work of Meaney and colleagues has focused on the influence of variations in maternal care, specifically the frequency of pup licking and grooming in the rat, on the development of behavioral and HPA responses to stress in adulthood.[87] In contrast to the offspring receiving high levels of maternal care, those receiving poor care showed increased vulnerability to stress-induced learned helplessness and enhanced ACTH and corticosterone release commensurate with reduced glucocorticoid receptor expression in the hippocampus, resulting in attenuated negative feedback regulation of the HPA axis.[87] Indeed, the frequency of pup licking and grooming was correlated with the level of hippocampal glucocorticoid receptor expression, revealing a direct relationship between maternal care and the phenotypic development of the offspring.[88] This influence of maternal care on the HPA axis is associated with epigenetic programing of glucocorticoid receptor expression, in particular the methylation status of the glucocorticoid receptor promoter, being hypermethylated in the offspring of low licking and grooming mothers and hypomethylated in those of high licking and grooming dams.[87]

Hypermethylation of the leukocyte glucocorticoid receptor gene was also observed in healthy human adults reporting a history of childhood adversity that was linked to altered HPA axis function.[89] Healthy young adults whose mothers experienced severe stress during pregnancy have enhanced cortisol responses during standard psychological testing.[90] Interestingly, maternal psychosocial stress during pregnancy was associated with a sustained increase in methylation of the glucocorticoid receptor promoter in the blood of their adolescent children.[91] Although there is considerable evidence for familial dysfunction in childhood enhancing stress reactivity,[17,92] interventions that target parental care of high-risk preschool children improve behavior and HPA axis activity.[93] It is of considerable significance that in Maeney's rodent licking and grooming model of maternal care, cross-fostering completely reverses the differences in the methylation state of the hippocampal glucocorticoid receptor promoter.[94] These data support growing evidence suggesting a capacity for the remodeling of epigenetic marks, including DNA methylation, throughout the lifespan of an organism.[87]

Although much attention has focused on epigenetic modifications of genes encoding glucocorticoid receptors,[87] CRF[95] and AVP,[96] which underlie changes in the stress response, it is important to emphasize that other related systems are also susceptible to programing. For example, maternal separation is associated with reduced $GABA_A$ receptor subunit expression in the locus ceruleus and amygdala, affecting behavioral stress responsivity in these rats.[97] Activation of ascending serotonergic systems during pre- and postnatal development regulates hippocampal glucocorticoid receptor expression and the corticosterone stress response.[98] Adverse early life events therefore clearly influence the epigenetic control of multiple regions of the genome in different brain areas to regulate the stress response.

STRESS AND THE REPRODUCTIVE SYSTEM

The reproductive system is under the control of the hypothalamic-pituitary-gonadal (HPG) axis, as described in considerable detail by other contributors to this book (see Chapters 11 and 26–28). Briefly, the function of this neuroendocrine system relies on astonishingly few GnRH neurons (~1000 in higher mammals) in the hypothalamus that synthesize and release their decapeptide into the hypophysial portal blood that stimulates the synthesis and release of the two gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), from the anterior pituitary gland. The gonadotropins then act on the ovaries and testes to stimulate gametogenesis and synthesis and release of gonadal sex steroid and peptide hormones. Feedback and feed-forward loops, particularly of the sex steroids, operate at several levels within the HPG axis to control or influence normal function, including pubertal maturation

and ovulation. GnRH and LH/FSH are released in a pulsatile fashion, which gave rise to the concept of the GnRH pulse generator by Knobil[99] (see also Chapters 11, 27, and 28). This neural construct is responsible for the rhythmic activation of the GnRH neurons and the release of the neurohormone from their terminals that eventuate in the pulsatile discharge of LH and FSH into the peripheral circulation.

Despite enormous efforts to identify the neural components of the GnRH pulse generator, they remain elusive. In vitro and ex vivo studies using immortalized cell lines and primary cultures of GnRH neurons, respectively, have indicated an ability of GnRH neurons per se to generate secretory pulses.[100,101] However, electrophysiological recording from single identified GnRH neurons in vitro have proven disappointing,[102] despite the occasional recording revealing a pattern of electrical activity that may reflect a neurosecretory burst underlying a pulse of GnRH secretion,[103] based on comparison with other neurosecretory systems (e.g. oxytocinergic neurosecretory burst underlying pulsatile release of oxytocin during milk ejection associated with lactation[104,105]; see also Chapter 13). The pattern of electrical activity that results in GnRH secretion thus remains a matter of speculation; the classical multiunit activity (MUA) volley recordings pioneered by Knobil are, to the present day, the most remarkable electrophysiological correlates of GnRH pulse generator activity[106,107] (see Figure 36.1).

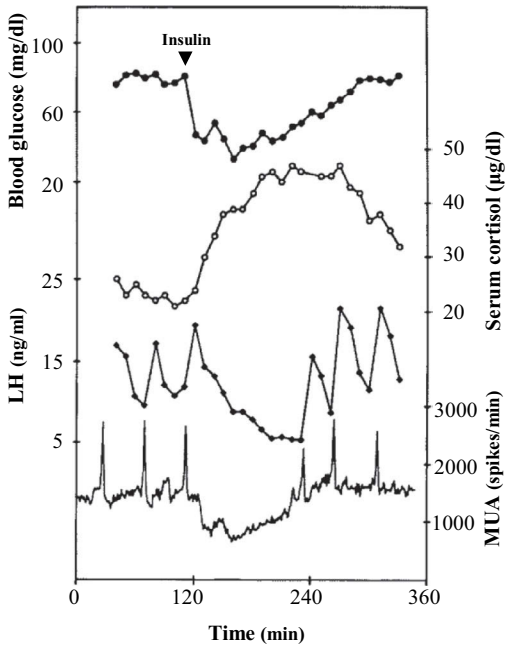

FIGURE 36.1 Effect of insulin-induced hypoglycemic stress on hypothalamic multiunit activity (MUA) volleys and on serum levels of LH and cortisol in a rhesus monkey during the early follicular phase of the menstrual cycle. Note the interruption of GnRH pulse generator activity coincident with the fall in blood sugar and its recovery despite the continued elevated levels of cortisol. *Reprinted with permission from Chen et al.*[107]

Moreover, these MUA volleys are recorded from the mediobasal hypothalamus in rats,[108–111] goats,[112] and rhesus monkeys[106,113] and yet it is only in the latter species that GnRH neurons are located in appreciable numbers in this area. Furthermore, pulsatile LH secretion was not impaired by complete deafferentation of the mediobasal hypothalamus in the rat, which isolates the GnRH neurons cell bodies from their secretory terminals in the median eminence.[100,114] These data generate a conundrum, but indicate that the GnRH pulse generator resides within the mediobasal hypothalamus of various species including rats and monkeys.[100,114,115] Recent discoveries showing a complex intermingling of GnRH dendrites or dendrons as they cascade down toward the median eminence, covered in spines to facilitate synaptic inputs, provides an anatomical architecture to facilitate pulse modulation and potentially pulse generation[116] (see Chapter 11). Moreover, there is emerging evidence[117] that in addition to the many well-established neurotransmitter systems implicated in GnRH secretion, the recently discovered kisspeptin system (particularly the kisspeptin neural population in the hypothalamic arcuate nucleus, known by the acronym KNDy), because of their co-expression of neurokinin-B and dynorphin A, may act as a critical player in the control mechanisms governing pulsatile GnRH secretion.[118–121] Indeed, in the median eminence, kisspeptin fibers densely comingle with GnRH fibers,[122,123] pulses of kisspeptin occur in temporal association with GnRH pulses,[124] kisspeptin antagonists block pulsatile GnRH/LH secretion in several species,[117] and critically intra-arcuate nuclear microinfusion of kisspeptin antagonists suppresses LH pulse frequency in the rat.[125] The role of kisspeptin and KNDy neuron signaling in the control of the GnRH pulse generator is discussed by others in this book (see Chapters 11 and 27).

Inhibitory Effects of Stressors on Pulsatile GnRH/LH Release

It is well recognized that reproduction is suspended or at least delayed when environmental conditions are unfavorable to support the high energy demands of maintaining pregnancy and rearing young. An obvious example of this in the natural world is that most mammals living at temperate latitudes exhibit seasonal variations in reproduction to optimize food availability and other favorable conditions. The critical nature of energy requirements for survival is finely tuned to the stress response with the rising circulating levels of glucocorticoids evident with increasing allostatic load. Allostatic overload, in terms of negative energy balance or metabolic stress, is a cardinal sign of reproductive impairment. States of undernutrition induced, for example, by anorexia or excessive exercise suppress reproduction to preserve energy sources for survival. This fundamental

topic is discussed at length by other contributors to this book (see Chapter 35). However, myriad stressors contribute to the allostatic load and affect reproduction. The complexity of their interactions and underlying mechanisms is gargantuan and, despite enormous progress, still remain to be completely elucidated.

The inverse relationship between the HPA and HPG axes had led to the hypothesis that activation of the HPA system during stress drives the suppression of the reproductive axis. However, the causality and extent of this relationship is far from clear and is all too commonly assumed. Although the pathophysiology of stress-related reproductive failure has not been fully elucidated, the effects of many stressors ultimately converge upon the reproductive neuroendocrine axis to alter secretory patterns of gonadotropic hormone secretion. A major goal is to elucidate the mechanisms, mediators, and sites within the brain and the HPG axis per se, whereby stressors disrupt ovarian and testicular function to reduce fertility. The complexity of stress research is confounded by many factors, including different stressors acting on several different brain areas involving stressor-specific pathways, neural circuits, and mechanisms, coupled with the vast number of stressors used experimentally to mimic the huge diversity of perturbations extant in the natural world. The nature of these challenges (i.e. acute, chronic, or a combination of stressors) affects the response. Developmental stage, age, gender, and endocrine status of the subject are also critical, as are species differences.

Stressors potentially can influence reproductive function at several levels of the HPG axis, but an action on the brain to reduce GnRH pulse generator frequency and hence LH pulse frequency predominates. Not only is the pulsatile nature of gonadotropic hormone secretion an obligatory component of the HPG axis, but critically, the GnRH pulse generator operates within a narrow frequency range, deviation from which results in reproductive failure.[8,126] There is a wealth of evidence from a huge literature spanning many decades that a wide variety of stressors reduce LH pulse frequency in many different species.[1] In contrast to monitoring GnRH pulse generator activity indirectly by measurement of LH pulsatility, there are considerably fewer studies that directly assess GnRH pulsatility for obvious technical reasons. The sheep is the champion animal model from the pioneering work of Clarke,[127] followed by others, including Caraty[128] and Karsch,[129] who collected serial hypophysial portal blood samples for the detection of GnRH pulses. Other large species, including cattle and horses, also avail the opportunity to measure GnRH pulses directly in pituitary and hypophyseal-portal blood.[130,131]

Immunological/Inflammatory Stressors

From the myriad stressors used experimentally, immunological/inflammatory challenges are common. The endotoxin lipopolysaccharide (LPS), which is a major constituent of the outer cell membrane of gram-negative bacteria, induces pathophysiological responses within the body that mimic an acute bacterial challenge and certain aspects of sepsis without causing infection per se. As with infection, endotoxins evoke the release of both peripheral and central cytokines, including interleukin-1 alpha (IL-1α) and IL-1 beta (IL-1β) and tumor necrosis factor-alpha (TNF-α),[132,133] which are responsible for coordination of the host's immune defense mechanisms. Administration of LPS suppresses LH pulse frequency in a variety of species, including rats,[41,111,134–136] sheep,[13,129,137] goats,[138] cows,[139] and monkeys.[140] In common with LPS, administration of cytokines, such as IL-1α, IL-1β and TNF-α, via intracerebroventricular injection suppresses LH pulse frequency without affecting LH pulse amplitude in rats.[111,132,134,141,142] Although intravenous administration of IL-1β apparently failed to suppress basal LH secretion in rats,[143] intravenous TNF-α suppressed LH pulse frequency without affecting LH pulse amplitude[111]; the latter study used a dose-dependent paradigm that was noticeably absent from the former study. As in the ovariectomized rat,[111] administration of LPS or IL-1α decreases LH pulse frequency but not pulse amplitude in the ovariectomized rhesus monkey.[140] However, levels of FSH were suppressed in the monkey,[144] yet unaffected in the rat.[142] Whether this is related to the longer half-life of FSH remains to be determined. These effects on pulsatile LH secretion in ovariectomized rats and monkeys differ from reports for the ovariectomized ewe, in which both LH pulse frequency and amplitude were affected by endotoxin.[13,129] Moreover, in the ewe, GnRH pulse frequency and amplitude measured in pituitary portal blood are also decreased by LPS.[13] FSH secretion is also suppressed by LPS in the ewe.[145]

In addition to the central mechanisms regulating GnRH secretion, bacterial endotoxin also acts to reduce pituitary responsiveness to GnRH in the ewe.[146] This effect is mediated by pathways that include the synthesis of prostaglandins[147] and cortisol,[148–150] both of which are increased by endotoxin.[149] Whether similar mechanisms operate in other species, such as rats and monkeys, remains to be fully elucidated. Indomethacin does not overcome the suppressive effects of LPS on LH secretion in gonadectomized rats,[151] although it is very effective in restoring LH pulsatility in ovariectomized rats that were adrenalectomized and replaced with corticosterone at basal levels[152]; a model that appears to be particularly sensitive to stress-induced perturbation of the GnRH pulse generator.

Glucocorticoids are not involved in the acute suppression of LH pulses after LPS administration in rats.[153] Indeed, glucocorticoids have been shown to have a protective effect on LH pulsatility under conditions

of infectious stress in the rat, mediated in part by suppression of prostaglandin synthesis in the hypothalamus.[152] Additionally, CRF-R2 antagonism attenuates the LPS-induced suppression of LH pulse frequency without altering the stress levels of corticosterone in the ovariectomized rat.[41] Conversely, CRF-R1 antagonism failed to attenuate LPS-induced suppression of LH pulse frequency, but it reduced corticosterone release as expected.[41] Although the sites of action of CRF-R2 in mediating the inhibitory effects on LPS on pulsatile LH secretion are unknown, neurotoxic lesioning of the central nucleus of the amygdala, which contains a prominent population of CRF neurons,[154] attenuated the response.[136] A role for GABAergic signaling in the medial preoptic area is evident because microinfusion of GABA antagonist into this region blocked the inhibitory response to LPS stress.[155] Further, this effect appears to be $GABA_A$, and not $GABA_B$, receptor mediated.[155]

The putative circuitry leading to the suppression of pulsatile LH secretion by immunological stress in the rat is shown in Figure 36.2.[156] In the rhesus monkey, a nonselective CRF receptor antagonist also blocks the inhibitory effects of LPS on LH secretion without altering the raised levels of cortisol.[157] The inability to prevent the cortisol increase in response to LPS might suggest either an inadequate dosage of CRF antagonist or a mechanism independent of CRF, such as AVP.[157] Although IL-1 receptor antagonists or antisera can completely block the inhibitory effects of IL-1 per se on LH secretion, the inhibitory effects of LPS are only partially blocked in rats and monkeys, confirming, not surprisingly, that other cytokines or factors are involved.[134,140] Indeed, TNF-α antibody also partially blocked the inhibitory effects of LPS on hypothalamic MUA volley and LH pulse frequency in the rat.[111]

Metabolic Stressors

Of the numerous metabolic perturbations that occur naturally or are experimentally induced, the ability of nutritional status, particularly undernutrition, to inhibit the HPG axis is readily inducible, profound, and extant

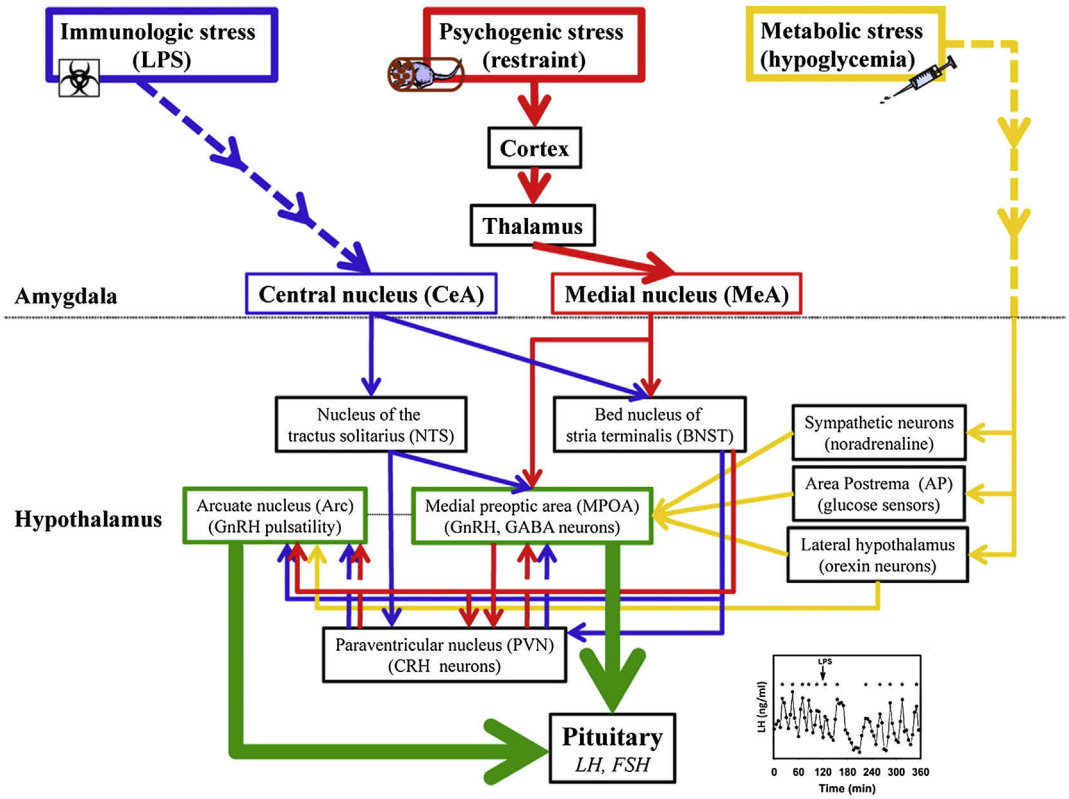

FIGURE 36.2 Putative circuitry leading to the suppression of pulsatile GnRH/gonadotropin secretion by immunologic stress (intravenous injection of bacterial LPS), psychogenic stress (confining the animal inside a restraint tube), or metabolic stress (insulin-induced hypoglycemia). Circuits in part are those directly inferred from the experiments of Lin et al.[136] in which either the medial or the central nucleus of the amygdala was chemically lesioned or the effects of stress on *Fos* expression in these nuclei were measured. The circuits leading to LH pulse suppression by hypoglycemia are unaffected by lesions in either amygdalar location, and the data supporting their routings are derived from other studies as cited in the text. The graphs in the lower part of the figure show the temporary interruption of episodic LH secretion after LPS, restraint or hypoglycemic stress in nonlesioned animals. *Modification from Merriam and Koenig.*[156]

in all species. The impact of nutritional states on reproduction is dealt with by other contributors to this book (see Chapter 35); however, a brief description will be provided here. In men and adult male rhesus monkeys, brief periods of fasting (i.e. 1–2 days) lead to marked decreases in circulating levels of LH, FSH, and testosterone.[158–161] The decrease in LH secretion is consequent to a reduction in LH pulse frequency, with no apparent suppression of LH pulse amplitude, suggesting that fasting affects the hypothalamic GnRH pulse generator rather than a suppression of pituitary sensitivity to GnRH.[158–160] Interestingly, similar short-term fasting (3 days) did not affect the pattern of pulsatile LH secretion in the follicular phase of women,[162] although a modest reduction in LH pulse frequency was observed with 4 days of fasting.[163] However, fasting for 10 days fails to affect pulsatile LH secretion in mildly obese postmenopausal women.[164] Interestingly, refeeding with a high caloric diet had very little normalizing effect on LH pulse frequency within 24 h in women with energetically suppressed LH pulsatility due to a combination of moderate dietary restriction and moderate exercise.[165] These data suggest that women's reproductive neuroendocrine axis is more resistant to caloric alterations than men or male monkeys. Nevertheless, acute fasting suppresses LH pulse frequency in female mice,[166] rats[167] and heifers.[168]

In the male rhesus monkey, refeeding resulted in an immediate increase in LH pulse frequency[169,170] that was proportional to the size of the refeed meal[171]; the type of nutrient in the meal[161] or the meal-induced insulin secretion[172] do not seem to be critical. Additionally, in the monkey suppression of GnRH pulse generator frequency after fasting was found to be a function of the metabolic status rather than the psychological state imposed by withholding food; overfeeding the day before fasting prevented the normal fasting-induced suppression of LH secretion without affecting the agitated behavior associated with food withdrawal.[160] Similarly, intragastric nutrient infusion immediately restored pulsatile LH secretion in fasted animals, although the monkeys continued to display behavioral agitation.[170] It is also of note that cortisol levels are not raised during the fasting period in men, despite profound suppression of LH pulses.[159]

Other forms of metabolic perturbations commonly used include insulin-induced hypoglycemia and competitive antagonism of glucose utilization with 2-deoxyglucose. Insulin-induced hypoglycemia is a highly quantifiable and reproducible stressor that inhibits LH secretion to which animals, including humans, do not habituate.[107,173] A profound reduction in GnRH pulse generator frequency in response to insulin-induced hypoglycemia is observed in the rat,[108,109,174–177] sheep,[178] and rhesus monkey.[107,179,180] Affects on LH pulse amplitude are also reported for the rat[177] and ewe,[178] although not in the monkey.[107,179,180]

An example of the acute inhibitory effects of hypoglycemic stress on hypothalamic MUA volleys and attendant LH pulses in the rhesus monkey is shown in Figure 36.1.[107] These inhibitory effects are readily reversed following restoration on an adequate glucose supply, suggesting that decreased GnRH pulse generator frequency is related to glucopenia and not insulin.[109,173,177–179] Although insulin-induced hypoglycemia is a potent activator of the HPA axis, the inhibition of GnRH pulse generator activity is unlikely to be mediated by cortisol because normal GnRH pulse generator activity was re-established despite the continuing elevation of the steroid[107,179] (see Figure 36.1). As with other stressors, the presence of the ovary or gonadal steroids exacerbates the inhibitory effects of hypoglycemic stress on pulsatile LH secretion.[107,174] Although hypoglycemia clearly suppresses basal LH secretion in men,[173,181] this is apparently not the case in women.[182] However, effects on pulsatile LH secretion in humans have not been determined. Hypoglycemic stress appears not to affect FSH secretion.[173,181,182] In addition to insulin-induced hypoglycemia, acute glucoprivation by 2-deoxyglucose administration profoundly suppresses pulsatile LH secretion in the rat.[152]

Several neurotransmitter systems, including CRF, AVP noradrenaline, opioids, and calcitonin gene-related peptide, are known to mediate the suppressive effects of metabolic stressors on GnRH pulse generator activity.[25,41,174,175,179,183,184] CRF-R2 and not CRF-R1 appears to mediate the inhibitory effect of hypoglycemic stress in the rat.[41] Our knowledge of the neurocircuitry involved in metabolic stress-induced suppression of the GnRH pulse generator is very limited (see Figure 36.2).[156] In contrast to restraint (discussed below) or LPS, the inhibitory effects of hypoglycemic stress on pulsatile LH secretion are not affected by lesioning of the central or medial nucleus of the amygdala in rats.[136] Although CRF antagonism blocks the inhibitory effect of hypoglycemic stress, this is not mediated at the level of the locus ceruleus.[185] However, hypoglycemic stress-induced suppression of LH pulses does involves the area postrema,[175] a key brainstem glucose detection site.[186] The lateral hypothalamic area represents another key site in glucose homeostasis, and its orexin-containing neurons are highly activated during hypoglycemic stress.[2] However, the site of action for orexin-mediated suppression of pulsatile LH secretion remains to be established.[187]

Psychological Stressors

Restraint is a commonly used psychological stressor. Early studies examining the effects of restraint stress on the HPG axis in the rat were limited to the measurement

of mean circulating LH levels, and they reported no change,[188] a decrease,[189,190] or a biphasic pattern with initial elevation and subsequent decline in LH levels[190]; the latter was more commonly observed in the intact male. Effects on FSH secretion were equally variable. More recently, acute restraint stress has been shown to decrease LH pulse frequency without changes in pulse amplitude in the ovariectomized rat,[19,41,110,136,155,191–193] although Nishihara and colleagues observed a reduction in both parameters.[152] Habituation to the inhibitory effects of restraint stress on pulsatile LH secretion can occur rather rapidly in the rat and is related, at least in part, to the level of stress reactivity. The Lewis rat, which is relatively hypoactive to stress, as indicated by reduced synthesis of hypothalamic CRF and secretion of corticosterone, habituated more rapidly to repeated restraint compared with the histocompatible Fischer strain, which is more reactive to stress.[18,19,194] Nevertheless, the habituation of the HPG axis to repeated restraint stress appears not to be related to corticosterone release as corticosterone levels remained elevated.[19]

In male and female rhesus monkeys, restraint in a primate chair suppresses LH pulses,[195] but they readily habituate to this psychological stress,[107] as was also observed in the common marmoset monkey.[9] Again, it seems unlikely that the raised cortisol is causally related to the suppression of LH pulses, because treatment with the opioid antagonist naloxone reversed the effects of restraint on LH secretion without affecting the cortisol levels.[195] In gonadectomized sheep, acute confinement or isolation/restraint stress decreases both LH pulse frequency and amplitude, and the degree of suppression is influenced by gonadal steroid replacement.[196] Transport stress during the follicular phase in the ewe also decreased LH pulse frequency and/or amplitude.[197] A model of psychosocial stress consisting of sequential layering of isolation, restraint, blindfold, and predator cues (barking dog sound and odor)[198] was shown to cause a robust elevation in cortisol and profound decrease in LH pulse amplitude without affecting LH pulse frequency in the ovariectomized ewe.[198,199] This decrease in LH pulse amplitude is a result of two components: firstly, a reduction in pituitary responsiveness to GnRH caused by cortisol acting via the type II glucocorticoid receptor at the pituitary level[198] and secondly, a central effect involving a reduction in GnRH pulse amplitude per se, that was revealed by measurement of GnRH directly in pituitary portal blood, which is independent of cortisol acting via the type II glucocorticoid receptor.[200] However, cortisol does decrease GnRH/LH pulse frequency in follicular phase ewes, an action that is dependent upon the presence of ovarian steroids, particularly estradiol, and sustained (27 h) stress-like levels of cortisol; an acute (6 h) cortisol increase is ineffective in suppressing GnRH pulse generator frequency.[150,201,202] These technically complex studies in the ewe by Karsch and colleagues reveal astonishing detail and insight into physiological mechanisms underlying psychosocial stress and undoubtedly other types of stress induced inhibition of reproductive neuroendocrine function that are difficult to achieve in other species with current experimental techniques.

Another key psychosocial factor is socially induced infertility, which is common in many species including rodents and primates. In many primate species, social status provides a model of psychogenic stress in which subordination is associated with reproductive compromise. Social suppression of fertility in subordinate female common marmosets is mediated by impaired hypothalamic GnRH secretion.[203] Receipt of aggression from a female conspecific reduces pulsatile LH secretion[204] and the preovulatory LH surge in the common marmoset.[9] Similarly, subordinate female rhesus monkeys are hypersensitive to estradiol negative feedback inhibition of LH secretion,[205] which probably accounts for the increased incidence of anovulation and luteal phase insufficiency characteristic of macaques exposed to psychogenic stressors.[206]

Our knowledge of the neurotransmitter systems and neurocircuitry underlying psychological stress-induced suppression of the GnRH pulse generator is equally fragmentary. Nevertheless, both CRF-R1 and CRF-R2 are involved in restraint stress-induced suppression of LH pulse frequency in the ovariectomized rat.[25,41,192] We have shown (unpublished observation) that intramedial preoptic area administration of a nonselective CRF antagonist blocks restraint stress-induced suppression of pulsatile LH secretion in the ovariectomized rat. Although intracerebroventricular administration of UCN2, the selective CRF-R2 ligand, dose-dependently suppresses LH pulses,[192] microinfusion of UCN2 directly into the medial preoptic area failed to suppresses LH pulses, unlike CRF per se, which indicates the medial preoptic area is a probable CRF-R1 site (unpublished observation).

Although CRF signaling in the BNST and locus ceruleus are involved in the inhibitory response to this psychogenic stress, the CRF receptor subtype in these loci has also not yet been determined.[25,41,192] Interestingly, acute restraint evokes LH release in proestrous rats, which is mediated by CRF-R1 in the locus ceruleus.[207] The locus ceruleus receives dense CRF innervation from several regions, including the BSNT,[208] and sends direct noradrenergic projects to GnRH neurons in the preoptic area.[209] Commensurate with the preferential stress modalities conveyed by the medial and central amygdalar nuclei, *vis-a-vis* psychological (e.g. restraint) and physiological (e.g. immunological), respectively, the medial amygdala plays a key role in restraint stress-induced suppression of the GnRH pulse generator that may also involve $GABA_B$ receptor signaling in

the medial preoptic area.[136,155] This contrasts with the role of $GABA_A$ receptors in the medial preoptic area in mediating the effects of LPS[149] (see Figure 36.2).[156]

Impact of Stress on the Hypothalamic Kisspeptin and KNDy System

A major advance in our understanding of the neural mechanisms controlling GnRH secretion came in 2003 with the identification of the critical role for kisspeptins and their receptor, KISS1R (earlier termed GPR-54), in reproductive physiology. Mutations in the *KISS1R* gene are associated with hypogonadotropic hypogonadism in humans[210,211] and similar defects are observed in *Kiss1r* knockout mice.[211] There is now unequivocal evidence that kisspeptins are extraordinarily potent stimulators of gonadotropic hormone secretion in all species studied[110,112,121,212–215]; an effect that, at least in part, involves direct activation of the GnRH neurons that express Kiss1r.[216] The two major hypothalamic populations of kisspeptin neurons that are crucial for the regulation of gonadotropic hormone secretion are located in the preoptic area and the arcuate nucleus (the latter in the KNDy population).[121,217] It is generally accepted that in rats and mice, the preoptic population (which includes those in the anteroventral periventricular nucleus (AVPV)) are critical for controlling the preovulatory gonadotropic surge, while there is increasing evidence that the arcuate population are involved in controlling the pulsatile mode of secretion.[100] In other species, such as sheep, monkeys, and humans, there are fewer kisspeptin neurons in the preoptic area, with the most prominent population residing in the arcuate nucleus, and the latter implicated in both surge and pulsatile modes of GnRH secretion[100,101,121,217–219]; however, the preoptic population is also implicated in surge generation in the macaque and ewe.[219,220]

Because stress-induced suppression of reproduction is associated with reduced gonadotropic hormone secretion, it is reasonable to postulate that the hypothalamic kisspeptin system is implicated in this inhibitory response. Studies using a wide variety of stressors, including LPS, restraint, and insulin-induced hypoglycemia, showed decreased kisspeptin (*Kiss1*) and *Kiss1r* mRNA levels in the arcuate nucleus and preoptic area, which was associated with reduced pulsatile LH secretion in the adult female rat.[135,221] LPS has also been shown to decrease levels of kisspeptin protein in the arcuate nucleus.[222] Under conditions of negative energy balance linked to decreased gonadotropic hormone secretion, such as undernutrition[223] or uncontrolled experimental diabetes[224] *Kiss1* and or *Kiss1r* expression in whole hypothalamus was decreased in rodents. In contrast, undernutrition (72 h fasting) resulted in downregulation of *Kiss1* but upregulation of *Kiss1r* mRNA expression in whole hypothalamus in prepubertal male and female rats,[225] which might explain the increased LH response to exogenously administered kisspeptin in these animals. Similarly, alcohol consumption in prepubertal female rats, which decreases LH secretion and disrupts puberty, suppressed *Kiss1* expression in the preoptic area and arcuate nucleus, but increased *Kiss1r* gene and protein expression in the preoptic area—although not in the arcuate nuclear area,[226] implying an overall reduction of kisspeptin signaling in the latter brain region.

Interestingly, administration of exogenous corticosterone achieving circulating concentrations equivalent to those detected in response to either acute or chronic stressors resulted in a concomitant decrease in *Kiss1* and increase in *Kiss1r* mRNA expression in both the preoptic area and arcuate nucleus in the adult ovariectomized rats.[135] It is tempting to speculate that this differential regulation of hypothalamic kisspeptin and its receptor may underlie the absence of LH pulse suppression in this particular experimental paradigm. Of note is evidence that corticosterone actually plays a pivotal role in maintaining LH pulsatility in the presence of a variety of stressors in the rat.[152] However, the expression profile of *Kiss1* and *Kiss1r* under experimental conditions of hypercorticosteronemia during the estrogen-induced LH surge or across the 4-day estrous cycle, which appear to be sensitive to glucocorticoid suppression,[227] remains to be determined. Additionally, further work is required to determine whether a similar differential regulation of hypothalamic kisspeptin and receptor expression is evident in other species, such as marmoset and rhesus monkeys, which fail to show suppression of LH pulses in response to acute stress levels of cortisol[9,107]; it would also be of interest to compare these data with the effects of chronic hypercortisolemia which does suppress gonadotropic hormone secretion in the monkey.[228] It is similarly unknown how glucocorticoids affect hypothalamic *Kiss1* and *Kiss1r* expression in other species, such as the sheep,[229] which clearly show a suppression of pulsatile LH secretion in response to acute physiological stress levels of these adrenal steroids.

The identification of glucocorticoid receptor immunoreactivity in most (87%) preoptic areas, but few (<3%) arcuate nuclear kisspeptin neurons, in the intact female rat provides evidence of a direct modulation of the kisspeptin system by glucocorticoids, although the physiological implication of the differential distribution of the receptor and its commonality across species remains to be elucidated.[230] Glucocorticoid receptor containing afferents to arcuate nuclear kisspeptin neurons could provide indirect pathways for glucocorticoid modulation of the arcuate kisspeptin system. However, in sheep there is a high percentage (~70%) of co-localization of glucocorticoid receptor with estrogen receptor alpha and progesterone receptor containing

neurons in both the preoptic and arcuate nucleus, which provides indirect evidence for KNDy neurons and preoptic kisspeptin neurons containing glucocorticoid receptors.[231]

Not only are the neural inputs to the preoptic area and arcuate nucleus for stress-induced suppression of *Kiss1*/*Kiss1r* expression undetermined, but few studies have addressed the stress-related neuropeptide systems that may be involved.[232] The classical stress neuropeptide CRF, which plays a pivotal role in stress-induced suppression of the GnRH pulse generator,[25,41,192,233,234] profoundly suppresses *Kiss1* and *Kiss1r* mRNA levels in both the preoptic area and arcuate nucleus when administered by intracerebroventricular injection in the rat.[135] Whether this CRF-induced reduction in *Kiss1*/*Kiss1r* expression directly or indirectly underlies the associated suppression of pulsatile LH secretion remains to be fully determined. The overlapping distribution of kisspeptin[235,236] and CRF-R1 and CRF-R2[24,237] in the preoptic area and arcuate nucleus provides the anatomical substrate for a functional interaction between the CRF and kisspeptin neuropeptide systems. Indeed, it was recently demonstrated that essentially all kisspeptin neurons in both of these hypothalamic sites showed CRF-R immunoreactivity,[230] although the CRF receptor subtype remains to be identified. However, close appositions between CRF fibers and kisspeptin neurons were sparse, leading to the suggestion of a nonsynaptic volume transmission between these signaling systems.[230]

Although CRF signaling in extrahypothalamic areas, including the BNST,[238] locus ceruleus,[185] and medial amygdala,[61] play a critical and stressor-specific role in suppression of the GnRH pulse generator, the link with kisspeptin expressed in these brain regions[239–241] remain to be examined. The inhibitory neurotransmitter GABA is also strongly implicated in stress-induced suppression of the HPG axis.[136,155,242] Moreover, the majority of hypothalamic kisspeptin neurons co-express $GABA_B$ receptors[239] and $GABA_B$ receptors in the medial preoptic area mediate psychogenic stress-induced suppression of pulsatile LH secretion in the rat.[136,155] Although the role for $GABA_B$ receptors in the kisspeptin neurons of the medial amygdala[239] is unknown, it was recently shown that *Kiss1* expression in the medial amygdala, and also the BSNT, were dramatically increased in adult $GABA_{B1}$ knockout mice, which might suggest these extrahypothalamic kisspeptin populations are normally inhibited by $GABA_B$ signaling.[239] However, the role of these extrahypothalamic kisspeptin populations to control of LH is unknown.

Adverse early life environments have been shown to have profound and long-lasting effects on the stress response throughout later life. Neonatal exposure to the immunological challenge LPS delays puberty and decreases *Kiss1* mRNA in the preoptic area in female rats.[243] This reduced *Kiss1* expression persists into adulthood[243] and may contribute to the disruption of estrous cyclicity in these animals.[244,245] Long-term programing of the HPA axis is also evident in these neonatal LPS-treated rats with persistent hypercorticosteronemia and increased stress reactivity in adulthood.[246,247] Early metabolic perturbations similarly affect reproductive function. Models of early-onset obesity, such as a high-fat diet or overfeeding due to small litter size, result in precocious acceleration of the GnRH pulse generator frequency and pubertal activation, as well as high levels of hypothalamic *Kiss1* expression, in the rat.[248,249] Conversely, postnatal undernutrition using a large litter paradigm in rodents resulted in delayed puberty, decreased hypothalamic *Kiss1* expression,[248] and defective development of kisspeptin neural projections that persisted into adulthood, causing lasting deleterious effects on the organization of key hypothalamic neural circuits involved in the control of reproduction.[250]

Despite these many advances, a great deal of further work is required to reveal the complex interaction between the stress system and the regulation of kisspeptin-KISSR signaling in the context of the reproductive axis. Additionally, although the discovery of the kisspeptin system, with its synaptic input to the GnRH neuron, provides the conduit for stress signals to indirectly affect GnRH secretion, preceding theories embraced the notion of stress neural circuits impacting directly as well as indirectly on the GnRH neural network. For example, for GABA, there is a dense GABAergic synaptic input to GnRH neurons in the medial preoptic area.[251] The direct effects of GABA on GnRH neurons are predominantly excitatory, although inhibitory responses are also evident.[252–254] However, intramedial preoptic area administration of GABA suppresses pulsatile LH secretion in vivo.[255] Moreover, stressors or microinfusion of CRF into the BNST or locus coeruleus (both of which inhibit pulsatile LH secretion) activate GABAergic neurons in the medial preoptic area[136,185,238] and, critically, intramedial preoptic area administration of selective $GABA_A$ or $GABA_B$ receptor antagonists block LPS or restraint stress-induced suppression of LH pulses, respectively, in the rat.[155] It is proposed that the primarily suppressive effects of GABA on LH secretion in vivo are most likely explained by indirect influences.[253] Nevertheless, the precise anatomical and functional interactions between the GABA, kisspeptin, and GnRH systems, in particular the identity and relative importance of direct versus indirect inputs to the GnRH neuron per se, in stress-induced suppression of the GnRH secretion—let alone GnRH pulse generator frequency—remain to be established; this is also true for the other key neurotransmitter and neuropeptide systems involved in stress and infertility.

STRESS AND THE FEMALE REPRODUCTIVE CYCLE

Follicular development is dependent on pulsatile LH and FSH stimulation occasioned by the GnRH pulse generator. Although there is a marked increase in GnRH pulse generator frequency during the transition from the late luteal to the early follicular phase of the menstrual cycle in higher primates, including women, that is probably an escape from the inhibiting influence of progesterone. This high frequency of approximately one pulse per hour does not appear to change significantly as the follicular phase progresses and circulating estradiol concentrations rise[113,256,257] (see also Chapter 28). When the estradiol secreted by the developing Graafian follicle exceeds a defined threshold for ~36 h, the preovulatory gonadotropin surge is initiated and ovulation ensues approximately 24 h later—the so-called positive feedback action of estrogen.[258] A similar acceleration of GnRH pulse generator frequency occurs in infraprimate species, including sheep[259] and cattle,[260] although the duration of the follicular phase varies considerably between species. Additionally, the rat shows a clear change in the pulsatile pattern of LH secretion across the 4-day estrous cycle, with a pulse interval of around 46–60 min from metestrus through to the morning of proestrus before the afternoon LH surge.[261] LH pulses are infrequent or absent during estrus, before returning to an approximate circhoral pattern on the morning of metestrus.[261] Without adequate GnRH pulse generator frequency, follicular development might be compromised and insufficient estradiol produced to induce the gonadotropin surge responsible for ovulation and corpus luteum formation. The preovulatory rise in estradiol is critical for the induction of the gonadotropin surge in all species despite important differences in the underlying neuroendocrine mechanisms (see Chapter 33 and the review by Plant comparing monkeys and rodents[262]).

Menstrual and Estrous Cycles: Stress and Ovulation

Disruptive effects of stress on the natural estrous cycle are well established in a wide variety of species, including mice,[263] rats,[100,264,265] sheep,[229,266–268] cows,[269] or menstrual cycle in monkeys[157,270,271] and women.[8,126] Considerable instructive data has been obtained using immunological/inflammatory stress. In the rat, intracerebroventricular infusion of IL-1β for 4–6 days caused a total disruption of the estrous cycle, characterized by persistent diestrous vaginal smears (indicative of low estrogen) and decreased circulating levels of LH and FSH.[151] GnRH gene expression was also markedly suppressed in GnRH neurons distributed between the rostral preoptic area/organum vasculosum of the lamina terminalis and the medial preoptic area in these animals. The percentage of GnRH neurons expressing the c-fos protein in the medial preoptic area during the afternoon of proestrus is also significantly decreased after central administration of IL-1β or peripheral administration of LPS.[151,272] Moreover, GnRH release at proestrus, as measured with a push–pull cannula implanted into the median eminence, is markedly suppressed by IL-1β.[151]

As discussed, cytokines and LPS are known to suppress pulsatile LH secretion in the rat,[41,111,134–136,142] which may contribute to disruption of estrous cyclicity and the preovulatory gonadotropin surge. However, it is also possible that immune challenge interferes with the expression of the LH surge independently of an effect on pulsatile gonadotropin secretion. The underlying mechanism by which an immune challenge could interfere with the surge in the rat remains to be established. Because the LH surge in the rat (in common with the mouse and hamster, but unlike most other species) is critically dependent upon a circadian mechanism,[262,273] immunological stress, in common with other stressors, may interfere either with the interaction between ovarian steroids and the neural substrate in the preoptic area that relays the positive feedback signal to the GnRH neural network or with the circadian signal that times the surge.

The positive feedback action of estradiol that triggers the preovulatory GnRH surge has been shown to be critically dependent on kisspeptin signaling in the AVPV.[274,275] Because endotoxin suppresses *Kiss1* and *Kiss1r* expression in the AVPV in the rat,[135,221] it is not unreasonable to suggest this may be the principal mechanism by which the preovulatory LH surge is disrupted. However, the expression of *Kiss1* in the AVPV neurons and the LH surge are phase-locked to the circadian oscillator located within the hypothalamic suprachiasmatic nucleus, implicating circadian control of kisspeptin in ovulation in rodents, including rats, mice, and hamsters.[276–278] Indeed, an interaction between the suprachiasmatic nucleus and the AVPV kisspeptin neurons via vasopressinergic projections, and a novel preoptic area GnRH gating mechanism to control ovulation has been proposed.[278] Moreover, it was shown that fibroblast growth factor 21 (FGF21), a fasting-induced hepatokine, acts on the suprachiasmatic nucleus to suppress the vasopressin-kisspeptin signaling cascade, thereby inhibiting the proestrous LH surge in mice and providing a novel mechanism for reproductive failure in response to nutritional challenges.[279] However, the relevance of this model to other species remains to be determined.

Mechanistic details have also emerged from studies in sheep, in which the gonadotropin surge is not tightly linked to a circadian system and therefore more akin to primates. In the ewe, endotoxin administration disrupts the estrous cycle by preventing the development of high-frequency LH pulses, which provide the critical drive

for the preovulatory estradiol rise and hence delayed or blocked the LH/FSH surge and estrus.[280] Interestingly, some ewes did not show a suppression of LH pulse frequency; yet, the estradiol rise and LH surge were still disrupted, suggesting that in addition to suppression of LH pulsatility other processes, such as ovarian follicular responsiveness to gonadotropic stimulation, might be impaired.

Immune challenge has been shown to inhibit ovarian estradiol secretion in response to gonadotropins in the rat.[281] In addition to endotoxin acting at the level of the hypothalamus to suppress the pulsatile secretion of GnRH into the pituitary portal blood,[129] it interferes with the ability of the surge-generating mechanism to respond to the preovulatory estradiol signal.[282,283] Unlike its acute suppression of GnRH/LH pulses, which occurs immediately, endotoxin does not acutely inhibit GnRH/LH release at the time of the surge, but rather acts to block the GnRH/LH surge some 10–20 h in advance of the surge,[13,129,283] during the critical estradiol-dependent stage (see Chapter 26 for details) when the steroid must be elevated to activate estrogen-sensitive neurons and the positive feedback signal is transduced to ultimately generate the surge.[284] Endotoxin does not affect the late signal-processing or the surge release stages when elevated estradiol is no longer necessary for successful surge generation.[282] In contrast to endotoxin, transport stress only delays the LH surge when applied immediately before or during the expected time of the LH surge in the ewe,[285] while insulin-induced hypoglycemia can delay the surge at any time before the surge.[286]

Although the detailed mechanisms underlying the role of kisspeptin in the positive feedback effects of estradiol to induce the preovulatory LH surge in the ewe are not fully established, especially the relative contribution of the preoptic area and arcuate kisspeptin populations,[218,287,288] it was shown that LPS-induced suppression of the spontaneous LH surge was associated with a clear decrease in c-fos expression in both kisspeptin neuronal populations.[267] Moreover, there was an increase in the number of CRF-R2 positive cells in the arcuate nucleus and internal zone of the median eminence, which might underlie the LPS-induced inhibition of kisspeptin neurones and disruption of the LH surge.[267] The recent identification of CRF receptor immunoreactivity in arcuate kisspeptin neurons, albeit in the rat,[230] would support this postulate.

Acute psychosocial stress inhibits pulsatile LH secretion in ovariectomized ewes by reducing both GnRH pulse amplitude[200] and pituitary responsiveness to GnRH.[198] Further, a combination of psychosocial stress, such as isolation and nervous temperament through genetic selection, resulting in greater cortisol release, suppresses LH pulse frequency when compared to calm sheep.[268] However, the estrous cycle of the ewe appears to be remarkably resistant to disruption by acute episodes of psychosocial stress, whether applied intermittently during a single follicular phase or repeatedly over the course of several estrous cycles.[289] Similarly, repeated exposure to acute psychosocial stress does not disrupt the estrous cycle in pigs.[290] These data contrast with studies in primates in which psychosocial stress causes prolongation of the follicular phase and luteal insufficiency.[206] Although intravenous infusion of cortisol across the course of the follicular phase (4-days) to achieve concentrations ranging from one third to maximal values induced by isolation stress reduced LH pulse frequency, and delayed or blocked the preovulatory estradiol rise and the LH and FSH surge in the ewe,[201] these plasma cortisol levels are probably more sustained and prolonged than those induced by repeat psychological stress paradigms and reflect more the chronic hypercortisolemia conditions associated with endotoxin stress, which does disrupt the estrous cycle in the ewe.

Functional Hypothalamic Amenorrhea

Clinically recognized forms of stress-induced anovulation and infertility in women include functional hypothalamic amenorrhea (FHA), anorexia nervosa, and exercise-associated amenorrhea. Although it was previously thought that these different forms of anovulation resulted from discrete stressors (FHA: psychosocial; anorexia: nutritional compromise; exercise-associated amenorrhea: excessive exercise), it is now recognized that each of these syndromes develops in response to a combination of psychosocial and metabolic stressors.[6,291] Compared with eumenorrheic women, those with FHA display mild indices of psychological stress including dysfunctional attitudes, difficulty coping with daily hassles, and higher dependence on interpersonal relationships.[292] Additionally, these patients exhibit a high incidence of subclinical eating abnormalities and a propensity to exercise intensively, which adds to their metabolic imbalance.[8] About 30% of women presenting with amenorrhea are diagnosed with FHA and the proximate cause is reduced LH pulse frequency and reduced levels of FSH. Behavioral interventions targeted at alleviating problematic attitudes, such as cognitive behavioral therapy, are not only highly effective at ameliorating FHA but also neuroendocrine and metabolic concomitants, such as hypercortisolism and hypothyroidism.[8]

To study the mechanisms underlying FHA, Cameron and colleagues used a nonhuman primate model in which mild psychosocial stress (novel room with unfamiliar conspecifics) combined with a mild diet, with or without a moderate exercise regimen, led to suppression of reproductive function in some, but not all, animals.[6,291] There is really no equivalent nonprimate model that embraces the nuances of FHA. In her cynomolgus

monkey model, Cameron observed that females were either: (1) highly stress resilient (HSR) and maintained normal menstrual cyclicity when exposed to the combined stressors across two menstrual cycles; (2) medium stress resilient (MSR) with ovulation in the first stress cycle, but not in the second stress cycle; or (3) stress sensitive (SS) with cessation of ovulation as soon as stress was initiated.[6,291] Interestingly, SS monkeys showed lower estradiol levels in the follicular phase and reduced progesterone in the luteal phase of their menstrual cycles prior to any stress exposure, suggesting the HPG axis is less robust than in the more stress resilient monkeys even in the absence of stress.[293] However, the possibility cannot be ruled out that the SS monkeys are slightly stressed under normal husbandry conditions, despite an absence of raised plasma cortisol levels.[294] Moreover, LH pulse frequency was lower in the SS monkeys in the absence of stress.[294] Additionally, animals that developed abnormal menstrual cycles in response to stress (MSR+SS monkeys) showed higher levels of cortisol and suppressed LH pulse frequency during stress exposure, with the latter reversed by CRF-R1 anatgonism.[294]

The failure of the CRF-R1 antagonist to block the stress-induced increase in cortisol secretion might suggest that activation of the HPA axis is not a primary neural mechanism underlying sensitivity to stress-induced anovulation.[294] However, it is difficult to reconcile this with the clinical data where women with FHA showed a reduction in cortisol levels after cognitive behavioral therapy coincident with resumption of ovarian activity.[8] In addition to the endocrine abnormalities and higher basal levels of CRF mRNA in the PVN under nonstress conditions, the SS monkeys also have a greater density of CRF fibers in the central nucleus of the amygdala, locus ceruleus, and serotonergic raphae nucleus, together with a higher noradrenergic output from the locus ceruleus; the latter further increased with moderate psychological and metabolic stress.[270,291,293]

With regard to the serotonergic system, it is downregulated in SS monkeys, as indicated by lower gene expression of tryptophan hydroxylase 2, the rate-limiting enzyme for 5-HT synthesis, SERT, 5-HT-receptor, subtype 1A in the dorsal raphe nucleus compared with HSR animals.[291] Interestingly, although polymorphism of the 5-HTTLPR (in particular, a preponderance for the short allele) is associated with increased sensitivity to stress and anxiety in humans and rhesus monkeys,[81–83] the short allele was not observed in the SS cynomolgus.[295] There is also reduced 5-HT innervation of the locus ceruleus in SS monkeys, the source of which might be the raphe.[270] Importantly, selective serotonin reuptake inhibitors (SSRI) increase peak estradiol and progesterone secretion only in SS monkeys, suggesting that adequate central serotonergic drive to the HPG axis is critical and SSRI's may be an effective treatment for FHA.[291] In the hypothalamus of SS monkeys, there is an upregulation of 5-HT_{2A} and 5-HT_{2C} receptors and an increase in GAD67 gene expression, which are inhibitory to the HPG axis.[296]

There are considerably less data on men. Stress related to prolonged military endurance training is associated with reduced plasma levels of gonadotropins and androgens and raised cortisol.[297] However, it is difficult to separate the relative contribution of psychological and metabolic stressors under these conditions and caloric deficits are known to readily suppress pulsatile LH secretion in men.[159] Nevertheless, anticipatory psychological stress suppressed LH and testosterone levels in men.[298]

CONCLUSION

We have a limited grasp of the neural mechanisms underlying stress-induced reproductive failure. Given the myriad stressors, the complexity of the neurocircuitry, and their stressor-specific nature, coupled with species differences—to mention just a few of the variables to consider—it is little wonder. Nevertheless, at the center of the neuroendocrine component of the reproductive system lies the GnRH pulse generator, which is unequivocally affected by stress and a reduction in its operational frequency is at the core of stress-related infertility. Less well characterized is the stress-induced reduction in GnRH pulse amplitude or LH pulse amplitude that may also impact on reproductive function.

Kisspeptin signaling has provided a recent focus on the neural mechanisms involved, not only in GnRH pulse generation but GnRH surge generation, although we have only begun to scratch the surface of the stress neuropeptide-kisspeptin interactions. Peripheral components of the HPG axis (i.e., the ovary and testis,) and the autonomic nervous system have not even been touched on in this review; the reader is directed to the elegant and extensive review by Ferin in the previous edition of this book.[1]

There are many unresolved questions concerning the effect of stress on reproduction. One of the greatest challenges will be a more complete understanding of the complex neural circuitry underlying the suppression of gonadotropic hormone secretion in response to various stressors. Their identification will help reveal the critical neurotransmitters or neuropeptides involved, thereby facilitating the discovery of novel therapeutics for stress-related reproductive disorders. However, we can anticipate significant redundancy in the neural circuitry, as evident in part by the common observation of partial blockade of the stress response with neuropeptide antagonism, nuclear lesions, or gene knockdown or silencing. A greater understanding

of the neural basis of individual variation or vulnerability to stress is essential. Finally, identification of the neural construct underlying the GnRH pulse generator would greatly facilitate elucidation of the pathophysiology of stress-related reproductive neuroendocrine disorders.

INTRODUCTION

Overview

The capacity to reproduce, more than almost any physiological process, undergoes enormous functional change across the life cycle. In the case of placental female mammals, the physical and psychological ability to maintain pregnancy, lactate, and care for offspring must be achieved if reproduction is to be successful. Reproductive processes must be further coordinated with external environmental forces such as food availability, social factors, and freedom from stressors, as well as internal factors such as disease states, hormonal deficiencies/excess, and immune challenges. In the longer term, reproductive competence is coordinated with chronological age, being attained at the onset of puberty, following an often extensive postnatal developmental period, and lasting through adulthood. With advanced aging, there are further reproductive changes, typically a loss of reproductive capacity in the female with partial or complete reproductive senescence. In contrast, aging effects on the male reproductive axis are much less pronounced, and reproductive capacity is typically sustained until very late in life.

Reproductive aging refers specifically to germ cells and the hormone-producing cells that support them, both within the gonad and at the hypothalamic and pituitary level. During the reproductive aging process, each level of the hypothalamic-pituitary-gonadal (HPG) axis undergoes alterations in structure, function, and synthesis/release of hormones. In addition, ovarian and testicular hormones exert feedback actions on the hypothalamus and pituitary, which may also change with aging. While reproductive aging occurs within the broader context of somatic aging, here we will focus on how the reproductive systems of females and males change with age, discussing physiological functions, hormones, and underlying mechanisms. For more detailed discussion of the GnRH neuronal network, the pituitary gonadotropes, sexual differentiation, the neuroendocrine control of puberty, and ovarian cyclicity the reader is referred to Chapters 7, 10, 11, 28, 32, and 33.

Hypothalamic-Pituitary-Gonadal (HPG) Axis

The control of reproduction across the life cycle involves three levels of regulation, each playing a unique and critical role. In the hypothalamus, a small group of a few thousand neurons that produce the neuropeptide gonadotropin-releasing hormone (GnRH)[1] provides the primary driving force upon the reproductive system through most of life. This small neural population, whose cell bodies are localized in anterior hypothalamic regions (rodents and primates) and the basal hypothalamus (primates), project neural processes to the median eminence/infundibulum at the base of the hypothalamus and just above the anterior pituitary gland. The GnRH decapeptide is released in pulses with intervals of 30 min to several hours, depending upon species, and in the case of females, upon menstrual cycle stage. From the median eminence/infundibulum, GnRH diffuses into the portal capillary system that transports it and other hypothalamic releasing/inhibiting hormones to the anterior pituitary gland to act upon target cells.[2] Specific to HPG function, a subpopulation of anterior pituitary cells called gonadotropes, which express GnRH receptors and

Knobil and Neill's Physiology of Reproduction, Fourth Edition

that synthesize luteinizing hormone (LH) and/or follicle-stimulating hormone (FSH), respond to the GnRH signal with release of LH and FSH into the general circulation. From there, LH and FSH act upon their receptors in the ovary or testis to affect the primary gonadal functions of gametogenesis and steroidogenesis. The steroid hormones, particularly estradiol and progesterone in females, and testosterone and estradiol in males, have powerful actions on reproductive and nonreproductive tissues and exert feedback control of hypothalamic GnRH neurons and pituitary gonadotropes. The gonads also secrete protein hormones that are involved in reproductive processes. Inhibin B in males and inhibin A and inhibin B in females play important roles in the selective suppression of FSH release from gonadotropes.

The relationships among the hypothalamus, pituitary, and gonad change throughout the life cycle. Gonadal development in the embryo begins early in gestation and occurs independent of the central components of the reproductive system, which develop later in gestation. Anti-Mullerian hormone (AMH) production from male testes leads to regression of the Mullerian system (Chapter 7). The testes also produce relatively high levels of testosterone that are critical for masculinization of the reproductive tract and other tissues, in response to maternal chorionic gonadotropins in primates. In contrast, the fetal ovaries are relatively quiescent. The hypothalamus and pituitary develop later in gestation, with hypothalamic GnRH neurons detectable approximately halfway through gestation. Shortly before/after birth, the gonads actively synthesize steroid hormones, the testis more so than the ovary, resulting in further reproductive developmental changes and sexual differentiation of the brain, the latter well-defined in rodents albeit less clear in primates (Chapter 47). In humans and nonhuman primates, infancy is characterized by robust pulsatile GnRH release, elevated levels of gonadotropins, and gonadal steroid secretion, with steroid secretion being more pronounced in males than females (Chapter 32). Following this "mini-puberty of infancy," gonadotropin release and gonadal hormone production are markedly decreased until the onset of puberty.

The pubertal process is well accepted as being governed by the activation of GnRH neurons by converging central nervous system inputs from other neurons and glia that signal through the neuropeptide, kisspeptin, as well as other neurotransmitters and neuropeptides. Steroid hormone feedback to the hypothalamus and pituitary also matures during this early phase of reproductive life. It is now well accepted in females that stimulatory central drive from a network of hypothalamic inputs to the GnRH system, together with a diminished drive from inhibitory neurotransmitters, are associated with puberty (see Chapters 30–32). These neural networks continue to play this role in adulthood; however, age-related changes in reproductive age processes are still relatively poorly understood.

The remainder of this chapter will focus on the sex-specific, age-related changes in the reproductive axis that occur from adulthood into aging and discuss the relationships between the hypothalamic, pituitary, and gonadal components of the axis. As was the case for our understanding of the neuroendocrine and gonadal physiology of puberty and normal reproductive function, animal models of reproductive aging provide an important complement to studies in men and women. Not only can animal models be used to address mechanistic issues that cannot be approached in the human, but they also emphasize both the common features and the unique reproductive strategies that have developed across species to ensure survival.

Historical Perspective

The age-related loss of menstrual function in women has been noted throughout recorded history. However, it was not until the late 1700s that discussion of the etiology of these changes transitioned from mystical to physical terms with John Leake's proposal that cessation of menses was caused by vascular comprise (for review, see Haney[3]). In 1952, the seminal studies of Block[4] documented the dramatic decrease in the number of follicles within the ovary as a function of age, establishing ovarian aging and the loss of steroid hormones as critical to the loss of reproductive function and vaginal bleeding. Changes in gonadotropin secretion after menopause and in menstrual cycles of older women were documented in the 1970s.[5] For many years, the selective rise in FSH on day 3 of the menstrual cycle in older women was the only clinically available marker of potentially declining fertility in such subjects Studies in the 1980s confirmed that this rise in FSH was due to the loss of ovarian secretion of both estradiol and the inhibins, particularly inhibin B.[6,7] Since that time AMH has been established as an unexpected marker of the number of ovarian follicles, and AMH and antral follicle count have been used as prognostic markers in infertility programs (for review see Broekmans et al.[8]). In 2001, the first Stages of Reproductive Aging Workshop (STRAW) utilized the findings from important cohort studies of women across the menopause transition to derive a codified description of reproductive stages across the lifespan, based primarily on changes in menstrual bleeding patterns and changes in FSH levels.[9] This staging system provided a critical scaffold for further studies and was updated a decade later (STRAW+10) to incorporate the results of longitudinal studies across the menopause transition and studies of fertility in older women,[10] as described below.

Perhaps the most important study in rodents is that of Krohn et al.,[11] in which ovaries were transplanted from

aged to young ovariectomized animals. These studies demonstrated that ovaries from old donors undergo folliculogenesis and ovulation in the young hosts, suggesting that reproductive failure with aging in rodents is not limited by the ovary, and paved the way for future studies on identifying the changes in the hypothalamic-pituitary axis that are responsible for the cessation of reproductive function during aging.

A reduction in testosterone levels in the spermatic veins of elderly men was first reported more than five decades ago.[12] However, subsequent studies using peripheral blood samples produced conflicting results due to small sample sizes as well as differences in the health of the cohorts studied, the methodology used, and the timing of the blood sampling.[13] It has only been in the last two decades that large epidemiologic studies have clarified the magnitude of the change in testosterone with aging[14–17] and subsequent detailed physiologic and histologic studies in both human and primate models have implicated alterations at both the hypothalamic and testicular levels that account for these changes.

FEMALE REPRODUCTIVE AGING

Reproductive Function in Normal Reproductive-Aged Women

Within 2–4 years of the first menstrual period, regular reproductive cycles are established in normal women. Cycles between 25 and 35 days (from the first day of menses in one cycle to the first day of menses in the subsequent cycle) are considered normal,[18] although cycle-to-cycle variability in an individual woman is considerably smaller (±2 days). Variability in overall menstrual cycle length both between and within women is largely due to differences in follicular phase length with luteal phase length remaining relatively constant.

The hormonal interactions between the hypothalamus, pituitary, and ovary, with the endometrium as a gonadal steroid end organ for reproduction, are tightly orchestrated and precisely timed (for review see Hall et al.[19]) (Figure 37.1). Estradiol is responsible for endometrial proliferation in the follicular phase, while both estradiol and progesterone are required for luteal phase preparation of the endometrium for implantation if conception occurs. If pregnancy does not occur, the loss of hormonal support of the endometrium that accompanies the decline in function of the corpus luteum results in endometrial shedding or menses, which provides an external marker for the beginning of a new cycle.

Changes in ovarian secretion of progesterone and estradiol modulate the frequency and/or overall

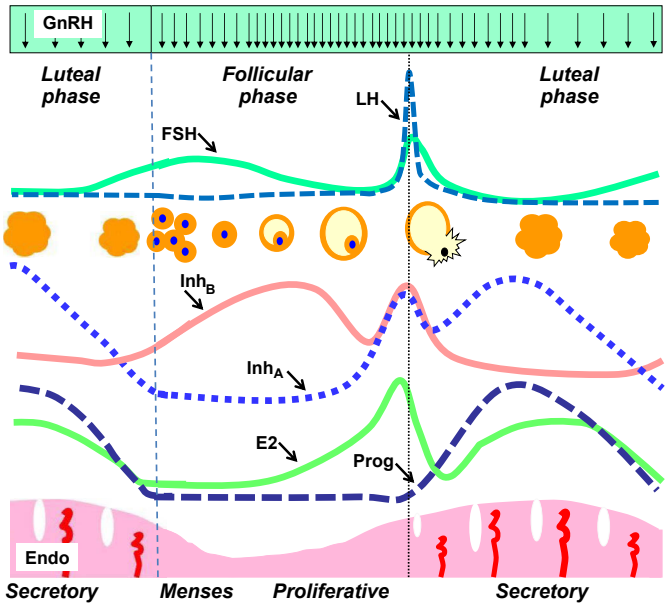

FIGURE 37.1 The hormonal, follicular, and endometrial dynamics of the normal menstrual cycle from the late luteal phase through menses and the beginning of a new cycle of follicle development, ovulation, and corpus luteum function and decline. Dynamic changes in the frequency of pulsatile gonadotropin-releasing hormone (GnRH) stimulate the integrated actions of follicle-stimulating hormone (FSH) and luteinizing hormone (LH), which are responsible for: (1) follicular development with secretion of estradiol (E2), inhibin B (Inh_B), and inhibin A (Inh_A); (2) the preovulatory LH surge and ovulation; and (3) secretion of progesterone (Prog), E2, and Inh_A from the corpus luteum. Secretion of E2 and Prog result in proliferative and secretory changes in the endometrium (Endo), preparing it for implantation should conception occur. If conception does not occur, endometrial shedding follows the decline in hormone secretion, which accompanies demise of the corpus luteum. *From Hall JE.*[19]

quantity of GnRH released, while both gonadal steroids and the inhibins influence the pituitary response to GnRH. Progesterone has a profound inhibitory effect on GnRH pulse frequency,[20,21] which ultimately influences the differential control of LH and FSH synthesis; slow frequencies of GnRH stimulation of the gonadotrope, as seen in the luteal phase, favor the synthesis of FSH over LH.[22] Estradiol is an important negative feedback modulator of overall GnRH secretion,[23] and low levels of estradiol have a further effect at the pituitary level, suppressing LH and FSH responses to GnRH.[24] Finally, inhibin B and inhibin A selectively suppress FSH, acting at the pituitary alone (for review, see Welt[25]).

During the luteal-follicular transition in women (Figure 37.1), there is a preferential rise in FSH over LH. This is due, at least in part, to the loss of pituitary inhibition of FSH secretion by estradiol and probably inhibin A from the waning corpus luteum.[26] Increased GnRH secretion, made possible by the loss of progesterone and estradiol feedback, is also necessary during

the luteal-follicular transition to achieve levels of FSH that are adequate for follicular recruitment.[27] Thus, our working model is that slower frequency GnRH stimulation in the luteal phase facilitates pituitary synthesis of FSH whose secretion is inhibited by estradiol and inhibin A. With the declining levels of estradiol and inhibin A that accompany the functional demise of the corpus luteum in the late luteal phase, FSH secretion is released from negative feedback but requires restoration of more robust stimulation by GnRH to attain levels that are capable of recruiting a new cohort of follicles.

While increasing levels of FSH are necessary for recruitment of a new cohort of follicles at the beginning of each reproductive cycle, restraint of FSH is equally important to ensure that only a single follicle reaches the preovulatory stage in women. It is widely appreciated that estradiol secretion from developing follicles contributes to the negative feedback control of FSH as the follicular phase progresses (Chapter 28). Distinguishing an additional role for inhibin in this critical process in women has been challenging in the absence of the ability to administer inhibin or inhibin antagonists. Several lines of evidence, however, do suggest that inhibin feedback plays an important role in the dynamics of FSH secretion across the normal menstrual cycle. As will be discussed below, lower levels of inhibin B are associated with higher FSH levels during the luteal-follicular transition and serve as a marker of reproductive aging in women. In this setting and in ovulatory women with premature ovarian insufficiency (POI) in whom inhibin B is also low, FSH levels remain higher than normal across the follicular phase despite estradiol levels that are equivalent to or higher than normal.[28,29] In addition, in women in whom POI is due to autoimmune oophoritis, FSH decreases in conjunction with follicle development and elevated inhibin B even in the virtual absence of estradiol.[30]

In women, generation of the preovulatory LH surge that is necessary for ovulation requires ongoing pulsatile GnRH secretion, but is otherwise fully dependent on the marked augmentation of gonadotropin responses to GnRH that results from the effect of rising levels of estradiol on pituitary gonadotropes[19] (see also Chapter 28). The mechanisms underlying the preovulatory surge in women stand in sharp contrast to those in other animal species in which increases in GnRH secretion, in many cases tightly entrained to circadian cues, augment the effect of positive estrogen feedback at the pituitary,[31] perhaps allowing for greater flexibility in responding to environmental signals. This difference between women and other mammalian species in the mechanisms underlying generation of the preovulatory LH surge becomes particularly important in providing a perspective from which to interpret and translate the data on reproductive aging in females across species.

Ovarian Aging in Women

In women, reproductive senescence is due, in major part, to depletion of follicles from the ovary. In the human ovary, the germ cell population reaches its maximum of 6–7 million at approximately 20 weeks of gestation when primordial follicles, consisting of primary oocytes surrounded by a single layer of flattened granulosa cells, begin to form. Primordial follicles, together with follicles that have grown to intermediate and small primary follicle stages, constitute the finite pool of resting follicles in the ovary (for review, see Gougeon et al.[32]). At the time of birth, the resting follicle pool has been reduced to approximately 1 million, primarily due to atresia, with a further reduction to 250,000 by the time of puberty. While the factors that control the early growth and development of follicles are incompletely understood, autocrine and/or paracrine actions of the transforming growth factor β (TGFβ) family appear to play a major role, as discussed in Chapter 21. Although FSH does not appear to be absolutely required for preantral follicular growth, it is possible that FSH may influence the early stages of folliculogenesis (see Chapters 28 and 29).

FSH increases during infancy, and this increase can last as long as 18 months in girls. During this time, estradiol levels are increased but are not high enough to indicate that a preovulatory follicle has formed, and ovulation does not occur.[33] In childhood, FSH is extremely low and does not rise again until the early stages of puberty, which can occur as early as 8 years old in normal girls. During and after puberty, follicles will leave the pool of resting follicles either by activation of further growth or by degeneration. The quiescent primordial follicles are recruited to further growth and differentiation through a highly regulated process that limits the size of each developing cohort. FSH provides a critical stimulus for recruitment of resting follicles into the growing follicle pool beginning in adolescence, while AMH, produced in granulosa cells from small growing follicles, restrains this effect of FSH.[34] It is from this growing pool of preantral follicles of 2–5 mm that the follicle destined to ovulate is selected. Further FSH-dependent development is supported by estradiol, activin, and other intraovarian factors.

The age at which ovarian function is ultimately lost is based on both the size of the initial primordial follicle pool and the rate of depletion of this pool. In women, there is a strong correlation between the size of the resting follicle pool and the number of growing follicles. However, this relationship is altered with aging. Until approximately 30 years of age in normal women, the loss of follicles from the resting pool is primarily due to atresia, while after

this age an increasing proportion is lost due to entrance into the growth phase.[35,36] Thus, as the overall number of follicles within the ovary declines, the percentage of growing follicles increases,[36,37] potentially representing an adaptation that prolongs reproductive cycles and estradiol secretion but hastens the onset of menopause. In contrast to rodents, in which the loss of follicles can be described by a simple exponential, follicle loss in women is accelerated from approximately age 35 onward, with cessation of reproductive cycles when the pool of resting follicles is reduced to between 100 and 1000.[38]

Age-related changes in oocyte quality parallel the decrease in follicle number. Fertilization and conception rates are lower in older reproductive-aged women, and there is an increased early pregnancy loss with increasing age. While it has been suggested that these results may be due to preferential selection of follicles with higher quality oocytes early in reproductive life[39], there is mounting evidence that the process of aging per se has a profound effect on the oocyte and follicular components that were established in early life. The finite pool of oocytes is therefore subjected to internal and environmental factors that may be detrimental to oocyte and follicle quality. For example, there is evidence for increased reactive oxygen species in the aging follicle,[40] a sign of oxidative stress and possibly mitochondrial dysfunction.[41] In addition, there is evidence of a decrease in mitochondrial number and function in oocytes from women with higher basal FSH and reduced numbers of oocytes retrieved in IVF cycles, both indicators of decreased ovarian reserve.[39] Oxidative stress plays a significant role in tissue aging, profoundly affecting cellular mechanisms. DNA double-stranded breaks (DSBs) accumulate with age and DNA repair mechanisms are poorly activated in the oocyte, leading to apoptosis and diminishing survival (see Chapters 1 and 2). It has been shown that shorter telomere length is related to poor oocyte performance in older reproductive-aged women.[42] Even in nondividing cells like oocytes, oxidative stress depletes telomeres, the important DNA sequences that cap chromosomal ends, prevent genomic instability, and are essential for normal chromosomal segregation. Thus, the findings of reduced telomere length in older women are consistent with evidence that meiotic spindle assembly is dysregulated in this same population,[43] a process that may underlie the increase in chromosomal errors such as nondisjunction that occur with reproductive aging in women.

The above mechanisms are relevant to important environmental factors associated with accelerated depletion of the follicle pool: chemotherapy, radiation, and smoking. Chemotherapy increases DSBs resulting in significant damage to the resting state oocyte,[44] while radiation has a similar effect, but on the dividing granulosa cells rather than the oocyte. Components of cigarette smoke bind the polycyclic aromatic hydrocarbon receptor on both oocytes and granulosa cells, activating proapoptic genes.[45] These findings are consistent with reduction in the age of menopause by approximately 2 years in smokers compared with nonsmokers.[46,47] Other factors shown in epidemiologic studies to shorten the time to menopause are previous pelvic surgeries[48,49] and low socioeconomic status.[50] While the data are not entirely consistent, long-term oral contraceptive use has generally been associated with a later age at natural menopsuase.[51,52]

One of the most powerful predictors of age at menopause in epidemiologic studies is family history. In fact, twin studies estimate that 44–85% of the variance in age at natural menopause is heritable,[53–55] and genome-wide association studies (GWAS) have identified at least 17 genes that are associated with the age at natural menopause in women. One of the initial genes implicated in age at menopause is that encoding mini-chromosome maintenance protein 8 (MCM8) on chromosome 20,[56] which is necessary for genome replication and is expressed in human oocytes.[57] Abnormalities in its function may therefore relate to crossover nondisjunction, a characteristic of aged oocytes. A meta-analysis of 22 GWAS in ~40,000 women with replication in ~14,500 women[58] confirmed previous identification of four loci associated with age at menopause on chromosomes 5, 6, 19, and 20[56] and identified 13 new loci. The 17 loci account for ~4% of the variability in age at menopause. Together, they function in diverse pathways including hormonal regulation, DNA repair, and immune function. Biological pathway analysis was consistent in emphasizing general biologic pathways for mitochondrial function, DNA repair, cell cycle and cell death, and immune response.[58] The importance of the DNA repair process was further emphasized by Titus et al. who demonstrated the obligate role of DSB repair genes, including *Brca1*, in oocyte survival in mice.[59] In addition, in young women with *BRCA1* mutations, reduced follicle reserve as reflected by low levels of AMH was observed.[59] Finally, it has recently been shown that specific genotypes confer an increased risk of earlier menopause in women who smoke that is dependent on the degree of smoking, is considerably higher than the increase due to smoking alone, and is not seen in women who do not carry these genotypes.[60] Together, these observations suggest that such gene–environment interactions are likely to contribute to the wide range in age at menopause in normal women.

Aging of the Hypothalamic-Pituitary Axis in Women

Response to the Loss of Ovarian Feedback

With the decline and eventual cessation of ovarian function, the hypothalamus and pituitary are freed from the negative feedback of ovarian steroids and peptides. There is a dramatic rise in serum levels of LH and

FSH due to both an increase in GnRH secretion and an increase in the pituitary response to GnRH as discussed below. The loss of ovarian steroid feedback accompanied by the loss of inhibin is associated with a 15-fold increase in FSH after menopause compared to a 10-fold increase in LH after menopause.[61]

THE HYPOTHALAMUS

Measurement of GnRH levels in peripheral blood does not accurately reflect hypothalamic GnRH secretion, and thus, indirect methods must be used to gain insight into hypothalamic function in women. Comparative data from animal models demonstrating that LH pulses are directly linked to antecedent pulses of GnRH[62] form the basis for the traditional use of the frequency of pulsatile LH secretion as a surrogate for GnRH pulse frequency. These data are supported in men and women by the recreation of LH pulses by exogenous GnRH administration in patients with GnRH deficiency[63] and by the abolition of LH pulses by high-dose GnRH antagonist administration in normal women.[64] While the glycoprotein-free alpha subunit (FAS) is secreted from the gonadotrope and the thyrotrope in response to GnRH and TRH, respectively, studies in euthyroid GnRH-deficient patients receiving GnRH and in normal euthyroid subjects following high-dose GnRH antagonist administration demonstrate that pulses of FAS reflect pulsatile secretion of GnRH, while tonic secretion of FAS is supported by TRH.[63,64] In settings of fast frequency GnRH secretion, as would be expected in postmenopausal women, FAS is a superior marker of pulsatile GnRH secretion due to its shorter half-life.[63] In addition, while the clearance of both LH and FSH are prolonged in postmenopausal women in association with estrogen deprivation,[65,66] the FAS clearance is not similarly affected.[65] Using FAS as a marker of GnRH secretion and a blood sampling interval of every 5 min to avoid underestimating the underlying GnRH pulse frequency, it has now been shown that secretory pulses occur at an interval of approximately every 50 min in postmenopausal women. This compares to significantly longer interpulse intervals of every 90 min in the early follicular phase and every 90 min to every 4 h across the luteal phase,[67] but is not significantly different from 55 min intervals in late follicular phase and during the midcycle surge (also determined using FAS and a 5 min sampling interval[68]).

Pulse frequency reflects only one aspect of GnRH secretion and cannot be assumed to reflect the overall quantity of GnRH secreted as the amount of GnRH secreted per bolus may also vary. Peptidergic GnRH antagonists that compete with GnRH for binding to the GnRH receptor[69] can be used to estimate the amount of endogenous GnRH being secreted. In this way, the change in LH as a function of GnRH antagonist dose is first used to define the dose–response relationship and a submaximal GnRH antagonist dose that allows competition at the GnRH receptor is then selected. The change in LH in response to incomplete GnRH receptor blockade, expressed in relation to pre-antagonist LH levels to control for variations in GnRH receptor number or postreceptor effects, can then be used to estimate the overall amount of endogenous GnRH being secreted.[70] Thus, at a given submaximal GnRH antagonist dose, the percent change in LH is inversely proportional to the amount of endogenous GnRH with which the antagonist is competing. Equivalent doses of a GnRH antagonist were less effective in suppressing LH secretion in postmenopausal compared with premenopausal women, indicating that the overall quantity of GnRH being secreted in postmenopausal women is greater than in premenopausal women.[23]

GnRH expression in the medial basal hypothalamus (MBH) is higher in postmenopausal compared with premenopausal women studied at autopsy,[71] consistent with the above findings in healthy young postmenopausal women. Menopause is accompanied by hypertrophy of a separate group of neurons in the infundibular (arcuate) nucleus that express kisspeptin (KiSS-1), neurokinin B (NKB), substance P, dynorphin, and estrogen receptor alpha (ERα) gene transcripts, but not GnRH.[72] KiSS-1, NKB, and ERα expression in these neurons is higher in postmenopausal compared with premenopausal women, while the number of these neurons expressing dynorphin is lower in postmenopausal women.[72] Studies in a number of animal species provide significant support for communication between neurons that colocalize KiSS-1, NKB, DYN, and ERα with GnRH neurons, suggesting that this may be a mechanism by which estradiol exerts negative feedback on GnRH and gonadotropin secretion, as discussed in Chapters 11, 26–28, and 33. The autopsy studies in women discussed above provide support for a similar mechanism in postmenopausal women, with increased NKB and KiSS-1, which are stimulatory to GnRH, but decreased DYN, which appears to be inhibitory.

STEROID NEGATIVE FEEDBACK The study of postmenopausal women provides the opportunity to examine the effect of estrogen feedback on gonadotropin secretion through administration of exogenous steroids and to determine whether feedback occurs at the hypothalamus, pituitary, or both. In this population, a month of estrogen administration, resulting in early to mid-follicular phase estradiol levels is associated with a decrease in mean levels of LH, FSH, and FAS,[73] although not to premenopausal levels. FAS pulse frequency does not change with this dose and duration of estrogen administration.[73] However, the overall amount of GnRH, assessed using submaximal GnRH receptor blockade as described above, decreases in response to a

similar regimen of estradiol replacement.[23] Furthermore, positron emission tomography (PET) studies using flurodeoxyglucose (FDG) uptake provide evidence for a decrease in metabolic activity in the medial basal hypothalamus after only 24 h of low-dose estradiol administration in postmenopausal women.[74] Taken together, these studies provide robust support for a hypothalamic site of estrogen negative feedback in women. In postmenopausal women, addition of 7 days of progesterone to achieve mid-luteal phase levels to low-dose estradiol resulted in further decreases in LH, FSH, and FAS.[73] FAS pulse frequency was markedly reduced[73] in conjunction with a reduction in the overall amount of GnRH[23] beyond that induced by estradiol alone, consistent with a hypothalamic site of progesterone negative feedback in women.

THE PITUITARY

While it is now well known from animal and human models that low-dose estrogen plays a key role in defining the gonadotropin secretory profile by inhibiting hypothalamic secretion of GnRH, the presence of a direct pituitary site of estrogen negative feedback has been more difficult to establish, particularly in women with an intact hypothalamic-pituitary axis. To overcome this limitation, the pituitary was isolated from endogenous GnRH input in postmenopausal women using a GnRH antagonist dose that completely inhibits pulsatile LH secretion by blocking the LH response to endogenous pulses of GnRH.[24] Because the GnRH antagonist is a competitive GnRH receptor blocker,[69] it was then possible to administer a range of doses of exogenous GnRH that could overcome the degree of blockade required to inhibit the LH response to endogenous GnRH, and to produce LH pulses that spanned the range of LH pulse amplitudes in postmenopausal women. This model thus served as a hypophysiotropic clamp, permitting control of the dose and interpulse interval of pituitary exposure to GnRH, both of which influence the LH response to GnRH. Results of these studies demonstrated a direct pituitary site of estrogen negative feedback on LH and FSH in women and a greater pituitary effect of negative feedback on FSH than LH,[24] contributing to the differential control of FSH and LH secretion. This view is consistent with studies of GnRH-deficient women receiving invariant pulsatile GnRH replacement regimens (see Chapter 28).

Extremely low to unmeasurable levels of LH and FSH in GnRH-deficient men and women, and their increase with GnRH replacement,[67] indicate that GnRH is absolutely required for normal secretion of both gonadotropins. However, administration of a GnRH-antagonist dose that results in a decrease in LH of over 90% suppresses FSH by only 40%,[75] consistent with dual control of FSH secretion in the setting of an intact HPG axis and the known selective stimulation of FSH by the autocrine and paracrine effects of activin in the pituitary.[25] Loss of estrogen negative feedback at the pituitary, which is greater for FSH than LH, combined with loss of the negative feedback of inhibin on activin-stimulated FSH, may contribute to the greater rise in FSH than LH at menopause.

Hypothalamic-Pituitary Aging and Changes in Steroid Feedback

As will be discussed below, there is significant evidence that age-related changes in the hypothalamus and pituitary play a critical role in reproductive aging in rodents, and it has been hypothesized that similar changes may contribute to reproductive aging in women.[76,77] During the menopause transition in women, however, the decline in ovarian function is associated with dramatic fluctuations in ovarian feedback on the central components of the reproductive axis, making it difficult to determine the potential contribution of aging of the hypothalamus and/or pituitary per se to reproductive senescence. The complete cessation of ovarian function, however, creates an open-loop setting, in which the hypothalamic and pituitary components of gonadotropin secretion can be examined as a function of aging. It has now been shown that there is a 30–40% decrease in both LH and FSH levels after menopause between the ages of 50 and 75,[61,78] providing evidence that aging itself influences the hypothalamic and/or pituitary components of the reproductive axis; although even in women in their eighth decade, FSH and LH are markedly elevated compared with follicular phase levels of these hormones in reproductive-aged women.

THE HYPOTHALAMUS

Using FAS as a marker of underlying GnRH secretion, as described above, and a 5 min sampling interval to maximize the chance of detecting the gonadotrope response to fast-frequency GnRH pulses, it has now been shown that GnRH pulse frequency decreases with aging after menopause from approximately one every 50 min in younger postmenopausal women to approximately one every 70 min in their older counterparts.[79] These studies resolve prior discrepancies in the literature based on the use of LH as a marker of GnRH secretion and a 10 min blood sampling interval.[78,80,81] In contrast, aging in postmenopausal women is associated with a further 14% increase in the overall amount of GnRH secreted[23] from that already due to the loss of ovarian function described above. Taken together, these studies suggest that there is an increase in the pulse amplitude of GnRH secreted with aging, although this does not completely compensate for the 22% decrease in GnRH pulse frequency with aging. These complex hypothalamic changes do not appear to completely account for the 30% decrease in LH and FSH

with aging after menopause in women, suggesting that aging may also dampen the pituitary response to GnRH.

THE PITUITARY

Changes in the ability of the pituitary to respond to GnRH as a function of aging have been examined using LH pulse amplitude[79,80,82,83] or the LH response to pharmacologic doses of GnRH,[80,83] with inconsistent results. Some of this variability may be due to difficulty in accurately identifying endogenous LH pulses in postmenopausal women. In addition, the assessment of the pituitary response to GnRH as a function of aging may be confounded by the decrease in GnRH frequency with aging and the known increase in gonadotropin response to GnRH with longer interpulse intervals.[84] Using the hypophysiotropic clamp model, described above, in which it is possible to control both the amount and prior interpulse interval of GnRH simulation of the pituitary, studies have now demonstrated that the pituitary response to GnRH is significantly attenuated with aging; both LH and FSH responses were 30% lower in older compared to younger postmenopausal women.[85]

STEROID NEGATIVE FEEDBACK WITH AGING

Studies of the hypothalamic and pituitary sites of steroid negative feedback and the effect of aging on both of these mechanisms have been performed in postmenopausal women. Estrogen negative feedback at the hypothalamic level remains intact in older compared with younger postmenopausal women. Thus, a month of low-dose estrogen administration is associated with a significant decline in circulating levels of LH, FSH, and FAS, and a parallel decrease in the overall amount of GnRH, estimated using submaximal GnRH blockade, with no effect on FAS pulse frequency in either age group.[23,73] Similarly, addition of progesterone resulted in a decrease in FAS pulse frequency in older and younger postmenopausal women accompanied by the expected decrease in overall amount of GnRH that did not differ with aging.[23,73] At the pituitary level, the direct effect of estrogen negative feedback on FSH is attenuated with aging, while the effect on LH is unchanged.[24]

ESTROGEN POSITIVE FEEDBACK WITH AGING Several lines of evidence have suggested that sensitivity to estrogen positive feedback may be lost with aging in women.[86,87] In women who collected daily urine samples for variable periods of time during the menopause transition, failure of positive feedback was observed in a small percentage of women despite similar peak late follicular phase estradiol levels, leading the authors to conclude that positive feedback was impaired in these women.[76] However, the overall pattern of estrogen exposure was attenuated in those who did not ovulate compared to those who did, and it is well known that both the dose and duration of estrogen exposure are critical for generation of gonadotropin surges in women.[88,89] In studies using a controlled graded steroid infusion paradigm that recreated early and late follicular phase levels of estradiol in younger and older postmenopausal women, the LH surge generated in the face of identical preovulatory patterns of estradiol was attenuated with age.[85] In these same studies, FDG-PET showed a dramatic increase in metabolic activity at the pituitary, but not the hypothalamus, in association with the LH surge.[74] Given the importance of increased pituitary responsiveness to GnRH in generation of the LH surge in women, attenuation of the steroid-induced surge with aging is consistent with the studies discussed above that demonstrate a decrease in pituitary responsiveness with aging.[90]

Integration of the Reproductive Axis with Aging in Women

From a physiologic perspective, the process of reproductive aging can be divided into two primary mechanistic periods: (1) *early ovarian aging* when cycles remain regular in the setting of interrelated "compensatory" hormonal changes; and (2) the *menopause transition*, during which there is marked variability in the ovarian response to gonadotropin stimulation and in ovarian feedback on gonadotropin secretion before the complete loss of reproductive function.

EARLY OVARIAN AGING: COMPENSATORY CHANGES

The age-related decrease in the number of follicles in the ovary is reflected in the number of antral follicles seen on ultrasound. Antral follicle count (AFC) is decreased as a function of age,[37,91,92] and declining AFC is associated with decreasing fertility.[93] AMH, which is expressed in small growing follicles,[34] reflects the declining pool of follicles in the ovary[37] and is relatively stable across the menstrual cycle.[94] AMH is strongly and directly associated with AFC, and both have been used extensively as predictors of outcome in in vitro fertilization (IVF) cycles.[93] Inhibin B is constitutively secreted from granulosa cells of growing follicles and increases in response to FSH[95] as a reflection of the dramatic increase in granulosa cell number that accompanies follicle recruitment. While inhibin B measured on day 3 of the menstrual cycle is also inversely related to age and the size of the follicle pool, it is less useful as a marker of ovarian aging and fertility potential because of its variability in relation to FSH dynamics across the cycle.

Inhibin B, however, is a particularly important gonadal feedback modulator of FSH secretion in the period of early ovarian aging. The selective increase in FSH over LH (Figure 37.2) that reflects the reduction in ovarian function and fertility in women ≥35 is associated with lower levels of inhibin B.[7,28] This increase in FSH

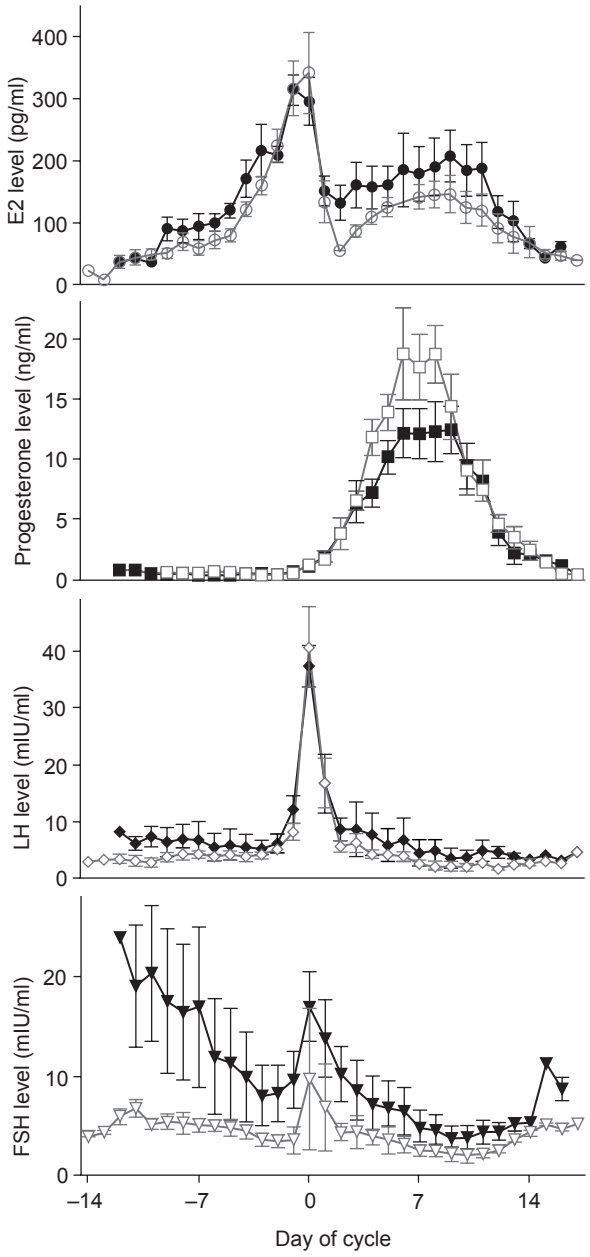

FIGURE 37.2 Relationships between estradiol (E2), progesterone, luteinizing hormone (LH), and follicle-stimulating hormone (FSH) over the course of a normal menstrual cycle in midreproductive women aged 18–38 (open symbols) and older reproductive women aged 43–53 (closed symbols). Hormones are standardized to the day of the LH surge (cycle day 0). Note that FSH concentrations in older women are elevated in the presence of comparable (or slightly elevated) levels of estradiol. Inhibin B levels (not shown in this figure) were lower during the follicular phase in older women. *Reprinted with permission from Santoro N et al.*[28]

drives increased recruitment of follicles into the growing pool and is responsible for the increased rate of spontaneous dizygotic twinning in older women[96] and the increased follicular phase estradiol levels in the face of the declining follicle pool in early reproductive aging even in the absence of development of more than one

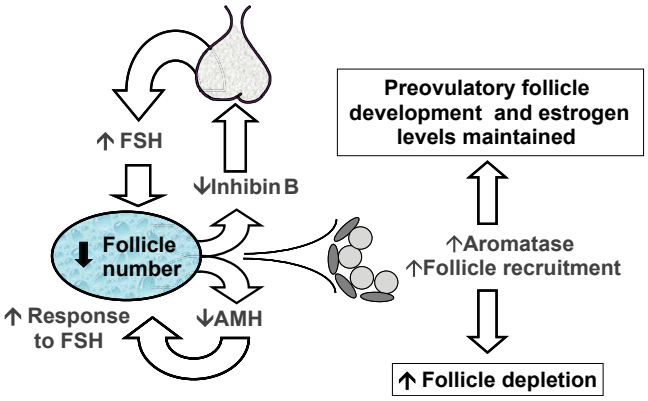

FIGURE 37.3 In early reproductive aging, the decrease in ovarian follicle number results in a decrease in inhibin B feedback on follicle-stimulating hormone (FSH) secretion from the pituitary and increased FSH levels. The decrease in follicle number is also associated with lower levels of anti-Mullerian hormone (AMH), increasing the ovarian response to FSH with: (1) increased recruitment of follicles into the growing pool from which the dominant follicle will be chosen and accelerated follicle depletion; and (2) an increase in aromatase activity, which also helps to maintain estradiol levels.

preovulatory follicle.[97] AMH restrains the stimulatory actions of FSH on recruitment of primordial follicles into the growing pool[34] as well as the FSH-dependent stimulation of aromatase,[98] but declines during this period due to the loss of follicles. A decrease in the androstenedione-to-estrone ratio in the follicular phase has been demonstrated in regularly cycling women ≥35 compared with their younger counterparts, consistent with increased aromatase activity.[99] It thus appears that lower levels of AMH in conjunction with elevated levels of FSH drive the accelerated depletion of the resting follicle pool after age 35 and are important for maintaining estradiol levels in the face of other evidence of declining ovarian function (Figure 37.3). Taken together, these integrated changes serve to extend fertility and maintain reproductive cycles and estrogen levels in the early stages of reproductive aging.

THE MENOPAUSE TRANSITION: MARKED BY VARIABILITY

The onset of irregular cycles marks the transition from the late reproductive years to the menopause transition. Large-scale cohorts have provided important insights into the overall pattern of hormonal changes that occur through this final transition to the end of reproductive life.[100,101] Taken together these studies indicate that the reciprocal relationship between declining levels of inhibin B and elevated levels of FSH occur relatively early in the process of ovarian aging, as discussed above, while estradiol secretion is relatively preserved. In fact, estradiol levels may not reach their nadir until a year after the final

menstrual period due to intermittent follicular activity that is insufficient to result in ovulation or menses. The increase in FSH precedes that of LH during the transition to the final menstrual period because of the earlier loss of inhibin with its selective inhibition of FSH. In addition, even with complete loss of ovarian function at the time of the final menstrual period and beyond, FSH levels are consistently higher than LH, possibly reflecting the dual control of FSH negative feedback by gonadal steroids and inhibin. While testosterone levels are lower in postmenopausal compared with premenopausal women, serum levels decrease before the final menstrual period and correlate better with age than with menopausal status.[101]

These aggregate changes do not reflect the marked variability in hormone levels that occur between women and within an individual woman from month to month over the 2–5 years of the menopause transition. Data from studies in which urinary hormone levels were collected over months indicate that, along with ovulatory cycles, estrogen levels can be low for prolonged periods followed by variable periods of time in which estrogen levels are very high[102] (Figure 37.4). The inconsistent estrogen response to FSH is not well understood. However, there is evidence from Doppler studies of reduced ovarian blood supply in the aging ovary.[103,104] This finding is supported by higher levels of vascular endothelial growth factor (VEGF), a marker of tissue hypoxia, in older reproductive-aged women.[105] These data suggest that FSH stimulation of viable follicles may well be impaired by a mismatch between the progressively decreasing and scattered follicles and their blood supply in the aging ovary.

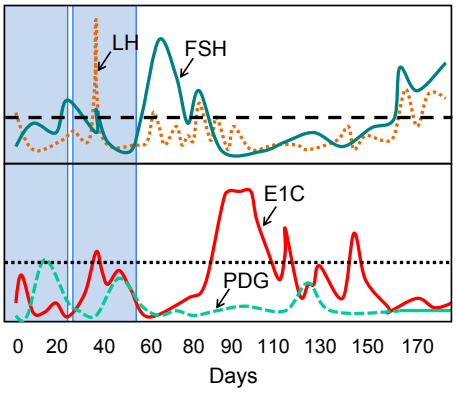

FIGURE 37.4 Daily urine samples over 6 months in a perimenopausal woman indicate marked variability in the pattern of LH, FSH, estrone conjugates (E1C), and progesterone diglucuronide (PDG). The dashed line in the upper panel indicates the upper limit of normal for FSH in young women, while the dotted line in the lower panel indicates the upper limit of normal E1C in young women. Shaded bars indicate cycles in which levels of PDG are consistent with ovulatory cycles. Adapted from Santoro et al.[102]

FSH levels are dramatically increased when estrogen levels are low, not only because of the loss of steroid and peptide feedback at the pituitary (Figure 37.5) but also because estrogen deprivation is associated with an increase in sialylation of FSH and a marked prolongation of its clearance.[66] Slowing of GnRH pulse frequency would also favor synthesis and secretion of FSH over LH. In the setting of variable responsivity to FSH, consistently elevated levels of FSH may subsequently drive follicle development and aromatase activity, accounting for estrogen levels during the menopause transition that may be two- to three-fold higher than in the preovulatory period of cycles in young women.[102]

During the menopausal transition, some increases in estradiol are followed by an LH surge, while some

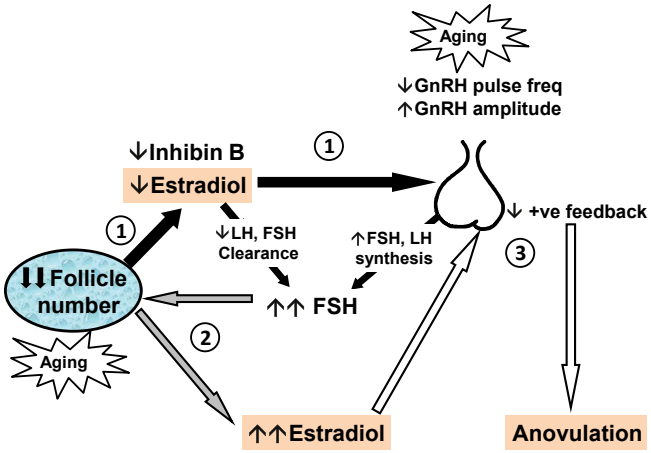

FIGURE 37.5 The transition to menopause is characterized by marked variability in the ability to recruit growing follicles from the aging ovary. Combined with the potential independent effects of aging on hypothalamus and pituitary, this variability results in three distinct patterns of hormonal changes and clinical symptoms: (1) the inability of follicle-stimulating hormone (FSH) to stimulate follicle recruitment results in low levels of both estradiol and inhibin B. These primary ovarian changes may be associated with vasomotor symptoms and sleep disturbance and result in the loss of gonadal hormone and peptide feedback at the pituitary. Combined with the possible age-related changes in hypothalamic gonadotropin-releasing hormone (GnRH) secretion (decreased pulse frequency and increased GnRH pulse amplitude), decreased negative feedback results in increased FSH secretion that is augmented by prolongation of the half-life of FSH secondary to low estradiol levels. The black arrows represent mechanistic changes that result in markedly elevated FSH levels; (2) markedly elevated FSH levels stimulate the remaining follicles, often resulting in extremely high levels of estradiol (gray arrows). Prolonged elevations in estradiol are frequently associated with marked breast tenderness, endometrial proliferation, and dysfunctional bleeding; (3) despite follicle development, abnormal patterns of estradiol, combined with the age-related loss of pituitary sensitivity to GnRH, results in inadequate LH surges and anovulation, further increasing the risk of irregular and heavy vaginal bleeding. These events repeat at irregular intervals before the complete loss of ovarian function following the final menstrual period and persistent hypoestrogenism.

are not. Generation of a preovulatory surge requires a highly specific pattern of increasing estrogen levels over an adequate duration,[88,89] both of which are likely to be altered in the face of asynchronous FSH and ovarian function as suggested by the pattern of estrogen excretion in anovulatory women transitioning to menopause.[76] The fact that the pituitary response to GnRH is attenuated with aging[90] (Figure 37.5) may also contribute to the approximately two-thirds of cycles in the year before the final menstrual period that are either anovulatory or have prolonged follicular phases,[106,107] resulting in irregular bleeding patterns along with varying breast tenderness, hot flashes, sleep disturbance, and possible mood changes.

UTERINE AGING

The ability to achieve and maintain a pregnancy in the setting of reproductive aging will be dependent on the uterus in addition to the hypothalamic, pituitary, and ovarian effects that have been discussed above.[108] Reports of successful pregnancies in women as old as 70 who received donor oocytes and exogenous hormonal support prior to implantation indicate that the aging uterus can support pregnancy. Early studies from donor oocyte programs that documented similar pregnancy, miscarriage, and delivery rates across all recipient ages provided support for this conclusion.[109–111]

However, more recent studies have documented an increased risk of preterm birth and low birth weight in donor egg recipients.[112] Other studies suggest that increasing age is associated with adverse outcomes that may be related to age-related myometrial dysfunction at the time of delivery. For example, increasing age has been associated with increasing stillbirth, after controlling for known maternal and fetal confounders.[113–115] In addition, increasing age is also associated with evidence of impaired contractile activity as there is an increased risk of cesarean section as well as longer duration of labor and operative vaginal delivery, when controlled for maternal and fetal confounders.[116] A biological basis for these associations is suggested by in vitro studies of uterine strips from mothers undergoing planned cesarean section that demonstrated that increasing age was also associated with reduced activity and increased multiphasic spontaneous myometrial contractions,[116] the latter of which have been associated with prolonged labor and an increased risk of emergency cesarean delivery.[117]

Standardization of Perimenopause/Menopause Terminology: STRAW+10

In 2001, the Stages of Reproductive Aging Workshop proposed a nomenclature and staging system for reproductive aging that included menstrual characteristics and qualitative hormonal changes.[9] The STRAW staging system facilitated research on the process of reproductive aging and the menopausal transition by introducing standardized terminology referenced to the final menstrual period. A decade later, our understanding of reproductive aging has advanced significantly. The studies of Hansen et al. confirmed the relationship of the decline in ovarian primordial follicle number from the peak reproductive to the late menopausal transition stages (STRAW stages −4 to −1) as defined by menstrual cycle characteristics.[118] FSH increased across the STRAW stages while AFC decreased. AMH also decreased across stages, but the ability of AMH to discriminate between stages was significantly compromised by assay sensitivity. While inhibin B tended to decrease across STRAW stages, changes were not significant, nor were changes in estradiol.

STRAW+10 incorporates a more detailed understanding of the hormonal changes that accompany ovarian aging both before and after the final menstrual period using information from STRAW+10 and other studies (Figure 37.6).[10] FSH cutoff levels are now possible because of international standardization of this measure. AFC and AMH have been used primarily in infertility populations, particularly in the setting of IVF. This, in addition to poor standardization of both measures across centers and poor sensitivity of AMH, limited the inclusion of AFC and AMH to qualitative descriptors in STRAW+10.

While issues of assay sensitivity have not been adequately resolved, the trajectory of AMH levels has now been described in large cohorts of girls and women from birth to post menopause, indicating an increase in AMH from birth to age 15, after which AMH levels plateau for a decade and begin to decrease with age after 25 years.[119] Application of AMH levels to longitudinal studies in normal women has now provided evidence that the combination of AMH and age,[120] and particularly the trajectory of AMH over time,[121] increases the precision of estimates of time to menopause in women over 35.

Hypothalamic-Pituitary Aging in Animal Models

Studies in rodents, primates, and other species permit a detailed understanding of structural and functional changes to the hypothalamus and pituitary with aging, while the use of experimental manipulations makes it possible to address the cause-and-effect of neural and hormonal changes and reproductive functional loss. There are a number of caveats to this approach, as the timing and progression of reproductive senescence in nonhuman species varies enormously,[122] with some animals maintaining reproductive competence to the very end of life and other species undergoing reproductive failure in mid-life, similar to women. In wild species,

Menarche FMP (0)

Stage	−5	−4	−3b	−3a	−2	−1	+1 a	+1b	+1c	+2

including humans prior to the last century, individuals rarely outlived the end of reproductive life.

While the hypothalamic control of reproduction is highly conserved in vertebrates in terms of the developmental organization, neuroanatomy, and functional importance of the GnRH system (see Chapter 33), menstrual cycles are limited to primates, meaning that a true menopause can only be studied in such species. Females of most other spontaneously ovulating species have estrous cycles that may differ substantially in length and in hormonal and physiological changes from these processes in women. This section will focus on experimental evidence of what is known about hypothalamic aging and regulation by steroid hormones during reproductive aging in female models. We will begin by discussing evidence in species in which most research has been conducted, laboratory rodents, and then compare and contrast nonhuman primate models. It should be noted that much research on release of GnRH has relied on measures of pulsatile LH and/or the LH surge. While a strong relationship between GnRH and LH often exists, the correspondence is not 100%, so caution is needed in attributing a change in LH levels to GnRH levels. We conclude with a brief overview of other aspects of pituitary and ovarian aging in animal models.

RODENTS

Rodents are an established laboratory model of reproductive aging, but rats and mice differ fundamentally from humans both in having a short estrous cycle (4–5 days) compared to the much longer menstrual cycle (~28 days) and in that their ovaries maintain viable follicles until relatively late in life.[123] Despite the presence of viable follicles, rodents undergo a transition from regular reproductive (estrous) cycles to irregular cycles to acyclicity at middle age,[124–126] indicating that the neuroendocrine system is driving this process independently of follicular loss.[123,127] Furthermore, transplantation studies of ovaries from aged to young ovariectomized rodents show that ovaries from old donors can begin to function in the young hosts, and undergo folliculogenesis and ovulation.[11] These findings suggest that reproductive failure with aging in rodents is not limited by the ovary. Therefore, rat and mouse models are useful in that they have enabled insight into how the hypothalamus changes with aging, both independent of and dependent upon gonadal steroid hormonal changes.

GnRH NEURONS

The hypophysiotropic GnRH neurosecretory system (referred to as GnRH1 neurons, but heretofore simply

called GnRH) of rodents comprises a population of about a thousand cells scattered in the preoptic area (POA) and basal hypothalamus[128,129] (see also Chapter 11). While sometimes fewer in number than in humans, and more rostral in distribution depending upon species,[1,130] the GnRH neuronal population in general is well conserved neuroanatomically in all mammalian species studied.[131] The GnRH system has been investigated for changes with aging, and results suggest little to no loss of GnRH perikarya numbers and no change in distribution.[132–138] Despite this, certain properties of GnRH neurons may change with aging. For example, the morphology, cytoarchitecture, and ultrastructure of GnRH perikarya and terminals change with aging,[139] suggesting that other properties of cells (e.g., their ability to synthesize or release the GnRH peptides) may occur.

Further evidence suggests a decrement in GnRH functional properties with aging. For example, experiments conducted in rats measuring pulsatile LH release, used as a proxy for pulsatile GnRH release,[140] show decreases in pulse amplitude in association with reduced mean concentrations of LH with aging. Similarly, the preovulatory LH surge is delayed and attenuated with aging.[141–145] GnRH mRNA, measured as an index of GnRH transcription, is elevated during preovulatory surges of young rats, but this is not detected in aging rats.[146,147] Finally, GnRH transcriptional activity, studied by co-expression of GnRH perikarya with the immediate early gene *Fos* or its gene product, is decreased in middle-aged compared to young rats during the preovulatory surge.[133,142] As a whole, these studies suggest a loss of activation of GnRH neurons in middle-aged rodents, prior to a loss of ovarian follicular complement. The fact that GnRH changes precede ovarian changes suggests at least some causality of the hypothalamus in reproductive senescence in rodents. However, because some of these studies focused on LH release as a proxy for GnRH release, it is not possible to discern hypothalamic from possible pituitary effects.

HYPOTHALAMIC NEURAL AND GLIAL NETWORKS THAT REGULATE GnRH

Hypophysiotropic GnRH neurons receive inputs from diverse stimulatory and inhibitory neurons, glia, and steroid hormone modulation (see Chapter 11). Therefore, aging of the hypothalamus is likely to include changes not just to GnRH cells and their properties but also to a broader hypothalamic network that controls GnRH synthesis and release. Of the many candidates for GnRH regulation during the entire life cycle, kisspeptin plays a dominant role, working in concert with other neuropeptides including neurokinin B and neuropeptide Y, neurotransmitters (glutamate, gamma-aminobutyric acid (GABA), norepinephrine) and neurotrophic factors (e.g., insulin-like growth factor 1 (IGF1), TGFα). Some neural inputs to GnRH neurons arise from projections to the GnRH cell bodies in the preoptic area, presumably to affect GnRH biosynthesis and/or to cause action potentials and subsequent release of the neuropeptide. GnRH dendrites also appear to be important for integrating inputs,[148,149] although this has not yet been reported in aging animals. Other inputs to GnRH neurons may occur locally at the site of GnRH nerve terminals in the median eminence. There, the stimulation of GnRH axons would result in increased GnRH neurosecretion, while inhibitory inputs to GnRH terminals would diminish GnRH release. It is important to differentiate between these three functional compartments of the GnRH cell because the source and nature of inputs to GnRH dendrites, cell bodies, and nerve terminals differs somewhat.[139,149,150] A discussion of evidence from rodent models showing structural and functional changes to selected systems, chosen for their key roles in GnRH regulation, and how their relationship to GnRH neurons changes with age follows.

KISSPEPTIN

In the rodent hypothalamus, there are two populations of kisspeptin neurons, one in the arcuate nucleus (ARC) and a second in the anteroventral periventricular nucleus (AVPV) in the anterior hypothalamus.[151] Hypothalamic kisspeptin signaling through its receptor, KISS1R, (aka GPR54 and encoded by the *KISS1R* gene) is critical for the acquisition of adult reproductive function[152] (see also Chapter 26), and in young adults, kisspeptin is crucial for preovulatory GnRH release.[153] Recent studies on hypothalamic kisspeptin show diminutions in its release and expression during the progression of reproductive decline, something that may impair GnRH gene activation and release. Gene expression of kisspeptin, and numbers of kisspeptin cells in the AVPV, are decreased during the LH surge of middle-aged compared to young rats.[154,155] This potential loss of drive to GnRH neurons is paralleled by the attenuated GnRH/LH surge described above. Replacement of kisspeptin via infusion into the preoptic area restored the attenuated LH surge in the middle-aged rats,[154] consistent with this idea. It is notable that in contrast to the AVPV, the population of kisspeptin neurons in the ARC does not undergo age-related change,[155] and this is important because it supports the hypothesis that the driving force to the GnRH/LH surge arises specifically from the AVPV and integrally involves kisspeptin inputs (see Chapter 11).

GLUTAMATE

Glutamate is considered to be the predominant excitatory neurotransmitter in the brain, and a well-known stimulatory regulator of GnRH cells.[156–158] Glutamate's actions on GnRH neurons occur through *N*-methyl-D-aspartate receptors (NMDAR)[159] and

non-NMDARs.[160,161] Glutamate activation of GnRH neurons is considered to be a critical event in the attainment of adult reproductive function,[158,162] and in adulthood, glutamate stimulates GnRH gene expression[163] and release.[164] With aging, there is decreased glutamate release in rodents[165] together with diminished response to its actions on postsynaptic membranes. Some of this age-related change is likely due to structural properties of glutamate receptors that confer functional responses to the ligand. Ionotropic glutamate receptors are made up of various combinations of subunits, the stoichiometry of which affect activation of the receptor and signal transduction.[166,167] Measurements of gene expression of NMDAR and non-NMDAR subunits demonstrate age-related changes in mRNA and protein in the hypothalamus[144,159,168] with likely functional consequences, as the ability of glutamate to activate GnRH neurons also diminishes with aging.[144,159,168] Protein expression of glutamate receptors,[122,159] and posttranslational regulatory processes (e.g., decreased phosphorylation of NMDAR subunits)[169] also occur in a manner that decreases the activity of glutamate. While initially controversial, it is now accepted that GnRH neurons co-express different classes of glutamate receptors,[137,163,170] and subpopulations of GnRH neurons respond to NMDA and non-NMDA pharmacological agents in electrophysiological studies.[171,172] Of relevance, the co-expression of GnRH neurons with glutamate receptor protein suggests stoichiometric changes in the ratio of receptor subunits, especially NR2a and NR2b, in aging compared to young female rats.[137] Thus, the stimulatory drive to GnRH neurons from glutamate decreases in the aging rodent hypothalamus. Interestingly, a pharmacological study on the interplay among glutamate, kisspeptin, and GnRH signaling revealed that glutamate and kisspeptin may modulate each other's activity on GnRH cells and contribute to the loss of GnRH output with aging.[154]

GABA

There are a few reports about another key amino acid neurotransmitter in the brain, GABA, and its regulation of the GnRH system during reproductive aging. In general, results suggest increased GABAergic signaling in the aging hypothalamus. Measurements of GABA release in the POA by microdialysis showed higher levels in middle-aged than young female rats.[173] Elevated gene expression of an enzyme involved in GABA biosynthesis, glutamic acid decarboxylase 67 (GAD67), was shown in middle-aged compared to young rats.[174] These results are consistent with pharmacological responses of GnRH neurons to GABAergic agonists/antagonists, although it is important to point out that electrophysiological responses of GnRH neurons to GABA are stimulatory, so they do not mirror the inhibitory pharmacological actions.[175]

STEROID HORMONE RECEPTORS AND FEEDBACK

A critical component to understanding age-related changes in the hypothalamic control of reproduction is how negative- and positive-feedback actions of ovarian steroid hormones undergo alterations with aging. While such changes have been reported, the mechanisms for and the consequences of such changes are still relatively unknown. The field of steroid hormone biology has expanded greatly in the last 20 years through discoveries of new nuclear and membrane receptors that bind estrogens and progestins (among other steroids, as described in Chapter 9). The nuclear estrogen receptors (ER) α and β and the progesterone receptor (PR) are abundantly expressed in the hypothalamus, with heterogeneous distribution across hypothalamic subnuclei.[176–178] Although GnRH neurons do not express ERα or PR (or if they do, it is at extremely low levels), they express ERβ, but this cannot explain most of the feedback actions of estradiol[179] (reviewed in Ref. 180; see also Chapter 11.). Several converging lines of research identified a membrane ER, GPR30 (also called GPER),[181,182] demonstrated the membrane localization of "nuclear" ERs,[183] identified other ER-responsive membrane ion channels,[184] and identified membrane progestin receptors (PGRMC).[185] These nonnuclear receptors are expressed in the brain, and their discovery has provided significant insights into some of the rapid actions of ovarian steroid hormones on the hypothalamus that cannot be explained by actions of nuclear hormone receptors acting as transcription factors. However, to our knowledge there are no studies on age-related changes in these membrane receptors, so future research is needed in this area. This is particularly important since there is emerging evidence for co-expression of GPER on GnRH neurons,[186] suggestive of a direct site of estradiol action on GnRH cells.

There are functional losses of both negative and positive feedback actions of estradiol and progesterone in the aging rodent hypothalamus. As discussed above, both endogenous LH surges in aging intact rats and steroid-induced LH surges in OVX rats are delayed and attenuated (reviewed in Ref. 187), indicative of a decrease in positive feedback. Furthermore, as rats transition from early persistent estrus (PE) to longer-term PE, steroid-induced positive feedback responses to estradiol plus progesterone declines.[188] Although in these studies peripheral LH was measured as a proxy for GnRH, these changes are consistent with the loss of activation of GnRH neurons as demonstrated by diminished FOS co-expression during the LH surge, in aging compared to young rats.[142,145] Similarly, negative feedback effects of steroids are also attenuated, as evidenced by the timing of the increase in LH in response to the removal of ovarian steroid feedback by OVX.[150]

Changes in steroid hormone gene expression have been reported in the aging brain in a few studies; these may relate to functional changes in steroid hormone feedback described above. For example, ERα mRNA levels in the periventricular POA are lower in old than middle-aged or young female rats.[189] Another study compared mRNA of ERα in POA and medial basal hypothalamus (MBH), showing no difference in POA but increased levels in MBH.[190] In addition, ERβ mRNA levels were higher in middle-aged than young rats in both of these regions.[190] PRs also undergo age-related changes, with decreased PR mRNA shown in AVPV of acyclic compared to cycling middle-aged female rats.[191]

Studies on protein expression of ERs and PR demonstrate changes, albeit relatively small ones, in the aging compared to the young rodent hypothalamus. No change in ERα cell numbers and density was found in aging, ovarian-intact rats.[192] Stereological measures of ERα cell numbers in four hypothalamic regions showed small but significant differences with age in AVPV and the ventromedial nucleus (VMN), with levels lowest in middle-aged compared to young and old rats (animals were OVX and given vehicle or estradiol treatment).[193] By contrast, no difference in ERα cell numbers in the medial POA and ARC was found in that same study. Measures of ERβ cell numbers in AVPV showed an age-related decline, but no change in the bed nucleus of the stria terminalis.[193] These results demonstrate the importance of regional specificity in performing these measures, as some but not all hypothalamic nuclei exhibited an age-associated change in steroid hormone receptor-immunoreactive cells. It is interesting that the AVPV is a site of dynamic changes in both ERα and ERβ cells because of this region's important role in the positive feedback signal from estradiol plus progesterone to induce the GnRH/LH surge, an absence of this event being a hallmark of reproductive aging in rodents.[141–145]

GLIAL-GnRH REGULATION

The hypothalamus expresses all of the major glial cells in the brain—astrocytes, microglia, and oligodendroglia—plus a modified astroglial cell, the tanycyte.[2] Tanycytes extend from the third ventricle to the median eminence, and GnRH fibers and terminals are interspersed among them.[194–196] Tanycytes contribute to the ability of secreted GnRH peptide to gain access to the portal capillary vasculature,[195] and dynamic changes in the relationship among tanycytes, GnRH terminals, and portal vessels occur in response to modifications in the steroid hormone milieu.[133,197,198] In young adults, tanycytes are organized in a largely linear fashion, with cell bodies near the third ventricles and processes extended to the pericapillary zone of the median eminence. This organization is lost with aging,[139,199] although the mechanism for this change and its functional significance is not well understood and to date has only been studied in OVX rats.

Further insight to the GnRH-glial connection with aging is provided by two studies. In one, direct contacts between GnRH membranes and tanycytes were quantified in the median eminence of young, middle-aged, and old OVX rats.[199] Results showed a small but significant age-related decline with aging. In another study, the association of GnRH neurons with astrocytes was determined in rostral POA, and shown to be both lower in middle-aged than young rats and to undergo fewer diurnal changes in the older group.[200]

Several other lines of research have indicated that the responses of GnRH neurons to glial neurotrophic factors declines with aging (reviewed in Ref. 194). For example, two members of the epidermal growth factor family, transforming growth factor-α (TGFα) and neuregulin 1β, indirectly stimulate GnRH release via signaling through the epidermal growth factor family of receptors (ERBB) that are expressed on hypothalamic glial cells.[195,201,202] During the GnRH/LH surge, there are temporal changes in expression of *Erbb4* (ERBB4 receptor) mRNA levels in the median eminence, ARC, and POA, and these are diminished in middle-aged compared to young rats.[203] Similar effects were seen for *Erbb1* mRNA.[204] Neuroanatomical work complimented this molecular work to show that immunolabeling of ERBB receptors differs between young and middle-aged rats.[203,204] As a whole, studies on GnRH-glial relationships suggest prominent age-related changes in structure and function, and a potential role in the attenuated GnRH/LH surge.

In summary (Figure 37.7), rodent models of reproductive aging demonstrate changes to functional and morphological properties of GnRH neurons. Neural and glial regulatory inputs to GnRH neurons appear to undergo a shift from being dominated by excitatory inputs to being dominated by inhibitory inputs. Changes in expression of receptors on GnRH neurons with age further contribute to a loss of responsiveness of GnRH cells to regulatory inputs. As a consequence, pulsatile GnRH release diminishes and there is attenuation of the GnRH/LH surge, with an overall decrease in the drive from GnRH neurons to the pituitary, and subsequently, the ovary.

NONHUMAN PRIMATES Studies on reproductive aging in nonhuman primates are limited by availability of aged monkeys, and work may be confounded by not knowing or being able to control the full life history of a 20- to 30-year-old animal. Nevertheless, the Old World macaques are an important model of aging because they undergo a natural menopause, beginning with irregularities in menstrual cycles and culminating in complete follicular atresia, albeit much later in their lifespan than in women.[205–207] New World monkey species may be more limited in that they do not experience

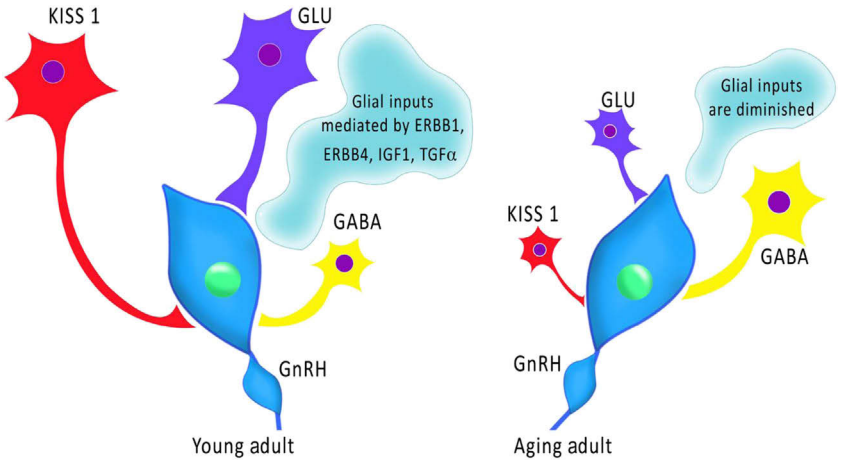

FIGURE 37.7 Schematic diagram showing age-related changes to hypothalamic regulators of gonadotropin-releasing hormone (GnRH) neurons, from the female rodent literature. In young adults (left), GnRH neurons receive excitatory inputs from kisspeptinergic (KiISS1) neurons from the anteroventral periventricular nucleus (AVPV). GnRH release is also strongly affected by excitatory glutamatergic (GLU) inputs, acting upon *N*-methyl-D-aspartate (NMDA) and non-NMDA receptors. Pharmacological studies suggest that GABAergic inputs are relatively modest at that age. In addition, glial cells produce neurotrophic factors through ERBB1, ERBB4, insulin-like growth factor 1 (IGF1), and transforming growth factor α (TGFα). In aging adults (right), the balance of these neurotransmitters and neurotrophic factors shifts, with the relative size of inputs to GnRH neurons shown smaller or larger compared to the young adult. GABA, gamma-aminobutyric acid.

a complete loss of follicular reserves nor do they exhibit menstrual cycles.[208] Regardless, the monkey literature is very important because it fills gaps in information that are more directly relevant to aging women with menstrual cycles, and which cannot be obtained in another way in humans.

GnRH NEURONS

Pulsatile GnRH release was measured from nerve terminals by push–pull perfusion of the median eminence of young adult and perimenopausal aging adult female rhesus monkeys, with results showing significant increases in mean GnRH concentrations in perimenopausal females.[209] That study also demonstrated that some aged monkeys had exceptionally high GnRH pulses. These results are consistent with increased hypothalamic GnRH mRNA in postmenopausal compared to young OVX rhesus monkeys,[210] and consistent with findings that humans also have elevated GnRH mRNA with aging,[71] underscoring the translatability of the monkey work to women. Measurements of serum gonadotropins and steroids in the same study in which pulsatile GnRH release was measured[209] demonstrated that LH and FSH were higher in aged monkeys (FSH significantly so), estradiol was decreased in the aged animals, and there were no differences in progesterone. Another study measuring pulsatile LH release in perimenopausal female rhesus monkeys demonstrated significantly higher mean concentrations and pulse amplitude compared to young monkeys,[211] consistent with the GnRH findings.[209] Longitudinal daily measures of serum reproductive hormones over several months in pre-, peri- and postmenopausal rhesus monkeys added to this work by showing aging-related increases in FSH and decreases in estradiol.[205] While LH did not differ significantly in overall levels in that study, the pattern of release was different. Decreased serum progesterone was also observed in the postmenopausal group, presumably because these animals were not ovulating and thereby not generating a corpus luteum.[205] Inhibin B and anti-Mullerian hormone were also measured in this latter study, both of which decreased with aging. This decrease in inhibin may also contribute to the increase in FSH, without an overall change in LH, in the aging macaques. As a whole, these studies on daily LH and FSH, pulsatile LH, and pulsatile GnRH release are consistent with the likelihood that decreased serum estradiol concentrations, and a reduction in negative feedback at the level of hypothalamus (and possibly directly at the pituitary), contribute to or are responsible for the aging-related increase in these hypothalamic and pituitary hormones. It is noteworthy that these age-related increases in GnRH and gonadotropins are the opposite of those reported for rodents (discussed above) and suggest fundamental species differences in these senescent processes.

Changes in GnRH and gonadotropin release in aging nonhuman primates are not reflected by neuroanatomical changes to the GnRH population. A study that counted GnRH cell numbers in female monkeys from ages 2–21 years detected between 55 and 470 neurons per individual, with no difference in GnRH neuron numbers with age in monkeys.[132] Those numbers were likely an underestimate as only one side of the brain was counted, and the antibody penetrated through less

than one-third of the tissue thickness; therefore, results should be extrapolated by at least six-fold. Nevertheless, even extrapolated results suggest no age-related change in GnRH cell numbers, a finding that replicates rodent work discussed earlier.

KISSPEPTIN, NEUROKININ B (NKB), AND PRODYNORPHIN (PDYN)

The neuroanatomical regulation of GnRH neurons in primates differs somewhat from that in rodents. In mice and rats, there are two discrete populations of kisspeptin neurons, one in AVPV and one in ARC, postulated to regulate positive and negative feedback actions of gonadal steroids onto GnRH neurons, respectively. There is a broader distribution of kisspeptin neurons in sheep and monkeys, including in the ARC and POA, and their relative importance in mediating negative and positive feedback effects in females is less well understood.[212,213] Aged postmenopausal rhesus macaques have elevated *KISS1* and *KISS1R* gene expression compared to premenopausal (OVX) monkeys in MBH.[210] Eghlidi et al. also reported increased *KISS1* mRNA levels in perimenopausal compared to premenopausal rhesus monkeys.[214] Rance's group had previously used *in situ hybridization* in adult OVX cynomolgus monkeys and found that *NKB* gene expression was profoundly decreased by estradiol treatment.[215] Eghlidi et al.[214] further showed increased *NKB* mRNA, but no change in *PDYN* mRNA, in the ARC. When OVX monkeys were compared to intact or OVX + E2 aged monkeys, *KISS1* and *NKB* genes were highest in the OVX group (no E2) and lowest in the OVX + E2 (long term, 4 + years of E2 treatment).[214] By contrast, the gene expression of receptors for kisspeptin, neurokinin B, and prodynorphin, *KISS1R*, *NK3R*, and *KOR*, respectively, did not change with age in intact monkeys or with E2 treatment in OVX monkeys.[214] Taken together, these data on kisspeptin and neurokinin B suggest that these cells are sensitive to both age- and estradiol-regulated changes and that negative feedback is very important in determining levels of gene expression.

STEROID HORMONE ACTIONS AND RECEPTORS

ERα and ERβ are widely distributed in the monkey hypothalamus, and some age-related changes were reported,[216] demonstrating an age-related decline in ERα and little difference in ERβ. However, there is a dearth of studies on whether there is any loss of negative or positive feedback on steroid hormone receptor levels in the aging monkey hypothalamus. One report on ovarian-intact Japanese macaques analyzed aging-related changes in serum hormones, ovulation, and response to steroid feedback.[217] When peri- and postmenopausal monkeys were given injections of estradiol designed to induce an LH surge, the negative and positive feedback effects were preserved in the aging monkeys. This is an interesting result because it shows: (1) prior to injection of estradiol, the old monkeys had higher LH concentrations than the young monkeys; (2) injections of estradiol suppressed plasma LH levels at both ages to approximately a similar level, with the nadir reached at 0.5 days; and (3) a positive feedback surge of LH followed at both ages, with the peak at 2.5 days post injection. Although not discussed by the authors,[217] the old monkeys actually appear to be more sensitive than young monkeys to the estradiol, both in terms of the negative and positive feedback responses.

PITUITARY AGING IN FEMALES As discussed earlier, it is difficult to dissociate the hypothalamic-pituitary levels of the HPG axis when gonadotropin measurements in peripheral circulation are used as a functional readout of hypothalamic GnRH release. While the relationship between GnRH pulses and gonadotropin release, especially LH, often exhibits close to a one-to-one concordance,[218,219] this relationship may break down during aging, especially since pituitary responsiveness to GnRH may be affected by aging, as discussed in the next paragraph. Such a breakdown, if any, might relate to changes in GnRH pulse frequency and concomitant effects on pituitary gonadotropin synthesis or half-life. Furthermore, FSH changes with aging may reflect not only changes to GnRH regulation but also to aging-related changes in inhibin.[205] Therefore, LH is a much better proxy than FSH for reflecting GnRH dynamics in aging animals.

We will begin by briefly discussing evidence from animal models for age-related changes in pituitary responsiveness to GnRH. The literature is mixed, but most studies indicate that there is a diminution in this response with aging. For example, a study using incubated pituitaries from young and middle-aged female rats showed that while basal LH release was similar, GnRH-stimulated LH release was lower in the middle-aged group in an estrous cycle stage-dependent manner.[220] Another study found that both basal and GnRH-stimulated LH release was lower in pituitary cultures from middle-aged compared to young rats;[221] in the latter study, middle-aged rats were in PE, while in the former,[220] middle-aged rats were still cycling, possibly explaining differences in basal release. Further work found that middle-aged rats with attenuated LH surges have decreased pituitary GnRH responses in vitro, whereas animals whose surges have not yet attenuated have normal GnRH responses.[222] An in vivo study evaluating LH responses over time to three doses of GnRH found an age-related decrease.[223] These data in rodents are consistent with a loss of pituitary GnRH responsiveness in women[90] and ewes.[224] However, it should be noted that to the contrary, several studies show little or no change in pituitary LH responses to GnRH.[225]

Other properties of the anterior pituitary gland undergo age-related change in females, but there are surprisingly few studies in this arena. Quantification of receptor binding sites for GnRH in pituitary membranes of young, middle-aged, and aged female mice showed no change with aging.[226] Thus, any changes in LH responsiveness to GnRH with age is likely due to other properties of the gonadotropes, such as GnRH receptor sensitivity, rather than number of binding sites per se. Another group reported that pituitary LH content was lower in PE middle-aged compared to cycling young rats.[221] Consistent with this, LHβ gene expression decreased between young cycling and middle-aged PE rats.[227] Clearly, further research is needed in order to clarify changes that are intrinsic to the aging pituitary gland of females.

Ovarian Aging in Animal Models

Ovarian aging in women is not well modeled by most natural animal models of reproductive senescence. First, true menstrual cycles are limited to humans, Old World monkeys, and apes (reviewed in Ref. 228). While mammalian species with spontaneous ovulation (e.g., rodents, dogs, sheep, cows, etc.) have reproductive cycles, these species do not menstruate. Second, complete exhaustion of the follicular pool with aging is almost never detected in species other than higher primates and some whales. One reason for this is that shorter-lived species may not outlive their ovarian pool. However, even relatively long-lived species such as macaques do not experience a complete loss of follicles, if at all, until the last few years of their lives.[229] As an example, rhesus monkeys can live for 30 years but can be fertile until their late twenties, an age comparable to that of a woman in her 80s.[209] Apes such as chimpanzees and gorillas do have very few ovarian follicles at the end of life (reviewed in Ref. 208,217), but it is obviously not feasible to conduct extensive research in these species. The tamarin, a New World monkey, has been used to explore ovarian aging. While these animals do not have complete follicular exhaustion with age, animals undergo changes in cycle length and often become anovulatory with advanced age.[230] Numbers of ovarian and follicular cell types were quantified in young, middle-aged, and old individuals.[231] Primary follicles, small preantral follicles, and large preantral follicles decreased in number with age, with the greatest decrease seen for primary follicles. Tamarins also have a steroidogenic interstitial gland in the ovary that enables steroidogenesis, mainly of progestins and androgens, until very late in life.[208] Thus, the removal of steroid negative feedback that happens in women is not well modeled by this species.

Rat and mouse models of ovarian aging must be used with caution because of the maintenance of viable follicles through the lifespan (reviewed in Ref. 123). Mouse models may be slightly better than rats, as mice have earlier follicular loss relative to rats,[232] albeit probably not complete. Other models such as the 4-vinylcyclohexene diepoxide (VCD)-treated rat are becoming popular because VCD destroys small preantral follicles.[233] Again, though, this is an artificial manipulation that is valuable for neuroendocrine and other endpoints but does not provide information on natural mechanisms of ovarian aging. Finally, genetic models may be informative in this regard. The follitropin receptor (FORKO) heterozygous mouse, lacking the FSH receptor, undergoes reproductive senescence at about 7–9 months and has a loss of follicles with aging.[234]

Summary of Animal Models of Reproductive Senescence in Females

Rodent models of reproductive senescence are important because they enable investigators to differentiate between the contribution of the different levels of the hypothalamic-pituitary-ovarian axis to aging processes. In particular, studies in rats and mice have highlighted how hypothalamic neural networks involved in GnRH regulation play a primary role in a loss of reproductive capacity. Results of these studies indicate that GnRH neurons have the intrinsic ability to continue to synthesize and release the GnRH peptide with aging, but that other regulatory inputs to GnRH cells undergo substantial changes resulting in a loss of GnRH output to the pituitary gland. Neurons that synthesize kisspeptin and neurokinin B appear to be quite important in these age-related functional changes, and the balance between excitatory amino acids (glutamate) and inhibitory amino acids (GABA) are also involved. As discussed earlier, other neurotransmitters as well as neurotrophic factors, and expression of their receptors on GnRH neurons, change with aging. The net result of this neural reorganization is a loss of drive to GnRH neurons and, consequently, diminished output to the anterior pituitary.

Monkey models provide great translational relevance to understanding menopause, due to similarities in the menstrual cycles of Old World primates and women. Monkey work has shown the critical role played by estradiol negative feedback in young adults and the consequences of the loss of that feedback at menopause. While rodents also experience negative feedback regulation, hypothalamic responses in primates show some fundamental differences from those in rodents. For example, kisspeptin gene expression increases in aging women and monkeys, whereas it decreases in aging rodents. In primates the increased kisspeptinergic activity is attributable to the loss of negative feedback from ovarian estradiol. In rodents, in which estrogen levels are maintained with aging, the decreased kisspeptin

activity likely reflects a change in neural circuitry and function. Thus, each species provides novel information on hypothalamic and ovarian changes, and their interactions, in female reproductive aging.

MALE REPRODUCTIVE AGING

Gender Differences

Reproductive aging in men exhibits a number of striking differences from the female. The most fundamental difference is that unlike the fixed complement of follicles seen in women, the germinal epithelium of the male can continue to generate fresh gametes throughout life. Accordingly, the reproductive lifespan of men may be as much as several decades longer than their female counterparts. Second, while aging in the female is characterized by an inexorable decline in ovarian function with follicle exhaustion following a relatively predictable time course, the process in the male is more modest and gradual and shows a high degree of variability. Third, while gametogenesis and steroidogenesis are very tightly coupled in the ovary and are both susceptible to the impact of aging, the same is not true in the male in whom aging tends to have a greater impact on testosterone production than spermatogenesis.[235–237] For this reason, we will discuss these processes separately following the dual compartment model of the testis that involves FSH regulation of Sertoli cell function on the one hand and LH regulation of testosterone production by Leydig cells on the other (see Chapter 16).

Methodological Challenges

Although studies of reproductive aging in the male are not complicated by the cyclical changes in gonadal function associated with the ovarian cycle, a number of methodological challenges nonetheless exist. The ideal model in which to examine the pure impact of aging on the reproductive system would be one that enjoys relative disease-free longevity. In the human there are the challenges of distinguishing the impact of aging from age-related illness, the inability to access the hypophysial portal circulation to measure endogenous GnRH and the difficulty of procuring testicular tissue. While studies in nonhuman primates have been pivotal to our understanding of the hypothalamic-pituitary-testicular axis particularly with reference to the regulation of puberty,[238] relatively few studies have utilized this model to evaluate age effects. There are obvious challenges to evaluating aging in animals living in the wild, while the suitability of captive animals as a model for natural aging is debatable, and there are significant costs associated with housing these animals over long periods of time. The Brown Norway rat is a useful model for elucidating mechanisms underlying male reproductive aging as this strain enjoys relatively healthy longevity and like the human exhibits declining function both peripherally at the testis as well as centrally at the hypothalamus and pituitary.[239]

Reproductive Aging in Men

Spermatogenesis

While the association between advanced maternal age and declining fertility has been unequivocally established, the role of paternal age is more controversial.[237] The impact of aging on fertility and spermatogenesis in men has been comprehensively reviewed in the third edition of this textbook in an excellent chapter by Handelsman.[240] Studies of men younger than 35 years of age found no relationship between the age of the father and time to pregnancy.[241,242] However, studies with a greater span of paternal age demonstrate an age-related decline in fecundity.[243,244] For example, a large UK population study of 8515 planned pregnancies showed that after adjusting for other factors, the probability that an ultimately fertile couple will take >12 months to conceive nearly doubles from ~8% when the man is <25 years to ~15% when he is >35 years.[243]

The cause of this modest but consistent reduction in male fertility with age has not been established and could potentially reflect age-related reductions in sperm numbers and/or function, a reduction in the frequency of coitus, or paternally mediated defects in embryo viability. Efforts to understand the impact of age on semen analysis have been hampered by difficulty recruiting subjects from the general population, which has resulted in small sample sizes and selection bias, which, in turn, have limited the generalizability of the findings. Most studies of healthy older men have shown that aging is associated with modest reductions in semen volume, total sperm output, and sperm motility.[245–247] In one of the largest studies to evaluate the relationship between age and semen parameters, in 6022 Israeli men across seven age groups ranging from <25 to >55 years optimal semen parameters were observed in men aged 30–35 years, while the most significant abnormalities occurred in men over 55.[247] Semen volume started to decline at age 35 and was 37% lower in men over the age of 55 compared to those under 35. It is noteworthy that the decrease in semen volume with age occurred despite a concomitant increase in the duration of abstinence with age, which normally tends to increase ejaculate volume. Sperm motility also showed a significant change with age, decreasing from 44 ± 21% in men under 25 years to 25 ± 18% in the oldest group.[247] The only parameter to actually increase with age was sperm concentration, which was 62 ± 44 million/ml in men <25 and

95 ± 103 million/ml in men over 55. However, whether this effect was directly due to age per se is not clear given that the older subjects also had a smaller semen volume and a longer duration of abstinence, both of which tend to increase sperm concentration. In contrast to sperm concentration, total sperm counts decreased with age and were 24% lower in the oldest versus the youngest age group. These data suggest that changes in semen parameters are likely to contribute to the decline in fertility in men with aging, but given the relatively modest magnitude of these changes, other factors including a decline in sexual activity are likely to be as, if not more, important.

FSH and Sertoli Cell Regulation

Longitudinal studies of men show a rise in circulating FSH levels with aging.[14,16,248] Interestingly, although the major negative feedback regulator of FSH in men is inhibin B,[17] cross-sectional studies indicate that levels of this gonadal peptide are only modestly lower in older than younger men.[249,250] Nonetheless, inhibin B levels show a strong inverse correlation with FSH and a strong positive correlation with testicular volume in older men.[249,250] Rigorous histomorphometric analysis of the testes of men who have died suddenly have shown a decrease in the Sertoli cell population with aging but no age-related decline in the number of germ cells per Sertoli cell, implying that there is a significant relationship between sperm production rates and the number of Sertoli cells.[251] These data suggest that the moderate reduction in testicular size with aging reflects a decrease in Sertoli cell mass, with relative preservation of Sertoli cell function (as evidenced by serum inhibin B levels) due to the compensatory increase in FSH secretion. This relationship is somewhat analogous to the state of compensated hypogonadism described later where normal Leydig cell secretion of testosterone is maintained by a compensatory increase in LH secretion.

Steroidogenesis (Epidemiological Studies)

Reproductive aging in men is characterized by a gradual and variable decline in serum testosterone levels from the fourth decade onwards that is quite distinct from the complete cessation of gonadal function that occurs at menopause. In the last 15 years or so, the publication of several large longitudinal cohort studies of American,[14–16] Australian,[252] and European men[248] has helped to provide some clarity in this controversial area, showing a reduction in total testosterone levels of 1–2%/year from the fourth decade onwards. In contrast, levels of the major binding protein for testosterone, sex hormone binding globulin (SHBG) increase by ~1.3–2.5%/year with age[14–16,252] such that the decrease in free testosterone levels is greater than that of total testosterone and is typically in the range of 2–3%/year. One cross-sectional study of men over the age of 70 showed that total testosterone levels remained stable with age, while free levels showed a significant decline.[253] The clinical significance of the disproportionately greater decrease in free testosterone levels with aging has not been established. The traditional teaching has been that it is only the free and bioavailable testosterone fractions that are biologically active. However, the demonstration that megalin, a receptor in reproductive tissues, can promote the cellular uptake of testosterone bound to SHBG through a process of endocytosis has thrown this free hormone hypothesis into question.[254] While the debate continues as to whether testosterone bound to SHBG is biologically active, Endocrine Society clinical practice guidelines recommend measurement of free or bioavailable testosterone in conditions associated with altered SHBG levels.[255]

Data on the impact of aging on the two major metabolites of testosterone (T), dihydrotestosterone (DHT) and estradiol, are more limited. The only large study to examine longitudinal changes in total DHT was the Massachusetts Male Aging Study (MMAS), which showed an increase of 3.5%/year.[16] However, in cross-sectional analyses, total DHT levels showed no age trend in either the MMAS cohort[16] or those of other studies.[256,257] The reason for the preservation of DHT levels in the face of decreasing levels of T, its major substrate, does not appear to be an increase in the activity of 5α-reductase as studies conducted in skin fibroblasts[258] and the prostate[259] show an actual decrease in 5α-reductase activity with age. Unlike testosterone, most studies show no change in estradiol levels with age,[248] although some show a decrease particularly in the levels of free estradiol.[260,261]

The clinical significance of the age-related change in testosterone is unclear for a number of reasons. First, the decline in testosterone is gradual, and a significant number of older men remain eugonadal. Second, even in the cohort of older men whose testosterone levels fall below the normal range for healthy young men, the threshold at which symptoms of androgen deficiency develop and adverse health outcomes ensue is uncertain and may differ for different target tissues.[262] Third, while epidemiologic studies show correlations between low testosterone levels and a variety of physical, cognitive, and metabolic endpoints, clinical trials of testosterone supplementation have yielded inconsistent results, and there is ongoing uncertainty concerning the long-term risk:benefit ratio.[263] While use of testosterone has increased dramatically in the last two decades in large part due to aggressive direct to consumer advertising, recent studies suggesting that testosterone therapy may increase the risk of cardiovascular events in men is likely to reverse this trend.[264–266]

In young healthy males, the reference range for testosterone is typically 300–1000 ng/dl depending on the assay methodology used. Estimates of the prevalence of

hypogonadism in aging men vary significantly depending on how the condition is defined. Using a purely biochemical definition based on plasma testosterone level alone without any reference to clinical symptoms, a prevalence of 20–50% has been reported depending on the age of the cohort and the predefined testosterone cutoff.[15,267] In contrast, the prevalence of hypogonadism when assessed by symptomatic androgen deficiency in combination with an arbitrary testosterone cutoff of <300 ng/dl is significantly lower at 5.6%.[267] When the diagnosis is further refined by systematically determining in a large population the testosterone threshold below which symptoms become increasingly prevalent, only 2.1% of middle-aged and elderly men meet criteria for hypogonadism, although this number increases with increasing age, obesity, and comorbid illness.[268] It is clear, therefore, that the potential exists to overdiagnose hypogonadism in older men and in some cases institute treatment that may be neither necessary nor beneficial. Thus, recent guidelines recommend that a diagnosis of hypogonadism only be made when consistent signs (e.g., gynecomastia, small testes, decreased body hair, reduced muscle mass, increased body fat) and symptoms (e.g., decreased libido, erectile dysfunction, decreased energy levels, low mood, poor concentration and memory) are present in association with unequivocally low testosterone levels.[255] Because of the considerable biologic variability in testosterone levels within subjects over time,[269] the diagnosis of age-related hypogonadism should never be based on a single blood sample as up to one-third of low levels are normal when repeated.

Patients with classical hypogonadism are traditionally classified as having either primary hypogonadism due to testicular failure or secondary hypogonadism due to hypothalamic-pituitary dysfunction.[255] However, the changes in the male HPG axis with aging appear more complex in that they involve multiple levels (Figure 37.8) and are significantly modified by other factors such as obesity and comorbidity. The situation is further complicated by the fact that a significant proportion of men with elevated gonadotropins continue to have normal testosterone levels.[270,271] Wu and colleagues recently proposed that this hormonal milieu could be viewed as a state of compensated hypogonadism, analogous to subclinical hypothyroidism, with the potential to progress to overt hypogonadism over time.[272] In an analysis of a large cross-sectional cohort of community-dwelling men (aged 40–79 years) in the European Male Aging Study (EMAS), they classified subjects into four categories of gonadal status using a testosterone threshold of 303 ng/dl and an LH of 9.4 U/l. The four categories were: eugonadal (T ≥ 303 ng/dl and LH ≤ 9.4 U/l); secondary hypogonadism (T < 303 ng/dl and LH ≤ 9.4 U/l); primary hypogonadism (T < 303 ng/dl and LH > 9.4 U/l); and compensated hypogonadism (T ≥ 303 ng/dl and LH ≥ 9.4 U/l). The majority of men were eugonadal (76.7%), with 11.8% having secondary hypogonadism, 2% primary hypogonadism, and 9.5% compensated hypogonadism. Despite the rise in LH levels that has been reported with aging,[14,16,248] most of the men with low testosterone levels had secondary hypogonadism for which obesity was the strongest predictor with age having no significant effect. Only a minority of men had primary hypogonadism despite the fact that aging is associated with significant changes in Leydig cell function as discussed later. Primary hypogonadism most likely represents the purest form of late onset hypogonadism in that it has the strongest relationship

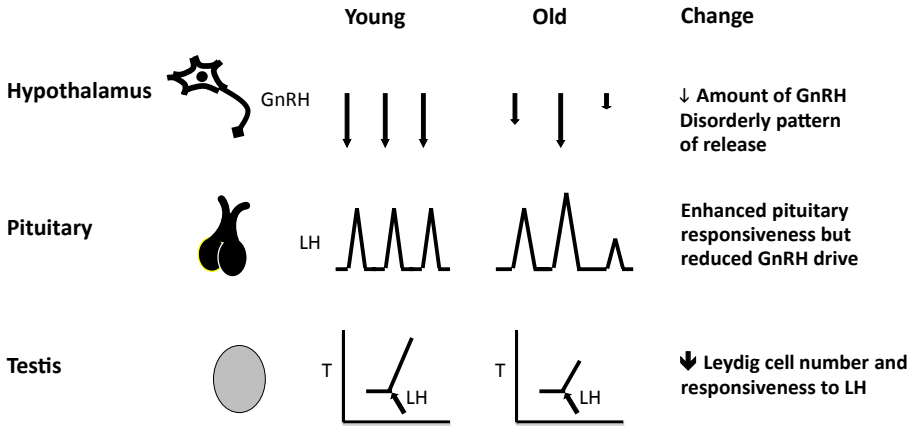

FIGURE 37.8 Changes in the hypothalamic-pituitary-gonadal axis with aging in the male. The arrows indicate that the amount of gonadotropin-releasing hormone (GnRH) secreted from the hypothalamus decreases with age as evidenced by frequent sampling studies showing lower luteinizing hormone (LH) pulse amplitude, where LH is used as a surrogate marker of GnRH,[276] a more disorderly pattern of release,[277] and greater LH suppression after administration of a submaximal GnRH antagonist dose.[278] In contrast, there is evidence of heightened pituitary responsiveness to GnRH Kaufman.[279–281] Functional studies demonstrate an age-related reduction in the amount of testosterone secreted per LH bolus,[282,283] which correlates with the histological demonstration of a reduction in Leydig cell number with aging.[284]

with age with the prevalence increasing from 0.1% in the 40–49 age group to 5.4% in those aged 70–79 years. Compensated hypogonadism is also strongly associated with age reaching a prevalence of 21% in men over 70 years. Given the wide reference range for testosterone, Wu et al. hypothesized that these men may have experienced a decrease in testosterone secretion within the normal range and that the high LH levels reflect a corresponding readjustment of the HPG feedback that partially restored the decline in Leydig cell testosterone secretion that occurred with aging. An alternative possibility is that although the testis is less responsive to LH stimulation, testosterone secretion in these men is unchanged because of an elevation in LH secretion due to a concomitant change in the set point of negative feedback at the hypothalamic-pituitary level.[273] However, as discussed, later studies on the impact of aging on testosterone-mediated negative feedback have not consistently shown this.[274,275]

While aging per se causes a modest decline in testosterone levels, data from several studies highlight that age-related increases in obesity and chronic illness as well as smoking and marital status have a significant impact on circulating testosterone levels.[16,270,285,286] In fact, the MMAS showed that obesity had a greater impact on testosterone levels than age alone and that a 4–5 kg/m^2 increase in body mass index (BMI) was associated with declines in total serum testosterone comparable to that seen with approximately 10 years of aging.[285] These data imply that the apparent age-related decline in testosterone may not be an inevitable consequence of the aging process but rather reflect health and lifestyle factors and thus be potentially preventable and/or reversible. This hypothesis was recently confirmed in a 4-year follow-up study of the EMAS cohort, which, similar to the longitudinal studies, showed that weight loss is associated with a significant rise in testosterone levels, while weight gain is associated with a corresponding decrease in testosterone levels.[287]

Aging in men is associated not only with a reduction in absolute levels of testosterone but also a blunting of the characteristic diurnal rhythm in the secretion of this steroid in young, healthy males.[288] The physiological significance of the diurnal rhythm in testosterone secretion is unknown.

Mechanism of Testosterone Decline with Age

Hypothalamus and Pituitary

As previously discussed, direct measurement of GnRH is not possible in the human due to its confinement to the hypophysial-portal circulation. However, frequent blood sampling studies performed in older men show lower LH pulse amplitude[276] and a more disorderly and chaotic pattern of LH release,[277] providing indirect evidence for a decrease in GnRH drive with aging (Figure 37.8). Others have employed a more direct approach to assessing GnRH secretion by measuring the degree of inhibition of endogenously secreted LH in response to increasing doses of a potent and selective GnRH antagonist in a cohort of men whose ages span the third to the eighth decades.[278] Increasing age was found to significantly potentiate the suppressive efficacy of any given antagonist dose on endogenously driven LH release consistent with a reduction in GnRH secretion in older men.

An alternative explanation for the reduction in LH pulse amplitude that is apparent in older men is that aging is associated with impaired pituitary responsiveness to GnRH. However, available evidence suggests that gonadotroph function does not change with aging in men. In fact, studies have shown that the LH response to GnRH is actually increased in older men (Figure 37.8), whether administered as a single bolus across a wide dose range[279,280] or as repetitive pulses through a portable infusion pump for 14 days.[281] Heightened gonadotroph responsiveness to small amounts of GnRH could potentially be due to upregulation of GnRH receptors, a hypothesis that cannot be directly addressed in the human.

Studies by Veldhuis and colleagues provide evidence for a key role of the ambient sex steroid milieu in regulating pituitary responsiveness. By examining the LH response to GnRH in young and old men before and after ketoconazole-induced androgen depletion, they showed that a hypoandrogenemic milieu sensitized gonadotroph response to GnRH stimulation disproportionately in the older men.[280] Thus, it appears that gonadotroph responses reflect important interactions between GnRH dose, testosterone concentrations, and age.

Human studies on the impact of aging on testosterone-mediated negative feedback have given quite conflicting results. Depending on the experimental paradigm employed, aging has been variably reported to either increase[274,275] or decrease[289,290] the negative feedback action of testosterone on GnRH and LH. Recent autopsy studies of hypothalamic samples from young and old men show morphological evidence of an age-related enhancement of kisspeptin signaling in the infundibular nucleus,[291] also known as the arcuate nucleus. While it has not been proven, it seems plausible that the enhanced kisspeptin signaling in older men is a consequence of a decline in the sensitivity of the *KISS1* neurons to androgen negative feedback.

Testis

Mechanistic studies of testicular size and steroidogenic function corroborate the age-related decline in testosterone demonstrated in epidemiologic studies. Studies using ultrasound have shown that the testicular

volume of men aged greater than 75 years is approximately 30% smaller than that of men aged 18–40 years (20.6 versus 29.7 ml).[249] Similarly, histological examination of the testes in autopsy specimens from men who died following trauma or myocardial infarction indicate that Leydig cell number is approximately 44% lower in men aged 50–76 years than those aged 20–48 years.[284] As histological examination showed no evidence that men with reduced numbers of Leydig cells had an increased number of other interstitial cells, this reduction in Leydig cell number with age appears to be due to cell degeneration and dissolution as opposed to dedifferentiation to other interstitial cell types.[292]

While Sertoli cell loss is a critical factor in determining age-related changes in sperm production, the reduction in Leydig cells only becomes a rate-limiting step when the complement of cells falls to fewer than 10% of that seen in young, healthy men.[293] In practice, such a profound reduction in testosterone is rarely encountered due to aging alone and typically requires a "second hit" either to the testis or to the hypothalamic-pituitary unit.

Functional studies have confirmed that the secretory capacity of the testis in response to both physiologic and pharmacologic stimuli is significantly lower in older than in younger men. Initial studies showed an age-related decline in the ability of the Leydig cells to secrete testosterone in response to stimulation with human chorionic gonadotropin (hCG).[294,295] However, the experimental design employed in these earlier studies has a number of limitations in that baseline LH concentrations were not matched, tending to be higher in the older than the younger men; the doses of hCG used were large and provided a pharmacologic stimulus compared to an endogenously secreted LH pulse; and, in addition, hCG has the potential to cause Leydig cell desensitization.[296] To overcome these methodological issues, Veldhuis and colleagues developed an LH clamp paradigm to determine the physiologic basis for the reduction in testosterone secretion with aging. They first used a GnRH antagonist to abolish endogenous LH secretion so that baseline LH levels were matched, and then stimulated Leydig cells with fixed pulses of recombinant human LH.[282,283] This more physiologic experimental paradigm showed that while basal testosterone secretion is unchanged across a span of five decades, there is an age-related decline in the amount of testosterone released per LH bolus.[282,283]

Reproductive Aging in Animals

Spermatogenesis

Histological studies of the testis in the Brown Norway rat have shown a reduction in Sertoli cell number and function, a decrease in seminiferous tubule volume and sperm content, and accelerated germ cell apoptosis with aging.[297] Aging has also been associated with a marked increase in the number of spermatozoa with abnormal flagellar midpieces as well as a reduction in the percentage of motile spermatozoa.[298] In addition, analysis of the ejaculate of old Wistar rats has shown a decrease not only in sperm count with age but also the percentage of spermatozoa developing progressive motility with the latter showing a substantial reduction at 24 months of age.[299] In contrast, available, albeit limited, data suggest that there is no difference in fertility between rats aged 2 months and rats aged about 17 months,[300] although advancing paternal age was associated with an increase in preimplantation loss.[301] Thus, male rats and men appear similar in the way that sperm quality is reduced with increasing age, but the consequences for fertility are relatively slight.

Steroidogenesis

Analysis of testosterone in fecal samples from wild baboons confirms an age-related decline analogous to the human,[302,303] but this effect may be confounded by variability in non-age-related factors such as predation and malnutrition. Studies performed in young and old rhesus monkeys show an enhancement of the diurnal rhythm in testosterone with age,[304] in contrast to the blunting of this rhythm that has been demonstrated in the human.[288] Although no significant age-related change in mean testosterone levels over 24 h was observed, a significant age-related difference in testosterone levels was evident between 1200 and 1600 h, with the older monkeys having much lower testosterone levels during the daytime.

Aging Effects on the HPG Axis

Hypothalamus and Pituitary

The impact of aging on the HPG axis in the rodent depends on the strain studied. As mentioned earlier, the Brown Norway rat has advantages over other strains in having unusual longevity without succumbing to obesity and cancer and is thus a useful model for studying the effects of aging without the confounder of illness. In vivo studies in the Brown Norway rat show a reduction in LH pulse amplitude similar to that seen in the human, while in vitro experiments demonstrate reduced basal and stimulated GnRH release by hypothalamic tissue.[297] While the number of GnRH neurons does not appear to decrease with aging, a reduction in the number of synaptic inputs to GnRH neurons has been observed,[305] as well as a reduction in GnRH mRNA and peptide.[297] These data therefore support a hypothalamic component to male reproductive aging in the rat similar to that seen in the human.

Testis

Rodent studies also confirm the age-related defect in Leydig cell function that has been observed in the human. Decreased sensitivity to individual LH pulses could

reflect either a reduction in LH receptor number or activation or a defect in post-receptor signaling. Studies in the aged male Brown Norway rat demonstrate decreases in testicular LH-driven cyclic AMP (cAMP) accumulation and in enzymes such as steroidogenic acute regulatory protein, which regulate the rate-limiting steps of steroidogenesis.[306,307] Neither the administration of exogenous LH to aging rats in vivo[308] nor the incubation of aged Leydig cells with LH in vitro was capable of reversing these defects,[309] indicating that deficits in LH secretion are unlikely to underlie the age-related decline in Leydig cell steroidogenesis. In contrast, culturing aged Leydig cells with a membrane-permeable cAMP agonist that bypasses the LH receptor-adenylyl cyclase cascade was capable of restoring testosterone production to levels comparable to those of young cells.[307] These experiments therefore provide evidence that inefficient LH signal transduction, leading to reduced cAMP production, is responsible for the reduced steroidogenesis that characterizes aged Leydig cells. It is possible that similar inefficiencies in LH signaling may underlie the states of primary and compensated hypogonadism seen in aging men.[270]

Free radical damage has been proposed as a potential mechanism for the reduction in cAMP generation in aged rat Leydig cells. This theory is supported by the demonstration of an age-related increase in the formation of reactive oxygen species by mitochondria[310] as well as an impairment of antioxidant defenses in aging Leydig cells.[311]

CONCLUSION

There are many questions that remain unanswered. The capacity to reproduce varies from the time of puberty to the end of life, with substantial sex differences in the timing of reproductive transitions, especially aging. In fact, why females undergo senescence so much earlier than males, especially in humans, is of great interest to biologists, sociologists, anthropologists, and others. The "grandmother hypothesis" has been proposed to explain the potential evolutionary and adaptive value for a woman to outlive her follicular complement. This concept, while controversial, suggests that a postmenopausal woman contributes to raising kin (e.g., grandchildren, nieces/nephews, etc.) and can share her long life of experiences with her social group.[312,313] The fact that men can reproduce to a much older age is consistent with natural selective pressures for the sex with the lesser investment in pregnancy, lactation, and (sometimes) parenting.

In women, ovarian aging per se is central to reproductive senescence. Studies to date suggest that both genetic and environmental factors play a role, alone or in combination, but such studies are in their infancy. Future research that seeks to understand the genetic and environmental factors that prolong the health of oocytes and their supporting structures or hasten their demise will be required to extend reproductive capacity to meet the social needs of women in industrialized countries. There is now evidence that neuroendocrine aging occurs in women as well as animals. It will be important to determine the degree to which modification of these changes can extend reproductive life. Markers of ovarian aging have been identified in infertility populations, but further studies will be required to determine if these markers can predict menopause in the general population. Finally, further studies on the effects of the loss of reproductive hormones on nonreproductive systems including the brain (cognition, sleep, vasomotor symptoms), metabolism, bone, and cardiovascular disease will be critical to healthy aging in women as will be development of individualized approaches to treatment that optimize risk and benefit based on genetic and environmental information.

Basic research on reproductive aging is hampered by limitations in the availability of aging animals; the high cost of maintaining and/or purchasing such animals; and morbidity and mortality associated with aging. Thus, alternative models have been developed such as ovariectomy or orchidectomy to model loss of gonadal hormones. While these experimental models are extremely important, they are typically conducted in young animals. Because young and aged animals (and humans) differ in both hormone-dependent and -independent manners, there is a great need to conduct experiments in age-appropriate models. Another experimental limitation in females is that few species experience menstrual cycles or undergo a true menopause, and those that do typically experience menopause relatively later in life than in humans. For example, in the rhesus macaque it has been estimated that females undergo menopause at the equivalent age of a 65- to 90-year-old woman,[209] compared to the typical age of 45–55 years in women. Thus, new models of menopause are needed that better approximate the hypothalamic, pituitary, and ovarian changes in women.

Aging has more modest effects on the HPG axis of men than women. The most significant changes occur peripherally at the level of the testis, with steroidogenesis being impacted much more than spermatogenesis. Further studies are needed to dissect the impact of age per se versus age-related illness on the HPG axis, as well as to determine the contribution of changes in semen parameters to the modest decline in fertility seen in older men. Further studies will be required to determine whether optimal aging in men is associated with age-related norms or is better achieved with replacement to levels in young men.

INTRODUCTION

An essential task of procreation is to diversify the genetic repertoire and select advantageous traits to pass on to offspring. Procreation in prokaryotes and some eukaryotes is more efficient than the sexual procreation exhibited by higher eukaryotes, especially in placental mammals. Fostering an offspring within the womb is a demanding task, requiring multiple regulatory safeguards at critical steps. Thus, reproduction in viviparous mammals has adapted a more complex and highly regulated system. The embarkment of a new life in eutherians first depends on the union between a sperm and an egg (ovum) resulting in successful fertilization; failure to achieve this union leads to their demise. A one-cell fertilized egg, hence termed "embryo", undergoes several mitotic cell divisions, ultimately forming a differentiated tissue called the blastocyst with two distinct cell populations: a pluripotent inner cell mass (ICM) and an outer layer of extraembryonic trophectoderm.[1] A reciprocal interaction between the blastocyst and the maternal uterus initiates the process of implantation, a process through which the vascular system of the embryo is subsequently brought into communication with the maternal circulation, leading to the establishment of a functional placenta and guiding the appropriate progression of pregnancy. Maternal resources filtered across the placenta with selective barrier properties nourish and protect the conceptus. Historically, the process of implantation was often referred to as nidation, the term originating from the word "nidus", meaning a nest or a breeding place, since the blastocyst implants in a specialized chamber (crypt) at the antimesometrial pole (Figure 38.1(A)).[2]

In a historical context, Corner in 1947 wrote that "…the uterine chamber is actually a less favorable place for early embryos than say, the anterior chamber of the eye, except when the hormones of the ovary act upon it and change it to a place of superior efficiency for its new functions."[3] Subsequently, it was realized that the establishment of pregnancy results from the culmination of an intimate relationship between the developing embryo and the differentiating uterus. However, although conceptually accepted, the nature of such two-way interaction between the blastocyst and the uterus is still a challenging question. Embryo–uterine interaction leading to implantation is only initiated when embryonic development is synchronized with the preparation of the uterus to the receptive state. Specifically, the embryo must develop to the blastocyst stage and gain implantation competency, and the uterus through steroid hormone–dependent changes must attain the receptive stage before successful implantation can occur.

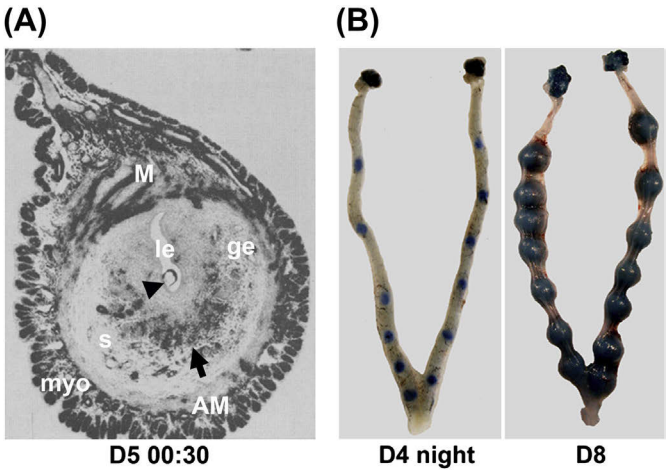

FIGURE 38.1 Increased endometrial vascular permeability upon attachment and implantation in the mouse. This figure is reproduced in color in the color plate section. (A) Transverse section of uterus on day 5 (D5) early morning (00:30) of pregnancy showing implantation at the antimesometrial pole within a crypt (arrowhead). This section also shows weak alkaline phosphatase activity in the uterine stroma (black, arrow). Note the edema in the outer areas of the mucosa, contrasting with the closely packed cells around the uterine lumen (presumptive primary decidual zone). Le, luminal epithelium; ge, glandular epithelium; s, stroma; myo, myometrium; M, mesometrial pole; AM, antimesometrial pole. *(Source: Reprinted with permission from Ref. 2.)* (B) Increased vascular permeability at the sites of blastocyst attachment with the uterine luminal epithelium was detected after an intravenous injection of a blue dye (Chicago Blue B6) solution in mice at midnight of day 4 (D4) and day 8 (D8) of pregnancy. On day 4, distinct blue bands (dark bands in this picture) indicate that the attachment process has been initiated.

The concept of uterine receptivity to implantation was first recognized by Alexander Psychoyos by utilizing embryo transfer experiments in pseudopregnant and delayed-implanting rodent models. Transferred blastocysts implanted only in uteri differentiated to a receptive stage.[4] Later, reciprocal embryo transfer experiments in delayed implantation mouse models, where blastocyst dormancy is maintained for many days by progesterone (P_4) treatment and reactivation is initialized with an injection of estrogen[a] (see the section Delayed Implantation (Mammalian Diapause)), found that blastocyst implantation competency is also a critical determinant for implantation in the receptive uterus.[5] A lack of synchrony between the embryonic development and the preparation of the uterus results in implantation failure.

PHYSIOLOGICAL AND MORPHOLOGICAL ASPECTS OF EMBRYO–UTERINE INTERACTIONS

Implantation is a prerequisite for subsequent development of the embryo. A significant number of pregnancy losses due to preimplantation embryonic death is common to many mammals and has been considered a selective process for the survival of superior embryos for implantation. However, dysregulated uterine events prior to, during, or after implantation are causes for poor pregnancy success rates in eutherians, either by immediate termination of pregnancy or by triggering adverse ripple effects that can be perpetuated through the remainder of pregnancy (see the section Adverse Ripple Effects Arising from Early Pregnancy Events). Therefore, a deeper understanding into preimplantation embryo development and implantation will help to identify aberrant mechanisms that can lead to unsuccessful or complicated pregnancy and provide strategies to improve infertility, prevent pregnancy complications, and/or develop novel contraceptive approaches to promote family planning. The achievement of uterine receptivity approaching attachment reaction is reflected in cellular and ultrastructural changes in the luminal epithelium, including gradual loss of cell polarity and the formation of microprotrusions from the apical surface called pinopodes.[6] The underlying mechanisms that coordinate blastocyst development to implantation competency with uterine receptivity are not yet fully understood.

Stages of Implantation

At the blastocyst stage, the trophectoderm of the developing embryo acquires competency to attach to the receptive uterine luminal epithelium that has been appropriately primed with the steroid hormones estrogen and P_4. If this condition of synchrony is met, an implantation-initiating adhesion cascade begins upon engagement of cell adhesion molecules at the luminal epithelial and trophectoderm surfaces (see the section Molecular Aspects of Embryo–Uterine Interactions). Many of these adhesion molecules transduce the signals necessary to sustain embryonic and maternal contributions to the formation of a placenta that supports fetal development through term.

Implantation begins when the blastocyst is placed in intimate physical and physiological contact with the uterine endometrium. Enders and Schlafke[7,8] classified the process of implantation into three stages: apposition,

[a] In this chapter, the term "estrogen" primarily includes estradiol-17β, estrone, and estriol, while estradiol-17β will specifically be abbreviated as E_2.

TABLE 38.1 Timing of Implantation in Various Species

Species	Day of Implantation	Ovarian Estrogen Requirement	Decidualization
Mouse	4.5[a]	Yes	Yes
Rat	5.5[a]	Yes	Yes
Hamster	3.5[a]	No	Yes
Guinea pig	5[a]	No	Yes
Rabbit	6.5[b]	No	Yes
Pig	13–14[b]	No	No
Cow	19–20[b]	No	No
Sheep	15–16[b]	No	No
Human	8[c]	?	Yes
Baboon	8[c]	?	Yes
Rhesus monkey	9[c]	?	Yes

[a] *Day 1, vaginal plug.*

[c] *Day 0, preovulatory estrogen or luteinizing hormone peak.*

adhesion, and penetration. Apposition is the stage when the trophectoderm cells become closely juxtaposed to the luminal epithelium. This is followed by the adhesion stage, when the association of the trophectoderm and the luminal epithelium is sufficiently intimate to resist dislocation of the blastocyst upon flushing the uterine lumen. The stage of penetration involves the invasion by the trophectoderm through the epithelium. Stromal cell transformation to terminally differentiated decidual cells (decidualization) is more extensive, and loss of the luminal epithelium is evident at this stage (see the section Molecular Aspects of Embryo–Uterine Interactions). These three stages of implantation are a continuous process over a period of time.

Apposition

In rodents, a generalized stromal edema occurs just prior to apposition. This event is thought to lead to uterine luminal closure and results in interdigitation of trophectoderm microvilli with those of luminal epithelia (apposition), followed by a closer contact between them (adhesion or attachment reaction). The luminal closure occurs throughout the entire uterus during pregnancy or pseudopregnancy, and thus this event does not necessitate the presence of blastocysts. Priming of the uterus with P_4 alone appears to be sufficient for this event to occur.

Attachment and Penetration

The attachment reaction is coincident with the localized increased stromal vascular permeability at the site of blastocyst contact as determined by intravenous injection of a macromolecular blue dye (uterine blue reaction) (Figure 38.1(B)).[4] The first sign of the attachment reaction in the process of implantation (day 1 = spermatozoa in the vaginal smear) occurs in the mouse and rat on the evenings of day 4 and 5, respectively, and day 6.5 in the rabbit.[4,9,10] In primates, the attachment reaction occurs approximately on day 8 in humans and baboons, day 9 in macaques, and day 11 in the marmoset.[11,12] In large domestic animals, the first signs of attachment occur on day 13 in pigs, day 20 in cows, day 16 in sheep, and day 19 in goats[13] (Table 38.1).

Although luminal closure and apposition occur in P_4-treated delayed-implanting mice, the attachment reaction fails under this condition. The superimposition of estrogen treatment is essential for this event. In mice, blastocysts are oriented with their ICMs directed toward the mesometrial pole, the site of entry of blood vessels into the uterus, while in humans the ICM is directed toward the antimesometrial pole. The mechanism by which the orientation of the blastocyst is achieved at the time of implantation remains elusive. There is evidence that in P_4-treated delayed-implantation mice, blastocysts are placed antimesometrially, and interdigitation (apposition) of luminal epithelial cell microvilli occurs with those of the abembryonic or lateral trophectoderm cells of the blastocyst with its ICM oriented toward the uterine lumen. This observation led to the suggestion that upon initiation of the attachment reaction and subsequent implantation process by estrogen, blastocysts retain the orientation they adopted during delay. During normal implantation in mice with the onset of luminal closure, blastocysts are placed at the antimesometrial side of the lumen along the uterine axis (Figure 38.1(A)). Shortly after the luminal closure, zona-encased blastocysts are located in implantation chambers with random orientation of their ICMs. However, with the beginning of the attachment reaction, blastocysts are correctly oriented with their ICMs directed at the mesometrial pole. This observation suggested that the trophectoderm of the entire blastocyst surface has the potential for attachment to the luminal epithelium, and that attachment occurs randomly immediately after the loss of zona pellucida. Evidence was presented to suggest that free movement of the ICM directs the correct orientation of the blastocyst. However, this issue still remains unsettled and warrants further investigation. All of these events from the luminal closure to the attachment reaction occur between about 86 and 92 h *post coitum* in mice.[14,15]

While implantation in mice occurs by displacing the luminal epithelium from the basal lamina to enhance trophoblast passage through the luminal epithelium into the stroma, humans exhibit an interstitial type of implantation in which blastocysts are embedded within

the subepithelial stroma. Ultrastructural studies show that implantation in humans is intrusive: trophoblast cells penetrate through the luminal epithelium and basal lamina into the stroma.[16] Although the significance of different implantation strategies adopted by different species is not clearly understood, one common feature is the increased endometrial vascular permeability at the site of blastocyst attachment in many animals studied. It is presumed that this increased permeability also occurs in the endometrial bed in human implantation, but this has not yet been clearly documented.

Penetration of blastocyst trophectoderm through the luminal epithelium and basal lamina into the stroma is required to provide nutrition to the developing embryo and establish a vascular relationship with the mother. This process varies considerably from species to species with respect to timing and cytological features.[16] In rodents, penetration of trophoblasts is usually followed by decidualization of endometrial stromal cells surrounding the implanting blastocyst, eventually embedding the embryo into the antimesometrial stromal bed.

Comparative Aspects of Implantation

On the basis of different types of blastocyst–uterine cell–cell interactions, Bonnet classified implantation into three categories: central, eccentric, and interstitial.[17] Central implantation occurs in mammals such as rabbits, ferrets, and some marsupials. In these species, blastocysts grow and extensively expand prior to implantation. In contrast, blastocysts of mice, rats, and hamsters are small and show modest expansion. In these species, an implantation chamber is formed by the invagination of the uterine epithelium, characteristic of eccentric implantation. In guinea pigs, chimpanzees, and humans, the implantation process is interstitial (i.e. blastocysts embed into the subepithelial stromal bed). Based on ultrastructural studies, Schlafke and Enders classified implantation into intrusive, displacement, and fusion types.[16] In intrusive types of implantation, such as in humans and guinea pigs, trophoblast cells penetrate through the luminal epithelium, reaching and extending through the basal lamina. The displacement type of implantation occurs in rodents, in which the luminal epithelium is freed of the underlying basal lamina, facilitating the spread of trophoblasts through the epithelium. The fusion type of implantation, in which trophoblast cells make connection with the luminal epithelium by forming symplasma, occurs in the rabbit. In many rodents, including mice and rats, implantation always occurs at the antimesometrial side of the uterus, whereas in some bats, implantation is mesometrial. The noninvasiveness type of implantation is observed in domestic animals such as pig, sheep, cow, and horse, and in wallaby.[18] Embryos in domestic animals maintain free-floating status longer than invasive conceptuses and become elongated up to 100 mm by day 12. This increase is due to the growth of the extraembryonic tissue, enabling an efficient avenue for receiving nutrition from uterine secretions until the attachment reaction occurs.

In sheep, the blastocyst enters the uterus on day 4 and hatches from the zona pellucida on day 9. After day 10, elongation of the blastocyst occurs and it develops first into a tubular and then to a filamentous form.[19] Starting on day 11, the spherical or slightly tubular blastocyst begins to elongate until it reaches a length of 25 cm or more by day 17 and resembles a long filament composed mainly of extraembryonic trophoblast.[20] Cellular and molecular mechanisms regulating blastocyst elongation are not well understood, but they may involve local production of prostaglandins (PGs) and growth factors. After day 14, the filamentous conceptus becomes immobilized in the uterine lumen. The first changes in the luminal epithelium occur on day 14 in both uterine horns.[21] In ruminants, distinct areas of projecting aglandular uterine mucosa called caruncles are involved in attachment reaction. The caruncles become edematous with a folded and depressed surface. Caruncular foldings are perhaps the first step in the formation of crypts that constitute the maternal side of the future placentomes, which receive hematotrophic nutrition for the conceptus.[22] Dome-like cytoplasmic protrusions also appear on the caruncular epithelial cells. On day 16, the trophectoderm begins to firmly adhere to the endometrial luminal epithelium. The interdigitation of the trophoblast and endometrial luminal epithelium is observed in both caruncular and intercaruncular areas of the endometrium. Trophectoderm adhesion to the epithelium progresses along the uterine horn, with completion around day 22.[23,24] Unlike sheep, attachment in horse and pig involves multiple sites covering most of the embryonic surface. In all of these ruminants, a notable decidualization is absent.

Hormonal Requirements for Implantation

In all eutherian mammals thus far studied, the uterus differentiates into a receptive state when the implantation-competent blastocyst engages in an effective two-way interaction to initiate attachment. This state of uterine receptivity lasts only for a limited time when the uterine milieu is conducive to support blastocyst growth, attachment, and subsequent events of implantation.[13,25–27] The master regulators that specify uterine receptivity are ovarian steroids: P_4, considered the "hormone of pregnancy", and estrogens.

These hormones are crucial for implantation in mice and rats, but ovarian estrogen is not essential for implantation in several species, including pigs, guinea pigs, rabbits, and hamsters; P_4 alone can support implantation.[25,28–32] Embryonic-derived estrogen is implicated in implantation in these species, and in fact, rabbit, pig, and horse blastocysts have the capacity to synthesize estrogens. The mouse embryo lacks aromatase, the enzyme for estrogen synthesis,[33] while rabbit blastocysts express the aromatase gene.[34] Whether preimplantation estrogen secretion by the ovary or embryo plays crucial roles in human implantation is not clearly understood.

The uterus is composed of heterogeneous cell types that respond uniquely to changing ovarian P_4 and estrogen levels. In mice and rats, the coordinated actions of P_4 and estrogen regulating uterine cell proliferation and/or differentiation in a spatiotemporal manner establish the window of uterine receptivity for implantation.[35] In adult uteri of these species, estrogen stimulates proliferation of epithelial cells, whereas this process in the stroma requires both P_4 and estrogen.[4,26,35] Similar steroid hormonal regulation of cell-specific proliferation and differentiation occurs during the peri-implantation period.[36] For example, on day 1 of pregnancy (vaginal plug) in mice, epithelial cells undergo proliferation due to preovulatory estrogen secretion. In contrast, rising P_4 levels arising from newly formed corpora lutea initiate stromal cell proliferation from day 3 onward, which is further stimulated by ovarian estrogen secretion on the morning of day 4. Coordinated effects of P_4 and estrogen then downregulate epithelial cell proliferation and initiate differentiation.[35] The preimplantation ovarian estrogen secretion is followed by localized increased endometrial capillary permeability at the site of the blastocyst upon attachment.[4,26,36] In pseudopregnant mice, the steroid hormonal milieu in the uterus is similar due to the presence of newly formed corpora lutea. Thus, the sensitivity of pseudopregnant uteri for implantation on days 1–4 is quite similar to that during normal pregnancy, and blastocyst transfer into a pseudopregnant uterine lumen during the receptive phase elicits normal implantation and decidualization.

In pigs, estrogen produced by the conceptus trophectoderm between days 10 and 15 of pregnancy acts on the endometrium and is considered essential for the establishment of pregnancy.[37] Estrogen seems to alter endometrial $PGF_{2\alpha}$ secretion in an endocrine manner (toward uterine vasculature) to an exocrine direction (toward the uterine lumen).[38] While $PGF_{2\alpha}$ from the uterus in the nonpregnant cycle is the principle signal for ovarian luteolysis, $PGF_{2\alpha}$ sequestered in the uterine lumen in the pregnant uterus is unavailable to exert luteolytic effects on corpora lutea. Additionally, increases in specific histotroph components occur in the lumen after the release of estrogens from the conceptus on day 11.[37,39] Placental estrogens also act on the epithelium in a paracrine manner and increase the expression of specific growth factors, which, in turn, act on the trophectoderm, stimulating cell proliferation and development.

The baboon has been studied as a nonhuman primate model to understand human implantation. Uterine receptivity and implantation in this species are classified into three phases. The first phase, between days 8 and 10 postovulation of the menstrual cycle, appears to be regulated by estrogen and P_4. The second phase is induced by blastocyst "signals" superimposed on the estrogen–P_4 primed receptive endometrium. This phase is associated with functional and morphological endometrial changes that are distinct from those observed between days 8 and 10 postovulation in a nonconceptual cycle. The third phase is initiated following attachment and implantation of the blastocyst. Evidence suggests that embryo-derived factors directly or indirectly influence endometrial receptivity and implantation in primates.[40,41]

In humans, the 28–30-day menstrual cycle begins with vaginal bleeding as a result of endometrial sloughing from P_4 withdrawal. A gradual rise in estrogen levels from maturing ovarian follicles then leads to extensive proliferation of the epithelium, stroma, and vascular endothelium, regenerating the endometrium and initiating the proliferative (follicular) phase. Numerous glands develop during this period, assuming tortuous morphology during the late proliferative phase. After ovulation, the luteal (secretory) phase commences with elevating P_4 levels from the newly formed corpus luteum. Glands become highly secretory with stromal cell differentiation ("predecidualization"). In the absence of a viable embryo, the corpus luteum undergoes luteolysis with a fall in P_4 levels, while an implanting blastocyst secretes chorionic gonadotropin, which maintains the corpus luteum to support pregnancy (see Chapters 23 and 28).

The impact of supraphysiological levels of estrogen on human endometrial receptivity, although controversial, has been investigated at the clinical level. In patients who respond excessively to gonadotropin stimulation (follicle-stimulating hormone (FSH) and human chorionic gonadotropin (hCG)) for ovulation induction during in vitro fertilization (IVF) cycles, high serum estradiol levels (>3000 pg/ml) on the day of hCG administration are detrimental to uterine receptivity,[42] regardless of the number of oocytes retrieved or serum P_4 levels. In addition, an increase in serum estrogen levels during the preimplantation period has been observed in high-responder compared to normal-responder patients.[43]

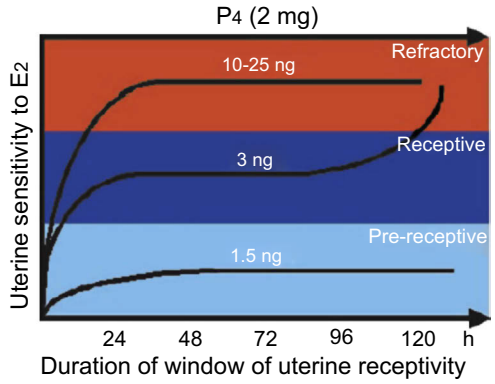

FIGURE 38.2 A scheme depicting modulation of the window of receptivity in the P4-primed uterus in response to changing estrogen levels in the mouse. This scheme shows that estrogen at a low threshold level extends the window of uterine receptivity for implantation, but higher levels rapidly close this window, transforming the uterus into a refractory state. *Source: Reprinted with permission from Ref. 5.*

Moreover, decreasing estrogen levels during the preimplantation period by a step-down FSH protocol increase implantation and pregnancy rates in high-responder patients.[44] There is also now evidence that E_2 at concentrations of $\geq 10^{-6}$ M in an in vitro culture induces a deleterious effect on embryonic adhesion to the substratum.[45] In mice, while lower estrogen doses maintain receptivity, higher doses transit the uterus to a nonreceptive phase (Figure 38.2).[5] Therefore, it may be possible to extend the window of implantation in humans by manipulating estrogen levels.[43,44]

Window of Implantation

Uterine sensitivity to implantation is classified as three different phases: prereceptive, receptive, and nonreceptive (refractory).[4,13] In mice, while the uterus is fully receptive on day 4 (the day of implantation), it is considered prereceptive on days 1–3 of pregnancy or pseudopregnancy, and by the afternoon of day 5, the uterus becomes refractory to blastocyst implantation. These phases have been defined by employing embryo transfer experiments in pseudopregnant rodents.[25]

Early work on uterine receptivity in mice demonstrated that the uterus in this species is only rendered receptive if exposed to estrogen 24–48 h after P_4 priming.[46] However, it is now known that the window of receptivity can be prolonged for an extended period by providing a low dose of estrogen in mice. Using an experimentally induced delayed implanting mouse model, a low dose of estrogen (3 ng/mouse) postpones uterine refractoriness to implantation for at least 4 days, while a higher dose of estrogen (10–25 ng/mouse) causes rapid closure of the receptive phase. Uterine nonreceptivity induced at high estrogen levels is accompanied by aberrant uterine expression of implantation-related genes.[5] This does not occur in normal implantation, presumably due to a small of amount of preimplantation estrogen secretion on day 4 of pregnancy. Using different genetic mouse models, it was shown that a short delay in the initial attachment reaction in mice during pregnancy creates adverse ripple effects resulting in developmental anomalies during the subsequent course of pregnancy.[47–51] These results suggest that careful regulation of estrogen levels is one of the important factors for improving implantation rates in IVF and embryo transfer programs.

Another critical factor determining the window of implantation is the blastocyst's state of activity (implantation competency). In the delayed implantation model in rodents, blastocysts undergo zona hatching, albeit at a slower pace, but they become dormant without initiating the attachment reaction even after P_4 priming of the uterus. However, a single injection of estrogen promptly initiates blastocyst activation and implantation in the P_4-primed uterus.

The process of implantation is considered a proinflammatory reaction, and increased vascular permeability at the site of blastocyst implantation is common to many species. Thus, it was suggested that histamine plays a role in implantation and decidualization.[52] Earlier observations suggested that uterine mast cells were the possible source of histamine, and its release from mast cells by estrogen was important for implantation.[53,54] This suggestion was based on the observations that local histamine application stimulates uterine hyperemic and edematous responses.[55] Furthermore, a histamine antagonist pyrathiazine or an inhibitor of histidine decarboxylase (HDC) was shown to interfere with implantation when instilled into the uterine lumens of rats and rabbits.[53,56]

Histamine works via at least four histamine receptor subtypes (H_1–H_4),[57–59] and blocking of both H_1 and H_2 receptors was shown to interfere with implantation in rats.[60] Subsequent studies also showed that histamine induces implantation in delayed-implanting rats when injected with a suboptimal dose of estrogen.[61] However, uterine mast cell numbers and histamine content are reduced both after estrogen treatment and during implantation,[52] and successful implantation and birth of live offspring in mast cell–deficient mice and other evidence have instead suggested that uterine mast cell histamine is not essential for implantation.[62,63] Thus, if histamine is involved in implantation, it should be provided either by major uterine cell types or by embryonic cells. While mouse blastocysts do not have the capacity for histamine synthesis,[64] HDC is expressed in uterine epithelial cells on day 4

of pregnancy in mice prior to implantation, but not in decidual cells.[65] In addition, H_1–H_3 receptor subtypes are not detectable in the uterus, but H_2 receptors are expressed in preimplantation mouse blastocysts. These observations as well as the inhibition of blastocyst zona-hatching and implantation by H_2 antagonists and an HDC inhibitor suggest that uterine histamine targets the blastocyst for implantation.[64] However, apparently normal implantation occurs in mice lacking HDC or H_2-type histamine receptor genes, suggesting the possible involvement of other vasoactive agents with overlapping functions or compensation by other histamine receptor subtypes upon deletion in this process.[58,66]

Although estrogen is essential for blastocyst activation and implantation in the P_4-primed mouse uterus, the mechanisms by which estrogen initiates these responses remain elusive. Evidence suggests that estrogen actions in uterine preparation and blastocyst activation for implantation are two distinct events. Indeed, embryo transfer experiments in delayed implantation recipient mice provide evidence that while E_2 initiates uterine events for implantation, catecholestrogens produced in the uterus from E_2 participate in the activation of dormant blastocysts toward implantation.[67] Blastocyst activation by catecholestrogens involves cyclooxygenase 2 (COX2)-derived PGs and cyclic adenosine monophosphate (cAMP).[67] These results provide evidence that both estradiol-17β and catecholestrogens are required for embryo–uterine interactions for successful implantation and that implantation occurs only when uterine receptivity coincides with the blastocyst's state of activity. Whether catecholestrogens have any role in implantation in other species is not known. Molecular pathways that are potentially involved in uterine receptivity and blastocyst activation are discussed in more detail in the see the section Molecular Aspects of Embryo–Uterine Interactions.

Endometrial Glands and Their Secretions

All mammalian uteri contain endometrial glands that synthesize, secrete, and transport a complex array of proteins and other factors termed histotroph.[22,68,69] The histotroph is a complex mixture of enzymes, growth factors, cytokines, lymphokines, hormones, transport proteins, and others. The idea that uterine secretions nourish the developing conceptus was discussed by Aristotle in the third century BC, and William Harvey in the seventeenth century. In 1882, Bonnet concluded that secretions of uterine glands are important for fetal well-being in ruminants.[70]

Evidence from primate and nonprimate species during the last century supports an unequivocal role for secretions of endometrial glands as primary regulators of the production of pregnancy recognition signals, implantation, placentation,[71–75] and conceptus survival and development. Studies on the uterine gland knockout (UGKO) ewe model, generated by continuous administration of a synthetic, nonmetabolizeable progestin in neonatal ewes from birth to postnatal day 56, reveal an essential role for endometrial glands and their secretions in normal estrous cycles and in peri-implantation conceptus survival and growth.[76–78] These ewes do not exhibit normal 17-day estrous cycles due to the inability of the uterus to produce sufficient luteolytic pulses of $PGF_{2\alpha}$. The lack of superficial or ductal glandular epithelium, coupled with an overall reduction in surface area of the luminal epithelium, reduces the numbers of oxytocin receptors that could respond to oxytocin, a luteolytic agent[77,79] (see Chapter 27).

Exogenous $PGF_{2\alpha}$ induces luteolysis in UGKO ewes, and they display normal estrus mating behavior.[76,78,80] However, adult UGKO ewes are unable to establish pregnancy, and the transfer of normal hatched blastocysts into the uteri of timed pregnant UGKO recipient ewes fails to rescue this defect.[76,77,81] Morphologically, normal blastocysts are present in uterine flushings of bred UGKO ewes on day 6 or 9 post mating, but not on day 14.[76] On day 14, uterine flushings of mated UGKO ewes contain either no concepti or severely growth-retarded tubular concepti.[81] Normally, the rapid elongation of the conceptus from a tubular to a filamentous form during the peri-implantation period in sheep (between days 11 and 13) is associated with the production of interferon tau (IFNτ, the type I IFN family member), the signal for maternal recognition of pregnancy that acts in a paracrine manner on the endometrial epithelia to inhibit the development of the luteolytic machinery.[79,82] Although the growth-retarded concepti in mated UGKO ewes produce little or no IFNτ, the endometrium of UGKO ewes nonetheless responds to intrauterine infusions of recombinant ovine IFNτ with increased expression of P_4-dependent IFNτ-stimulated genes, such as Wnt7a, which signals pregnancy recognition through endometrial factors.[79,83–85]

IFNτ regulates expression of a number of IFN-stimulated genes (ISGs) differentially in uterine epithelium and stroma, which are considered to play roles in endometrial differentiation and conceptus implantation in sheep.[86] The type I IFN receptor subunits, IFNAR1 and IFNAR2, are expressed in all major endometrial cell types, with the highest expression found in the luminal epithelium.[87] However, the majority of ISGs are induced in response to the conceptus or IFNτ only in the uterine stroma and deeper glandular epithelium, which is apparently due to the expression of IFN regulatory

factor 2 (IRF2), a potent repressor of gene transcription, in the superficial epithelium.[88–92] IFNτ acts in a paracrine fashion on uterine luminal and glandular epithelial cells to suppress transcription of ERα and oxytocin receptor genes,[93,94] thereby preventing development of the endometrial luteolytic mechanism. Therefore, the actions of IFNτ may not be completely limited to inhibition of luteolysis but may also be involved in inducing genes important for conceptus growth and uterine receptivity.

DELAYED IMPLANTATION (MAMMALIAN DIAPAUSE)

Delayed implantation (embryonic diapause) occurs when the embryo achieves a state of suspended animation with temporary arrest in blastocyst growth and metabolic activity within a synchronously quiescent uterus without implantation. Nearly 100 mammals in seven different orders have been shown to undergo delayed implantation.[95,96] In many species, the developmental arrest during diapause occurs at the blastocyst stage. Likewise, the endocrine landscape that physiologically governs embryonic diapause is represented by diverse strategies in different species.[97] Two functionally distinct categories of embryonic diapause are known.[96] Facultative diapause is best observed in rodents and marsupials (wallabies and kangaroos) characterized by developmental arrest induced by maternal conditions, including lactation, insufficient diet, shortage of drinking water, and other forms of stress.[96] It is believed to be a mechanism for synchronizing parturition with favorable environmental conditions for neonatal survival.[97] The second category is obligate diapause and can occur during every gestation period of a given species (Figure 38.3).

Obligate diapause is prevalent in mustelids, bears, seals, and some wallabies.[96] In most mammals displaying discontinuity of embryonic development, the progression to the blastocyst stage and postimplantation development follow a preordained, species-specific program. Species within the mustelid family display periods of embryonic diapause that are variable between

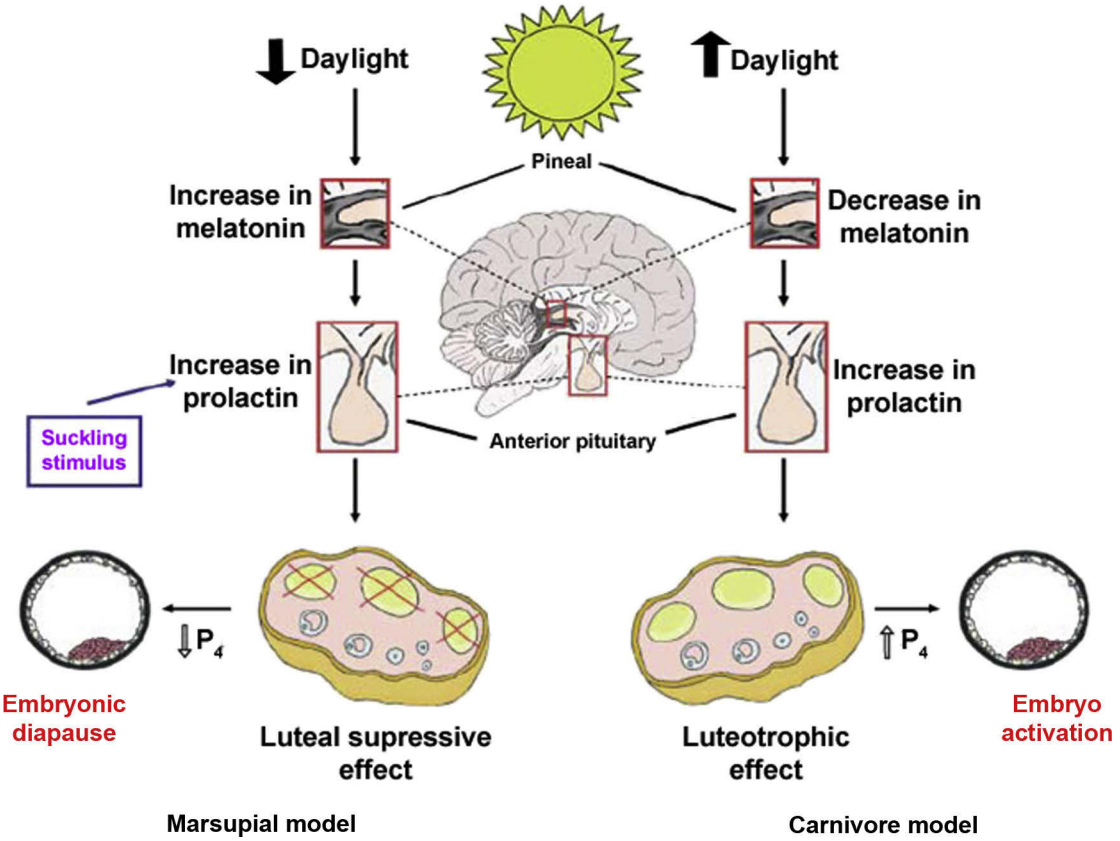

FIGURE 38.3 **Strategies for embryonic diapause for marsupials and carnivores.** In the marsupial model, which exhibits both obligate and facultative delay, suckling stimulus and increased melatonin secretion associated with nocturnal periods in excess of the summer solstice upregulate prolactin, which then inhibits luteal activation, thereby initiating and maintaining diapause. In the carnivore model, which exhibits obligate delay, the photoperiod associated with the vernal equinox decreases melatonin secretion, releasing prolactin from inhibition. Prolactin activates the corpus luteum (CL), provoking release of progesterone (P_4) and other factor(s) that terminate diapause. *Source: Reprinted with permission from Ref. 96.*

individuals but can be in excess of 350 days in the fisher (*Martes pennanti*), or be as brief as 3 weeks in the mink (*Mustela vison*).[96,98] Delayed implantation has been shown not to occur in certain species, including hamsters, rabbits, guinea pigs, or pigs. However, a recent interspecies embryo transfer study reports that embryos from nondiapausing sheep can undergo dormancy when transferred to a delayed implantation mouse uterus, and could subsequently be reactivated to produce normal offspring upon transfer back into the donor uterus.[99] This study concludes that embryos from a species deemed incapable of undergoing diapause are competent to enter embryonic diapause if the uterine environment favors this event, suggesting that all mammals inherently possess the capacity for embryonic diapause under the appropriate direction from maternal signals. Whether humans and their close primate relatives are capable of delay is under debate.[100]

Environmental, Neural, and Pituitary Regulation of Embryonic Diapause

Seasonal cues synchronize reproductive events in mammals, and it was recognized early on that photoperiod plays an important role in the termination of diapause and subsequent induction of implantation.[98] The lengthening of days prior to and after the vernal equinox influences the timing of implantation in numerous species, including the spotted skunk (*Spilogale putorius*)[101] and the mink.[96] Day length—or, more precisely, a regime of photoperiod in which minks are exposed to light during a critical period from 12 to 16 h after dawn—provides a facultative signal that induces implantation.[102] Melatonin produced by the pineal gland is considered the primary mediator of the photoperiodic regulation of diapause.[103] The essential factor regulated by melatonin proved to be prolactin, as implantation could be advanced by treatment with prolactin[104] or dopamine antagonists[105] (Figure 38.3), but further delayed by dopamine agonists.[104] Indeed, prolactin alone induces implantation in hypophysectomized mink,[106] and prolactin overcomes the effects of chronic melatonin treatment on the termination of diapause.[103] Prolactin executes its effects directly on the mink corpus luteum.[107] Although functional prolactin receptors are present in the mink uterus,[108] it is not known whether prolactin has a role at the level of the endometrium. Following ovulation, the ovarian follicle collapses and forms the corpus luteum.[109] The corpus luteum undergoes a remarkable structural reduction in size as diapause ensues, secreting low levels of P_4.[97,107] In contrast to the pattern of terminal differentiation that characterizes corpus luteum development in most species, the mink corpus luteum retains its mitotic potential during the period of diapause.[110] In response to the pituitary prolactin signaling that terminates diapause, the corpus luteum is rejuvenated, a process characterized by a several-fold increase in corpus luteum volume and in P_4 output.[107] As in other species, P_4 is essential for implantation and for the maintenance of gestation in mustelids. Nonetheless, numerous attempts to induce precocious implantation during diapause with P_4 or P_4 in combination with estrogens have been unsuccessful, suggesting that luteal factors other than P_4 are required for successful implantation in this species.[105] In the ferret (*Mustela putorius*), a mustelid species that does not undergo delay, a luteal protein factor has been shown to be necessary for implantation to occur.[111] Further studies have identified a secretory form of glucose-6-phosphoisomerase, also known as autocrine motility factor, as the luteal protein required for implantation in the ferret.[112] Its role in other species with embryonic diapause has not yet been confirmed.

Ovarian Regulation of Diapause in Rodents

In mice and rats, ovariectomy prior to the presumed "estrogen surge" on the morning of day 4 of pregnancy results in implantation delay, and a state of dormancy is initiated in blastocysts within the uterine lumen.[4,113] This condition is referred to as delayed implantation, and can be maintained for many days by continued treatment with P_4. A single injection of estrogen in the P_4-primed delayed implantation mouse rapidly initiates implantation and blastocyst activation.[4,26,114] The primary estrogen required for the activation of blastocysts for implantation is mediated by 4-hydroxyestradiol (4-OH-E_2), a cytochrome P450 (CYP) 1B1-generated metabolite of E_2 known as catecholestrogen.[67] Since CYP1B1 in the mouse uterus converts E_2 into 4-OH-E_2, E_2 injection is sufficient to initiate implantation in vivo. In contrast, dormant blastocysts cultured in vitro require 4-OH-E_2 to be activated for implantation. Blastocysts then can develop to term when sufficient amounts of P_4 and E_2 are provided.[67,115] Lactational delay is induced when mice become pregnant with postpartum ovulation. A delay of 1–7 days in implantation occurs in most lactating mice, and the length of delay is tightly associated with the number of sucking pups.[116] Sucking induces the secretion of prolactin through the alterations in hypothalamic function, which in turn suppresses ovarian estrogen secretion. Thus, an appropriate dose of estrogen resumes implantation in lactational delay.[117]

Activation of dormant blastocysts appears to involve an "early response" to catecholestrogens, since dormant blastocysts transferred into delayed implanting recipient uteri within 1 h of E_2 administration show implantation, while similar blastocysts transferred beyond this 1 h period fail to implant.[67] These results suggest that a rapid response to estrogen in the uterus occurs that is critical to implantation. In contrast,

dormant blastocysts cultured in the presence of a catecholestrogen, but not estradiol, gain implantation competency, and upon transfer implant in pseudopregnant recipients well beyond the 1 h "window" of estradiol treatment. Similar results were also obtained by culturing dormant blastocysts in the presence of PGE_2 or a permeable analog of cAMP, suggesting that this effect apparently involves the PG signaling pathway.[67] For example, co-incubation of dormant blastocysts with a selective COX2 inhibitor and 4-OH-E_2 efficiently blocks their activation and implantation upon transfer to suitable recipients. This effect of the COX2 inhibitor was partially reversed by addition of PGE_2 to the culture media. The results strongly suggest that the action of 4-OH-E_2 on dormant blastocysts is mediated via the PGs, leading to an increase in intracellular cAMP levels. However, it is still a mystery how catecholestrogens mediate activation of blastocysts. Although nuclear ERα is present in both the active and dormant blastocysts,[118] dormant blastocysts do not respond to estradiol and fail to attain implantation competency in vitro. In contrast, dormant blastocysts do respond to a catecholestrogen 4-OH-E_2 and become implantation-competent in vitro. The ER antagonist ICI-182,780 fails to reverse this response, suggesting that nuclear ER signaling is not critical to blastocyst activation.[67] These observations are surprising in the light of findings that ERα, ERβ, and estrogen-responsive finger protein mRNAs are expressed in preimplantation embryos.[119,120] Examining the direct roles of estrogens and/or P_4 in preimplantation embryo function and how steroid hormone signaling in the embryo and uterus is coordinated for implantation require further investigation.

In the ovariectomy model, dormant blastocysts survive as long as several weeks in utero, but the survival rate and their developmental competency are inversely correlated with the length of dormancy.[121,122] Since dormant blastocysts can survive in the delayed implanting uteri without exogenous P_4 in mice, P_4 does not seem to be an absolute requirement for the survival and retention of dormant blastocysts, but may be required for the longevity of blastocyst dormancy and to maintain the quiescent state of the uterus.[121,123]

The Embryo in Diapause

The experimentally delayed implantation model of rodents has widely been used to study molecular and cellular aspects of embryonic dormancy[124] (see the section Delayed Implantation (Mammalian Diapause)). During diapause, embryos appear to undergo a slow expansion in the absence of mitotic proliferation and are "metabolically dormant".[124,125] DNA synthesis and cell proliferation stop within 2–3 days of delayed implantation, but a low level of RNA synthesis is maintained. In this model, estrogen injection reactivates dormant blastocysts within 12 h and implantation resumes by 18 h. The reactivation of development comprises a rapid increase in size, followed by renewal of cell proliferation within 48–72 h. There is evidence[126] to indicate that fibroblast growth factor 4 (FGF4), produced by the ICM of the mink embryo, drives proliferation of the trophoblast cells prior to implantation.[127] In mice, terminal differentiation of the trophoblast is associated with endo-reduplication, where chromosomes replicate without proceeding through mitosis,[128,129] and there are some intriguing indications that such endocycles may also occur in mink trophoblast during its escape from diapause.[130] Another peculiarity of the carnivore blastocyst is that it remains encapsulated in the zona pellucida, which is breached at multiple sites by trophoblast outgrowths only at the time of implantation.[131] The progression of trophoblast into the endometrium does not differ greatly between species that exhibit diapause.[131,132]

A global gene expression analysis identified molecular pathways distinguishing blastocyst dormancy and activation in mice.[133] The major functional categories of altered genes include cell cycle, calcium signaling, adhesion molecules, and energy metabolic pathways. Thus, the two different physiological states of the blastocyst, dormancy and activation, are molecularly distinguishable in a global perspective. Heparin-binding epidermal growth factor (EGF)–like growth factor (HB-EGF) is an important mediator of embryo–uterine interactions during implantation.[134] Expression of this ligand is induced in activated blastocysts along with its potential receptors of the ErbB family,[133] supporting the importance of this signaling mediator in the initiation of implantation. EGF receptor (EGFR), COX2, and histamine type 2 receptor (H_2), the factors that are associated with blastocyst attachment reaction, are expressed in normal or activated blastocysts but are downregulated in dormant blastocysts (Figure 38.4).[27,64,123,135–137] In contrast, the G protein–coupled cannabinoid receptor CB1, which responds to endocannabinoids, is downregulated in activated blasto cysts, but remains upregulated in dormant blastocysts[138] (see the section Molecular Aspects of Embryo–Uterine Interactions). Collectively, these findings suggest that a complex molecular network regulates blastocyst dormancy and activation.

One of the intriguing features of dormant blastocysts is the activation of autophagy.[122] Autophagy, meaning self-eating, is a major cellular catabolic pathway by which macromolecules and organelles are recycled and used.[139] Dormant mouse blastocysts seem to utilize this pathway to prolong their survival in utero, and inhibition of autophagic pathway is associated with reduced blastocyst survival and compromised developmental competency in the ovariectomized model of delayed implantation in mice.[122]

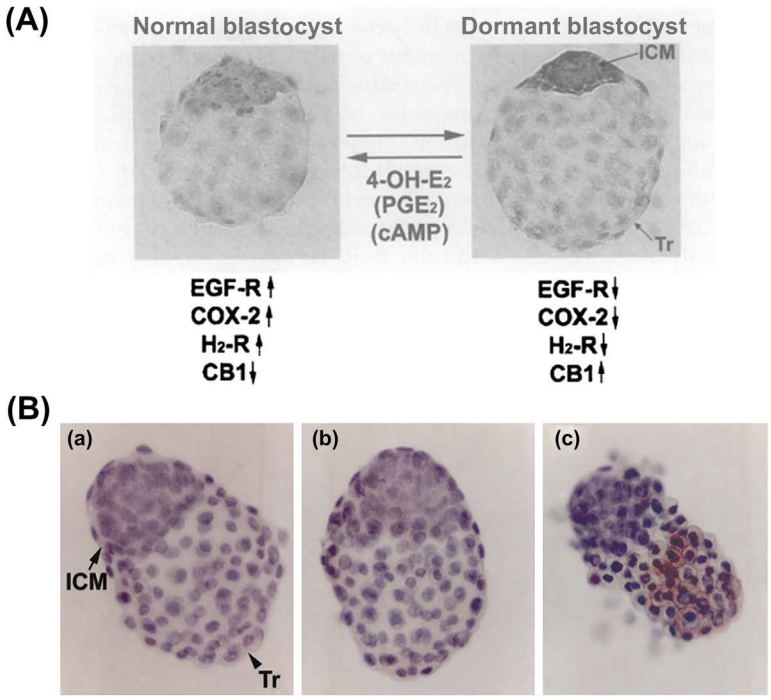

FIGURE 38.4 Molecular markers for blastocyst dormancy and activation. This figure is reproduced in color in the color plate section. (A) Although normal and dormant blastocysts apparently show morphological differences, several molecular markers are regulated reversibly by the blastocyst's state of activity. 4-OH-E_2, PGE_2, or cAMP can activate dormant blastocysts in vitro and either up- or downregulate specific marker molecules as indicated. Likewise, if normal blastocysts are induced to undergo dormancy by the use of delayed implantation in the uterus before the attachment reaction, expression of these markers is shifted in the reverse direction. EGFR, epidermal growth factor receptor; COX2, cyclooxygenase-2; H2R, histamine type 2 receptor; CB1, brain-type cannabinoid receptor. (B) Dormant blastocysts recovered from P_4-primed delayed-implanting mice on day 7 were cultured for 24 h in Whitten's medium, in the presence of (a) vehicle; (b) E_2; or (c) 4-OH-E_2. Blastocysts were processed for immunostaining and counterstained with hematoxylin. Red deposits indicate the sites of immunoreactive COX2. ICM, inner cell mass; Tr, trophectoderm. *Source: Reprinted with permission from Refs 67,137.*

Collectively, the delayed implantation models in mice and in other species could be exploited more extensively to better understand the molecular signaling that emanates from the uterus and influences blastocyst dormancy and vice versa.

Uterine Factors in Embryonic Diapause

As the host of the embryo during diapause and an ultimate place for implantation, the uterus plays a significant role in both the initiation and termination of discontinuous development in obligate delay. Indeed, embryos from nondiapausing sheep become dormant when placed in a mouse uterus under delay; upon transfer back into the donor ewe uterus, these embryos are reactivated and can produce normal offspring.[99] In addition, mink embryos in diapause co-cultured with uterine cell lines displayed the capacity to reinitiate embryonic development in vitro, providing further evidence that the uterus maintains diapause in this species.[140] The factors associated with inhibition of renewed development are not known. Histochemical evidence demonstrates that the transition of the mink uterus from delay to implantation is accompanied by increases in the quantity and distribution of glycosaminoglycans.[141] This concurs with observations of low levels of protein synthesis by the uterus during delay in the spotted skunk, followed by increased protein synthesis a few days prior to implantation.[142] Recent studies in mink have also identified a role for polyamine synthesis in embryonic diapause; polyamine deprivation in utero can induce the reversible arrest of embryonic cell proliferation.[143]

Studies of candidate gene expression during implantation in species with obligate delay have revealed patterns similar to those seen in the traditional rodent models. EGF and its receptor are present in the spotted skunk uterus during both the delay and postimplantation phases of gestation, and EGF activity is significantly elevated during the implantation process.[144] Leukemia inhibitory factor (LIF), a member of the interleukin 6 (IL6) family of cytokines essential for implantation in the mouse, is expressed in the uterine glands just prior to and after implantation in the mink.[145,146] LIF receptors were found in uterine glands and invading trophoblast during implantation in the spotted skunk.[147] COX2 (encoded by *Ptgs2*), another gene essential for mouse implantation, is not present in the uterus during diapause in the mink[148] or skunk uterus,[149] but is expressed in the trophoblast and endometrium of both species during implantation. Products of COX2 activity that subserve the implantation process are not well known, but prostaglandin E and D are implicated in the upregulation of transcription of the angiogenic factors associated with implantation.[96,150]

The *Msx* family of transcription factors is shown to play vital roles in fertility (see the section Molecular Aspects of Embryo–Uterine Interactions). Findings of persistent uterine *Msx1* during implantation delay and downregulation upon blastocyst activation, along with the findings that loss of uterine competency is correlated with missing *Msx1/Msx2* expression, also suggest a role of *Msx* genes in embryonic diapause.[151] Indeed, sustained uterine expression of *Msx* family members is

correlated with diapause in the mouse, American mink, and Australian tammar wallaby, with rapid downregulation with impending implantation.[152]

MOLECULAR ASPECTS OF EMBRYO–UTERINE INTERACTIONS

Although pregnancy events have always been a subject of curiosity, the field of reproductive physiology would not have progressed without the intellectual tenacity of pioneers in the field. Thoughtful and keen observations of early scientists greatly added to our understanding of reproductive biology. The current state of our knowledge of preimplantation and implantation physiology is the result of the accumulation of scientific observations gathered over many years.

Despite experimental success in initiating embryonic development outside the womb and in identifying numerous signaling molecules involved in the embryo–uterine dialog, there is still a significant knowledge gap in understanding the in vivo events of implantation. The successful implantation of an embryo is contingent upon cellular and molecular cross-talk between the uterus and the embryo. The coordination of the endocrine as well as cellular and molecular events via paracrine, autocrine, and/or juxtacrine factors acts in a dynamic manner to produce within the uterus a favorable environment, the receptive state, to support implantation.[153] The embryo also functions as an active unit with its own molecular program of cell growth and differentiation. Thus, deficiencies in uterine receptivity, embryo development, or the embryo–uterine dialog will compromise fertility.[153]

Implantation is a complex process involving spatiotemporally regulated endocrine, paracrine, autocrine, and juxtacrine modulators that span cell–cell and cell–matrix interactions.[153–155] However, the precise sequence and details of the molecular interactions involved have not yet been fully defined. Furthermore, the implantation process varies among species, thus precluding the formulation of a unified mechanism. In addition, ethical restrictions and experimental difficulties prevent direct analysis of embryo–uterine interactions during implantation in humans.

mRNAs encoding specific proteins are expressed in the uterus in a spatiotemporal manner and have helped to identify various genes with speculative roles in implantation.[153–155] Transgenic mouse models have furthered our mechanistic understanding regarding the roles of many genes in uterine receptivity and implantation, although the systemic deletion of many of these genes led to embryonic lethality, precluding the identification of their roles. The field was further advanced by the generation of conditionally deleted mouse models.[153] Despite this advancement, dynamic and overlapping expression patterns made it challenging to ascertain stage-specific roles. This section primarily focuses on the collective advances in the molecular basis of implantation in mice (Figure 38.5).[153]

Uterine Responsiveness to Hormone-Dependent Factors

Estrogen and P_4 effects in the uterus are primarily regulated by nuclear estrogen receptors (ERα and ERβ) and progesterone receptors (PRA and PRB). Differential uterine expression of ER and PR during the peri-implantation period in mice suggests that coordinated effects of estrogen and P_4 in uterine events for implantation are mediated via these nuclear receptors.[156] Furthermore, mouse models devoid of each receptor gene are informative as to how these receptors are involved in uterine biology.

ERα (encoded by the gene, *Esr1*) is the primary driver of estrogen action for uterine receptivity and implantation since *Esr1*$^{-/-}$ females are infertile.[157] However, further experiments using *Esr1*$^{-/-}$ mice showed that P_4 alone is sufficient to support decidualization (deciduoma) in response to artificial stimuli.[158,159] These results suggest that *Esr1*$^{-/-}$ mice have defective implantation, perhaps due to the failure of the attachment reaction but not due to the failure of decidualization events.[160] Microarray analysis of RNA from the *Esr1*$^{-/-}$ uterus also demonstrates a minimal response to estrogen,[161] suggesting that ERα is essential for proliferative and genomic responses of the uterus.

Female mice devoid of ERβ (*Esr2*) exhibit subfertility.[162,163] As in *Esr1*$^{-/-}$ or *Esr1*$^{-/-}$/*Esr2*$^{-/-}$ double-knockout mice, defects in the hypothalamic–pituitary–gonadal (ovarian) axis are apparent in *Esr2*$^{-/-}$ female mice.[163] The uterus of the *Esr2*$^{-/-}$ mouse retains full biological function, as demonstrated by uterine weight increase with E_2 administration.[162] Full genomic responsiveness to estrogen in these mice is also seen by microarray analysis.[161,162] Additionally, although *Esr2*$^{-/-}$ female mice exhibit subfertility, those that achieve pregnancy carry and deliver full-term pups, indicating that uterine function in terms of implantation, decidual response, and parturition is normal. These results point toward a minimal importance of ERβ in the adult uterus for estrogen response or pregnancy.

Mice deleted of progesterone receptor (*Pgr*$^{-/-}$) exhibit pleiotropic reproductive abnormalities, including impaired ovulation, uterine hyperplasia, and decidualization.[164] Selective ablation of the PRA isoform showed infertility with a milder phenotype, suggesting that PRA and PRB serve as functionally distinct mediators of P_4 action in vivo.[165] Experiments using both *Pgr*$^{-/-}$ and PRA$^{-/-}$ mice further reinforced the requirement of P_4 in decidualization.[164,165]

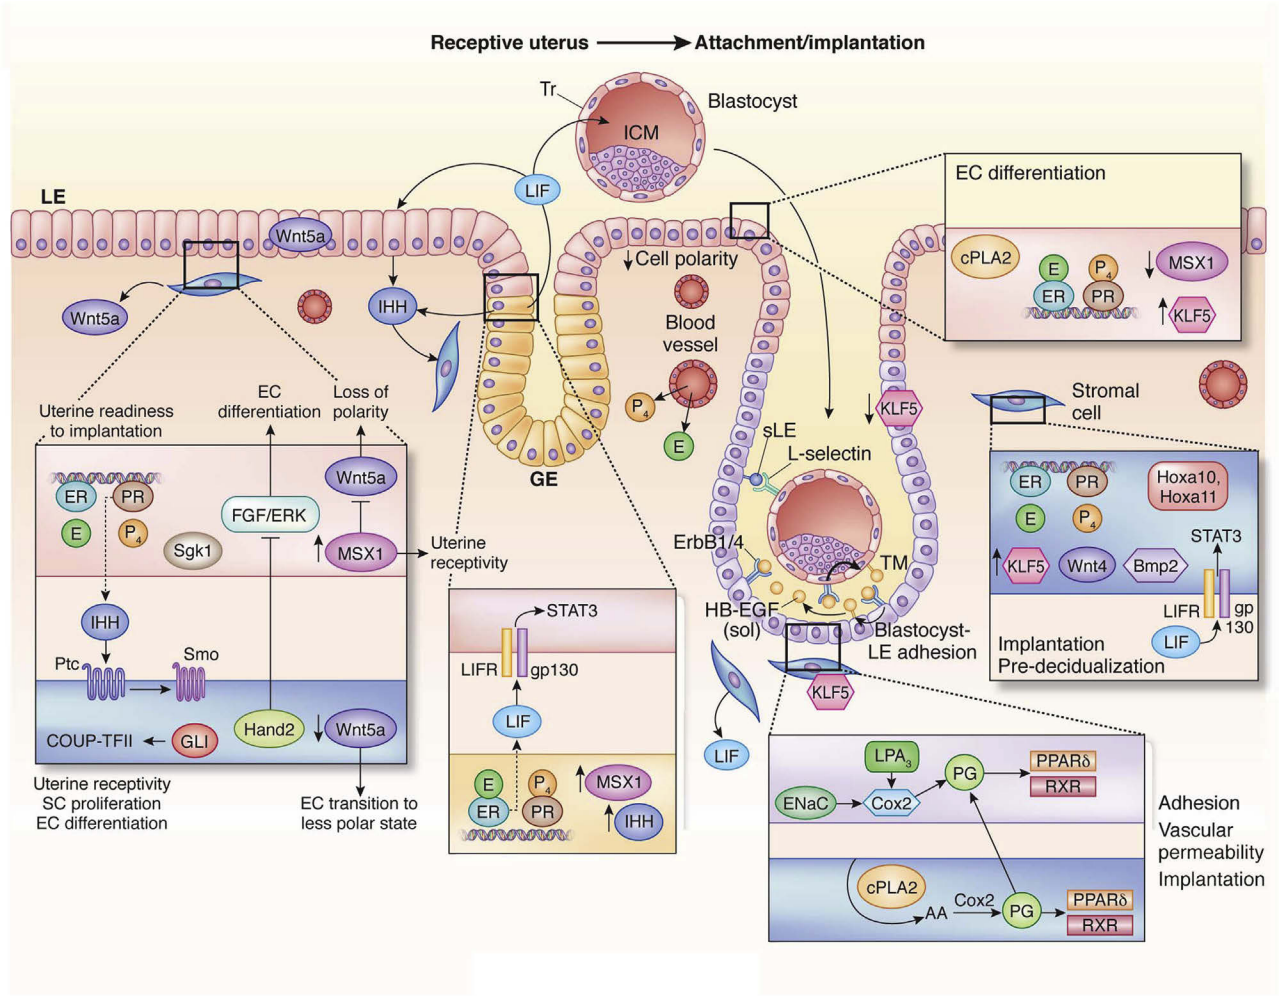

FIGURE 38.5 Signaling network for uterine receptivity and implantation. This figure is reproduced in color in the color plate section. This is a hybrid cartoon, based on mouse and human studies, portraying compartment- and cell type–specific expression of molecules and their potential functions necessary for uterine receptivity, implantation, and decidualization. Interplay of ovarian P_4- and/or E_2-dependent and P_4- and/or E_2-independent factors in the pregnant uterus in specific compartments contributes to the success of implantation in a juxtacrine–paracrine–autocrine manner. During attachment, interactions between the blastocyst and luminal epithelium (LE) involve ErbB1/4 and both transmembrane (TM) and soluble (Sol) forms of HB-EGF, as well as L-selectin ligands (sLE) expressed by the luminal epithelium to L-selectin receptors on the blastocyst. The other key signaling pathways for uterine receptivity and implantation are also shown. AA, arachidonic acid; BMP2, bone morphogenetic protein 2; cPLA2α, cytosolic phospholipase A2α; COUP-TFII, chicken ovalbumin upstream promoter transcription factor 2; Cox2, cyclooxygenase 2; E, estrogens; EC, epithelial cell (luminal and glandular epithelia); ENaC, epithelium sodium channel; ER, estrogen receptor; ErbB1/4; epidermal growth factor receptor 1/4; ERK, extracellular signal–regulated kinase; FGF, fibroblast growth factor; GE, glandular epithelium; gp130, glycoprotein 130; Hand2, heart- and neural crest derivatives–expressed protein 2; HB-EGF, heparin-binding epidermal growth factor-like growth factor; Hoxa10/11, homeobox A10/11; ICM, inner cell mass; IHH, Indian hedgehog; KLF5, Kruppel-like factor 5; LIF, leukemia inhibitory factor; LIFR, LIF receptor; LPA3, lysophosphatidic acid receptor 3; MSX1, muscle segment homeobox 1; P_4, progesterone; PG, prostaglandin; PPAR-δ; peroxisome proliferator-activating receptor δ; PR, progesterone receptor; Ptc, Patched; RXR, retinoid X receptor; SC, stromal cell; SGK1, serum- and glucocorticoid-inducible kinase 1; Smo, Smoothened; STAT3, signal transducer and activator of transcription 3; Tr, trophectoderm; Wnt4/5a, Wingless-type MMTV integration site family members 4/5a. Compartment colors: blue, stroma; pink, luminal epithelium; orange, glandular epithelium; purple, epithelium at the attachment site. *Source: Reprinted with permission from Ref. 153.*

While both *Esr1*$^{-/-}$ and *Pgr*$^{-/-}$ mice show severe phenotypes of female reproductive failure, these mice have been used as model systems to study steroid hormonal regulation of several genes. Das and coworkers reported a non-ER-mediated estrogen signaling pathway that is resistant to an ER antagonist ICI-182,780 in *Esr1*$^{-/-}$ uteri.[160] Lactoferrin (LF) is a well-known estrogen-responsive gene in mice, and many natural or synthetic estrogens can induce this gene in wild-type uteri.[160] In contrast, while estradiol was not able to induce this gene in *Esr1*$^{-/-}$ uteri, a catecholestrogen 4-OH-E_2 was effective in this response. Since induction by 4-OH-E_2 was resistant to an ERα antagonist (ICI-182,780), ERα does not appear to mediate this effect. The possibility

that an alternative estrogen signaling pathway independent of nuclear ERs exists in the mouse uterus was further explored.[166] Using a differential display technique, it was found that several genes are upregulated or downregulated by estradiol and 4-OH-E_2 in both wild-type and *Esr1*$^{-/-}$ uteri independent of nuclear ERs. The upregulated genes were immunoglobulin heavy chain binding protein (Bip), calpactin I (CalP), calmodulin (CalM), and Sik-similar protein (Sik-SP), while the gene that encodes secreted frizzled related protein2 (SFRP2) was readily downregulated. An ER antagonist failed to neutralize these responses in both wild-type and ERα$^{-/-}$ mice, suggesting that these are ER-independent early responses. This provides compelling evidence that an alternative estrogen-signaling pathway is operative in the uterus. However, it is still unclear whether early estrogenic responses are mediated by a putative cell surface estrogen receptor[167] or by other nuclear receptors, such as ERγ or estrogen receptor–related receptors.[168,169] Alternatively, this could be explained by estrogen signaling via a membrane receptor of the G protein–coupled receptor family. Although several putative membrane progesterone receptors have been cloned,[170,171] whether similar types of membrane estrogen receptors are present in the uterus is not presently known.

ERα and PRA are expressed in all major uterine tissue compartments, and thus their compartment-specific contributions in uterine receptivity have been difficult to elucidate. Mice with epithelial cell-specific deletion of *Esr1* still show epithelial cell proliferation after estrogen exposure.[172] However, PR distribution between uterine compartments remained unchanged, suggesting a role for stromal ERα. Nonetheless, *Esr1*$^{-/-}$ females showed implantation failure with dysregulated expression of other estrogen-responsive genes, perhaps due to uterine failure to achieve receptivity. On the other hand, P_4 failed to attenuate estrogen-induced cell proliferation in females deleted of epithelial *Pgr*, suggesting a direct role of P_4 in inhibiting epithelial estrogen action.[173] These females are infertile with reduced expression of Indian hedgehog (*Ihh*) and LIF, resulting in poor uterine receptivity. This study also showed direct binding of PR to the *Ihh* promoter in the epithelium. However, these results are not consistent with those from a recombination study showing epithelial *Ihh* expression regulated by stromal PR.[174] Cell-specific expression of estrogen- and P_4-responsive genes in the uteri of these compartment-specific deleted mice would be worthwhile. Nevertheless, the results show that a reciprocal dialog between the epithelium and stroma is necessary for appropriate uterine receptivity and implantation.

Estrogen and P_4 execute their uterine functions by inducing and refining multiple paracrine, juxtacrine, and autocrine factors in a spatiotemporal manner. LIF is a mediator of estrogen function during implantation. LIF is critical for uterine receptivity because its deletion leads to implantation failure in mice.[175,176] By binding to its receptor, LIFR, and partnering with co-receptor gp130, LIF activates downstream signaling through signal transducer and activator of transcription 3 (STAT3).[177] This signaling is necessary for implantation as uterine deletion of *gp130* (*IL6st*)[151] or *stat3* (Sun et al., unpublished data) causes implantation failure. *Lif* expression is higher in the human endometrium at the time of implantation, but remains at lower levels in infertile women.[2,178,179] Whether LIF is required for human uterine receptivity and implantation requires further investigation.

Global deletion of tumor suppressor protein p53 (*Trp53*$^{-/-}$) showed small litters with inferior implantation and reduced *Lif* expression on day 4.[180] However, *Trp53*$^{-/-}$ mice show a range of phenotypes including exencephaly, especially in females, and widespread cancer at early reproductive age.[181,182] Males have also been shown to have compromised spermatogenesis.[183] Therefore, these mice may not be ideal to study reproduction. In contrast, another study using mice with uterine deletion of *Trp53* (*p53*$^{d/d}$) showed normal implantation but developed spontaneous preterm birth[184] (see the section Adverse Ripple Effects Arising from Early Pregnancy Events). These two studies cannot be compared directly because of the different approaches utilized (systemic versus conditional deletion).[180,184]

Many P_4-responsive genes participate in peri-implantation events in the uterus. The P_4-inducible immunophilin co-chaperone FKBP52 is required for optimal PR activity. *Fkbp52*$^{-/-}$ mice are infertile, with enhanced uterine estrogen-like signaling resulting from impaired P_4 responsiveness.[185,186] However, this P_4 resistance could be overcome with successful implantation and pregnancy by delivering excess P_4, depending on the genetic background of mice.[187] It was later shown that *Fkbp52*$^{-/-}$ mice are more vulnerable to oxidative stress due to diminished expression of a unique antioxidant *Peroxiredoxin 6* (*Prdx6*).[188] When exposed to oxidative stress such as paraquat, *Fkbp52*$^{-/-}$ mice showed implantation failure even with P_4 supplementation. This failure was reversed by supplementation with antioxidants. These data suggest that FKBP52 has more than one role in uterine biology. FKBP52 also plays a role in decidualization and endometriosis in mice and humans.[189,190] Steroid receptor co-activator 2 (SRC2, also known as *Ncoa2*) is also recruited by PR for its function.[191] Uterine deletion of *Ncoa2* led to pregnancy failure during the peri-implantation period due to defective progesterone action.[192] Since SRC2 is present in the human endometrium, it may play a role in optimizing P_4 function in human reproduction.[193]

P_4 signaling induces *Ihh* in the uterus, the deletion of which leads to implantation failure due to defective uterine receptivity.[194,195] *Ihh* is expressed in the epithelium

and interacts with its receptors patched and smoothened in the stroma, mediating stromal cell proliferation. These results implicate that Ihh executes epithelial–stromal interaction in a paracrine manner for uterine receptivity and implantation. In the human endometrium, expression of *Ihh* and its receptors is upregulated by progestins.[196] A proposed downstream target of Ihh is chicken ovalbumin upstream promoter–transcription factor (COUP-TFII, also known as *Nr2f2*) and is expressed in the subepithelial stroma.[197] Conditional deletion of *Nr2f2* in PR-expressing tissues leads to infertility due to implantation failure with excessive estrogenic signaling in the epithelium, suggesting that COUP-TFII participates in balancing ER versus PR activities. Paradoxically, stromal and myometrial deletion of *Nr2f2* deletion showed normal implantation with defective placentation. Incomplete uterine *Nr2f2* deletion is suggested as a cause for this phenotype discrepancy.[198]

Heart- and neural crest derivatives–expressed protein 2 (Hand2) is a P_4-induced stromal transcription factor that was shown to play a role in uterine receptivity and implantation in mice.[199] Mice missing uterine *Hand2* showed implantation failure with increased estrogenic activity and epithelial cell proliferation via FGF–ERK signaling. It was suggested that stromal Hand2 participates in uterine receptivity by altering epithelial differentiation. Whether the infertility phenotype in these mice could be reversed by excess P_4 administration or inhibitors of FGF-ERK signaling remains to be seen. A recent study also implicates Hand2 in decidualization.[200]

Fibroblast growth factor 7 (FGF7, also known as keratinocyte growth factor), is an established paracrine mediator of hormone-regulated epithelial growth and differentiation.[201] In all organs studied, FGF7 was uniquely expressed in cells of mesenchymal origin. Intriguingly, expression of FGF7 in the porcine uterus is exclusively restricted in the endometrial luminal epithelium and particularly abundant between days 12 and 15 of the estrous cycle and pregnancy.[202] Endometrial FGF7 mRNA levels are highest on day 12 in pregnant gilts and day 15 in cyclic gilts, and greater on day 12 of pregnancy than on day 12 of the estrous cycle. FGF7 protein was detected in the uterine flushings of both day 12 cyclic and pregnant gilts. The receptor for FGF7, known as FGF receptor 2 (FGFR2) or KGF receptor, is detected in both the endometrial epithelium and conceptus trophectoderm. Treatment of endometrial explants from day 9 cyclic gilts with estradiol increases FGF7 expression.[203] Furthermore, treatment of porcine trophectoderm cells with recombinant rat FGF7 increases their proliferation, phosphorylates fibroblast growth factor receptor 2 (FGFR2), activates the mitogen-activated protein kinase (MAPK or ERK1/2) cascade, and increases expression of urokinase-type plasminogen activator, a marker for trophectoderm cell differentiation.[203] Collectively, these results indicate that estrogen, the pregnancy recognition signal from the pig conceptus, increases uterine epithelial FGF7 expression and that FGF7, in turn, stimulates the proliferation and differentiation of the conceptus trophectoderm in the pig, which is the only species possessing a true epitheliochorial type of placentation except the camel.[202,203]

Uterine Responses to Factors Independent of Estrogen and P_4

Numerous genes crucial for uterine receptivity and implantation in mice are regulated by estrogen and P_4. However, there are transcription factors that are apparently not directly altered by these hormones but greatly influence uterine receptivity and implantation. *Msx1*, an ancient evolutionarily conserved homeobox transcription factor, plays a critical role in craniofacial development.[151] *Msx1* is also transiently expressed in the pregnant mouse uterine epithelium on the morning of day 4 of pregnancy, the day of uterine receptivity.[204] Expression then gradually disappears approaching the attachment reaction and remains undetected thereafter. These observations suggest that Msx1 is important for receptivity. Expression of *Msx2*, another member in the family, is very low to undetectable in the uterus during this time; however, *Msx2* is upregulated in *Msx1*-deficient uteri and exhibits a similar pattern to the expression of *Msx1* as observed in wild-type mice. This finding provides evidence for a compensatory role of *Msx2* in the absence of *Msx1*. Uterine deletion of *Msx* genes showed graded levels of infertility depending on single or double deletion.[151] Mice with uterine inactivation of *Msx1* ($Msx1^{d/d}$) produce small litter size or no litters, while mice with deletion of both *Msx1* and *Msx2* ($Msx1/Msx2^{d/d}$) show complete infertility due to failed or defective implantation with loss of uterine stromal *bone morphogenetic protein 2* (*Bmp2*) expression, and restricted *Ptgs2* expression in the luminal epithelium at the site of blastocyst apposition. Notably, mice with uterine inactivation of *Msx2* have normal fertility.[151] The implantation failure as noted in this study was later confirmed by another group.[205]

Msx1 expression is rapidly downregulated approaching implantation and thereafter, and it persists in delayed implantation uteri until implantation is induced by estrogen. Implantation largely fails in P_4-primed delayed implantation $Msx1^{d/d}$ uteri following estrogen treatment. These results suggest that *Msx* genes are critical for maintaining uterine readiness to implantation. *Lif* expression is downregulated in *Msx*-deleted uteri, but LIF supplementation cannot rescue implantation in deleted mice. The relationship between LIF and Msx remains to be explored.

Msx genes are likely to be involved in human implantation since they are downregulated in the endometrium

during the window of implantation similar to that which occurs in mice (reviewed in Refs 151,155). The luminal epithelium transits from a higher to lower polar state approaching blastocyst attachment.[206] This transition is absent in *Msx1/Msx2*$^{d/d}$ uteri at the anticipated time of implantation. Wnt5a, a noncanonical Wnt and a known mediator of cell polarity, is upregulated in the uterine epithelium and stroma in *Msx1*$^{d/d}$ and *Msx1/Msx2*$^{d/d}$ mice. In addition, the *Wnt5a* promoter shows Msx1 binding sites in a human uterine cell line. Further studies indicated that Wnt5a-β-catenin/E-cadherin signaling is a potential downstream target of Msx and participates in implantation by altering cell polarity with respect to adherens junctions.[151]

E-cadherin, a calcium-dependent adhesion molecule, participates in the formation of the epithelial adherens junctions in cooperation with α- and β-catenins.[207,208] E-cadherin is a critical factor for blastocyst formation, since its deletion leads to defective embryonic development resulting in failure to form the trophectoderm.[209,210] E-cadherin is implicated in uterine–embryo interactions because of its homotypic adhesive activity.[211] The components of the adherens junctional complex are expressed in the subepithelial stroma surrounding the implanting blastocysts, with apoptosis occurring in the luminal epithelium.[211,212] This junctional complex, in turn, forms a barrier surrounding the embryo, perhaps restricting passage of injurious stimuli from the maternal circulation. The results suggest that temporal and cell-specific expression of the adherence junction proteins in the uterus result in molecular guidance that is important for blastocyst attachment and subsequent invasion.

Kruppel-like factor 5 (*Klf5*), a zinc finger–containing transcription factor, is also not directly regulated by ovarian hormones in the uterus but is critical for implantation.[213] In mouse uteri, KLF5 is expressed in the luminal and glandular epithelia but disappears with initiation of decidualization on day 5. At this time, proliferating stromal cells around the implantation site show *Klf5* expression with simultaneous downregulation in the epithelium. Decidual cell expression disappears upon stromal differentiation. These results suggest that KLF5 participates in cell-specific proliferation and differentiation. Mice with uterine deletion of *Klf5* (*Klf5*$^{d/d}$) are infertile due to defective implantation.[213] Surprisingly, blastocysts remain entrapped within the uterine lumen past the anticipated time of implantation and can still initiate decidualization, albeit at a much reduced extent. *Hoxa10* and *Bmp2* expression in the stroma is crucial for decidualization; however, their expression is negatively impacted by *Klf5* deletion. This partial decidual response is not sustained, and embryos ultimately degenerate. These findings support an earlier study showing that a functional luminal epithelium is critical for the full-fledged decidual response.[214] Taken together, the results suggest that signals originating from a blastocyst yet to be defined are transmitted through the epithelium to initiate decidualization without direct physical contact of the blastocyst with the stroma.

Molecular Signature for Attachment Reaction and Implantation

Cross-talk between the implantation-competent blastocyst and receptive uterus is essential for the attachment reaction, an initial step in implantation. The attachment reaction coincides with increased uterine vascular permeability solely at the site of blastocyst apposition.[4,13] The differentiation of the uterus to the receptive stage and blastocyst attachment to the luminal epithelium are coordinated by diverse and overlapping gene expression patterns. The expression of various growth factors and their receptors in the uterus in a temporal and cell-specific manner during the peri-implantation period suggests that these factors are important for implantation.

The EGF family of growth factors includes EGF itself, transforming growth factor alpha (TGF-α), heparin-binding EGF-like growth factor (HB-EGF), amphiregulin, betacellulin, epiregulin, and neuregulins.[136,215] HB-EGF has emerged as an important molecular link in directing embryo–uterine interactions for the attachment reaction in mice. It is the earliest molecular marker to be found in the uterine luminal epithelium exclusively at the sites of blastocysts, appearing several hours before the attachment reaction in mice[9] (Figure 38.6(A)). This induction is followed by the expression of betacellulin, epiregulin, neuregulin 1, and COX2 around the time of the attachment reaction.[136,215,216] In contrast, amphiregulin is expressed throughout the uterine epithelium on the morning of day 4 of pregnancy and is well characterized as a P_4-responsive gene in the uterus.[217] Around the time of the attachment reaction, strong expression of amphiregulin in the luminal epithelium is only found around the implanting blastocysts, and this expression is absent by the morning of day 5. However, amphiregulin-deficient mice or compound knockout mice for EGF–TGFα–amphiregulin apparently do not exhibit implantation defects.[218,219] Since HB-EGF, betacellulin, epiregulin, neuregulin, and amphiregulin all show overlapping uterine expression patterns around the blastocyst at the time of attachment reaction,[74,215] it is possible that a compensatory mechanism rescues implantation in the absence of one or more members of the EGF family.

EGF-like growth factors interact with the receptor subtypes of the erbB gene family, which is composed of four receptor tyrosine kinases: ErbB1 (EGFR), ErbB2, ErbB3, and ErbB4. They share common structural features, but differ in their ligand specificity and kinase activity.[221] The initial dimerization between coexpressed receptors upon ligand binding constitutes the classical mechanism

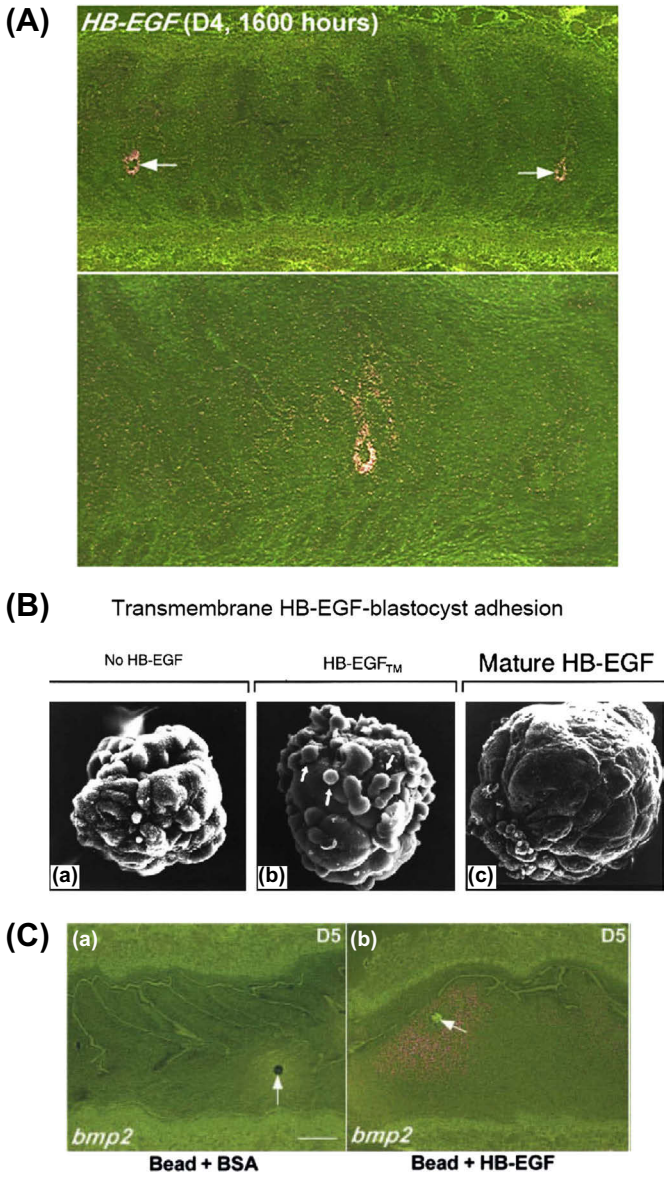

FIGURE 38.6 HB-EGF serves as a reciprocal mediator between the luminal epithelium and activated blastocyst during attachment reaction. This figure is reproduced in color in the color plate section. (A) In situ hybridization of HB-EGF mRNA (dark-field) in the mouse uterus at 1600 h on day 4 of pregnancy. Note distinct hybridization signals in luminal epithelial cells surrounding two blastocysts in a longitudinal section. Arrows demarcate location of blastocysts. (B) Scanning electron microscopy of blastocysts co-cultured with 32D cells (a murine myeloid cell line). Zona-free day 4 (0900 h) mouse blastocysts were co-cultured with (a) parental 32D cells, (b) 32D cells displaying transmembrane form of HB-EGF^{TM}, or (c) 32D cells synthesizing soluble form of HB-EGF for 36 h. After extensive washing to remove loosely adhering cells, blastocysts were fixed and examined by scanning electron microscopy; magnification 800×. Arrows point to 32D cells. (C) *Bmp2* gene expression in response to beads preloaded with HB-EGF. Beads (7 beads/horn) preabsorbed either in BSA (control) or HB-EGF (100 ng/ml) were transferred into uterine lumens of day 4 pseudopregnant mice. Mice were killed on day 5 to examine *Bmp2* expression at the sites of beads. Arrows indicate the locations of the beads. Note localized stromal expression of *Bmp2* at the sites of beads preabsorbed with HB-EGF. Bar: 75 mm. *Source: Reprinted with permission from Refs 9,135,220.*

of action of EGF-like ligands. Spatiotemporal expression patterns of EGF gene family members and ErbBs in the uterus during the peri-implantation period suggest compartmentalized functions of EGF-like growth factors in implantation.[136]

Numerous growth factors and their receptors are expressed in preimplantation embryos of several species, suggesting their roles in preimplantation mammalian development.[222,223] ErbB1 (EGFR), ErbB2, and ErbB4, the receptor subtypes for the EGF family of growth factors, are expressed in the mouse blastocyst,[123,224] and EGF or TGFα has beneficial effects on embryonic development in vitro.[225] There is evidence that embryonic ErbB1 and/or ErbB4 interact with uterine HB-EGF during blastocyst implantation, making HB-EGF a unique molecule for blastocyst–luminal epithelium adhesion.[135,224] HB-EGF is expressed in both soluble and transmembrane forms in the uterine luminal epithelium at the site of the blastocyst prior to the attachment reaction.[9,144] Both ErbB1 and ErbB4 are expressed in implantation-competent blastocysts, but downregulated in dormant blastocysts during delayed implantation.[123,224] Furthermore, while a recombinant soluble HB-EGF can promote blastocyst growth and differentiation, cells that express the transmembrane form of HB-EGF can adhere to active, but not dormant, blastocysts in vitro, suggesting HB-EGF's paracrine and juxtacrine effects[135] (Figure 38.6(B)). By directing an HB-EGF–toxin conjugate toward wild-type and erbB1$^{-/-}$ blastocysts, it was found that HB-EGF could also interact with embryonic ErbB4 and heparan sulfate proteoglycans.[224] Furthermore, Affi-Gel blue beads carrying recombinant HB-EGF can elicit implantation-like responses with Bmp2 induction and subsequent decidualization upon transfer to a receptive uterus (Figure 38.6(C)).[220] Collectively, these results suggest that an interaction between uterine HB-EGF and blastocyst ErbBs is important for the attachment reaction. However, the absolute necessity of HB-EGF in implantation requires additional genetic evidence. While global *Hegf1* deletion exhibits perinatal lethality,[226] its conditional deletion in the uterus defers blastocyst implantation beyond the normal window, producing smaller litter size; complete pregnancy failure is avoided at least in part due to compensatory actions by amphiregulin.[227] It should also be noted that early events of implantation do not appear to be affected by blastocysts deficient in either ErbB1 or ErbB4,[228,229] although the implantation-initiating efficiency of blastocysts deficient in more than one receptor type needs to be tested to delineate the functional redundancy among the receptor family.

Implantation-competent blastocysts can produce HB-EGF, and this growth factor induces its own expression in the uterus in a paracrine manner.[133] The results elucidate an important dual role of HB-EGF in both the blastocyst and uterus during implantation. These results provide

evidence that one of the signaling molecules involved in establishing a hierarchy of events between the embryo and uterus for implantation is HB-EGF, which originates in implantation-competent blastocysts. This autoinduction loop of HB-EGF is perhaps the first example of molecular cross-talk between these two different entities that leads to the initiation of the implantation process. In conclusion, detailed expression and gene-targeting experiments with all of the EGF family of ligands and receptors will be required to define the paracrine, autocrine, and/or juxtacrine roles of a specific ligand or its receptors in implantation.

These studies in mice led to investigation of the function of HB-EGF in human implantation. Among many growth factors, HB-EGF appears to play a role in implantation and embryonic development in humans. Its expression is maximal during the late secretory phase (cycle days 20–24) when the endometrium becomes receptive for implantation[230,231] and is co-expressed with pinopodes.[232] In addition, cells expressing the transmembrane form of HB-EGF adhere to human blastocysts displaying cell surface ErbB4.[233] In fact, HB-EGF was shown to be one of the most potent growth factors for enhancing the development of human IVF-derived embryos to blastocysts and subsequent zona hatching.[234] Thus, cumulative evidence suggests that HB-EGF has a significant role in preimplantation embryo development and implantation as a paracrine and/or juxtacrine factor in various species.

Temporal and cell-specific expression of TGFβ and receptor isoforms in the uterus during the peri-implantation period also suggests that this growth factor is also important for implantation.[235–237] TGFβ was shown to be involved in the implantation process by modulating immunological responses. TGFβ derived from the seminal vesicle gland was identified as a major active constituent in the seminal plasma of several mammalian species, where it reaches concentrations >200 ng/ml.[238] In mice, exposure to semen at mating activates an inflammatory response in the uterine mucosa,[239] and in women, sexual intercourse causes similar inflammatory events in the cervix.[240,241] The response is activated when seminal TGFβ triggers synthesis of several pro-inflammatory cytokines and chemokines in female reproductive tract epithelial cells, notably granulocyte macrophage colony-stimulating factor (GM-CSF) and IL6.[242]

Many glycoproteins and carbohydrate ligands and their receptors are expressed in the uterine luminal epithelium and blastocyst cell surfaces around the time of implantation.[243,244] Primary adhesion molecules that are implicated in implantation are selectins, mucin 1 (Muc1), integrins, and the trophinin–tastin–bystin complex. The selectin adhesion system likely plays an important role in human implantation.[245] On the maternal side, selectin oligosaccharide ligands are expressed in the receptive uterine epithelium, and on the embryonic side trophoblast cells express L-selectin receptors. Beads coated with specific selectin ligands adhere to the trophoblast, suggesting that the trophoblast cell surface receptors are functional. This study suggests that trophoblast L-selectin mediates interactions with the uterus to establish an adhesion mechanism for implantation.

Muc1, a stretch of long carbohydrate moieties, is expressed on the apical surface of the mouse luminal epithelium during the prereceptive period. Muc1 acts as an antiadhesive masking molecule. The physical hindrance created by these carbohydrate branches is considered to prevent interaction between the embryo and the luminal epithelium of the uterus prior to the attachment reaction.[246] This is consistent with timely downregulation of Muc1 from the luminal epithelium throughout the uterus before the attachment reaction on day 4 of pregnancy in mice.[74] This seems paradoxical to the observation that overall Muc1 expression increases in the rabbit and human uterus during the receptive period. However, it was later revealed that there is indeed a decrease in Muc1 levels at the site of implantation in rabbits.[247] In humans, the situation appears to be more complicated. During the apposition phase, the presence of an embryo increases the levels of Muc1 in the epithelium, but at the adhesion phase, the embryo induces cleavage of Muc1 to clear this glycoprotein from the implantation site.[248] Collectively, these findings suggest that Muc1 acts as an antiadhesive molecule that must be removed from the implantation site.

Extracellular matrix (ECM) and integrins are thought to be responsible for trophectoderm attachment and adhesion to the luminal epithelium. Each integrin is composed of two subunits, α and β, and each αβ combination has its own binding specificity and signaling properties. As membrane-associated receptors, integrins possess short cytoplasmic tails with no enzymatic activity. Signaling by integrins is mediated by associating adaptor proteins that bridge them to the cytoskeleton, cytoplasmic kinases, and transmembrane growth factor receptors.[249] Integrin subunits αv, α4, α5, β1, β3, and β5 are constitutively expressed on both the conceptus trophectoderm and the apical surface of the luminal epithelium in ewes during the peri-implantation period.[88] The members of the integrin family serve as receptors for various ECM ligands and modulate cell–cell adhesion and signal transduction cascades.[249] Trophoblast interactions with the ECM are mediated primarily by integrins,[250–256] and several ECM components that are upregulated in the peri-implantation endometrium, including fibronectin, laminin, and collagen type IV,[257–259] support trophoblast outgrowth in vitro.[254,256] Several members of the integrin family including αvβ3 are known to interact with the RGD (Arg–Gly–Asp) peptide sequence present in many ECM proteins, such as fibronectin, collagen type II and

IV, entactin, and vitronectin[254–256]; hexapeptides containing the RGD sequence can block trophoblast outgrowth on many ECM proteins.[260] Notably, trophoblast adhesion to type I laminin is independent of its RGD sequence and is primarily mediated through interaction of α7β1 with the E8 integrin recognition domain of laminin.[253,261]

Integrins are expressed in the human uterus with both constitutive and cycle-dependent patterns of expression.[262,263] Characterization of integrin expression during the menstrual cycle further defined three specific integrin family members expressed during a narrowly defined time between days 20 and 24 of a typical 28-day cycle in women.[264–268] Among the integrins, αvβ3 has been shown to be localized to the luminal epithelium.[269] Temporal and spatial expression of this integrin and its ligand osteopontin (OPN) correspond to the specialized surface modifications known as pinopodes,[270,271] which are also expressed during implantation in other animal species.[272–274] In mice, αvβ3 is expressed in both the uterine luminal epithelium and the blastocyst during implantation. It has been shown that an intrauterine injection of an RGD peptide or a neutralizing antibody against αvβ3 reduces the number of implantation sites in mice and rabbits.[272] Lower expression of αvβ3 has been associated with infertility and recurrent pregnancy loss in women. In women with histologic delay (luteal phase defect) or other diagnoses associated with suspected implantation defects, integrin expression is consistently delayed or absent.[262,265,275–279]

Among others, α5β1, α6β1, and αvβ3 are expressed in the mouse embryo throughout the peri-implantation period, while several others exhibit stage-specific expression.[250] Integrins are also expressed in the differentiating trophoblasts at later stages,[250] suggesting their roles in trophoblast differentiation and adhesion. A role for fibronectin via integrin binding in blastocyst outgrowth was further confirmed in vitro using antibodies against αv, α5, β1, or β3 that are inducible by fibronectin inhibited adhesiveness of the outer surface of the trophoblast.[252] In addition, a gene-targeting experiment revealed that deletion of the β1 gene results in ICM defects and embryonic lethality.[280] However, the mutant embryos form morphologically normal blastocysts and initiate implantation, but trophoblast invasion becomes defective. Adhesion-competent, late-blastocyst-stage trophoblasts undergo intracellular signaling initiated upon ligation of α5β1 and αvβ3 by fibronectin.[281] Integrin signaling mobilizes cytoplasmic Ca^{2+} and induces the trafficking of intracellular vesicles, resulting in stronger adhesion to fibronectin at the apical surface. Therefore, blastocyst adhesion to the endometrium during implantation is considered to be regulated by the endogenous developmental program, as well as through interactions with ECM components in the local environment.[282,283] Although there is evidence that the embryo is a site of action for integrin signaling, it is not yet clear if the uterus is also a site of action of this signaling. Results of gene-targeting experiments of integrin subunits are not very informative in relation to their roles in implantation because of the complex phenotypes and apparent compensation by other subunits.[284–287]

Invasive mouse trophoblasts adhere, spread, and migrate on ECM substrates,[251,254,288] and penetrate three-dimensional ECM structures.[62,289] OPN is an acidic phosphorylated glycoprotein component of the ECM detected in the epithelium and in secretions of many tissues, including the uterus.[290] OPN binds to integrin heterodimers (αvβ1, αvβ3, αvβ5, αvβ6, αvβ8, α4β1, α5β1, and α8β1) via its RGD sequence and to α4β1 and α9β1 by other sequences to promote cell adhesion, spreading, and migration.[290] OPN is implicated in implantation in ruminants and humans. In sheep, OPN expression is increased in pregnant sheep uteri during the peri-implantation period (days 11–17) when attachment of concepti to uterine luminal epithelium occurs.[291,292] Secreted OPN binds to integrin heterodimers expressed by the trophectoderm and the uterus to (1) stimulate changes in morphology of the conceptus extraembryonic placental membranes, and (2) induce adhesion between the luminal epithelium and trophectoderm for implantation and placentation.[290] OPN is also present in uterine luminal flushings from cyclic and pregnant gilts.[293] In humans, the spatiotemporal distribution of OPN protein correlates with the expression pattern of αvβ3 integrin, appearing approximately 7 days after ovulation.[294] In the mouse uterus, OPN is highly expressed in the metrial gland in the developing decidua.[295] However, OPN-deficient mice are fertile, suggesting OPN is not essential for fertility in mice.[296]

Trophinin is a transmembrane protein that can mediate homophilic interactions between two different cell types, including an interaction between human endometrial and trophoblastic cell lines.[297] Trophinin requires the presence of a cytoplasmic protein, tastin, to sustain adhesion between these two cell types. In addition, the presence of bystin, another cytoplasmic protein, is required for effective interaction between trophinin and tastin. This adhesion complex that is present in trophoblastic teratocarcinomas and endometrial adenocarcinomas mediates adhesion between them. In humans and monkeys, trophinin is specifically expressed in cells involved in implantation. Furthermore, the trophinin complex was detected in trophoblast and decidual cells at the human fetal–maternal interface as early as the sixth week of pregnancy.[298] Trophinin, tastin, and bystin are all highly expressed in fallopian tube epithelial cells of women with tubal pregnancies, suggesting their role in ectopic pregnancy, a condition unique to humans.[299,300] In mice, trophinin expression is distinct from that in humans and trophinin-deficient mice do

not exhibit fertility defects, suggesting that this adhesion molecule is not crucial to implantation and placentation in mice.[300] However, trophoblast cell activation by trophinin ligation has been shown in human trophoblast (HT-H) cells[301] with apoptosis of human endometrial epithelial cells via PKCδ signaling.[302]

Decidualization

Following blastocyst attachment with the luminal epithelium, decidualization is initiated at the antimesometrial site where blastocysts implant. This process, characterized by stromal cell proliferation and differentiation into a specialized type of cells (decidual cells) with polyploidy, is critical to the establishment of pregnancy in many species. Normally, the implanting blastocyst is the stimulus for decidualization. However, a similar process (deciduoma) can be experimentally induced in the pseudopregnant or hormonally prepared rodent uterus by intraluminal infusion of various agents, including oil.[13] In 1908, Leo Loeb was the first to induce tumorlike deciduoma in guinea pigs and described that this event required an endometrium, hormonal conditioning, and stimulation by a nonspecific stimulus such as glass beads.[303,304] It was later found that other nonspecific stimuli such as intraluminal infusion of oil, air, or trauma can also initiate deciduoma in pseudopregnant or steroid hormonally prepared uteri.[13] This field was later advanced by the work of M.C. Shelesnyak, Vincent Defeo, Bruce Moulton, J.M. Yochim, and others.[305–308] However, there is evidence that the initial uterine reactions induced by nonspecific stimuli are different from those induced by blastocysts.[220,309]

The decidual cell reaction is always preceded by increased endometrial vascular permeability.[4,310] Pulse-labeling experiments with ^{3}H-thymidine provided evidence that decidual cells originate from undifferentiated stromal cells.[307,311] In mice, differentiating stromal cells surrounding the blastocyst initially form the primary decidual zone (PDZ) on day 5. This zone is avascular and densely packed with epithelioid-type cells. By day 6, the PDZ is well formed, and a secondary decidual zone (SDZ) is formed at the periphery of the PDZ, which degenerates progressively up to day 8. At this time, DNA synthesis is high in the SDZ, but very low in the PDZ.[35] After day 8, placental and embryonic growth slowly replaces the SDZ, which is reduced to a thin layer of cells called the decidua capsularis. The mesometrial decidual cells ultimately form the decidua basalis.[312] Presumed functions of decidua are to provide nutrition to the developing embryo, protect the embryo from immunological responses of the mother, regulate orderly trophoblast invasion into the uterine stroma, and direct placentation.

Decidualization involves a complex interplay of cell cycle regulators, transcription factors, morphogens, cytokines, and signaling pathways. The mechanisms by which the cell cycle events govern decidualization are poorly understood. The cell cycle is tightly controlled at two checkpoints: the G1-S and G2-M phases. Normally, the operation of these phases involves a complex interplay of cyclins, cyclin-dependent kinases (cdks), and cdk inhibitors (CKIs). The well-known regulators of mammalian cell proliferation are the three D-type cyclins (D1, D2, and D3).[313] In mice, the expression of cyclin D3 is upregulated in decidualizing stromal cells at the implantation site and is associated with cell proliferation.[314–316] Furthermore, cyclin D3 is associated with the large polyploid cells that are defined as terminally differentiated stromal cells. Coordinated expression of cdk4 and cyclin D3 at the site of implantation in mice on day 5 suggests that these regulators play roles in decidualization. However, the expression of p21 with concomitant downregulation of cyclin D3 and cdk4 in the PDZ at the implantation site on the afternoon of day 5 supports the view that cell proliferation activity of cdk4–cyclin D3 ceases with the development of the PDZ. On the other hand, the expression of cdk4–cyclin D3 in the decidualizing stroma outside the PDZ is consistent with their role in proliferation of the stroma at the SDZ. The presence of cyclin E, cyclin A, and cdk2 with concomitant downregulation of cyclin B and cdk1 in these cells supports the view that these cells are entering the endocycle pathway. The physiological significance of stromal cell polyploidy during decidualization is still unclear. The life span of decidual cells during pregnancy is limited, and their demise makes room for the rapidly growing embryo. Since most decidual cells become polyploid during their lifetime, it is speculated that polyploidy limits the life span of decidual cells. Furthermore, one of many functions of the deciduum is to support embryonic growth that requires increased protein synthesis. Polyploidy thus may ensure increased synthetic capacity by increasing the number of gene copies for transcription.

Uterine luminal epithelial competency is critical for normal decidualization, suggesting that signals emanating from the epithelium influence stromal decidualization.[214] This is now evident from mouse studies in which luminal epithelial function was compromised.[151,213] For example, *Ptgs2* is normally expressed in the epithelium and stroma at the site of the implanting blastocyst.[317] In systemic *Lif*$^{-/-}$ or females with uterine deletion of *Msx1/Msx2*, *Ptgs2* expression is restricted to the luminal epithelium,[151,176] whereas *Ptgs2* is expressed only in the stroma in females with uterine deletion of *Klf5* around the time of implantation.[213] These results suggest aberrant communication between the luminal epithelium and stroma. In conclusion, a functional loop involving the blastocyst, luminal epithelium, and stroma appears critical to proper decidualization. Further studies are

needed to identify the blastocyst- and/or epithelial-derived signals critical to decidualization.

In mice, abdominalB (*AbdB*)-like homeobox (*Hox*) genes *Hoxa10* and *Hoxa11* are expressed in the stroma of the receptive uterus with robust increases upon decidualization, and are essential for decidualization. *Hoxa10*$^{-/-}$ females have decidualization failure due to reduced P_4 responsiveness and dysregulation of P_4-responsive genes with reduced stromal cell proliferation.[318,319] *Hoxa11*$^{-/-}$ females have a similar but more intense infertility phenotype.[320] The defective decidualization in *Hoxa10*$^{-/-}$ mice is also reflected in downregulation of a cell cycle regulatory axis engaging cyclin D3, cdk6, and p21.[318,320] In women, *Hoxa10* and *Hoxa11* are upregulated in the receptive endometrium, suggesting their importance in decidualization.[137,321] SGK1 (serum- and glucocorticoid-inducible kinase 1), a regulator of epithelial ion transport and cell survival, is reported to be critical for implantation and maintenance of the decidual–placental interface integrity in mice. SGK1 also showed differential expression patterns in pregnancy pathologies in women.[322] Mice with deletion of cytokine receptor *IL11Rα1* or sphingosine kinases *Sphk1/Sphk2* manifest aberrant decidualization as well.[3,323,324]

In vitro culture systems modeling human decidualization induced by P_4, estrogen, and dibutyryl cAMP involve numerous signaling molecules, including prolactin and insulin-like growth factors (IGFs). In humans, decidualizing stromal cells express high levels of IGF binding protein 1 (IGFBP1).[325–328] Its proposed roles in reproductive physiology are numerous, and its aberrations are implicated in preeclampsia, fetal growth retardation, and polycystic ovarian syndrome.[328] Similarly demonstrated in the liver system, IGFBP1 expression is regulated in primate uterine stromal cells by binding of the transcription factors HOXA10 and FKHR (Forkhead box protein O1, also called FOXO1) to its promoter.[329]

A large number of decidual cells undergo endo-reduplication (polyploidy) (i.e., repeated rounds of DNA replication without cytokinesis). Decidual endo-reduplication is considered to support embryonic growth by increasing gene transcription. Decidual cell polyploidy is critical to pregnancy success in mice, since mice with inactivation of death effector domain-containing protein (DEDD) show faulty decidualization with reduced polyploidy and embryonic loss prior to placentation, leading to infertility; the attachment reaction is normal.[330] DEDD forms a complex with cyclin D3, cdk4/6, and protein kinase B to execute its function. While decidual polyploidy is well established in rodents, this phenomenon is only sparsely reported in humans[331] and requires closer assessment.

As mentioned here, stromal cells at the blastocyst attachment site undergo decidualization. The initiation of this process ("predecidualization") in humans can occur during receptivity in the absence or presence of a blastocyst, but becomes more robust with implantation. The significance of "predecidualization" in humans may be to prepare the endometrium for implantation and seems analogous to heightened stromal cell proliferation with expression of decidual marker genes prior to implantation in mice.

Decidualization is a critical step toward appropriate placental development. The nature of placentation varies between species and is broadly classified according to the degree of invasiveness and association of maternal and fetal structures. Placentation strategies range from simple superficial epitheliochorial placentas of domestic animals (horses, cows, sheep, and pigs) to the endotheliochorial placentas in carnivores and hemochorial placentas in rodents, humans, and nonhuman primates. In the epitheliochorial type of placentas, the uterine luminal epithelium remains intact along with the embryo, and associated membranes are restricted to the uterine lumen throughout gestation; this is as opposed to endotheliochorial and hemochorial types of placentas, in which the conceptus invades and/or erodes the uterine epithelium and embeds into the endometrial stroma.[332] Despite the diversity of placentation strategies, the initial events of apposition, attachment, and adhesion between the uterine luminal epithelium and conceptus trophectoderm are shared among species. In sheep, the trophectoderm adhesion to the epithelium progresses along the uterine horn and appears to be completed around day 22.[21,24] Unlike sheep, the attachment in horses and pigs involves multiple sites covering most of the embryonic surface. In all of these ruminants, a notable decidualization is absent.

Signaling Spanning Different Phases of Early Pregnancy

It is difficult to understand the stage-specific functions of many critical genes due to their overlapping uterine expression at more than one stage of pregnancy. One such gene is *Lif*, which is expressed in a biphasic manner in the uterus, first in glands on the morning of day 4 and then in the subepithelial stroma at the site of blastocyst attachment on the evening of day 4[333]; to date, it has not been clarified which phase of *Lif* expression is essential for implantation. A notable example is *Pla2g4a*$^{-/-}$ mice, which lack the enzyme cytosolic phospholipase A2α (cPLA2α). Mice with this deletion exhibit aberrant implantation with retention of glandular *Lif* expression but a loss of stromal *Lif* expression.[47] Cell-type-specific deletion may help dissect the contribution of each phase of *Lif* expression. Other such molecules are Hand2, KLF5, BMP2, and COX2, which are expressed at the time of blastocyst attachment and persist during decidualization.

Prostaglandins

Since implantation is thought to be a proinflammatory reaction, one early detectable marker is an increased uterine vascular permeability at the site of blastocyst attachment. COX-derived PGs have been shown to facilitate these effects.[317] PGs possess vasoactive, mitogenic, and differentiating properties[334] and are implicated in various female reproductive functions. Early studies showed that during artificially induced decidualization, uterine concentrations of PGs increase in a temporal pattern accompanied by increases in endometrial vascular permeability, an early event in the endometrial response to decidualization.[335–340] These studies used pharmacological inhibitors of PG synthesis, which substantially attenuated the increased endometrial vascular permeability changes[335,341,342] and subsequent decidualization.[338,343,344]

PGs are produced via the COX pathway. COX exists in two isoforms, COX1 and COX2, and is the rate-limiting enzyme in the biosynthesis of PGs. COX mediates the conversion of arachidonic acid into PGH_2, which is then converted to various PGs by specific synthases.[334] The COX isoforms are encoded by two separate genes and exhibit distinct cell-specific expression, regulation, and subcellular localization, although they share similar structural and kinetic properties. COX1 is considered a constitutive enzyme that mediates "housekeeping" functions. In contrast, COX2 is an inducible enzyme and is induced in a variety of cell types by growth factors, cytokines, and inflammatory stimuli.[334] Since COX2 is primarily responsible for increased PG production during inflammation, this isoform is the target for developing selective anti-inflammatory drugs.[345,346] COX2 overexpression is also associated with tumorigenesis.[347,348] PGs normally execute their functions by interacting with cell surface G protein–coupled receptors, but they can also function as ligands for nuclear peroxisome proliferator-activated receptors (PPARs).[349–352]

Because of the "proinflammatory" characteristics of ovulation and implantation, participation of PGs in these processes has been speculated.[353,354] For example, PGs are considered to participate in follicular rupture during ovulation[355] (see Chapters 22 and 28). This is consistent with gonadotropin-mediated induction of PG endoperoxide synthase 2 (*Ptgs2*, encoding Cox2) in ovarian follicles preceding ovulation.[355,356] PGs are also implicated as important mediators of increased endometrial vascular permeability during implantation and decidualization.[216] Both *Ptgs1* and *Ptgs2* exhibit a unique pattern of expression in the peri-implantation mouse uterus.[216] *Ptgs1* is expressed in uterine luminal and glandular epithelial cells on the morning of day 4 of pregnancy, but its expression is downregulated in the luminal epithelium by the time of the attachment reaction. This ubiquitous expression suggests its role in generalized uterine edema that may be involved in luminal closure for blastocyst apposition. In contrast, *Ptgs2* is expressed in the luminal epithelium and underlying stromal cells at the antimesometrial pole solely at the site of blastocyst attachment. *Ptgs2* expression then moves to the mesometrial side (the presumptive site of placentation) by day 6 of pregnancy.[317] Employing the delayed implantation model, this study also showed that the expression of *Ptgs2* in the receptive uterus requires the presence of active blastocysts. Gene-targeting experiments further demonstrated that COX2-derived PGs are essential for ovulation, fertilization, implantation, and decidualization, asserting that COX2-derived PG signaling is required at several stages of pregnancy.[317,357,358] Experiments with $Ptgs1^{-/-}$ mice suggest that the loss of COX1 is compensated by the expression of COX2 for implantation.[359] Among various PGs, the levels of prostacyclin (PGI_2) are highest at the implantation sites of wild-type mice and implantation defects are partially restored in $Ptgs2^{-/-}$ mice by administration of a more stable prostacyclin agonist, carbaprostacyclin.[360] A recent study reports that the activation of epithelial sodium channels can induce *Ptgs2* for implantation.[361]

The role of PGs is further illustrated by the reduced fertility of female mice lacking $cPLA_2\alpha$, which is involved in the liberation of arachidonic acid from membrane phospholipids for PG synthesis by the COX system.[362–364] The reduced fertility in these females is due to deferral of "on-time" implantation, leading to subsequent retarded feto-placental development and reduced litter size.[47] Collectively, these results indicate that the $cPLA_2$–COX2 axis is crucial to implantation.

COX2 is also expressed in the uterus, blastocyst, or both during implantation in a variety of species with different modes of implantation, including sheep, minks, skunks, baboons, pigs, and hamsters.[148,149,212,365,366] In hamsters, COX2 and PGE synthase are coexpressed and produce PGE_2 as a major PG product in implantation sites.[212] COX2 expression in human endometrium has also been reported.[367,368] These results suggest a conserved function of COX2 in implantation in various species. It has also been shown that, depending on the genetic background, *Ptgs1* upregulation can improve female infertility in *Ptgs2*-deficient mice.[369]

Membrane receptors for PGE_2, $PGF_{2\alpha}$, PGD_2, PGI_2, and thromboxanes are prostaglandin E (EP_1–EP_4), prostaglandin F (FP), prostaglandin D (DP), prostaglandin I (IP), and thromboxane A (TP), respectively; they belong to the G protein–coupled family of cell surface receptors.[370,371] Although PGE_2 synthase is expressed at the implantation sites with the presence of PGE_2 and EP receptors,[371–373] and although PGE_2 has been shown to be associated with implantation and decidualization,[338] gene-targeting experiments show that three of the four EP receptor subtypes (EP_1–EP_3) are not critical

to implantation. EP_4 deficiency mostly results in perinatal lethality, and thus its role in implantation has not yet been fully explored.[371] Mice deficient in FP or IP show normal implantation. PGs can also exert their effects by utilizing PPARs that belong to a nuclear hormone receptor superfamily.

PGs also appear to be important for embryonic functions relevant to preimplantation embryo development and implantation. Preimplantation embryos produce PGs, and inhibitors of PG synthesis have been shown to inhibit embryonic growth, functions, and zona hatching in vitro.[245,374] Dormant mouse blastocysts can achieve implantation competence if cultured in the presence of PGE_2 or a permeable analog of cAMP. This effect apparently involves the COX2-signaling pathway,[67] yet normal development of *Ptgs1*$^{-/-}$/*Ptgs2*$^{-/-}$ double-mutant embryos in the uterus suggests that PGs of embryonic origin are not essential for embryo development.[375] However, compensation by maternal PGs in embryonic development cannot be ruled out.

The nuclear receptor superfamily of transcription factors modulates expression of target genes by binding to specific DNA elements. The members of this superfamily span from well-characterized steroid hormone receptors to orphan nuclear receptors with no known ligands. Steroid hormone receptor aside, the PPAR family of nuclear receptors has been implicated in female reproductive events. Three members of the PPAR family are PPARα, PPARγ, and PPARδ. To act as a transcriptional activator, PPARs must heterodimerize with a member of the retinoid X receptor (RXR) subfamily.[351,360] The ligands for PPAR include natural and synthetic eicosanoids, fatty acids, and hypolipidemic and hypoglycemic drugs, and there is evidence that PPAR–RXR dimers mediate nuclear signaling of PGs.[376]

PPARδ has been shown to participate in various physiological processes, including embryo implantation.[360] As mentioned here, PGs produced via the COX2 pathway are essential for implantation. During early pregnancy in mice, PGI_2 is the most abundant PG in the uterus, and its levels are higher at implantation sites than at interimplantation sites. Consistent with the finding that COX2-driven uterine PG production is crucial to implantation, *Ptgs2* and PGI synthase (*PGIS*) are coexpressed at implantation sites, suggesting the availability of PGI_2 to uterine cells. Among known PGI_2 receptors, such as IP, PPARα, and PPARδ, PPARδ is co-localized with *Ptgs2* and *PGIS* at similar regions of the implantation sites; the expression of IP and PPARα was very low to undetectable. PPARδ expression requires the presence of active blastocysts, since it is not detectable in the uteri of delayed-implanting mice.[377]

PPARδ is indeed functional as a PGI_2 receptor, since administration of cPGI or L-165,041 (a selective PPARδ agonist) to *Ptgs2*-deficient mice improves implantation and decidualization,[360] providing evidence for a role for PPARδ in embryo implantation. Three independent groups have reported diverse phenotypes of PPARδ knockout mice.[378–380] Because of severe early developmental defects of PPARδ mutant embryos, it has been very difficult to utilize this model to directly address whether the absence of maternal PPARδ affects implantation as in *Ptgs2*-deficient mice. While maternal PPARδ is considered critical for implantation and decidualization, embryonic PPARδ is necessary for placentation.[381] Therefore, a mouse model with stage- and uterine-specific deletion of PPARδ is necessary to address this issue. Uterine expression of PPARδ has also been reported in rats and humans.[382,383]

Endocannabinoid Signaling

Psychoactive cannabinoids are active components of marijuana that work via activation of the G protein–coupled cell surface receptors, CB1 and CB2, encoded by *Cnr1* and *Cnr2*, respectively.[384,385] The discovery of these receptors led to the identification of endogenous cannabinoid ligands (endocannabinoids), arachidonoylethanolamine (anandamide, also abbreviated as AEA) and 2-arachidonoylglycerol (2AG).[386,387] The mouse uterus synthesizes anandamide, and the fluctuation of its uterine level during early pregnancy coincides with the window of uterine receptivity for implantation.[388] Indeed, this signaling pathway plays significant roles in embryo development, oviductal embryo transport, uterine receptivity, placentation, and parturition in mice,[389] asserting that the endocannabinoid system is active at most stages of pregnancy. Anandamide levels were found to be lower in the receptive uterus and at the implantation sites, but were higher in the nonreceptive uterus and at interimplantation sites.[388] The P_4-treated delayed implantation uterus also showed elevated levels of anandamide, but the levels were downregulated with the termination of delayed implantation by estrogen.[138] Ligand-receptor signaling with cannabinoids and its receptor CB1 also directs preimplantation embryo development and implantation. CB1 is expressed in the embryo from the two-cell stage at the time of zygotic gene expression through the blastocyst stage.[390] Embryonic CB1 is functional, since two-cell embryos cultured in the presence of natural cannabinoids, synthetic cannabinoids, and endocannabinoids fail to develop to the blastocyst stage; this failure occurs between the eight-cell and blastocyst stages. The effect is reversible by a CB1-selective antagonist.[391] Furthermore, the endocannabinoid anandamide at a low concentration stimulates blastocyst differentiation and trophoblast outgrowth, while at higher concentrations it inhibits these events via differential regulation of MAPK and Ca^{++} signaling.[392,393] These results suggest that a narrow range of cannabinoid concentrations regulate the embryonic developmental program.

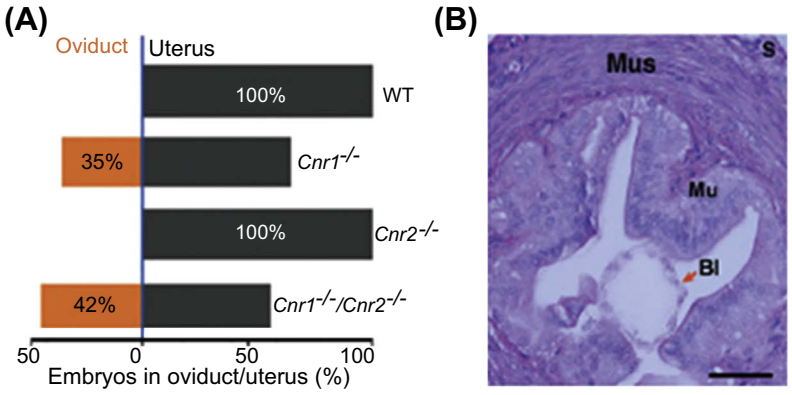

FIGURE 38.7 Impaired oviductal embryo transport causes pregnancy loss in *Cnr1*$^{-/-}$ but not *Cnr2*$^{-/-}$ mice. This figure is reproduced in color in the color plate section. (A) Percentage of embryos recovered from oviducts or uteri in WT and *Cnr1*$^{-/-}$ mice on day four of pregnancy. (B) A representative histological section of a day 7 pregnant *Cnr1*$^{-/-}$ oviduct showing an entrapped blastocyst (Bl, arrow) at the isthmus. Mus, muscularis; S, serosa; Mu, mucosa. Bar, 100 μm. *Source: Reprinted with permission from Ref. 394.*

A tightly regulated level of uterine anandamide and embryonic CB1 during early pregnancy is important for preimplantation embryonic development and implantation. Indeed, embryos develop asynchronously in CB1 (*Cnr1*) mutant mice during the preimplantation period. *Cnr1*$^{-/-}$ females show compromised fertility with blastocysts retention in the oviduct (Figure 38.7).[394] This retention is due to a collaboration of oviductal CB1 with adrenergic receptors to direct the timely passage of embryos through the oviduct. This is consistent with the later finding that Fallopian tubes of women with ectopic pregnancy show downregulation of *CNR1*.[395] Moreover, implantation fails to occur in wild-type mice, but not in *Cnr1*$^{-/-}$/*Cnr2*$^{-/-}$ double-mutant mice, when they are maintained by experimentally induced, sustained levels of exogenously administered cannabinoids.[138] Notably, persistent high levels of AEA resulting from deficiency of *fatty acid amide hydrolase* (*Faah*, encoding FAAH) that metabolizes AEA leads to defective implantation.[396]

The observation that heightened levels of cannabinoids inhibit implantation in mice subsequently led to the discovery that elevated levels of anandamide due to its reduced metabolism induce spontaneous pregnancy losses in women.[397,398] Thus, regulated cannabinoid signaling perhaps functions as a physiological surveillance system that assures implantation of healthy embryos, but not of abnormal embryos that result from aberrant expression of CB1 or their exposure to aberrant levels of endogenous or exogenous cannabinoid ligands. Endocannabinoid signaling is also important for directing the differentiation of trophoblast stem cells, and its aberrant signaling gives rise to compromised placentation and trophoblast invasion in the mouse uterus.[399] Microarray analysis on embryos in which endocannabinoid signaling via CB1 is silenced (*Cnr1*$^{-/-}$) or elevated (*Faah*$^{-/-}$) leads to similar changes in downstream targets, compromising trophoblast migration.[400] Taken together, these results suggest that tight regulation of endocannabinoid signaling is critical for early pregnancy success.

Morphogens

The reciprocal communication between the uterus and embryo in implantation shares many features with epithelial–mesenchymal interactions during development, and both processes involve evolutionarily conserved signaling molecules, including BMPs, Wnts, and hedgehogs. In mice, *Bmp2* is locally expressed in the subepithelial stroma at the site of blastocyst attachment, followed by heightened expression in decidua.[220] Although BMP regulators Crim1 and Dan are expressed along with Bmp2 at later times, its antagonist Noggin is expressed in the stroma at the time of uterine receptivity but disappears with stromal *Bmp2* expression upon attachment and thereafter. Deletion of *Bmp2* in the uterus results in failure of decidualization and infertility with apparently normal attachment reaction.[401] Notably, Affi-Gel blue beads carrying recombinant BMP2 did not elicit implantation-like responses upon transfer to a receptive uterus, but they affected embryo spacing when blastocysts were co-transferred with the beads.[220] However, how BMP2 signaling influences decidualization in the context of BMP receptors and antagonists has not been explored in depth. Of the *Bmp* genes that have been examined in the receptive uterus, *Bmp4–Bmp7* and *Bmp8a* did not exhibit the highly localized expression pattern as seen for *Bmp2* during attachment. *Bmp7* is expressed during early decidualization; however, its function has yet to be determined.[220]

Spatiotemporal expression of Wnt ligands, receptors, and inhibitors in mouse and human uteri during the reproductive cycle and pregnancy implicates roles for Wnt signaling in early pregnancy events.[204,402,403] Wnt signaling is mediated by canonical and noncanonical signaling pathways with respect to subcellular localization of β-catenin, transcriptional regulation of target genes, and co-receptor identity. Studies in TOPGAL (a Wnt-signaling activity reporter) mice found canonical Wnt signaling in the luminal epithelium and myometrium at the time of blastocyst attachment, suggesting a role for canonical signaling in implantation.[404]

Wnt4 is expressed in the subepithelial stroma during implantation and becomes more intense in decidualization,[405] while its antagonist *sfrp4* is expressed in the uterine stroma during the receptive phase and is downregulated upon attachment.[204] Wnt4 expression is dysregulated in *Lif*$^{-/-}$ and *Hoxa10*$^{-/-}$ mice[204]; uterine deletion of Wnt4 confers infertility with defective adenogenesis.[405] In contrast, *Wnt7a* is expressed in the epithelium, and its systemic deletion incurs infertility with defective implantation and aberrant development of the oviduct, uterus, cervix, and vagina along the anteroposterior axis and is associated with loss of *Hoxa10* or *Hoxa11* with disorganized myometria.[406] Conditional uterine deletion incurs infertility and defective gland formation.[407] On the contrary, β-catenin overexpression leads to uterine glandular hyperplasia, suggesting a role for canonical signaling in gland formation.[408] Collectively, compromised fertility and implantation failure observed with uterine deletion of *Wnt4* and *Wnt7a*, respectively, are perhaps consequential to structural aberrations and sparse gland formation.

Genes encoding the components of the hedgehog-signaling pathway (i.e., Ihh, the multipass transmembrane hedgehog-binding protein/receptor, PATCHED (PTC), and the transcription factors GLI1–GLI3[409–411]) are expressed in a dynamic temporal and spatial pattern during preparation of the uterus for implantation.[194] The expression of Ihh increases in the luminal epithelium and glands starting from day 3 and reaches high levels on day 4. During the same time, the expression of Ptc, Gli1, and Gli2 is upregulated in the underlying mesenchymal stroma. Transcription of Ihh in ovariectomized mice is induced by P_4 but not by estrogen. Lower induction of Ihh, Ptc, and Hoxa10 is also observed in response to P_4 treatment in the uteri of PR mutant mice lacking nuclear PR. This finding suggests that this hormone regulates Ihh via both nuclear receptor–dependent and independent pathways. Furthermore, in uterine explant cultures, recombinant N-terminal mature fragment Sonic hedgehog stimulates the proliferation of mesenchymal cells and the expression of noggin. These findings suggest that hedgehog generated by the epithelium functions as a paracrine growth factor for stromal cells during the early stages of pregnancy.[194] P_4 regulation of Ihh expression in the mouse uterus was confirmed by another group of investigators.[412] Uterine deletion of Ihh shows implantation failure due to compromised uterine receptivity.[195]

Connexins

Connexins (Cx), the gap junction–forming proteins, direct intercellular communication and permit the passage of small molecules between the cytoplasm of neighboring cells, thereby coupling cells electrically and metabolically.[413,414] They are composed of transmembrane proteins and belong to a multigene family with high sequence homology among various species.[415] During implantation, a local induction of Cx26 expression, which is restricted to the luminal epithelium surrounding the implantation chamber, is observed in rats and mice.[416,417] In addition, expression of Cx26 is significantly increased after induction of decidualization. Local increases in Cx26 transcript in response to embryo recognition are ER independent during implantation and decidualization.[418] Thus, endometrial connexin expression could be under regulation by two distinct signaling pathways: Cx26 can be induced by estrogen via ERα, or it can utilize an ER-independent signaling pathway during embryo implantation and decidualization. The physiological role of these respective signaling pathways at the local level of the uterine epithelium upon embryo recognition remains to be investigated.

Matrix Remodeling and Angiogenesis

Angiogenesis, a process by which new blood vessels develop from preexisting vessels, and tissue remodeling are two hallmark events during implantation and decidualization. The changing endocrine state of the female during the reproductive cycle and pregnancy results in extensive remodeling of uterine tissues.[258,419] For example, various basement membrane components, such as type IV collagen, laminin, fibronectin, and proteoglycans, in the human uterus undergo changes throughout the menstrual cycle and pregnancy.[419] Likewise, the ECM components undergo remodeling during mouse uterine stromal cell decidualization.[258]

Matrix metalloproteinases (MMPs) and tissue inhibitors of MMPs (TIMPs) are thought to be key mediators for matrix degradation during implantation and decidualization.[419–424] There is evidence that a balance between a select set of MMPs and TIMPs is important for implantation. Mechanisms regulating the MMP and TIMP genes during the peri-implantation period are not clear, although growth factors and cytokines including the EGF and TGFβ family members and LIF have been shown to modulate MMPs and TIMPs.[419] The cathepsin family of cysteine proteases is also implicated in implantation. Cathepsin B and L are expressed in mature, invasive trophoblast cells, and the injection of synthetic inhibitors into pregnant mice during the early phase of implantation resulted in implantation failure.[425] Altered levels of certain matrix remodeling molecules are associated with unexplained infertility and recurrent miscarriages.[426]

Under normal physiological conditions, angiogenesis primarily occurs in the uterus and ovaries of the adult during the reproductive cycle and pregnancy.[427] Increased vascular permeability and angiogenesis are crucial to successful implantation, decidualization, and placentation. A number of studies provided indirect and descriptive evidence for the potential roles of estrogen

and P_4 in these processes in various species.[427–430] These studies primarily examined the changes in the whole uterus of the expression of a number of gene products known to regulate vascular permeability and angiogenesis, including vascular endothelial growth factor (VEGF) and its receptors, without investigating the angiogenic status of the uterus. Thus, in vivo roles for estrogen and P_4 in uterine angiogenesis are not fully appreciated.

VEGF, originally discovered as a vascular permeability factor,[428] is also a potent mitogen for endothelial cells and a key regulator of vasculogenesis and angiogenesis.[431] Targeted disruption of even one allele of the VEGF gene results in embryonic death in utero during midgestation with aberrant blood vessel formation.[432,433] Differential splicing of the VEGF gene generates several VEGF isoforms in both humans and mice; $VEGF_{121}$ and $VEGF_{165}$ are the predominant isoforms in humans, while $VEGF_{120}$ and $VEGF_{164}$ are the most abundant isoforms in mice.[430,434] VEGF effects are primarily mediated by two tyrosine kinase receptors: FLT1 (VEGFR1) and FLK1/KDR (VEGFR2).[435–438] FLK1 is the major transducer of VEGF signals that induce chemotaxis, actin reorganization, and proliferation of endothelial cells.[431,439,440] Another multifunctional VEGF receptor was identified as neuropilin 1 (NRP1). While NRP1 functions as a receptor for at least five different ligands, it is expressed in human endothelial cells as a $VEGF_{165}$-specific receptor.[441]

Murine VEGF isoforms and their receptors FLT1, FLK1, and NRP1 are differentially expressed in the mouse uterus in a spatiotemporal manner during implantation, and the predominant $VEGF_{164}$ isoform interacts with FLK1 and NRP1.[429,430] These results suggest that the VEGF system is important for uterine vascular permeability and angiogenesis during implantation. Others have also shown the expression of VEGF and its receptors in the uterus during pregnancy and in response to steroid hormones.[428] For example, estrogen rapidly induces uterine vascular permeability and VEGF expression transcriptionally via nuclear ER,[428] and the VEGF gene contains estrogen response elements (EREs).[442] P_4 also upregulates uterine VEGF expression via activation of nuclear PR at a slower rate.[442] Since estrogen rapidly stimulates uterine vascular permeability and VEGF expression, and since vascular permeability is considered a prerequisite for angiogenesis, it was widely believed that estrogen is a potent stimulator of uterine angiogenesis during normal reproductive processes in vivo. However, estrogen and P_4 seem to have different effects in vivo. By generating *Flk-LacZ/Esr1*$^{-/-}$ and *Flk-LacZ/Pgr*$^{-/-}$ mice to investigate the angiogenic status in *Esr1*$^{-/-}$ and *Pgr*$^{-/-}$ mice using an Flk-reporter line, it was determined that estrogen promotes uterine vascular permeability but profoundly inhibits angiogenesis, while P_4 stimulates angiogenesis with little effect on vascular permeability. These effects of estrogen and P_4 are mediated by differential spatiotemporal expression of proangiogenic factors in the uterus.[443] Cell type-specific expression of VEGF isoforms and their receptors during embryo implantation has also been reported in mink and in primates.[150,444–447]

VEGF effects are complemented and coordinated by another class of angiogenic factors, the angiopoietins.[448] VEGF acts during the early stages of vessel development,[432,433,449] whereas angiopoietin 1 (Ang1) acts later to promote angiogenic remodeling, including vessel maturation, stabilization, and leakiness.[450–452] In contrast to agonistic functions of Ang1, Ang2 behaves as an antagonist. They interact with an endothelial cell–specific tyrosine kinase receptor, Tie2.[453] There are two additional members of the angiopoietin family, Ang3 and Ang4, but definitive biological functions of Ang3 and Ang4 remain unclear. It is now shown that while VEGF and its receptor Flk1 are primarily important for uterine vascular permeability and angiogenesis prior to and during the attachment phase of the implantation process, VEGF together with the angiopoietins and their receptor Tie2 direct angiogenesis during decidualization following implantation.[454]

PGs are also involved in uterine vascular permeability and angiogenesis during implantation and decidualization. Specifically, COX2-derived PGs participate in these processes.[454] Thus, one cause for failure of implantation and decidualization in *Ptgs2*$^{-/-}$ mice is the deregulated vascular events in the absence of COX2. The attenuation of uterine angiogenesis in these mice is primarily due to defective VEGF signaling rather than the angiopoietin system. Collectively, the results provide evidence that while ovarian steroid hormones influence uterine vascular permeability and angiogenesis during the preimplantation period, COX2-derived PGs direct these events during implantation and decidualization by differentially regulating VEGF and angiopoietin signaling.[443,454]

Using reporter mice *Ptgs2*$^{-/-}$ × *Flk1LacZ* reporter mice, it was shown that COX2-derived PGs influence uterine angiogenesis in decidualization by differentially regulating VEGF and angiopoietin signaling cascades.[454] Uterine angiogenesis in *Ptgs2*$^{-/-}$ mice is compromised due to defective VEGF, but not angiopoietin, signaling, which could be rescued by introducing exogenous PG. Since PGs coordinate VEGF and angiopoietin signaling during decidualization, one contributor of compromised implantation and decidualization in *Ptgs2*$^{-/-}$ mice could be dysregulated vascular events.

Hypoxia-inducible factors (HIFs) are intimately associated with vascular events and induce VEGF expression by binding to the hypoxia response element in the VEGF promoter. HIFα isoforms function by forming heterodimers with the ARNT (HIF-β) family members. In the uterus, expression of HIFs and ARNTs does not correlate with VEGF expression during the preimplantation

period (days 1–4) in mice. In contrast, their expression follows the localization of uterine VEGF expression with increasing angiogenesis during the postimplantation period (days 5–8). This disparate pattern of uterine HIFs, ARNTs, and VEGF expression on days 1–4 of pregnancy suggests that HIFs have multiple roles in addition to the regulation of angiogenesis during the peri-implantation period. Steroid hormones also differentially regulate HIFs, with P_4 primarily upregulating uterine HIF1α expression while estrogen transiently stimulates that of HIF2α.[455] The definitive role of HIFs in regulating uterine angiogenesis warrants further investigation.

ADVERSE RIPPLE EFFECTS ARISING FROM EARLY-PREGNANCY EVENTS

Pregnancy is a feedforward program, and any disturbances to its normal course will terminate pregnancy at the time of insult or propagate defects throughout pregnancy. Compromised pregnancy outcome could result from adverse ripple effects originating from the initial insult during early pregnancy or from independent adverse effects during specific stages. Thus, determining the cause of late-stage disturbances warrants assessment of early defects. For example, dysregulation of HB-EGF, shown from studies in the mouse to be a molecular link between the embryo and luminal epithelium prior to and during attachment (as discussed in this chapter), is associated with preeclampsia, high blood pressure, and elevated urinary protein excretion in humans,[456] and presents clinical relevance that early defects can lead to pathological states later in pregnancy.

Adverse Consequences of Defects in Attachment or Implantation

Several knockout mouse models have been identified to better understand the propagation of early defects throughout the course of pregnancy. The first evidence of adverse ripple effects was shown in mice lacking *Pla2g4a* (cPLA2α) (Figure 38.8).[47] cPLA2α produces arachidonic acid from membrane phospholipids required for PG synthesis, primarily by COX2. *Pla2g4a* is co-expressed with *Cox2* in the uterus. Implantation in *Pla2g4a*$^{-/-}$ females occurs beyond the normal window of implantation (deferred implantation), leading to adverse ripple effects that are reflected in embryo crowding, retarded feto-placental growth, increased rate of resorption, and smaller litter size.[47] This phenotype is consistent with those of physiological experiments in which blastocysts were transferred into wild-type recipient uteri beyond the anticipated time of implantation.[47] cPLA2α is also expressed in the human endometrium,[457] suggesting its conserved role.

A similar phenotype was reported in mice deleted of *Lpar3* (LPA3), a receptor for lysophosphatidic acid.[48] Resemblance in phenotypes between *Pla2g4a*$^{-/-}$ and *Lpar3*$^{-/-}$ females is ultimately attributed to reduced production of COX2-derived PGs and thus the timing of implantation. Indeed, a similar observation was noted in *Ptgs2*$^{-/-}$ mice, depending on the genetic background.[369] Collectively, these findings provide evidence that the LPA3–cPLA$_2$α–COX2 signaling axis is essential for on-time implantation; an aberration of this signaling pathway defers initial attachment and perpetuates adverse effects throughout the remainder of pregnancy. Although administration of PGs rescues deferred implantation seen in *Pla2g4a*$^{-/-}$ or *Lpar3*$^{-/-}$ females, it does not rescue embryo spacing as embryo crowding still persists.[47,48]

There is evidence that haploinsufficiency of certain genes can disrupt normal physiological functions. One example is adrenomedullin (ADM), which is present in numerous tissues, including reproductive organs. ADM is secreted by decidua and trophoblast cells.[458,459] In humans, ADM levels are high in pregnancy but return to baseline levels after parturition.[460] Altered ADM levels in the feto-placental tissues are associated with spontaneous abortion, gestational diabetes, and preeclampsia.[460] In mice, *Adm*$^{-/-}$ fetuses die in utero due to placental insufficiency resulting in failure of neural tube closure, hydrops fetalis, and cardiovascular malformation.[49] Earlier studies have shown that *Adm*$^{+/-}$ mice have normal implantation but exhibit embryo overcrowding and placental anomalies, fetal growth restriction, and shallow invasion of spiral arteries indicative of preeclampsia.[49] However, it was later found that *Adm* is expressed in the uterine luminal epithelium and stroma during the peri-implantation period, and embryo transfer experiments in *Adm*$^{+/-}$ females showed compromised uterine receptivity with reduced pinopode formation (marker of receptivity) and poor implantation rate.[50] Collectively, the results suggest that defects early in pregnancy in *Adm*$^{+/-}$ females contributed to late adverse effects.

Transcription factors also regulate the window of uterine receptivity and implantation. For instance, *Msx1*$^{d/d}$ uteri show embryo crowding and a higher resorption rate, as seen in *Pla2g4a*$^{-/-}$ or *Lpar3*$^{-/-}$ females.[151] Notably, while PG signaling is present throughout pregnancy, *Msx1* is transiently expressed in the receptive uterus. This suggests that deficits even at the stage of receptivity can interfere with developmental programming in pregnancy. Uterine deletion of *Klf5* also confers deferred implantation with compromised pregnancy outcome.[213] *Klf5* is first expressed in the epithelium prior to and during blastocyst attachment; *Klf5* expression later switches to the decidua after epithelial expression becomes undetectable. These results suggest that the period spanning uterine receptivity, attachment, and decidualization is

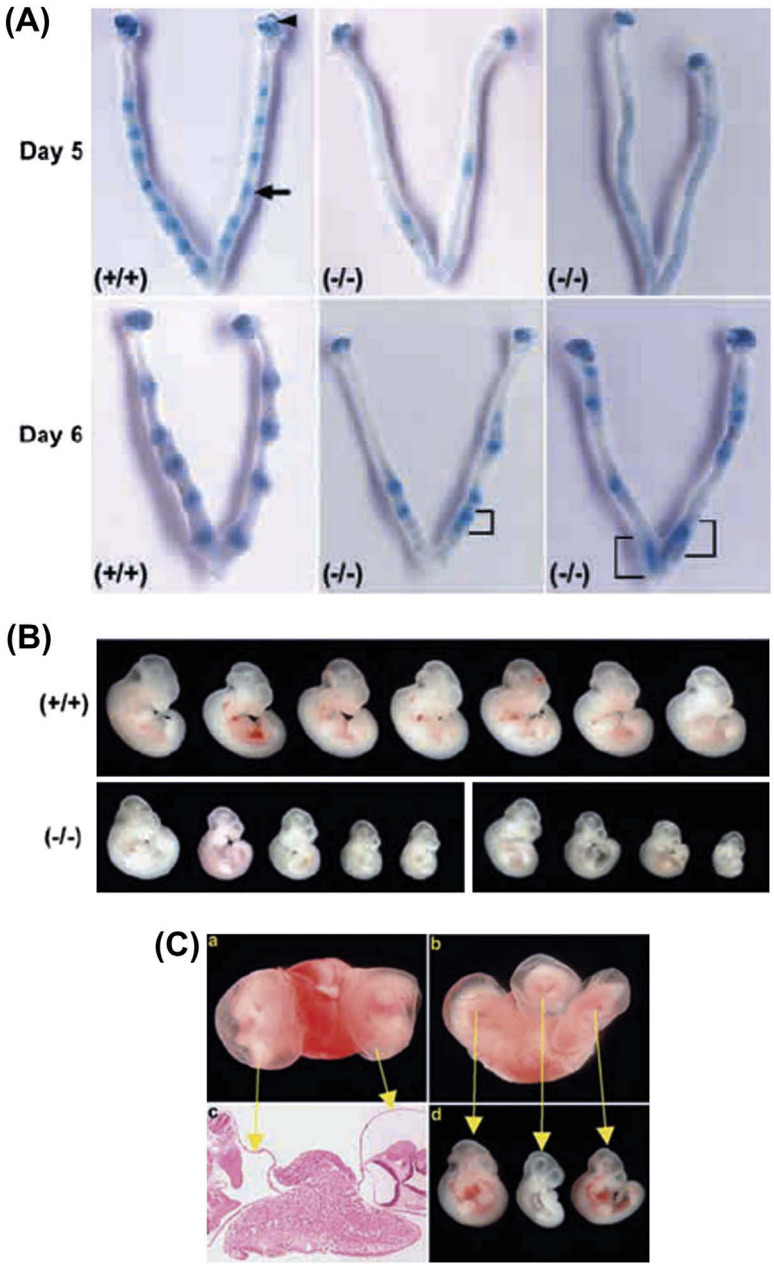

FIGURE 38.8 Defective postimplantation development in *Pla2g4a*$^{-/-}$ mice. This figure is reproduced in color in the color plate section. (A) Representative photographs of uteri with implantation sites (blue bands) on days 5 and 6. Note very few or no implantation sites on day 5, but unevenly spaced implantation sites on day 6 in *Pla2g4a*$^{-/-}$ mice. Arrowhead and arrow indicate ovary and implantation site, respectively. Brackets indicate crowding of implantation sites. (B) Photographs of embryos isolated from implantation sites of one representative wild-type and two *Pla2g4a*$^{-/-}$ mice on day 12. Note retarded and asynchronous development of embryos in *Pla2g4a*$^{-/-}$ mice. (C) Representative photographs of conjoined embryos in a placenta (a, c) and three embryos in the same decidual envelope (b, d) from *Pla2g4a*$^{-/-}$ mice on day 12. (c) A histological section of (a) with two embryos; embryos shown in (d) are from (b). Yellow arrows indicate the source of the embryos from the decidual envelope. *Source: Reprinted with permission from Ref. 47.*

susceptible to insults that later initiate adverse events during the course of pregnancy.

Adverse Effects Originating from Dysregulated Decidualization

While the section Adverse Consequences of Defects in Attachment or Implantation described poor pregnancy outcome and/or subfertility resulting from deferred implantation, defects during decidualization also lead to adverse pregnancy outcome with placentation abnormalities, intrauterine fetal growth restriction (IUGR), and difficult parturition. For example, a signature of preeclampsia is shallow spiral artery invasion by trophoblast cells.[461–463] Poor trophoblast invasion into decidua with poor remodeling of decidual arterioles is also considered a contributing factor for preeclampsia, precluding normal placentation.[51,399,464] Defective decidualization can also lead to preterm birth.[184] Mice with uterine deletion of *Trp53* ($p53^{d/d}$) show normal implantation but have increased incidence of spontaneous preterm birth with dystocia, abnormal or difficult labor, and fetal death.[184] Compromised decidualization is due to premature decidual aging resulting from more terminally differentiated, polyploid cells. These changes are signified by increased levels of pAkt, p21, COX2, and senescence-associated growth restriction. Interestingly, preterm birth in $p53^{d/d}$ females was rescued by celecoxib,

a selective COX2 inhibitor, suggesting COX2 as a critical physiological mediator of decidual senescence. Many risk factors that predispose to preterm birth, such as gene mutation, infection and inflammation, and stress, also trigger cellular senescence via mammalian target of rapamycin complex 1 (mTORC1) signaling (reviewed in Ref. 465). These results may suggest that these risk factors converge to a common pathway toward early cellular senescence of the decidua due to increased mTORC1 signaling. An mTORC1 inhibitor, rapamycin, has been shown to attenuate senescence and increase life span in mice.[466] In fact, *p53*$^{d/d}$ deciduae have high mTORC1 activity that is inhibited by rapamycin, rescuing the preterm birth phenotype.[465]

FUTURE DIRECTIONS: EVOLVING TECHNOLOGIES AND DISCOVERIES

Although considerable information regarding the roles of growth factors, cytokines, homeotic genes, transcription factors, morphogens, and lipid mediators in implantation has been generated, their hierarchical blueprint in directing uterine and embryonic function during implantation remains to be integrated. Further investigation is required to understand whether these pathways function independently, function in parallel, or converge to common signaling pathways to execute reciprocal interactions between the embryo and uterus during implantation. Thus, our understanding of the implantation process is still far from complete. Many of the genes, which are expressed in an implantation-specific manner and appear to be important for implantation, cannot be studied mechanistically because deletion of these genes results in embryonic lethality. Uterine cell type- or embryo-specific conditional deletion of genes of interest is urgently needed to better understand the definitive roles of these genes in uterine biology and implantation. Our failure to identify suitable uterine cell-specific promoters is a hindrance to achieving this objective. There is also a difficulty in identifying the critical roles of signaling molecules within a gene family because of the redundant or compensatory functions of the gene products within the family.

Strategies comparing global gene expression profiles between the implantation and interimplantation sites have identified novel genes in the implantation process. Thus, a genome-wide screening approach coupled with functional assays will help elucidate these complex signaling pathways. Experiments should be pursued to compare global gene expression patterns between wild-type and gene-deleted mouse uteri and blastocysts under defined physiological experimental conditions. The results obtained from these experiments may help uncover new signaling molecules and pathways not previously identified. The advent of microarray technology and sequencing of the mouse and human genomes have allowed us to analyze implantation-related genes in a global perspective. In mice, microarrays have been used to identify genes that show differential expression at implantation versus interimplantation sites,[467] or at implantation versus postimplantation periods,[468] or genes that are differentially regulated by changes in estrogen and P_4 signaling.[412,469–474] Comparison of the array results of implantation versus interimplantation sites to those of P_4-treated uteri versus estrogen-stimulated uteri led to identification of a number of genes with previously recognized roles in implantation and a number of new genes related to implantation and steroid hormonal regulation. Closer examination of these genes and comparing the results from similar microarray experiments and RNA sequencing may provide clues to the identity of important genes or gene families in the implantation process. In humans, microarray technology has been used to identify genes associated with the window of uterine receptivity.[277,475] A comparison of the results shows differential regulation of a small number of genes around the time of uterine receptivity for implantation. Interestingly, there are a number of genes that are also differentially expressed in mouse models of implantation and human uterine receptivity.

Gene regulation in the context of implantation can be further defined by studying noncoding RNAs, including long-noncoding RNAs, piwi-interacting RNAs, microRNAs (miRNAs), and small interfering RNAs, with exploitation of the parallel leaps in sequencing technology. Although expression analysis of these RNAs has been periodically attempted, their function in the uterus during implantation remains relatively unanswered. For example, COX2's dynamic expression pattern is refined posttranscriptionally by miRNAs, namely, mmu-miR-101a and mmu-miR-199a,[476] and there is evidence for additional uterine miRNAs in implantation.[477] Until more information is gathered regarding their regulation and mechanism of action, the function of these noncoding RNAs in implantation will remain limited. Nonetheless, this is an exciting area of research with potential to have great bearing on the dynamic changes seen during implantation.

Currently, emerging techniques in proteomics are also being applied to the understanding of uterine biology.[478,479] Proteomics is a powerful tool to map cellular protein profiles at a defined physiological state. Use of this technology has been sporadic to study implantation biology. Recent advances in in situ mass spectrometry provide opportunities to generate a spatiotemporal map of proteins and their modifications (Figure 38.9). This technology should be more widely used to generate information at specific stages of pregnancy.[480,481] With advances in high-efficiency mass spectrometry

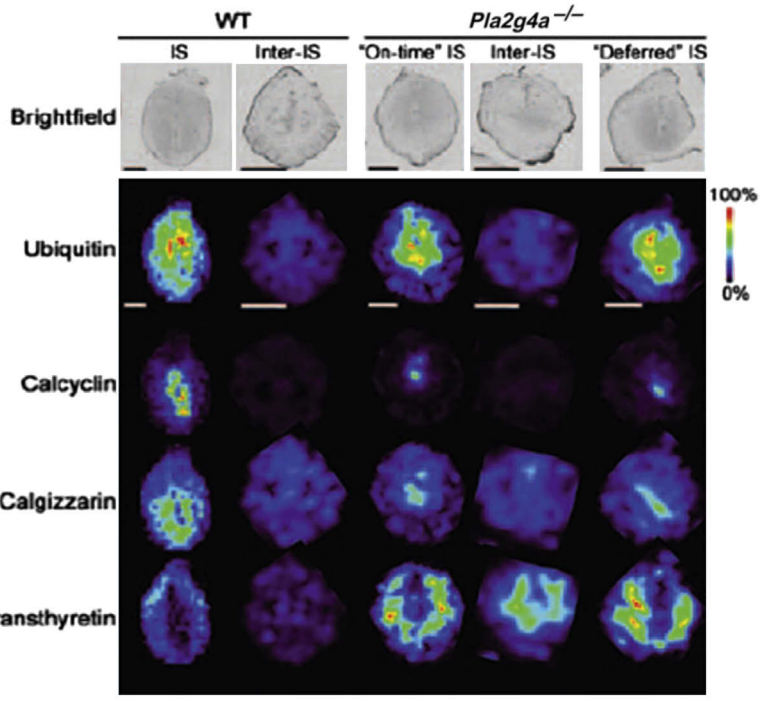

FIGURE 38.9 Proteome profiles differ between WT and *Pla2g4a*$^{-/-}$ uteri on day 6 of pregnancy, regardless of implantation timing. This figure is reproduced in color in the color plate section. Optical images of a WT implantation site (IS) and interimplantation site (inter-IS) and *Pla2g4a*$^{-/-}$ deferred and on-time IS (*upper panel*). Bar, 670 μm. Ion intensity maps are shown below their respective bright-field images. *Source: Reprinted with permission from Ref. 480.*

technology (MALDI-MS), it may now be possible to identify novel low-abundance proteins and lipid mediators involved in implantation, particularly those secreted by blastocysts. In many species, including rodents and humans, the most limiting factor is the availability of the adequate amount of tissues required for biochemical and molecular biology experiments. With the advent of microscale proteomics and genomic approaches, it is hoped that more information on embryonic signals is likely to be forthcoming. In the same vein, advanced technologies in metabolomics and lipidomics can also be used to profile metabolites and lipids to assess the physiological state of the uterus during specific stages of pregnancy.

Recent advances in imaging technology should be embraced to study implantation and pregnancy events. With the availability of high-resolution live imaging and tracking systems, the development of 3D culture systems to study implantation could provide valuable information regarding dynamic changes and interplay of molecules in situ. For example, tracking systems using fluorescent tags to monitor specific proteins at the interface of the trophectoderm and epithelium can be used to monitor their interactions.

Characterization of microbiota in different systems is a subject of intense research, and the study of the host–microbiome relationship[482] is an emerging field with implications for both health and disease knowledge. For example, studies have shown correlations of specific gut microbiome with the adaptive immune system,[483] increased risk of metabolic disease,[484] and behavior.[485] Considering the significant correlation of infection and inflammation with preterm birth,[486] efforts should be directed to characterize the influences of gut and oral microbiota on pregnancy outcome. It is possible that mapping the uterine microbiome profile may allow for predictions of adverse pregnancy outcomes, provide insight into the environmental milieu of the uterus, and may even lead to the development of uterine probiotics to optimize uterine health and fertility.

The genome–epigenome interaction and passage of nongenomic information through generations are also subjects of intense research. Environmental endocrine disrupters or composition of maternal diets during pregnancy can also have transgenerational consequences on offspring's health, ranging from lipid metabolism and sex determination, through epigenetic changes.[487–489] More mechanistic approaches are needed to understand the role of the uterine epigenome. It has been reported that transposable elements are differentially regulated in decidualization.[490]

Several limitations, including ethical restrictions in using human blastocysts, preclude the study of direct embryo–uterine interactions. In this respect, renewable sources of oocytes and spermatogonia using inducible pluripotent stem cell (iPSC) technology have recently been identified,[491,492] and several reports of renewable in vivo sources of oocytes have been generating attention and debate.[493,494] These avenues can potentially provide the basic tools to develop in vitro culture systems to study aspects of human implantation. Interestingly, the generation of trophoblast stem cells to embryonic stem cells and vice versa has been reported in mice.[495,496]

CONCLUSION

Infertility and rapid population growth are two pressing global reproductive health issues. The processes of preimplantation embryo development and uterine preparation for implantation are two major determinants for reproductive success. Basic and clinical research to better understand these events is important in order to help alleviate problems of female infertility, improve fertility regulation in women, and lead to the development of new and improved contraceptive approaches. Interactions between the major uterine and embryonic cell types with respect to endocrine, paracrine, juxtacrine, and autocrine factors during implantation are extremely complex.[153–155] Thus, exploring and defining the molecular landscape during the critical time of implantation necessitates well-thought-out experimental designs in the context of both embryonic and uterine contributions to formulate a more meaningful blueprint. As Boving wrote,[497] "The conceptus and uterus have mastered everything they need to know about implantation. We scientists have not." This mission is not easily achievable in humans due to experimental difficulties, ethical considerations, and current restrictions on research with human embryos. Therefore, model systems will continue to be used for studying embryo–uterine interactions during implantation. In addition, efforts should be directed to establish reliable in vitro systems to study implantation, which are not currently available. However, experiments using endometrial biopsy samples to identify molecules associated with human uterine receptivity (window of implantation) during the menstrual cycle with respect to changing estrogen and P_4 levels should continue to be pursued to better understand this process in humans.

Although the mechanics and cellular architecture of the implantation process vary, certain basic features are common to many species. For example, implantation occurs at the blastocyst stage, there is a defined "window" of uterine receptivity for implantation, a reciprocal interaction between the blastocyst and the uterus is essential for implantation, and a localized increase in uterine vascular permeability occurs at the site of the blastocyst during the attachment reaction. Identification and characterization of signaling pathways in these steps may elucidate a unifying scheme relevant to understanding the mechanism of human implantation.

Acknowledgments

We thank Koji Yoshinaga for his insight in preparing this chapter. This chapter is dedicated to the late M.C. Shelesnyak, Alexander Psychoyos, and Anne McLaren as a tribute to their lifelong dedication to reproduction research and passion for scientific pursuits. We thank Serenity Curtis for editing the manuscript and many individuals who participated in research in the Dey lab. Research in the Dey lab was supported in part by U.S. National Institutes of Health (NIH) grants (HD12304, HD068524, and DA06668), the March of Dimes, and the Grand Challenges Explorations Initiative through the Bill & Melinda Gates Foundation. J.C. is supported by an NIH National Research Service Award Fellowship (F30AG040858). H.J.L. is supported by a National Research Foundation of Korea (NRF) grant funded by the Korean government (MEST) (No. 2011–0016513). We apologize for not citing numerous relevant works due to space constraints.

INTRODUCTION

The human placenta is a disc-like organ that is usually circular or slightly elliptical, measuring 22 cm in diameter and 2.5 cm in central thickness, and weighing an average of 470 g at full term (Figure 39.1). For all eutherian mammals, the placenta forms the interface between the fetus and the mother, providing all functions that are essential for fetal survival, growth, and development, including regulation of gas exchange, supply of nutrients, removal of waste products, production of essential hormones, and establishment of immunological defense.[2]

The name *placenta* means "cake" in Latin, and it is also derived from *plakous*, which means "flat cake" in Greek. It was first introduced in the sixteenth century by Realdo Columbo at the University of Padua in Italy.[3] The role of the placenta in providing nutrients to the developing fetus has been known since the fifth century BC, yet it was initially assumed to reflect direct communication between the fetal and maternal blood. The recognition of separate maternal and fetal blood circulations was attributed to William Harvey in the seventeenth century, a concept later proven by William and John Hunter in the eighteenth century, who used molten wax to demonstrate utero-placental vessels and separated circulations.[4] Weber and Dalrymple were the first to describe the placental villi and their capillary structure, followed by the identification of two trophoblast layers by Langhans in 1882. Advances in chemistry, microscopy, and blood flow physiology during the first half of the twentieth century led to the initial discoveries of the placental biosynthetic functions, and the detailed description of blood flow in the intervillous space by Ramsey and Donner.[5]

The placenta is made of cells derived from the fetus. On the side of the placenta facing the fetus, the umbilical cord is usually inserted near the center of the placental disk. The umbilical cord delivers blood from the fetus to the placenta via two umbilical arteries. Blood returns to the fetus via the umbilical vein. The remainder of the fetal side (chorionic plate) of the placenta is covered by an amnion. The maternal side of the placenta (basal plate) directly surfaces the maternal decidua, the lining of the uterus during pregnancy. This side of the placenta is characterized by grooves that divide the maternal-facing surface into 10–40 lobules (cotyledons), each connected to septa within the placenta. These lobules usually harbor one or several villous trees (Figure 39.1), but they are not autonomous, and two cotyledons are frequently supplied by the same villous tree. Although, in general, a deviation of placental shape from a circle is deemed functionally insignificant, recent data suggest an association between elliptical placentas and low birth weight.[6] Similarly, an eccentric umbilical cord insertion is associated with fetal vessel abnormalities.[7]

The main functional unit within the human placenta is the villus. The outermost layer of each villus is the multinucleated syncytiotrophoblast, which is bathed in maternal blood. Immediately subjacent to this layer are the mononucleated cytotrophoblasts, which near term form a discontinuous layer. The stroma of each villus is formed by fibroblasts and placental macrophages (Hofbauer cells). Within the stroma are the fetal blood vessels, surrounded by endothelial cells. The extravillous trophoblasts populate the placental septa and the chorionic and basal plates. Extravillous trophoblasts also invade the maternal decidua and inner one-third of the

myometrium, where they provide anchorage and support to the vasculature, and invade the blood vessels to enhance vessel dilation and ensure placental perfusion.[8]

COMPARATIVE PLACENTATION

Although all eutherian animals share the principle functions of the placenta, marked species differences exist with respect to structure and physiology, rendering the comparison of the human placenta with placentas of other animals rather complex.[9] Consequently, there is no single animal placenta that can fully capture the biology of the human placenta. Whereas the mouse pregnancy is commonly used as a model system for certain aspects of human pregnancy, this mainly reflects the ease of performing genetic manipulations in the mouse, the low cost, and the fact that the *maternal–fetal barrier interface* in the mouse placenta, like its human counterpart, is hemochorial (see the fourth criterion, discussed in the next paragraph).

Several criteria are used to define the placenta of different species. A first, central criterion is *placental vascularity*, which defines the original source of chorion vasculature. In the choriovitelline placenta, found in many marsupials, the vessels are derived from the extraembryonic mesoderm that covers the yolk sac. In most mammalian organisms, the placenta is chorioallantoic, with placental vessels originating in the allantois, the hindgut diverticulum that develops into the umbilical cord. A second criterion is *placental shape*, defined by the site of interaction of the maternal and fetal tissues. For example, in the pig's diffuse placenta, the interaction takes place over the entire chorionic sac. In the cotyledonary placenta, found in ruminants, maternal–fetal interaction is mediated within caruncles, located in nonglandular areas of the endometrium. Many carnivores have a zonary placenta, characterized by a belt of placental tissue within the chorion. Most rodents, as well as primates and humans, exhibit a discoid placenta. A third criterion is *maternal–fetal interdigitation*, which is defined by the characteristics of the maternal–fetal interaction structure. These interfaces are summarized in Figure 39.2. Notably, while the human placenta features a three-dimensional treelike villous structure, the mouse and many other rodents exhibit a labyrinthine interface, with a complex interdigitated surface for fetal–maternal interaction. A fourth criterion is the *maternal–fetal barrier interface* (Figure 39.3), which plays a pivotal role in defining the placental transport function.[9] This barrier can be invasive or noninvasive. In the noninvasive

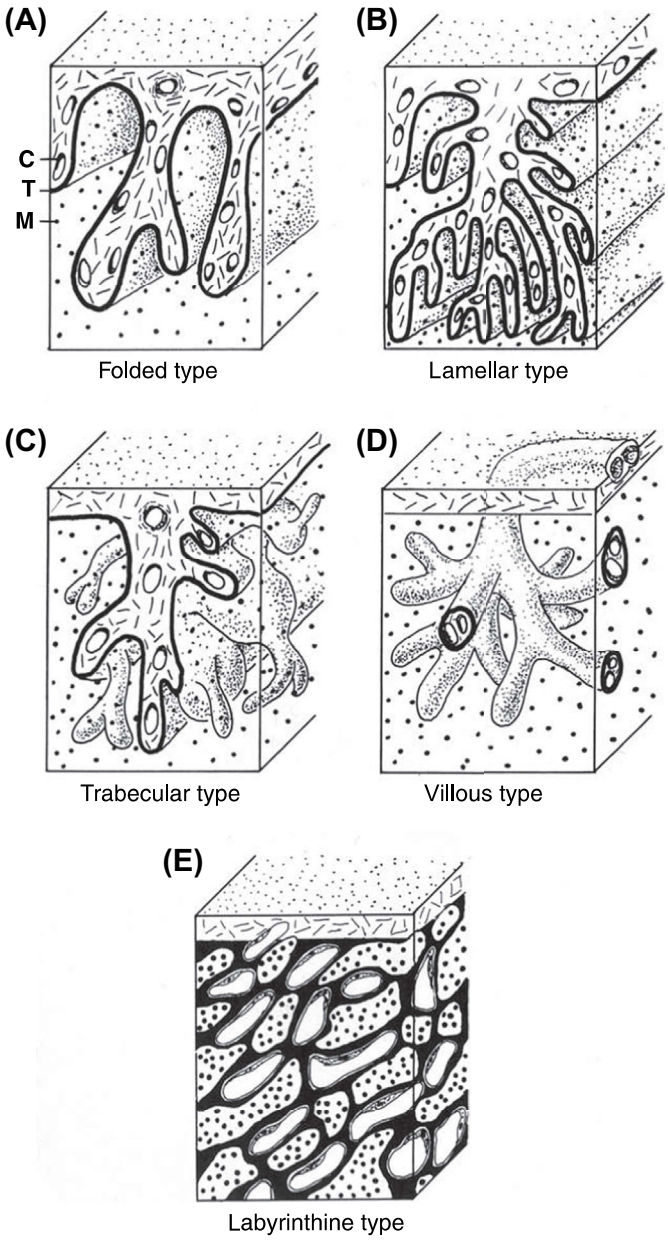

FIGURE 39.2 Examples of interdigitation between the maternal and fetal tissues at the maternal–fetal interface. The type of interdigitation may be (A) folded, (B) lamellar, (C) trabecular, (D) villous, or (E) labyrinthine. M: maternal tissue or maternal blood; T: fetal trophoblast (black); C: fetal capillaries and fetal connective tissue (stroma).

epitheliochorial interface (Figure 39.3(A)), the trophoblast is attached to the uterine epithelium but does not invade into it. In a similar noninvasive synepitheliochorial interface, the fetal binucleate cells fuse with the epithelium, yet without invasion. In the endotheliochorial interface (Figure 39.3(B)), trophoblast invasion leads to destruction of the uterine epithelium, thus reducing the barrier between the fetal and maternal vessels. The invasive hemochorial interface, characterized by direct contact between trophoblasts and the maternal vessels, is further defined by the number of cell layers separating the maternal and fetal blood, with a hemotrichorial interface (Figure 39.3(C)) that characterizes the mouse placenta, and a hemodichorial interface (Figure 39.3(D)) that characterizes the human placenta in early pregnancy.[10] In late human pregnancy, however, the placenta is partly hemomonochorial, because the cytotrophoblast cell layer is discontinuous (Figure 39.3(E)). A fifth criterion is the relative direction of the *maternal and fetal blood flow*.[9,11] When blood flows are concurrent, the maternal and fetal bloodstreams run in the same direction, whereas in the commonly found countercurrent flows, the maternal and fetal bloodstreams run in opposite directions. A mixture of the two types of flows results in cross-current flows. A more complex flow pattern is found in the human villous tree, where multivillous blood flow results in a variable flow of all types. Lastly, the *yolk sac* defines the transient need of eutherian animals for nutrients and other exchange functions prior to the formation of the functional placenta. In certain species, such as rodents, the yolk sac inverts and remains functional for the remainder of the pregnancy, where the yolk sac's endodermal lining apposes the uterine epithelial glands, enabling the absorption of large proteins, immunoglobulins, and lipid derivatives throughout pregnancy.[9,12]

HUMAN PLACENTAL MORPHOLOGY

The Placental Villus

The villus is the basic functional unit within the human placenta (Figure 39.1) and is the key site for exchange of gases, nutrients, and waste between the mother and the fetus. The trophoblast is located in the periphery of each villus, with the multinucleated syncytiotrophoblast in direct contact with maternal blood (Figure 39.4). The syncytiotrophoblast maintains polarity, with a microvillous plasma membrane (MVM) facing the maternal blood on the apical side, and a basal plasma membrane (BM) located adjacent to cytotrophoblasts and the basement membrane. It is not surprising that the syncytiotrophoblast MVM, interfacing directly with the maternal blood, harbors receptors to many types of plasma proteins, growth factors, immunoglobulins, and other soluble ligands, all directly linked to intracellular signaling cascades.[15] Subjacent to the layer of syncytiotrophoblast are the cytotrophoblasts, which usually lack direct contact with the maternal blood. The cytotrophoblasts are attached to a basement membrane that is composed primarily of type IV collagen, heparin sulfate, and fibronectin. The mononucleated cytotrophoblasts form a continuous layer in the first trimester, resulting in a complete trophoblast bilayer. Later in gestation, the cytotrophoblasts continue to proliferate yet become more

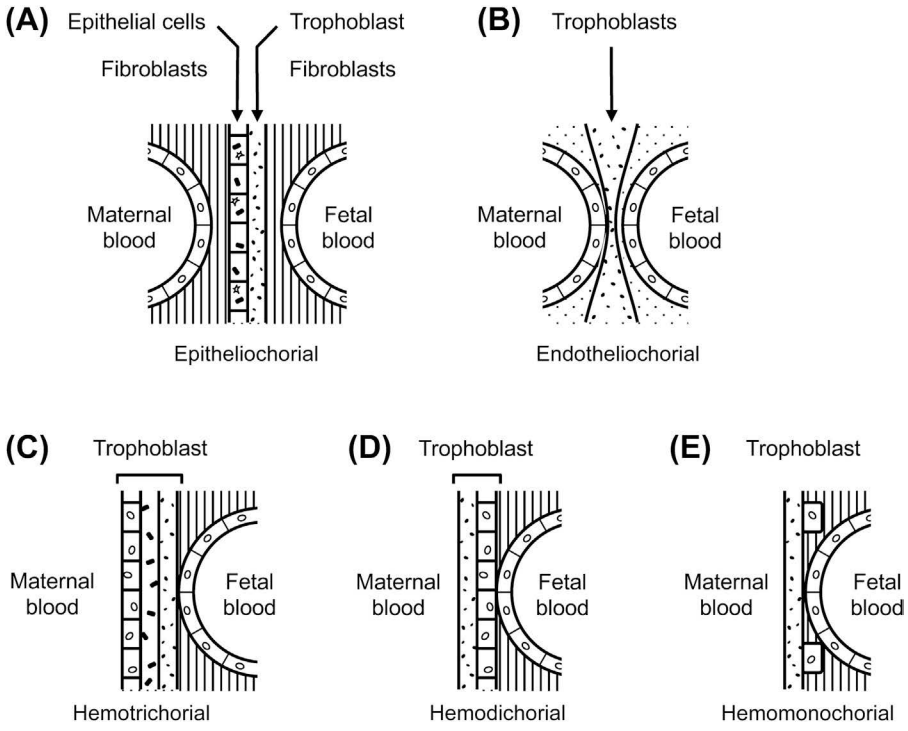

FIGURE 39.3 Examples of the maternal–fetal barrier in the placenta. Panel (A): Epitheliochorial placenta, with six layers separating the maternal and fetal blood. From left: Maternal capillary endothelium, maternal endometrial connective tissue, maternal endometrial epithelium, fetal trophoblasts, chorionic connective tissue, and fetal capillary endothelium. Panel (B): Endotheliochorial placenta, where the trophoblast is in direct contact with maternal capillary endothelium. Panel (C): Hemotrichorial, where the trophoblast is directly bathed in maternal blood. Panel (D): Hemodichorial, which is the same as (C), but with only two layers of trophoblasts. Panel (E): Hemomonochorial, which is the same as (D), but with only one layer of syncytiotrophoblast and interspersed cytotrophoblasts.

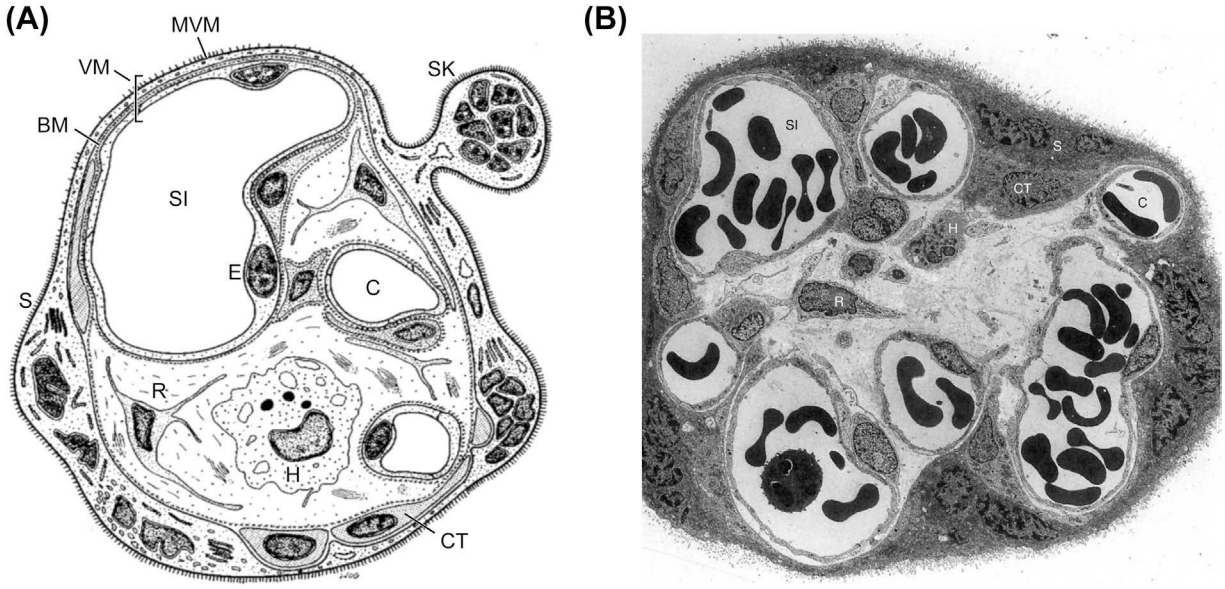

FIGURE 39.4 A terminal villus, shown in cross-section. Both panels illustrate the narrow interface between the maternal and fetal compartments. Panel (A): A schematic showing the key structural elements of the syncytiotrophoblast. *(Source: Reproduced with permission from Ref. 13.)* Panel (B): Electron micrograph of a typical, terminal villus (magnification ×2000). Abbreviations (not all shown in the two panels): VM: vasculosyncytial membrane; MVM: microvillous membrane; S: syncytiotrophoblast; CT: cytotrophoblast; C: capillary; SI: sinusoid; H: macrophages (Hofbauer cells); R: stroma with fibroblasts; E: endothelial cell; BM: basal membrane; SK: syncytial knot. *Source: Reproduced with permission from Ref. 14.*

sparse and noncontinuous, contributing to 10–15% of the total trophoblastic volume.[16] The balance among cytotrophoblast proliferation, differentiation, and apoptosis is influenced by diverse signals, such as hypoxia,[17–19] and is exquisitely orchestrated by trophoblastic proteins, growth factors, and other molecular signals, many of which have been previously interrogated in the mouse.[20–25] Differentiation of trophoblasts is characterized by fusion into syncytia, a process that occurs normally throughout pregnancy and is highly regulated by ligands such as endothelial growth factor (EGF), cyclic adenosine monophosphate (cAMP), and human

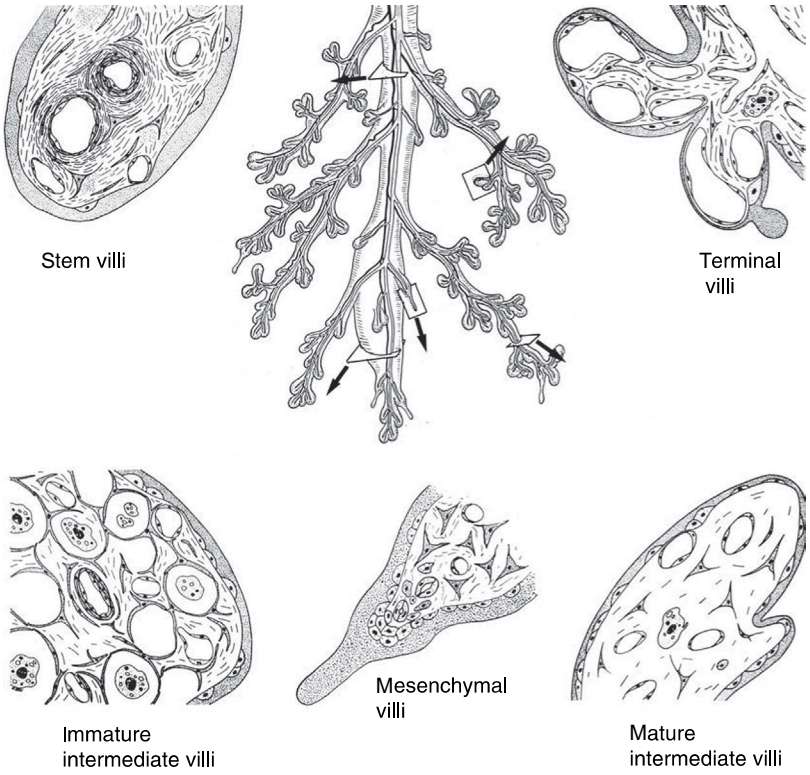

FIGURE 39.5 A simplified representation of the peripheral part of the mature placental villous tree, together with a typical cross-section depiction of different villous types. See text for details. *Source: Reproduced with permission from Ref. 1.*

chorionic gonadotropin, and by steroid hormones and genetic and epigenetic pathways.[26–30] Fusion of trophoblasts involves mechanisms that play a role in cellular apoptosis, with caspase 8 activation and the flipping of phosphatidylserine from the cell membrane inner leaflet to the outer side.[31,32] Indeed, apoptosis is commonly observed in human syncytiotrophoblasts, likely mediating the formation of clustered nuclei in syncytial knots, with subsequent shedding of cell fragments and apoptotic bodies into the maternal circulation. This process occurs more commonly in the third trimester of human pregnancy.[31,33–36] Syncytin 1, expressed from a human endogenous retrovirus, is a membrane glycoprotein that exhibits fusogenic activity in many cell types and plays a key role in mediating the fusion of mouse and human placental trophoblasts.[37,38] Syncytin is highly expressed in trophoblasts, along with its syncytin receptor, amino acid transporter 2 (ASCT2).[39,40]

The stroma of placental villi includes fibrous tissue comprising fibroblasts along with reticular, collagen, and elastic fibers.[41] At the base of the stem villi (discussed further here), these fibers blend with extravascular smooth muscle cells, creating regulatory myofibroelastic units that are believed to provide tensile support to stem villi. The stroma also includes placental macrophages (Hofbauer cells), which are fetal-derived macrophages that likely originate early in gestation from villous mesenchymal cells, and later from fetal bone marrow–derived macrophages.[8,42,43] In addition to villous immunological defense, these cells participate in the modulation of vasculogenesis and trophoblast differentiation. Placental villi also harbor fetal blood vessels, from small sinusoids in terminal villi to larger arteries and veins in stem villi. Arteries and arterioles within stem and intermediate villi are characterized by a smooth muscle coat and by an adventitia that blends with the stromal connective tissue. During the last third of pregnancy, the terminal villi capillaries are supported by a basement membrane (Figure 39.4).

The Placental Villous Tree

Early during placental development, the chorionic plate trabeculae give rise to placental lobules that form villous trunks.[44] These trunks gradually bifurcate to form either terminal villi within the intervillous space or anchoring villi at the basal plate. In general, as the placenta matures during pregnancy, some of the early villi morph into more differentiated tissues, characterized by smaller villi and narrower intervillous space. Several types of villi exist within the placenta, and are characterized by size, stromal components, and vessel structure (Figure 39.5). *Stem villi* (diameter: 80–3000 μm) are characterized by a compact fibrous stroma, with large, centrally located arterioles and venules. These villi are unlikely to participate in feto-placental exchange and largely provide tensile support to the villous tree.[3] *Mesenchymal villi* are the precursors of more differentiated immature

intermediate villi; they are characterized by unorganized stromal and vascular structures.[45] *Immature intermediate villi* form direct continuations of stem villi, and are generally found within the central regions of the lobules.[46] They are less compact than stem villi, and their cells form fiber-free intercommunicating channels in which arterioles and venues are embedded. *Mature intermediate villi* measure 80–120 μm in diameter, and they are more differentiated, with loose stroma, scant fiber cells, and capillaries that comprise at least half the villous volume. Finally, *terminal villi* measure less than 80 μm in diameter; they form the smallest and, functionally, the most important unit that mediates maternal–fetal exchange (Figures 39.4 and 39.5). Terminal villi are characterized by a variable distance between the capillaries and the syncytial microvillous membranes, representing areas of very thin membranes (vasculosyncytial membrane; Figure 39.4) as well as areas of cell bodies and stromal tissue. The capillaries typically occupy more than 50% of the terminal villous diameter. Functionally, fetal exchange is likely to occur mainly in vasculosyncytial membranes, which measure 0.5–2.0 μm wide and are devoid of cell bodies. An extension of syncytiotrophoblasts, basal membrane and endothelial cells separate the fetal and maternal blood compartments (Figure 39.4).[47,48]

The development of the villous tree is initiated at the chorionic plate's trabeculae, with the formation of syncytial trophoblastic sprouts.[45,49] Mesenchymal villi are formed with invasion of stromal tissue, followed by capillaries, into the syncytial sprouts. Rapid growth during the first trimester leads to initial sprouting of immature intermediate villi. Placental growth slows during the third trimester, at which point placental differentiation is characterized by the development of terminal villi.[45,50] Placental blood vessel development is characterized by capillary formation within the villi on day 21 post conception, with differentiation of hemangiogenic cells within mesenchymal villi.[42] This process, which takes place in a hypoxic environment, is regulated by vascular endothelial growth factor, placental growth factor (PlGF), and their receptors.[51–56] Arterioles and venules develop within the branching villi and are connected by a paravascular network of capillaries.[49,57] The arterioles and venules transform into coiled capillary loops within mature intermediate villi and terminal villi. Capillary sinusoids form from interspersed areas of vascular dilatation that reduce blood flow resistance, which is particularly germane at the vasculosyncytial membranes.

The maternal blood reaches the intervillous space through openings of the maternal spiral arteries within the basal plate (Figure 39.1), opposite the center of each lobule. Uterine veins are located more peripherally with respect to each lobule. Blood flow from each artery is initiated at the lobular center and progresses peripherally.[11] The perfusion of the intervillous space is dependent upon the pressure gradient between the maternal uterine arteries and veins, and the resistance within the intervillous space.[49] Notably, the intervillous space is irregular, and includes lakes, clefts, and fusions among neighboring villi.[34] Most functional perfusion-imaging studies, performed using the rhesus macaque, suggested that flow changes are influenced by the fetal perfusion of the villous tree. Thus, fetal flow also impacts the maternal perfusion of the intervillous space.[58]

After early development, placental location, growth, and the depth of villous invasion can be longitudinally assessed until term using ultrasound.[59] Sonographic assessment of the placental parenchyma can be used to distinguish normal from abnormal structures, including layer thickness, cystic changes, calcifications, subchorionic fluid collection, and a snowstorm appearance characteristic of trophoblastic vesicles in molar pregnancy. Advances in Doppler ultrasound, particularly color Doppler, enable noninvasive, dynamic, and quantitative real-time assessment of placental and uterine blood flow, including a detailed flow analysis in small vascular beds. Ultrasound Doppler has also become essential for clinical management of pathological pregnancies that stem from placental dysfunction.[60,61] Another noninvasive and dynamic imaging technique that has gained momentum is magnetic resonance imaging (MRI), which provides detailed information not only on placental structure and growth but also on dynamic blood flow changes within vessels and in the intervillous space.[62]

Because placental villi mediate oxygen transport to the fetus and are subject to physiological and pathological changes in oxygen levels, it is not surprising that changes in oxygenation may impact the development of the villous tree.[63] Importantly, the effect of oxygen depends on the precise stage of villous tree development, where hypoxia in early pregnancy promotes the invasion and migration of extravillous trophoblasts toward the oxygen-enriched environment near decidual blood vessels.[63–67] Conversely, hypoxia after weeks 12–14 of pregnancy has been implicated in diverse mechanisms of injury, such as direct cellular hypoxia, occurring when oxygen delivery is diminished (e.g., hypobaric hypoxia); maternal heart or lung diseases[68–70]; tissue reoxygenation, occurring during hypoxia reperfusion; and potentially even relative hyperoxia, which may occur when oxygen extraction is reduced, leading to increased delivery of oxygen further downstream. Although the precise mechanism of such injuries and placental tissue response is lacking, it is clear that each of these forms of injury, alone or in combination, may result in altered villous architecture and cellular morphology, culminating in cellular dysfunction.[71] Tissue response to these injuries also depends on the developmental stage. For example, during early villous branching, altered oxygen levels may result in reduced terminal bifurcation.

Changes in oxygenation also stimulate cytotrophoblast proliferation and/or reduced syncytial fusion, with histological changes consistent with villous ischemia and infarct.[72–74] Chronic hypoxia throughout gestation elicits an adaptive response that consists of increased vascularization of terminal villi, cytotrophoblast proliferation, villous membrane thinning, and reduced deposition of perivillous fibrin, all contributing to maintenance of maternal–fetal exchange.[68,75] Some of these responses, including increased terminal villous vascularization and thinning of the villous membrane, are also observed in chronically anemic mothers.[76,77]

The Basal Plate, Extravillous Trophoblast, and Nonvillous Support

The entire maternal–fetal interface stretches from the base of the space (Figure 39.1) at the chorionic plate to the inner third of the myometrium, termed the "junctional zone". The extravillous trophoblasts, representing trophoblasts that do not contribute to placental villi, are located within the junctional zone, and also within the chorion and chorionic plate, the placental septa in the basal plate, and the placental cell islands. Extravillous trophoblasts include the interstitial trophoblast within the junctional zone but outside the vessel wall, and the endovascular trophoblasts within the decidual and myometrial vessels. The interstitial trophoblasts are the common type of extravillous trophoblast late in gestation, and they appear as large, polygonal cells with a single intensely stained nucleus, embedded within fibrinoid. In the first trimester of pregnancy, there is a preponderance of small invasive interstitial trophoblasts, which gradually diminish until term.

The most superficial part of the junctional zone is the basal plate, which is found on the placental side after placental separation at delivery.[78] The basal plate develops from mononucleated extravillous trophoblasts which invade the decidua, with some cells forming the junctional giant cells, and others invading the decidua to generate the basal plate blood-derived fibrinoid (fibrin-type fibrinoid, or Rohr's fibrinoid). Other fibrinoid layers include the matrix-type fibrinoid, which is formed from extracellular matrix and is found deeper within a mix of trophoblasts and decidual cells. Another layer of blood derived, fibrin-type fibrinoid (Nitabuch's fibrinoid) is found on the most superficial surface of the basal plate, and represents the typical placental–decidual separation layer. The deeper part of the junctional zone, closer to the maternal uterine wall, is termed the "placental bed" and harbors a mixture of necrotic decidual cells and extravillous trophoblasts. Lastly, extensions of the basal plate into the intervillous space are termed placental septa, which are incomplete extensions of junctional zone fibrinoid, and harbor maternal components, including decidual cells and even small maternal veins.[79,80]

Trophoblastic cell columns connect large stem villi to the basal plate, a process that involves invasion of the basal plate by cytotrophoblasts early in pregnancy, and extends to the placental bed and the spiral arteries. These villi are therefore termed "anchoring villi". As pregnancy progresses, cytotrophoblast proliferation slows down, and the trophoblastic cell columns slowly degenerate until they are rarely seen in the term placenta. When columns at the tip of primary villi are not connected to the basal plate, the proliferating cytotrophoblasts are embedded in fibrinoid, forming trophoblastic cell islands.

Spiral arteries and veins that feed the placental bed are critical for maintenance of placental perfusion. The average number of spiral arteries in the term placenta is 100, and that of draining veins is 50–200. Blood flow to the placental bed is ensured by physiological remodeling of utero-placental arteries. In fact, prior to trophoblast invasion, there is already marked disorganization of spiral artery walls, even outside the implantation site, with endothelial vacuolization, disorganized vascular smooth muscle cells, and lumen dilation.[81] Physiological transformation is advanced by the invasion of extravillous trophoblasts near the arterial wall, causing deposition of fibrinoid. In the final stage of remodeling, the walls of the spiral arteries are invaded by endovascular trophoblasts that are derived from interstitial trophoblasts within trophoblastic cell columns.[82,83] These cells invade into the vessel wall media and intima, resulting in fixed-dilated vessels. The process affects the spiral arteries from the decidual end to the inner third of the myometrium, rendering the blood vessels dilated and incapable of constricting in response to vasotonic stimuli. This process seems to be more efficient in the center of the placenta, with reduced efficiency toward the placental margin.[84]

HUMAN PLACENTAL DEVELOPMENT

Developmental Milestones

Understanding key events during early and late placental development is essential in order to evaluate placental support to the developing embryo during different stages of pregnancy. While exceeding the scope of this chapter, important insights into pathologies related to placental function stem from examination of normal placental development. This section summarizes key steps in early and late placental development, delineated using morphological stages. Whereas many studies in this area were performed using human tissues obtained during early or late pregnancy, data using animal models

of pregnancy, including primates, enable physiological studies into development, function, and placental blood flow. Mouse models of pregnancy have been used not only in genetic, molecular, and metabolic studies (discussed further in this chapter) but also in the elucidation of principles underlying placental blood flow. For example, mouse sonographic studies, coupled with computerized tomographic imaging of mouse placental vascular casts, and even dynamic MRI, have helped to characterize placental vascular development and define functional or pathological changes in placental blood flow.[85,86]

The Prelacunar Stage

The extraembryonic trophoblast is the first cell lineage to differentiate during early blastocyst development and prior to implantation. Within 6–7 days after fertilization, the blastocyst attaches to the uterine endometrium (Figure 39.6(A) and (B); see also Chapter 38). At that point, the inner cell mass and blastocele are surrounded by a single layer of mononuclear trophoblasts, with cells overlying the inner cell mass defining the contact point with the endometrium. The trophoblasts that interface with the maternal endometrium fuse with the lateral borders of neighboring cells to form the first multinucleated syncytiotrophoblasts (Figure 39.6(B) and (C)). This process is completed by day 11 after implantation of the human embryo, when a complete syncytium surrounds the fully implanted blastocyst.[3]

The Lacunar Stage

A hallmark of this stage of development, lasting between days 8–12 after fertilization in human pregnancy, is the formation of fluid-filled spaces (lacunas) within the syncytiotrophoblast located at the implantation site (Figure 39.6(C)). These lacunas are the precursor of the intervillous spaces. Concomitantly, the endometrial epithelium regrows to cover the entire site, and the embryo begins to differentiate into defined layers, and is surrounded by a chorionic sac that includes trophoblasts and extraembryonic mesoderm. Formation of the lacunas subdivides the trophoblastic mantle into three major zones: the chorionic trophoblasts near the embryo, which will form the chorionic plate; the lacunar zone, which will develop into the intervillous space; and the trophoblastic shell, which interfaces with the endometrium to form the basal plate. At approximately day 12 of human pregnancy, progenitor extravillous trophoblasts from the chorion invade the three layers, and they extend deeply and laterally into the maternal endometrium (Figure 39.6(D)). These invasive cytotrophoblasts penetrate the uterine glands and cells around and within the spiral arteries, forming the endovascular trophoblast,[78,87] and transform the contractile spiral arteries into noncontractile, constantly dilated arteries,

as described in this chapter. Concomitantly, the syncytiotrophoblast interfaces with the maternal capillaries to form a direct connection between the lacunas and maternal blood, thus forming the intervillous space.[88] Once fully functional, the intervillous space fills with maternal blood and enables hemotrophic support to the embryo.

The Villous Stage

Proliferation within the cytotrophoblastic cores at the wall of the lacunas, along with trabecular elongation and branching, leads to the formation of primary villi, surrounded by the trabeculae that become the intervillous space (Figure 39.6(D–F)). The extraembryonic mesoderm penetrates into the villi to form the villous core, with cytotrophoblasts at the most distal end creating cytotrophoblastic columns, which invade toward the maternal uterine capillaries. The column cells also become a source for renewal of extraembryonic trophoblast. Proliferating hemangioblastic progenitors differentiate within the extraembryonic mesoderm to form the early first fetal capillaries,[42] which remain clogged at this point. Similarly, the trophoblastic columns invade maternal vessels, plugging their distal segments and blocking the maternal and fetal circulation, thus maintaining feto-placental hypoxia until the end of the first trimester.[63,64] The plugs start to lyse by 8–9 weeks of human pregnancy, beginning at the placental periphery and progressing centripetally (Figure 39.7). Perfusion of the placental bed results in increased oxygen tension from less than 10 mmHg to nearly 55 mmHg.[63] Doppler analysis of the intervillous space between 12 and 14 weeks of gestation confirms a fully developed villous tree manifesting a gradual decline in resistance from the umbilical vessels to the chorionic arteries and stem villi. Doppler ultrasound has also confirmed the general progression of intervillous bed perfusion from the periphery to the center, a process that is completed around 20 weeks of pregnancy.[91]

Development of Nonvillous Placental Components

The chorion lining the inner surface of the trophoblastic vesicle develops from the extraembryonic mesoderm on day 14 of human pregnancy, and it is separated at this point from the amnion by the extracoelomic cavity (Figure 39.7(B)). An expansion of the amniotic cavity brings the amnion and chorion together, until the two membranes "fuse" at 11–13 weeks post conception. This process is initiated at the cord insertion site and continues toward complete fusion within several weeks.

The connecting stalk, which is the precursor of the umbilical cord, is formed by mesenchymal cells, and it connects the amnion cavity and the extracoelomic cavity. Fetal blood vessels, which appear in the allantois after the third week of human pregnancy, fuse with the chorionic intravillous vessels to form the feto-placental circulation during the fifth week of human pregnancy. The chorionic plate of the placenta is formed by the proliferation of cytotrophoblasts and degeneration with deposition of fibrin-type fibrinoid. Fetal allantoic vessels fuse with this layer and begin to connect with vessels formed independently within villi. In extraplacental sites, the chorion apposes the maternal capsular decidua. With growth of the fetus and amniotic cavity, these layers fill the entire

uterine cavity by approximately 15 weeks of human pregnancy, forming the attachment of the chorion with the decidua. Maternal–fetal exchange in those membranous sites communicates the fetal compartment through the amniotic cavity, not the placenta. The full thickness of the fetal membranes, which measure 0.25 mm at term, includes the innermost amniotic epithelium, with the subjacent amniotic mesoderm, the chorionic mesoderm, and the outer cytotrophoblast layer.

Molecular Control of Placental Development

Although a detailed description of the molecular processes underlying placental development is beyond the scope of this chapter, this section illustrates key regulators and principles underlying the function of these molecular regulators. Whereas the description in the preceding section focused mainly on human development, most molecular events that shape placental development have been studied in the mouse, where genetic manipulations in vivo provide definitive information on gene function that governs placental development. The mouse not only is a convenient model of genetic manipulations but also features a hemochorial, discoid (albeit labyrinthine) placenta, and many genes that regulate mouse placental development have orthologs in the human placenta. Indeed, more than 80% of genes that cause a phenotype in the mouse placenta are also expressed in the human.[92] Notably, progress in this field was largely made through reverse-genetics studies, where deletion or overexpression of a mouse gene led to an intended or coincidental placental phenotype. Because functional data about these genes in the human placenta are fairly rudimentary, the description here centers on molecular regulation of early mouse placental development. Interestingly, most regulators of mouse placental development identified thus far are not placenta specific. Thus, placental expression of many genes may represent evolutionary changes in promoter usage, the evolution of members of large family genes, or the introduction of genes into the placenta through endogenous retroviruses.[93]

Similar to human development, the first cell lineage committed within the early mouse blastocyst is the trophectoderm, which differentiates from the morula–blastocyst outer cell layer as early as embryonic day (E) 3.5, one day before implantation begins, and will contribute to placental cell lineages.[94,95] Several transcription factors are essential for early trophectoderm differentiation, including caudal-type homeobox 2 (CDX2); eomesodermin (EOMES), which is downstream from CDX2; and transcriptional enhancer factor domain family member 4 (TEAD4), which is upstream of CDX2 and coordinates the expression of CDX2.[96,97] A different set of transcription factors is expressed within the inner cell mass and maintains its cellular pluripotency.[95] The action of CDX2 and EOMES is potentiated by E74-like factor 5 (ELF5). The *Elf5* gene is methylated in the inner cell mass, preventing inner cell mass cells from entering the trophectoderm lineage.[98]

Implantation in the mouse takes place between E4.5 and E8.5 (Figure 39.8). Early proliferation of the polar trophectoderm, which is the trophoblast near the inner cell mass, is stimulated by fibroblast growth factor 4 (FGF), which also regulates CDX2 and EOMES, both essential for the development of trophoblast stem cells.[21] Unlike the human placenta, the mural trophectoderm cells within the blastocyst wall undergo a process of replication of the genome without cell division (endoreduplication) to form the trophoblast giant cells, which are critical for blastocyst attachment, adhesion, and invasion into the decidualized uterine epithelium.[99] The formation of trophoblast giant cells is regulated by several basic helix–loop–helix transcription factors, including HAND1 (heart and neural crest derivatives expressed protein 1) and STRA13 (stimulated by retinoic acid 13) that promote giant cell differentiation, and MASH2 (mammalian achaete scute-like homolog 2), which suppresses their differentiation.[100] The role and function of endoreduplication remain unclear.[101,102] Secondary giant cells differentiate from ectoplacental cone cells. The established mouse placenta has four types of trophoblast giant cells. The first type expresses proliferin (*Plf*) and is found in the wall of the spiral arteries, where it regulates artery remodeling. The second type, the parietal trophoblast giant cells, expresses prolactin family members *Plf*, *Prl3d1*, and *Prl3b1* and is found along the implantation site in direct contact with uterine decidual and immune cells, where it regulates decidualization and maternal–fetal exchange. The third type expresses *Prl3d1* and *Prl3b1*, and is found in the vascular canals, where it regulates vascular physiology. The fourth type expresses *Prl3b1* and cathepsin Q (*Ctsq*), and is located in labyrinthine sinusoids, where it regulates vessel physiology and endocrine function.[103] At late stages of development, the trophoblast giant cells secrete a wide array of hormones and paracrine signals that control pregnancy

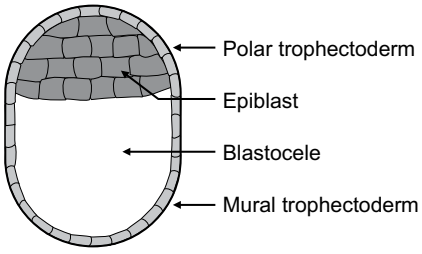

FIGURE 39.8 The blastocyst and the origin of trophoblastic cell lineage. A schematic that represents mouse embryonic day 4.5, or human embryonic day 6–7.

adaptation through regulation of vascular tone, angiogenesis, and diverse physiological functions.[103,104]

A number of genes are involved in the development and maintenance of the ectoplacental cone trophoblast and its differentiation into spongiotrophoblasts. Some of these gene products are hypoxia-responsive genes, such as the aryl hydrocarbon receptor nuclear translocator (ARNT), which partners with hypoxia-inducible factor 1 to regulate gene expression. Hypoxia or deletion of *Arnt* results in reduced spongiotrophoblast size.[100] A key player in spongiotrophoblast development is trophoblast-specific protein alpha (TPBPA, also known as, 4311). TPBPA is expressed in the early ectoplacental cone, with later expression restricted to the spongiotrophoblasts.[105] Leukemia inhibitory factor and MASH2 are critical for trophoblast giant cell differentiation into spongiotrophoblasts, and HAND1 regulates differentiation of giant cells derived from the mural trophectoderm and the ectoplacental cone.[101,106] While the precise role of spongiotrophoblasts remains to be established, this layer, which lies between the parietal trophoblast giant cells and the labyrinth, harbors specific secretory cells, such as glycogen trophoblast cells. Differentiation of more specialized cells within the spongiotrophoblast is largely unknown. Insulin-like growth factor 2 (IGF2) and the cyclin-dependent kinase 2 (P57Kip2) promote differentiation of spongiotrophoblasts into glycogen cells.[100,107]

By E8.5, the allantois comes into contact with the chorion beneath the ectoplacental cone, forming the initial blood vessel precursors. This event marks the beginning of labyrinth formation.[108] The labyrinthine zone is analogous to the human villous tree and largely mediates the maternal–fetal exchange.[107] Notably, the labyrinthine trophoblast has three layers of trophoblasts, with two inner layers of syncytiotrophoblast and an outer interrupted layer of cytotrophoblast. Glial cells missing homolog 1 (GCM1) is essential for labyrinth formation and syncytialization, with deletion resulting in midgestation death due to failure of labyrinth development.[21] Many other genes are involved in murine labyrinth formation and maintenance, such as extraembryonic, spermatogenesis, homeobox 1 homolog **(***Esx1*); peroxisome proliferator-activated receptor gamma (*Pparg*); retinoid X receptors (*Rxrs*); the Jun B proto-oncogene (*JunB*); retinoblastoma (*Rb*); and the enzymes argonaute2 (*Ago2*) and *p38*.[100,107]

Placental hormones are critical for the regulation of placental development and function. For example, chorionic gonadotropins control progesterone production, endometrial receptivity, and other essential functions.[93] Members of the prolactin family stimulate growth and lactogenic activity, and they promote placental blood flow and other aspects of adaptation to pregnancy.[104] The interferon-τ (*Ifnt*) gene regulates the production of progesterone from the corpus luteum by suppressing luteolytic signals.[109]

Diverse epigenetic, imprinting, and micro-RNA (miRNA) pathways are also critical for placental development. Genomic imprinting is a process by which one allele is epigenetically silenced in a parent-of-origin manner, and it commonly occurs through methylation, histone modification, or an RNAi mechanism. There are more than 100 imprinted genes in the human or mouse genome. Many of them are expressed in the placenta and regulate placental development and function.[110,111] In general, the parental conflict theory postulates that paternally expressed genes are designed to stimulate fetal growth, whereas maternally expressed genes tend to limit nutrient supply to the embryo in order to preserve maternal reproductive sources.[111,112] As the placenta governs transport functions that are essential for fetal growth, it is not surprising that general changes in imprinting patterns impact fetal growth.[113–115] Altered expression of selected imprinted genes that regulate placental thickness, surface area, or vascularity (e.g., *Igf2*; the maternally imprinted H19 long intergenic noncoding RNA (lincRNA); growth factor receptor-bound 10 (*Grb10*); and pleckstrin homology-like domain, family A, member 2 (*Phlda2*)) affect passive diffusion or transporter-mediated properties of the placenta, impacting fetal–placental weight (termed "placental efficiency").[116,117] Nonetheless, the correlations of placental morphology with fetal size are inconsistent, with enlarged placentas that are not associated with larger embryos in *H19-*, *Phlda2-*, and placenta-specific 1 (*Plac1*)-null mice, and smaller placentas in *Igf2P0*-null mice associated with efficient placental function, characterized by the upregulation of glucose transporters.[117] In addition, temporal or spatial expression patterns of imprinted genes may vary between biallelic expression to monoallelic expression during pregnancy.[117] Lastly, imprinted genes are commonly responsive to changes in the environment, with influences such as culture medium during in vitro fertilization, and protein and alcohol consumption, markedly affecting placental gene expression.

Similar to many other organs and tissue types, the placenta expresses diverse types of small noncoding RNAs. Among these species, miRNAs are the most abundant and represent the best characterized class.[118,119] Generally, miRNAs function coordinately in fine-tuning the expression of mRNAs and proteins that shape development and physiology. Further supporting the role of miRNAs in placental development, a mutation in mouse *Ago2*, which disables the miRNA processing machinery, causes reduced labyrinth formation and fetal growth restriction, resulting in embryonic lethality.[120] Other miRNA biogenesis proteins are expressed in human placental trophoblasts and may be germane for placenta development, yet mice deficient in these proteins exhibit

developmental defects that precede placental formation, impeding research into their role in the placenta. Although the function of most placental miRNA remains to be determined, certain patterns have emerged, including the expression of three miRNA clusters—the chromosome 19 miRNA cluster (C19MC), the chromosome 14 miRNA cluster (C14MC), and miR-371-3—which dominate the placental miRNA landscape.[121] Processes that occur in the placenta during the first trimester, such as trophoblast proliferation, migration, and invasion, are shaped by miRNA expression.[122] Specific examples include miR-378a-5p, which targets Nodal, an inhibitor of trophoblast proliferation, migration, and invasion[123]; and miR-148 and miR-152, which regulate human leukocyte antigen G expression.[124] H19, which is located in chromosome 7 in the mouse and in 11p15.5 in the human, regulates fetal and placental growth. This locus also expresses miR-675, which is expressed from the mouse placenta in late gestation (after E15.5) and attenuates cell proliferation. A deletion of miR-675 in mice increases placental size, likely acting through silencing growth-promoting IGF1 receptor (*Igf1r*).[125] Interestingly, miR-675 excision from H19 is regulated by the RNA-binding protein, human antigen R, which, in turn, is regulated by the placenta-specific miR-519.

The most abundant family of all human placental miRNAs is C19MC.[118,126] This primate-specific cluster is located on chromosomal region 19q13.41 and encodes 46 highly related miRNAs within a ~100 kb region of genomic DNA.[127] The expression of the C19MC cluster is imprinted, with expression from the paternally inherited chromosome that is regulated by a CpG-rich region located ~17 kb upstream of C19MC.[128] Although the function of the C19MC in the placenta remains to be determined, the unique abundance and regulation of placental C19MC miRNAs suggest an important role in trophoblast biology.

Unlike the insignificant role of the human yolk sac after week 10, the mouse yolk sac enlarges rapidly and forms the inverted yolk sac placenta. Early yolk sac development is influenced by the ligands FGF and retinoic acids, and the transcription factors GATA binding protein 6 and sex-determining region Y (Sry)-box 17.[129] After segregation to the primitive endoderm and epiblast, the primitive endoderm gives rise to the parietal endoderm and visceral endoderm components of the yolk sac. The parietal endoderm governs transport functions between the uterine wall and the yolk sac, and is in direct contact with the Reichert membrane, which separates the parietal endoderm from the trophoblast giant cells.[130] The visceral endoderm contributes to the intraplacental and visceral yolk sac, which is formed at E7.5 and is in direct contact with the extraembryonic mesoderm to facilitate the transport of gases, nutrients, and waste between the mother and the fetus. The mouse yolk sac remains important for protein and sterol metabolism until term.[131]

METHODS TO STUDY PLACENTAL TRANSPORT FUNCTIONS

Considering the ethical limitations on experiments in pregnant women, most mechanistic studies are based on in vitro approaches such as cultured primary human trophoblasts from the three trimesters of pregnancy, placental cell lines, and human placental explants. While clearly important, these approaches do not capture the complexity of perfusion and transport functions. Moreover, unlike most metabolically active tissues that involve the processing and partitioning of nutrients and metabolic products between tissues and blood, the placenta harbors two distinct yet intertwined circulatory systems, fetal and maternal. Placental transport and metabolic function are at the interface of two systems. Complexity is increased by the ongoing anatomical and physiological changes that occur in each of the two compartments during pregnancy, and the existence of potential competition for limited resources between the mother and the fetus. Thus, optimal pregnancy outcome depends on a homeostatic balance among metabolically active tissues within the mother and, separately, within the fetus. It is therefore clear that in vivo as well as ex vivo systems that capture the placental dual-perfusion system are critical for adequate examination of placental transport function. Such systems span diverse animal models, including genetically modified mice, ex vivo perfused placental cotyledons from humans, and ex vivo perfused mouse placentas. While the characteristics of the maternal–fetal interface are most helpful in order to understand the function of the placental interface, it should not be assumed that the mere structure, the number of layers, the blood flow, or the animal's location on the evolutionary tree, as discussed in this chapter, implies transport efficiency. It also seems simplistic to assume that placental "efficiency" can be measured in terms of a feto-placental weight ratio, which is nearly 7:1 in the human but more than 10:1 in the mouse. The following sections in this chapter summarize key observations based on single or combined approaches to analysis of placental transport function.

BASIC CONCEPTS IN MATERNAL–FETAL EXCHANGE

Pathways of Placental Transfer: Transtrophoblastic Channels

Substances can be transferred across epithelial barriers either between cells via intercellular water-filled spaces

(paracellular transport) or through cells (transcellular transport). In classical epithelia, such as the kidney and intestine, paracellular ion and solute transport is largely controlled by dynamic regulation of the permeability of tight junctions, which are multiprotein complexes connecting the apical ends of adjacent columnar epithelial cells. However, because the syncytiotrophoblast is a true syncytium, no intercellular spaces exist in the transporting epithelium of the human placenta. Thus, it is suggested that the term "transtrophoblastic channels", rather than "paracellular channels", be used for water-filled channels traversing the syncytiotrophoblast. The existence of transtrophoblastic channels is supported by physiological data obtained in several species with hemochorial placentas, demonstrating that the transplacental flux of small inert hydrophilic molecules is proportional to their water diffusion coefficients (reviewed in Ref. 132). This relationship can be accounted for by the presence of water-filled channels that are continuous with the fluid on both sides of the syncytium. Furthermore, evidence of transfer of large molecules such as alpha-fetoprotein[133] and horseradish peroxidase[134] across placental cotyledons perfused in vitro, and the recovery of fetal lymphocytes and other fetal blood cells (reviewed in Ref. 135) in the maternal circulation in vivo, are consistent with the existence of transtrophoblastic channels. On the other hand, the ability of the syncytiotrophoblast to generate and maintain significant concentration differences for a large number of molecules across the placental barrier, including Ca^{2+} and amino acids, strongly suggests that the total area occupied by water-filled channels traversing the syncytium is very small. Therefore, the primary route of transport across the placental barrier for nutrients and important ions is transcellular, in most cases mediated by specific transport mechanisms.

Importantly, for molecules that are actively transported to the fetus, the presence of transtrophoblastic channels tends to decrease net transfer by allowing a "back flux" of molecules to the maternal circulation. Furthermore, the direction of the hydrostatic pressure gradient in the human placenta in vivo is in the fetal-to-maternal direction,[136,137] resulting in a hydrodynamic water flow toward the mother. Thus, net flux from the mother to the fetus through water-filled channels requires a significant concentration difference between maternal and fetal blood as a driving force for diffusion to overcome the back flux toward the mother. The structural correlate to the transtrophoblastic channels remains elusive, yet it is possible that temporary breaks in the syncytial barrier constitute the water-filled pathway supported by the functional data. Such breaks are likely to occur in the human placenta, given the extreme thinness of the barrier in terminal villi and the mechanical forces it is subjected to by maternal blood entering the intervillous space from the spiral arteries. Indeed, trophoblastic denudations associated with fibrin deposits may be the result of such temporary breaks in the barrier.[133]

Pathways of Placental Transfer: Transcellular Transport

Maternal–fetal exchange via the transcellular route involves transfer across the two polarized plasma membranes of the syncytiotrophoblast. The transfer of a molecule across the placental barrier can be limited by the rate of blood flow on the two sides of the barrier ("flow-limited" transport) and/or by diffusion across the barrier itself ("diffusion-limited" transport). For example, the transfer of oxygen across the placental barrier is blood flow-limited because it is a small molecule with high lipid solubility, allowing rapid diffusion across the syncytiotrophoblast and fetal capillary endothelium. As a result, even short-lasting reductions in placental perfusion may affect fetal oxygenation. In contrast, the transfer of nutrients such as glucose and amino acids is predominantly diffusion-limited by the transport properties of the barrier itself. For molecules with flow-limited transport, there are generally no specific transporters in the barrier, and the transport is characterized as "nonmediated". On the other hand, for most molecules with diffusion-limited transport, there are specific transporters, binding proteins, or receptors that are expressed in the syncytiotrophoblast plasma membranes or cytosol, which increase the rate of transfer ("mediated transport").

Nonmediated Transport

The rate of transplacental transport of molecules that lack specific transport mechanisms is dependent on the physical and chemical properties of the molecules, in particular their charge, size, lipid solubility, and degree of protein binding. Thus, electrical charge, low lipid solubility, a high degree of protein binding, and high molecular weight are all molecular properties that impede passive diffusion between the two blood circulations. The same physical–chemical properties govern the nonmediated transfer of pharmaceutical drugs across the placental barrier. For example, oral anticoagulants such as dicumarol have relatively low molecular weights and cross the placental barrier quite readily, whereas heparin, which is a charged molecule with a high molecular weight, is hardly transferred across the barrier. Nonetheless, many drugs are subjected to mediated uptake, metabolism by cytochrome 450 enzymes, and/or extrusion from the syncytiotrophoblast by efflux pumps such as P-glycoprotein, limiting the value of physical–chemical properties in predicting placental drug transfer.

Mediated Transport

The transplacental transfer of most nutrients and ions is mediated by specific transport mechanisms. When mediated transport does not require energy expenditure, the transport is termed "facilitated transport" or "facilitated diffusion". The term "active transport" implies that energy is consumed, either directly (primary active transport) or indirectly (secondary or tertiary active transport). The most common pathway for mediated transport in the placental barrier is the presence of transporter proteins in the syncytiotrophoblast plasma membranes. Maternal–fetal glucose transfer is an example of facilitated transport, mediated by facilitative glucose transporters expressed in the MVM and BM of the syncytiotrophoblast. Calcium efflux across the BM, mediated by Ca^{2+}-ATPase, is an example of primary active transport. Na^{+}-dependent transport systems for amino acids, such as System A, represent a secondary active transport mechanism. Transplacental transport may also be facilitated by the expression of receptors in the MVM (e.g., the transferrin receptor, which binds the transferrin–iron complex in maternal blood, thereby facilitating the placental uptake of iron) or binding proteins in the syncytiotrophoblast cytosol (such as fatty acid–binding proteins).

Endocytosis–Transcytosis

This process constitutes a special form of transport, which involves intracellular vesicle formation by invagination of the plasma membrane on one side of the syncytiotrophoblast. Subsequently, vesicles may be transported to the opposite side of the cell, where the vesicle content can be released into the extracellular space following fusion of the vesicles with the plasma membrane. Endocytosis and transcytosis can be nonmediated in that vesicles are formed at the plasma membrane incorporating fluid and any dissolved solute (fluid-phase endocytosis). Vesicles can be transferred across the syncytium via Brownian movement. Mediated endocytosis involves the binding of a specific ligand to a receptor in the plasma membrane, which initiates the invagination of the plasma membrane. In addition, for mediated endocytosis, vesicle transfer across the cytoplasm may be facilitated and guided by specific cytoskeletal components. Endocytosis–transcytosis plays an important role in the transplacental transfer of immunoglobulin G (IgG), iron, and lipoproteins.[138]

Placental Micro- and Nanovesicles

Located at the surface of the placenta and bathed in maternal blood, the trophoblast that overlays the basement membrane and fetal capillary endothelial cells is positioned to mediate the crucial cross-talk between the maternal host and the semiallograft fetus. In addition to the release of hormones, growth factors, and other trophoblastic peptides, the microvillous membrane of the syncytiotrophoblast produces micro- and nanoparticles of diverse sizes, which are released into the maternal circulation. This shedding process may be enhanced in conditions associated with disruption of the microvillous membrane surface, such as preeclampsia (Figure 39.9).[139] The released materials include large trophoblastic fragments, single cells and syncytial knots (size generally >1 μm), apoptotic bodies of diverse sizes, microvesicles (0.15–1 μm), exosomes (40–150 nm), and nonpackaged molecules.[140] While the precise content of each of the vesicles remains to be determined, many of these vesicles seem to participate in immune signals.[141,142] Notably, exosomes are known to harbor a significant fraction of plasma miRNAs, which recently emerged as mediators of intercellular communication.[143,144] Selected placenta-specific miRNA species are found in the maternal circulation during pregnancy, and their levels rapidly decline in the first 24 h postpartum.[126,145] Pregnancy-related changes in circulating

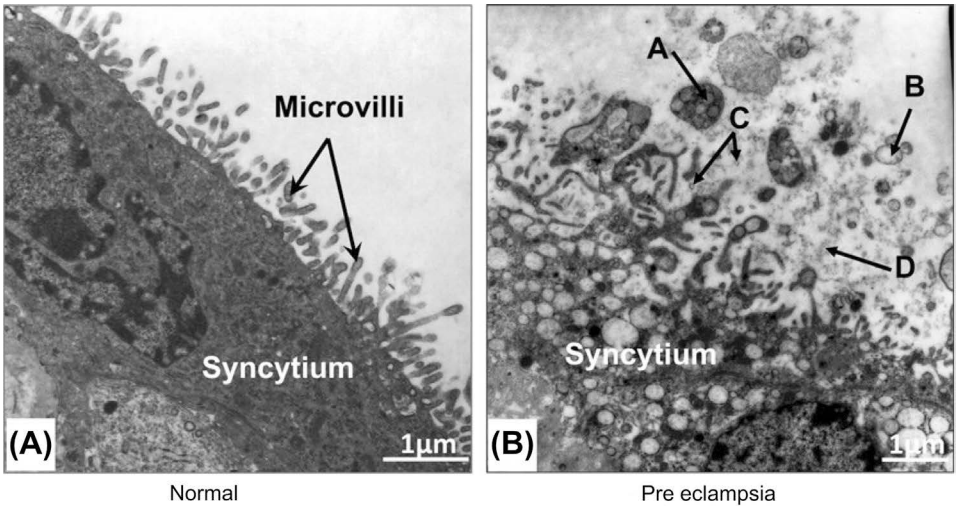

FIGURE 39.9 Ultrastructure of normal and preeclamptic syncytial microvillous plasma membrane (MVM) surface. Panel (A): Normal term syncytium showing a regular MVM. Panel (B): Syncytium from a pregnancy complicated by severe preeclampsia, showing loss of surface integrity, distorted microvilli, and shedding of debris ranging from (A) large cellular fragments containing swollen endoplasmic reticulum characteristic of apoptotic bodies, to (B) microvesicles, (C) exosomes, and (D) fine cellular material. *Reproduced with permission from Ref. 139.*

placental miRNAs are not uniform, with miR-526a increasing by 700-fold between nonpregnant women and those in the third trimester of pregnancy, but only by 2.8-fold for miR-518e.[145,146] During the first trimester of pregnancy, trophoblast exosomes may contribute to the establishment of maternal immune tolerance, possibly via impaired T-cell signaling, downregulation of natural killer (NK) cell receptor NKG2D, and enhanced apoptotic pathways through Fas ligand, tumor necrosis factor (TNF)-related apoptosis-inducing ligand, and programmed cell death protein.[118,141,147] Whereas the transport of free miRNAs or exosome-packaged miRNAs between trophoblasts and the maternal blood is direct, transport of miRNA between the fetus and the placenta, or from the fetus through the placenta into the maternal circulation, is more intricate and involves passage through fetal capillary endothelial cells, the basement membrane, and trophoblasts.

Factors Influencing Placental Transfer: An Overview

In general, the rate of transport across the placental barrier is determined by the driving forces and the characteristics of the barrier. The extent to which these factors influence net transfer is highly dependent on each specific molecule. Differences in concentrations (ΔC) and electrical potential ($\Delta\Psi$) constitute the driving forces for nonmediated and facilitated diffusion, even though potential differences affect only molecules with an electrical charge. Water transfer via transtrophoblastic channels and the transcellular route is driven by osmotic ($\Delta\pi$) and hydrostatic pressure differences (ΔP). Water moving through transtrophoblastic channels (bulk flow) also carries solutes (often referred to as "convection"). Finally, the driving force for active transport is ATP hydrolysis.

In many species, there is an electrical potential difference between the maternal and fetal extracellular fluids (reviewed in Refs 132,148). The source of this potential difference is not entirely clear, yet evidence suggests that two oppositely oriented electrical currents, one across the placenta and the other across the decidua, generate the net maternal–fetal potential difference (PD_{mf}).[132] The transplacental potential difference is a result of active ion transport, which is the predominant transport mechanism for all main ions. The recorded PD_{mf} is significant in some species, such as the goat (−80 mV, sign indicating the polarity of the fetus with respect to the mother), the sheep (−40 mV), and the rat (+15 mV). In contrast, the PD_{mf} in the human is small (−2.7 mV) in midgestation and close to zero at term. Because the PD_{mf} is generated by the sum of the placental and decidual currents, this measurement may not provide accurate information with respect to the local potential differences at the placental barrier. In addition, potential differences across individual components of the placental barrier affect the flux of charged molecules. For example, the potential difference across the syncytiotrophoblast microvillous plasma membrane in vitro was recorded to be −32 mV early in the first trimester and −21 mV at term.[149]

The barrier properties that may influence the transfer rate of molecules are illustrated in Figure 39.10. In the term human placenta, there are only two complete cell layers separating the fetal and maternal circulations: the syncytiotrophoblast and the fetal capillary endothelial cell. Fetal capillaries in the placenta are of the continuous type, allowing the unrestricted passage of molecules of the size of glucose and amino acids between cells through intercellular spaces but partly restricting the transfer of large molecules such as immunoglobulins.[150] As described in this chapter, the syncytiotrophoblast is the main transporting epithelium of the human placenta. While in early pregnancy the cytotrophoblasts form a continuous cell layer between the syncytium and the fetal capillaries, in late pregnancy the cytotrophoblasts are relatively sparse (Figure 39.10), establishing a central role of the syncytiotrophoblast MVM and BM in determining transport.

The overall rate of transfer of a molecule is proportional to the total effective exchange surface area (Figure 39.10, #1). Thus, the villous surface area is an important determinant of placental transport capacity. Additionally, changes in blood flow influence the available effective exchange surface area, because inadequate blood flow on both sides of the barrier will lead to ineffective exchange. The passive properties of the MVM (Figure 39.10, #2) and BM

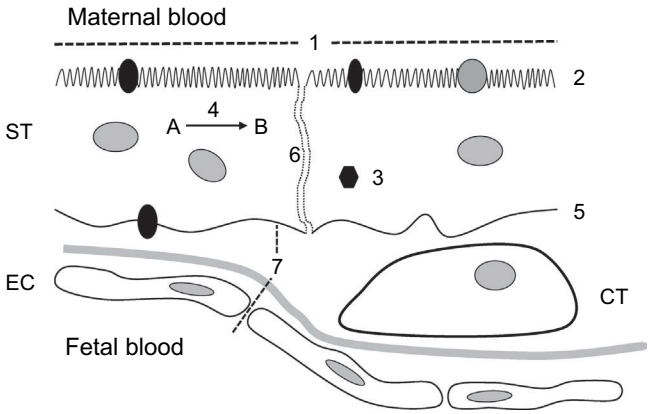

FIGURE 39.10 Properties of the placental barrier that may influence the overall transfer rate. See text for details. ST: syncytiotrophoblast; CT: cytotrophoblast; EC: endothelial cell.

(Figure 39.10, #5), such as lipid composition and fluidity, are important determinants for nonmediated transport. The thickness of the villous membrane (i.e., the distance between the maternal and fetal blood) also influences placental diffusing capacity.[151] During gestation, the thickness of the villous membrane gradually declines principally due to expansion of the fetal capillary bed, a process that is associated with increased diffusing capacity.[152,153] The expression and activity of transporters (e.g., glucose transporters), channels (e.g., calcium channels in the MVM), enzymes (e.g., MVM lipoprotein lipase), and receptors (e.g., transferrin receptor in MVM, mediating iron uptake) in the MVM and/or BM are critical for mediated transport. Indeed, for most substances, the movement across the MVM and/or BM is the rate-limiting step in transplacental transfer. These transmembrane transport steps are also highly regulated. For some molecules, including fatty acids and Ca^{2+}, the presence of cytosolic binding proteins (Figure 39.10, #3) is essential for facilitated transfer across the syncytiotrophoblast. An additional property of the placental barrier that may influence the overall transfer rate of some molecules (e.g., glucose, lactate, and amino acids) is metabolic interconversion or catabolism within the syncytiotrophoblast (Figure 39.10, #4). Transtrophoblastic channels (Figure 39.10, #6) may mediate maternal–fetal exchange of water and solutes. Finally, molecules delivered to the fetal side of the syncytium must move across the basement membrane and capillary endothelium (Figure 39.10, #7).

PLACENTAL TRANSPORT OF SPECIFIC MOLECULES

Oxygen

Oxygen is critical not only as a substrate in fetal–placental oxidative metabolism but also for placental growth, invasiveness, and regulation of trophoblast gene expression. In response to long-term experimental reduction of umbilical blood flow or maternal hypobaric hypoxia, the fetal sheep becomes hypoxemic and growth restricted, suggesting that limited oxygen supply restricts fetal growth.[154] This hypothesis is difficult to prove because interventions to produce fetal hypoxemia likely alter a multitude of other factors, including placental blood flow, nutrient delivery, and carbon dioxide removal. However, studies in chick embryos, a model in which the effects of changes in oxygenation on the fetus can be investigated in isolation, have confirmed a role for oxygen supply in the regulation of fetal growth.[155]

Placental oxygen transfer is limited by blood flow rather than by diffusion across the barrier, because oxygen is rapidly transferred from maternal to fetal blood due to the high permeability of the placental barrier to respiratory gases. Although direct evidence for this assumption in the human is lacking, experimental support for flow limitation of maternal–fetal oxygen transfer is observed in sheep (reviewed in Ref. 154). Collectively, these studies demonstrated that umbilical oxygen delivery was linearly related to blood flow in response to acute reductions in either umbilical or uterine blood flow. Importantly, the fetus maintained oxygen consumption by increasing fetal fractional oxygen extraction, resulting in a lower umbilical arterial pO_2. This compensatory mechanism is of major physiological importance during labor and physical exercise, where short periods of reduced blood flow reduction are common. In response to chronic blood flow reduction, however, fetal sheep were not able to maintain normal oxygen consumption, which was associated with decreased fetal growth rate.[154] Because O_2 transfer is flow limited, the geometry of placental blood flow influences the efficiency of transport (reviewed in Refs 156,157). The types of geometric arrangement of blood flow on either side of the placental barrier, as discussed in this chapter, may explain differences in oxygen transfer efficiencies among species.

Net transfer of oxygen in the maternal–fetal direction is facilitated by a marked difference in pO_2 between maternal and fetal blood. This difference is large when comparing pO_2 in maternal arterial blood (100 mmHg) and in the umbilical vein (approximately 34–41 mmHg at the end of pregnancy).[158,159] This large pO_2 gradient cannot be attributed to restriction of oxygen diffusion across the placental barrier, but is likely to be due to the mixing of "arterial" and "venous" blood in the intervillous space, resulting in a pO_2 at the maternal side of the exchange barrier that is much lower than in maternal arterial blood. Furthermore, it has been estimated that as much as 40% of uterine oxygen uptake is consumed by the placenta itself,[160] which further contributes to the maternal–fetal gradient. Other factors that facilitate the movement of oxygen in the maternal–fetal direction are higher hemoglobin concentrations in fetal blood, resulting in a significantly higher oxygen carrying capacity, and a higher affinity of fetal hemoglobin (HbF) for oxygen compared to maternal hemoglobin (HbA). The higher oxygen affinity of HbF is due to its lower affinity to 2,3-diphosphoglycerate, causing a left shift in the oxygen–hemoglobin dissociation curve.

Many vascular beds (such as the brain, muscle, or kidney) are characterized by extensive local autoregulation, which can modify blood flow in response to changes in either oxygen delivery or demand. There is little evidence supporting significant autoregulation or reactive hyperemia in the placental circulation. Short-term regulation of placental oxygen transfer is therefore limited to changes in fetal oxygen extraction and, to some extent,

decreased affinity of hemoglobin for oxygen when CO_2 is bound (the Bohr effect). Long-term regulation involves increased hematocrit (polycythemia) in fetal blood in response to hypoxemia, which will increase the oxygen carrying capacity. However, increased red blood cell mass may result in elevated viscosity, increased peripheral resistance, and decreased blood flow, curtailing any advantages with increased erythrocyte volume.

Acid–Base: Carbon Dioxide, Protons, and Lactate

The fetus relies on the placenta for regulation of its acid–base balance. This delicate balance is mainly dependent upon the exchange of carbon dioxide, protons, and lactate across the placental barrier (Figure 39.11).

Carbon Dioxide

The fetus and the placenta continuously produce large amounts of carbon dioxide as a result of oxidative metabolism. In postnatal life, CO_2 is readily eliminated via the lungs. It is also in equilibrium with carbonic acid, which can rapidly produce protons. In the context of fetal acid–base balance, CO_2 is characterized as a "respiratory acid". Bicarbonate transporters are unlikely to have a major role in placental CO_2 elimination, which primarily takes place as diffusion of dissolved gas. Carbon dioxide is highly soluble in lipids. Transplacental transfer of CO_2 is therefore believed to be blood flow limited. Due to mild physiological hyperventilation of pregnancy, arterial partial pressure of carbon dioxide (pCO_2) is lower in pregnant women (26–34 mmHg) when compared to nonpregnant women (38–42 mmHg). Umbilical vein pCO_2 at term ranges from 38 to 45 mmHg, providing a substantial diffusion gradient that promotes fetal–maternal CO_2 transfer. Blood CO_2 is predominantly present as H^+ and HCO_3^- ions. Some CO_2 is associated with deoxygenated Hb, as carbamino–Hb, and only a small amount is dissolved. In the placenta, CO_2 is eliminated across the placental barrier, and this process is facilitated by conversion of H^+ and HCO_3^- to CO_2, a reaction catalyzed by the action of carbonic anhydrase expressed in erythrocytes, endothelial and trophoblast cells. Reduced placental and/or umbilical blood flow may cause respiratory acidosis, which is normalized following the reestablishment of adequate blood flows. Oxygenation influences placental CO_2 transfer because binding of oxygen decreases the affinity of hemoglobin to bind CO_2.

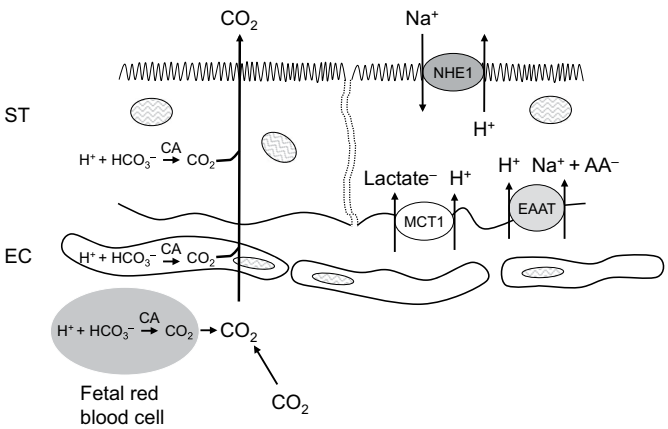

FIGURE 39.11 The role of the placenta in fetal pH regulation: transport of CO_2 and protons. Carbon dioxide readily diffuses across the placental barrier as dissolved gas. Metabolically produced protons are eliminated across the placenta, mediated by H^+–lactate co-transport in the BM, which is, in turn, mediated by MCT1, followed by extrusion of protons in exchange for sodium across the MVM and mediated by the sodium–proton exchanger (NHE). It is also possible that excitatory amino acid transporters (EAAT), which are known to co-transport Na^+, H^+, and anionic amino acids, contribute to the transfer of protons across the BM. MCT1: monocarboxylate transporter 1; CA: carbonic anhydrase; ST: syncytiotrophoblast; EC: endothelial cell.

Protons

Acid equivalents produced by fetal metabolism cannot be eliminated by transfer of CO_2 across the placenta, but require movement of protons from the fetal to the maternal circulation. Although transport of bicarbonate in the opposite direction could alleviate a proton load, a transport mechanism mediating bicarbonate transfer in the maternal-to-fetal direction remains unknown. The sodium–proton exchanger (NHE) is the most important placental transporter involved in acid–base regulation. There are at least nine distinct human NHE genes (NHE1/SLC9A1–NHE9/SLC9A9, where SLC9A9 is solute carrier family 9, subfamily A, member 1). This family of transporters is involved in a host of physiological processes that include not only the removal of intracellular protons in exchange for sodium but also the regulation of cell volume, proliferation, and apoptosis. NHEs are highly active in the MVM,[161] mediating the export of protons from the syncytial cytosol into maternal blood (Figure 39.11). Studies in villous fragments ex vivo have confirmed that NHE is critical for maintenance of intracellular pH in the syncytiotrophoblast.[162] Pharmacological[163] as well as protein expression data[164,165] suggest that NHE1 is the major isoform expressed in the MVM, with lower expression of NHE2 and NHE3.[164] NHE activity has been reported to be absent from the BM,[166] consistent with a very low expression of NHE1–3 in this membrane.[164] Studies in term villous fragments have demonstrated that placental NHE is activated by epidermal growth factor, sphingosine-1-phosphate, aldosterone, and cortisol.[167,168] Estrogen is known to decrease placental NHE3 expression and activity in the baboon.[169]

Lactate

Lactate is an important energy source in the fetal heart, brain, and skeletal muscle. Fetal levels of lactate

are higher than maternal levels. The placenta may be a source of lactate even when oxygen supplies are adequate. However, the placenta is also an important site for clearance of fetal lactate, especially in cases of fetal hypoxia. Lactate is transported across cell membranes by members of the monocarboxylate transporter (MCT) family (SLC16), which mediate H^+–lactate co-transport. Both the MVM[170] and BM[170] efficiently transport lactate in the presence of a proton gradient. The predominant MCT isoform in the MVM is MCT4, whereas MCT1 is the main form in the BM.[170]

It is believed that the primary route for placental elimination of metabolically produced protons by the fetus involves H^+–lactate co-transport across the BM, followed by extrusion of protons in NHE-based exchange for sodium across the MVM (Figure 39.11). It is also possible that excitatory amino acid transporters, which are active in the BM,[171] contribute to the transport of protons from the fetal compartment into the syncytiotrophoblast across the BM. These transporters mediate the cellular uptake of anionic amino acids, coupled to the co-transport of Na^+ and H^+.

Sodium, Potassium, Iodide, Chloride, and Bicarbonate

Sodium

Sodium is the predominant extracellular cation. The osmotic pressure produced by this ion is an important determinant of extracellular volume. Sodium transport across epithelia typically involves passive entry across the apical membrane by several mechanisms, and an active efflux step across the basolateral membrane mediated by Na^+K^+–ATPase. Placental sodium transport fits this general model, with several unique characteristics. A large number of Na^+-dependent co-transporters are active in the MVM. These transporters utilize the inwardly directed sodium gradient across the MVM to energize the co-transport of amino acids (Table 39.2), phosphate, biotin, and succinate, or the efflux of molecules such as protons via exchange mechanisms. Akin to other cells, low intracellular sodium concentrations in the syncytiotrophoblast are maintained by Na^+K^+–ATPase. However, unlike typical epithelia in which the sodium pump is expressed exclusively in the basolateral plasma membrane, Na^+K^+–ATPase is expressed and active in both the BM and MVM[174] of human syncytiotrophoblasts. It has been proposed that excessive Na^+ efflux across the BM may result in overhydration of the fetal compartment, resulting in elevated blood pressure or polyhydramnios.[174] Therefore, the sodium gradient that drives nutrient and ion uptake and waste removal is counterbalanced by an efficient Na^+K^+–ATPase-dependent, MVM-based mechanism that returns sodium to the maternal compartment and maintains the gradient. Although this model remains hypothetical in the human placenta, there is significant experimental support for the presence of a similar mechanism in the rat placenta.[132]

Potassium

Potassium is the main intracellular cation. Na^+K^+–ATPase constitutes the primary pathway by which K^+ is taken up into many cells, including syncytiotrophoblasts. Potassium is believed to exit the syncytium passively through a large number of different potassium channels that are present in the syncytiotrophoblast membranes,[198,199] driven by the large outwardly directed electric and concentration gradient. It is unclear which of these channels participate in transplacental K^+ transport across the MVM and BM.

Chloride

Chloride is the main extracellular anion. It is transported across plasma membranes in a process mediated by multiple mechanisms, including exchange with bicarbonate or through channels. Chloride uptake is also

mediated by co-transport with Na^+ and can leave cells by co-transport with K^+. A wide range of chloride transporters and channels are expressed in the MVM. Far less information exists regarding chloride transport through the BM. The anion exchanger 1 (AE1, SLC4A1) is present in the MVM throughout gestation[200–202] but not in the BM.[201] Electrophysiological studies using isolated human villi, as well as experiments with reconstituted liposomes, have provided evidence for a high-conductance ("maxi") chloride channel in the MVM.[203,204] Intermediate diphenylamine-2-carboxylic acid (DPC inhibitable) and small protein kinase A–ATP–cAMP-activated chloride channels have also been identified in the MVM. Additional MVM chloride channels include CLI5, cystic fibrosis transmembrane regulator, and multidrug resistance protein 1 (MDR1) P-glycoprotein. The physiological roles and mechanism of action of these chloride transporters and channels remain unclear. It is highly unlikely that net transplacental chloride transport is mediated by passive transport via transtrophoblastic channels, because chloride concentrations are 5 mM higher on the fetal side of the barrier, fetal side is slightly negative,[132] and the direction of the hydrostatic pressure gradient in the human placenta in vivo is in the fetal-to-maternal direction.[136,137] Thus, the concentration and electrical gradients as well as hydrodynamic water flow toward the mother through the transtrophoblastic channels would all favor passive chloride movement in the fetal–maternal direction.

Bicarbonate

Bicarbonate transporters are members of the SLC4 family as well as the SLC26 SLCA family of sulfate transporters, some of which also transport bicarbonate. Based on protein expression and functional data, AE1 (SLC4A1), a transporter that exchanges chloride for bicarbonate is present in the MVM[200,201] but not in the BM.[201] Given the intracellular and extracellular concentrations of chloride and bicarbonate and the MVM localization of AE1, this transporter is predicted to mediate chloride entry into the syncytium and bicarbonate efflux into the maternal blood. However, the physiological function of transport of bicarbonate to the maternal circulation is unclear.

Iodide

Iodide transfer from the mother across the placenta is essential for fetal thyroid hormone production, and likely begins early in the second trimester. The mechanisms responsible for placental iodide transport remain to be fully established, but likely involve uptake across the MVM, mediated by the sodium iodide symporter (NIS, also known as SLC5A5), which is expressed in the placental MVM[205] and in cultured trophoblasts.[205] Pendrin (SLC26A4), a Cl^-–OH^-–HCO_3^- exchanger that also transports iodide, is expressed in the MVM[205]; however, the role of this transporter in maternal–fetal iodide transfer is unclear because pendrin mediates iodide efflux in other tissues. Recently, it was reported that the human Na^+–multivitamin transporter (hSMVT, also known as SLC5A6), which is expressed in the placenta, mediates cellular uptake of iodide,[206] but the contribution of hSMVT to placental iodide transport is currently unknown.

Water

Near term, the human fetus accumulates 22 ml of water per day. Because only approximately 20% of this can be accounted for by metabolically produced water, the large fraction of fetal water accretion must be transferred from the maternal circulation, predominantly transported across the placenta.[132] The driving forces for net maternal–fetal water transfer, and the pathways for water and solute transfer across the placental barrier in the human, are not fully defined. Existing information regarding hydrostatic pressure in umbilical circulation and intervillous space[136,137] suggests a higher hydrostatic pressure in the fetal side of the placenta, which would promote transfer of water from the fetus to the mother. Because differences in colloidal osmotic pressure[132] also promote water movement toward the mother, net transplacental movement of water must be driven by a gradient of solutes. However, no significant gradient has been clearly demonstrated when maternal and fetal osmotic pressures are measured. This apparent contradiction may be reconciled by studies demonstrating that the syncytiotrophoblast plasma membranes have significant water permeability.[207] Thus, given the large surface area of the placental barrier, only a very small solute gradient is needed to account for net fetal water accumulation. It is therefore possible that water accumulation by the human fetus could be driven by a solute gradient across the placental barrier that is small enough to be within the margin of error of standard osmolarity measurements.[207] Available data from experiments using the human placenta suggest that solutes that are actively transported into the fetal compartment generate a small osmotic gradient, which causes osmotic water movement via a transcellular pathway. Subsequently, water recirculates back to the maternal compartment through transtrophoblastic channels driven by the hydrostatic and colloid osmotic pressure gradients, preventing overhydration of the developing fetus. A similar model has been proposed for the rat placenta.[132]

The aquaporins (AQPs) are a family of membrane water channels.[208] Cells expressing aquaporins in the plasma membrane have a 2- to 50-fold higher permeability to water than cells lacking water channels. There are 13 mammalian AQP isoforms, some of which (e.g., AQP3, AQP8, and AQP9) also transport glycerol. In addition, AQP9 has been shown to transport other polar solutes, including

amino acids and sugars.[209] AQP8 transports ammonium as well as water.[210] Replace by AQP3, AQP8, and AQP9, and/or protein are expressed in the human syncytiotrophoblast.[211,212] However, the role of these aquaporins in the syncytiotrophoblast remains to be fully established, and evidence to suggest significant AQP-mediated water permeation across isolated microvillous and basal plasma membranes is lacking.[207]

Calcium

During pregnancy, the fetus accumulates approximately 30 g of calcium, predominantly in the third trimester, when fetal bone mineralization occurs. As in other cells, the intracellular calcium concentration in the syncytiotrophoblast is four magnitudes lower than extracellular concentrations, which is critical for the function of intracellular calcium as a signal transducer.

In principle, the transfer of calcium across the syncytiotrophoblast occurs in three distinct steps (reviewed in Ref. 213) (Figure 39.12) similar to calcium transport in the intestinal epithelium. The first step involves calcium entry across the MVM into the cell. This is followed by Ca^{2+} mobilization through the cytosol in association with calcium-binding proteins. The third step, calcium is transported out of the cell, in a process mediated by Ca^{2+} ATPase. Members of the transient receptor potential (TRP) gene family, specifically TRPV5 and TRPV6, are calcium-selective channels serving as apical calcium entry pathways in absorptive and secretory tissues. Of these channels, TRPV6 is highly expressed in the placenta and is functional in cultured primary human

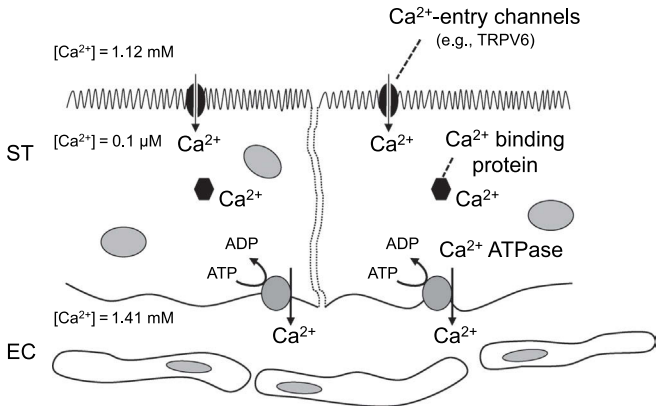

FIGURE 39.12 Placental calcium transport. Calcium is believed to enter the syncytiotrophoblast across the MVM via Ca^{2+}-entry channels such as TRPV6. In the cytoplasm, calcium is rapidly sequestered into intracellular compartments or bound to calcium-binding proteins, such as calmodulin or calbindin, which transport calcium through the cytoplasm and buffer intracellular calcium. The plasma membrane Ca^{2+} ATPase, which is highly expressed and functional in the BM, is the primary mechanism for Ca^{2+} efflux out of the syncytiotrophoblast into the fetal circulation. TRPV6: transient receptor potential cation channel, subfamily V, member 6; ST: syncytiotrophoblast; EC: endothelial cell.

trophoblasts.[214] Store-operated channels (SOC), which are calcium channels in the plasma membrane that are activated by depletion of intracellular calcium stores, are expressed and are functional in the syncytiotrophoblast of term villous fragments,[215] potentially representing a pathway for calcium entry across the MVM. Furthermore, ATP increases calcium influx into trophoblasts in a process mediated by interaction with the P2 purinergic receptor family.[216] Several studies showed the presence of L-type voltage-dependent calcium channels (VDCCs) in trophoblasts, particularly in the MVM.[217–219] However, the specific physiological function of these channels is poorly understood, because Ca^{2+} uptake in the MVM is insensitive to L-type calcium channel blockers.[220] It has been suggested that MVM L-type calcium channels are involved in cellular signaling and regulation of protein secretion from trophoblasts.[213] In addition to these calcium-selective channels, numerous nonselective cation channels have been identified in the MVM, such as polycystin-2,[221] which also may contribute to Ca^{2+} entry into syncytiotrophoblasts. TRPV5, TRPV6, and L-type VDCC have been shown to be expressed and functional in the BM[222]; however, the function of these BM channels remains to be established.

Once calcium enters the cytoplasm, it is rapidly sequestered into intracellular compartments, or is bound to calcium-binding proteins such as calmodulin or calbindin. Sequestration into the endoplasmic reticulum allows for regulation of intracellular calcium concentrations and release of calcium in response to signaling through the diacylglycerol–protein kinase C–inositol P_3 pathway. Cytoplasmic calcium-binding proteins transport calcium through the cytoplasm and buffer changes in intracellular calcium. Studies in the rat placenta showed that calbindin-D_{9k} is highly expressed in late gestation, where it is the rate-limiting step in transplacental transport.[223] However, reports remain conflicting with respect to the expression of calbindin-D_{9k} in the human placenta.[224,225]

There are two principal mechanisms by which Ca^{2+} is actively transported out of the cell against a significant electrochemical gradient: the Na^+–Ca^{2+} exchanger and the calcium pump (or Ca^{2+} ATPase). Whether the Na^+–Ca^{2+} exchanger is expressed in the syncytiotrophoblast remains unclear.[226,227] Functional studies indicate that Na^+–Ca^{2+} exchange does not play a major role in Ca^{2+} efflux in syncytiotrophoblasts.[228] The plasma membrane Ca^{2+} ATPase (PMCA), on the other hand, is highly expressed and functional in the BM[226,229] and constitutes the predominant mechanism for the maintenance of low free intracellular calcium concentrations in the syncytium. Notably, there are four isoforms of PMCA (PMCA1–4). PMCA1 and PMCA4 are ubiquitous, including in the syncytiotrophoblast BM.[229] The activity of the BM calcium pump significantly increases from gestational week 32 through 37, suggesting an increased

transport capacity during the period of maximal fetal skeletal mineralization.[229]

Our understanding of the mechanisms regulating placental calcium transport is incomplete. The influence of the major calcitropic hormones, parathyroid hormone (PTH), calcitonin, and 1,25-dihydroxycholecalciferol (vitamin D), on placental calcium transport has been studied mainly in animal models (reviewed in Ref. 132), and revealed that vitamin D stimulates and calcitonin inhibits placental calcium transport in the sheep, but not in the rat, placenta. Evidence also suggests that parathyroid hormone–related peptide (PTHrP) is the primary hormonal regulator of placental calcium transport. PTHrP is synthesized by several fetal tissues, such as the parathyroid glands, as a 141-amino-acid pro-hormone. It is subsequently cleaved into several fragments of smaller molecular weight. Synthetic PTHrP midmolecule fragments (67–86 or 38–94) have been shown to maintain the calcium gradient across the sheep placenta.[230] In mice with homozygous deletion of the PTHrP gene, placental transport of calcium is decreased and the normal Ca^{2+} concentration gradient across the placental barrier (fetal Ca^{2+} concentrations > maternal) fails to develop. Transplacental calcium transport increased in PTHrP-deficient fetuses by administration of PTHrP (1–86) or PTHrP (67–86) to the fetus, but not PTHrP (1–34) or intact PTH.[231] These studies suggest that the midmolecular region of PTHrP plays a critical role in stimulating the placental transport of calcium, at least in some species. Human placental Ca^{2+} ATPase can be activated by PTHrP (38–94),[232] consistent with the possibility that fetal PTHrP regulates placental calcium transport also in pregnant women.

Immunoglobulins

Among all subclasses of immunoglobulins, only IgG is transferred at a significant level across the human placenta. The levels of IgG in the first and early second trimesters of pregnancy are low, with increased transport in the second half of pregnancy, which continue to gradually increase until term.[233,234] The rate of IgG transport is subtype specific, with a declining order of transport rate for IgG1, IgG4, IgG3, and IgG2. At term, the level of IgG1 in the fetal blood exceeds that of maternal blood.[233,235]

A first step in IgG transport is binding of the Fcγ component of IgG to the syncytiotrophoblast, with subsequent transport of the whole molecule within a coated vesicle.[236] The human neonatal Fcg receptor (FcRn), which is homologous to major histocompatibility complex class I, is expressed in the syncytiotrophoblast and mediates IgG uptake into the placenta.[237,238] FcRn exhibits a pH-dependent interaction with IgG, exhibiting high affinity to IgG at lower pH and low affinity at high pH. It is thus assumed that binding to FcRn does not take place at the blood facing the trophoblastic microvillous membrane, where the pH is neutral, but within the acidic environment of trophoblastic endosomes, which protects the IgG against degradation.[237,239] Following the transfer of IgG across the syncytiotrophoblast, it is either transported via the basal membrane to the stroma, where it binds Fcγ receptors that are expressed in Hofbauer and stromal cells,[237] or transferred across the fetal capillary endothelial cells into the fetal circulation. Fetal endothelial cells express FcγRIIb2, but its function is not entirely clear.[240] Lastly, it is noted that uptake of IgG in rodents likely occurs mainly via the yolk sac, which exhibits a high expression of Fc receptors.[241]

Glucose

Glucose is the primary substrate for energy metabolism in the placenta and fetus. In the absence of significant fetal gluconeogenesis, the fetus is critically dependent on transplacental glucose transfer. Of the total amount of glucose taken up by the placenta from the uterine circulation, 30–40% is consumed by the placenta itself. Classical studies by Widdas demonstrated that transplacental glucose transport in the sheep is mediated by facilitated diffusion.[242] Numerous studies have subsequently confirmed that placental glucose transport is facilitated, Na^+ independent, saturable, stereospecific, and selective

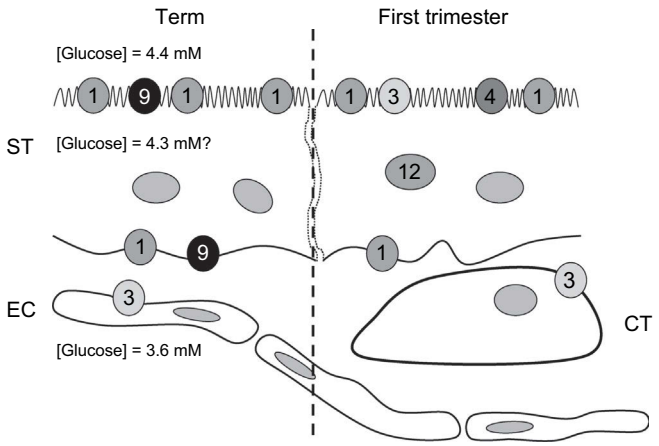

FIGURE 39.13 Placental glucose transport. Glucose transfer across the human placenta is facilitated by glucose transporters (GLUTs; isoforms indicated by numbers) expressed in the two polarized syncytiotrophoblast plasma membranes. At term (left panel), GLUT1 is the primary glucose transporter in the placental barrier, with threefold higher expression in the MVM than in the BM. Transport across the BM is believed to be the rate-limiting step in transplacental glucose transfer. GLUT9 is also expressed in the MVM and BM; however, the functional importance of this transporter in the placenta remains to be established. In the first trimester (right panel), at least four different GLUT isoforms are expressed in the syncytiotrophoblast: GLUT1, GLUT3, GLUT4, and GLUT12, of which GLUT4 and GLUT12 are sensitive to regulation by insulin. ST: syncytiotrophoblast; EC: endothelial cell.

in all species studied (reviewed in Ref. 243). The human placenta is no exception, because glucose transfer is facilitated by glucose transporters expressed in the two polarized syncytiotrophoblast plasma membranes (Figure 39.13).[175,244,245] Consistent with the facilitated nature of the transport process, fetal plasma glucose concentrations are lower than maternal levels.[246] However, given the high placental glucose consumption, the maternal–fetal concentration difference (less than 1 mM) is remarkably small, illustrating the high capacity of the placental glucose transport system.

The facilitative glucose transporter family (glucose transporter (GLUT) also known as SLC2) includes 14 isoforms that share common structural features, such as 12 transmembrane domains, both N and C termini facing the interior of the cell, and an extracellular *N*-glycosylation site. Many of the GLUT isoforms are expressed in the human placenta (Figure 39.13 and Table 39.2); however, only a few of these are likely to be important in mediating maternal–fetal glucose transport.

GLUT1 (SLC2A1) was the first GLUT isoform to be cloned and characterized and is ubiquitously expressed. GLUT1 protein is expressed in most placental cells, including the syncytium, cytotrophoblasts, and endothelial cells.[175–177] GLUT1 expression is particularly high in the syncytiotrophoblast plasma membranes, with threefold higher expression in the MVM compared to the BM,[175] reflecting the higher glucose transport activity in the MVM.[175] Given the six- to sevenfold larger area of the microvillous surface of the syncytiotrophoblast compared to the BM at term, it has been estimated that the total glucose transport capacity of the MVM may be 20-fold higher than that of the BM.[175] As a result, the glucose concentration within the syncytiotrophoblast may be maintained close to glucose concentrations in the intervillous space, providing a maximal gradient for transfer to the fetus.[175] Based on these findings, it was suggested that transport across the BM constitutes the rate-limiting step of transplacental glucose transport.[175] Alternatively, glucose transporter abundance in the placental barrier may have a lesser impact on transplacental glucose transport, because glucose transfer is highly dependent upon placental and umbilical blood flow.[247] Maternal–fetal glucose transport is likely to be influenced by both of these factors. With all other factors kept constant, any alteration in glucose transporter expression or activity in the BM is likely to alter glucose flux across the barrier, a concept that is supported by studies in polarized BeWo cells[248] and mathematical modeling of glucose transport in the human placenta.[249]

GLUT3 (SLC2A3) is a high-affinity glucose transporter, which was considered to be neuron specific. However, GLUT3 protein is also expressed in other cells and tissues with a high glucose demand, in particular in spermatozoa, preimplantation embryos, and certain cancer cells. In the first trimester, GLUT3 protein is expressed in cytotrophoblast cells[177] and in the MVM.[177,178] GLUT3 protein is also expressed in fetal capillary endothelium in the term placenta.[179] Although GLUT3 mRNA is present in term trophoblast,[179] studies of trophoblast GLUT3 protein expression in the MVM have generated conflicting results.[175,178,179] GLUT4 (SLC2A4) is of major physiological importance because of its critical role in insulin-stimulated glucose uptake in muscle and adipose tissue. Whereas GLUT4 protein is expressed in the cytoplasm and MVM of first-trimester syncytiotrophoblasts,[177] at term the transporter is expressed in stromal cells but not in trophoblasts.[180] GLUT9 (SLC2A9) is a high-affinity transporter for glucose, fructose, and urate. Alternative splicing results in two proteins, GLUT9a and GLUT9b, which differ in their N terminal. These isoforms appear to determine transporter trafficking to apical or basolateral domains in polarized epithelia. GLUT9 is highly expressed in the kidney and liver, and was recently shown to be present in the human placenta, with GLUT9a predominantly expressed in the BM and GLUT9b in the MVM.[181] GLUT12 is an insulin-sensitive isoform that is mainly expressed in muscle, small intestine, and prostate. GLUT12 is also expressed in the syncytiotrophoblast in early pregnancy and in the villous stroma at term.[182]

There are striking differences in glucose transporter expression in syncytiotrophoblasts between the first trimester and term (Figure 39.13). In the first trimester, at least four different GLUT isoforms are expressed in the syncytiotrophoblast: GLUT1, GLUT3, GLUT4, and GLUT12,[177,182] of which GLUT4 and GLUT12 are sensitive to regulation by insulin. However, in late pregnancy GLUT1 is the primary GLUT isoform mediating glucose transport across the placental barrier in the human.[175,177] These differences may explain experimental findings that insulin stimulates placental glucose uptake primarily in the first trimester.[177] It is possible that the expression of insulin-sensitive glucose transporters in the first-trimester syncytium is critical for regulation of glucose transport and support of feto-placenta growth in early pregnancy, prior to the establishment of blood flow in the intervillous space after 12 weeks of gestation. In addition, first-trimester fetal physiology is characterized by anaerobic metabolism and therefore a high demand for glucose, which may require a different set of transporters. Thus, the high expression of insulin-sensitive glucose transporters in the first-trimester MVM may be necessary in order to meet the relatively high glucose requirements of the developing embryo.[177]

Because the GLUT1 transporters are not saturated at normal blood glucose levels, net maternal–fetal glucose transfer is also dependent on the glucose concentration difference between maternal and fetal blood. Insulin regulation of placental glucose transport at term

remains controversial, with some studies showing that insulin increases placental glucose uptake, whereas other investigators have reported no effect.[250] In a first-trimester trophoblast cell line, glucose transport activity was stimulated by insulin, IGF-I, and IGF-II.[251,252] Placental glucose transporter activity was not affected by hormones such as leptin, GH, IGF-I, insulin, and cortisol in primary villous fragments from term placentas.[253] Glucocorticoids are known to decrease placental glucose transporter expression. Corticotrophin-releasing hormone (CRH) increased GLUT1 and decreased GLUT3 mRNA and protein expression in cultured primary human trophoblasts isolated from term placentas.[254] Because CRH is produced locally in the placenta, these findings are consistent with autocrine–paracrine regulation of placental glucose transport by CRH. Increased oxidative stress in placental explants causes reduced glucose uptake as well as lowered expression of GLUT1. Chronic hypoxia in vivo, as in high-altitude pregnancies, also reduces the expression of GLUT1, but the effect is restricted to the BM and not in the MVM.

Amino Acids

Amino acids are required for fetal protein synthesis, and they constitute critical precursors in many biosynthetic pathways, including the synthesis of porphyrins, nitric oxide, neurotransmitters, and nucleotides. Nonessential amino acids are also used as fetal energy substrates. It is estimated that 32% of the energy requirement of well-nourished fetal sheep is met by amino acid oxidation.[255] For most amino acids, the concentrations in the umbilical vein are two- to threefold higher than in the uterine vein, demonstrating that the transfer of amino acids across the placental barrier is an active process (reviewed in Refs 256–258). This is also supported by the observation that placental concentrations of amino acids are, in general, much higher than in the blood on either side of the placental barrier (Figure 39.14).

There are two main types of amino acid transporters—accumulative transporters and amino acid exchangers—both of which are found in the MVM. Accumulative transporters mediate cellular uptake, resulting in increased intracellular amino acid concentrations. Amino acid exchangers, in contrast, exchange one amino acid for another, resulting in altered amino acid composition without changing total concentration.[259] The primary driving forces for amino acid uptake across the MVM mediated by accumulative transporters are (1) the inwardly directed Na^+ gradient (e.g., the System A transporter and the taurine transporter), and (2) the potential difference between the intracellular and extracellular environments, which is the driving force for uptake of the cationic amino acids (arginine, histidine, and lysine). The L-amino acid transporter system is an example of

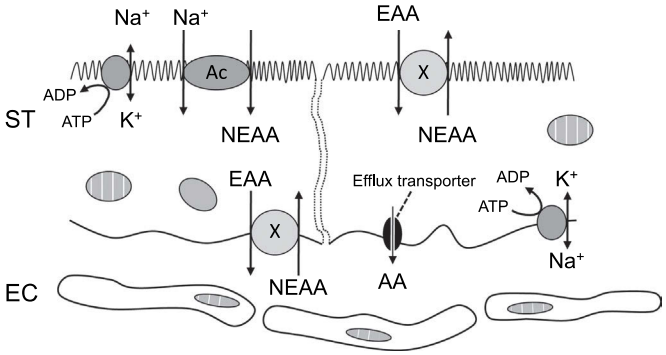

FIGURE 39.14 A model for placental amino acid transport. The uptake of amino acids from the maternal circulation across the MVM into the syncytiotrophoblast represents the active step of amino acid transport and is mediated by accumulative transporters (Ac) and amino acid exchangers (X). Accumulative transporters mediate cellular uptake, resulting in increased intracellular amino acid concentrations. Amino acid exchangers, on the other hand, exchange one amino acid for another, resulting in altered amino acid composition without changing the total concentration. The driving forces for the amino acid uptake mediated by accumulative transporters are the inwardly directed Na^+ gradient, or the potential difference with the inside of the cell negative. Exchangers, such as System L, use the steep, outwardly directed concentration gradient of some nonessential amino acids (NEAA) to drive the uptake of essential amino acids (EAA) against their concentration gradients. In all of these cases, the energy for the uphill transport is ultimately generated by the Na^+K^+–ATPase. Amino acids are transferred across the BM by facilitated diffusion driven by the outwardly directed concentration gradient mediated by exchangers and efflux transporters. ST: syncytiotrophoblast; EC: endothelial cell.

an exchanger, which uses the steep outwardly directed concentration gradient of some nonessential amino acids to drive the uptake of essential amino acids, such as leucine, against its concentration gradient. The energy for the uphill transport of amino acids is ultimately generated by the Na^+K^+–ATPase, which extrudes sodium in exchange for potassium, thereby maintaining a low intracellular Na^+ concentration and creating a potential difference across the plasma membrane.[174] Subsequently, amino acids are transferred across the BM by facilitated diffusion driven by the outwardly directed concentration gradient (Figure 39.14). While accumulative transporters and exchangers are sufficient to account for the uptake of all amino acids in most cells, in transporting epithelia, such as the syncytiotrophoblast, efflux transport mechanisms in the BM are needed to allow net transfer of all amino acids across the epithelium.[258]

The asymmetric distribution of amino acid transporters between the syncytiotrophoblast MVM and BM is critical in order to generate a net flux of amino acids from mother to fetus (Figure 39.14). The human syncytiotrophoblast expresses at least 20 different amino acid transporters (Table 39.2), with each transporter mediating the uptake of several amino acids, and each amino acid can be transported by multiple transport systems. Specifically, accumulative transporters and amino acid exchangers are

present in the MVM, whereas amino acid exchangers and efflux transporters predominate in the BM. Figure 39.14 represents a simplified depiction of placental amino acid transport pathways. Notably, it does not take into account placental amino acid metabolism or complex interactions among transporters. A series of studies of amino acid metabolism in the sheep fetus revealed that there is an intricate cycling of amino acids between the placenta and the fetal liver (reviewed in Refs 260,261). Specifically, glutamate is taken up from the umbilical, rather than the uteroplacental circulation, and is oxidized or converted to glutamine. Glutamine is released from the placenta into the fetal circulation, taken up by the liver, and, in part, converted to glutamate. A similar placental–liver cycle exists for serine and glycine. The physiological function of these interorgan exchanges of some amino acids and their relevance to the human placenta remain to be established.[258] A mathematical model, recently applied to amino acid transport in the human placenta and validated using experimental data, indicated that the flux of serine and alanine is particularly sensitive to changes in transporter abundance in the BM.[262]

Neutral Amino Acids

Classical studies have identified System A as a major sodium-dependent transporter that mediates the uptake of small zwitterionic nonessential neutral amino acids into the cell. System A is pH sensitive, and it displays extensive hormonal and adaptive regulation. System A activity establishes the high intracellular concentration of nonessential amino acids, which are used to exchange for extracellular essential amino acids via System L. Thus, System A activity is critical for cellular uptake of both nonessential and essential amino acids. There are three isoforms of System A: sodium-dependent neutral amino acid transporter 1 (SNAT1), SNAT2, and SNAT4 (Table 39.2). Of these isoforms, SNAT1 and SNAT2 share extensive similarities in substrate profiles and transport mechanism, although SNAT2 is more widely expressed than SNAT1. SNAT4 also transports cationic amino acids, independent of Na^+, and is predominantly expressed in the liver. However, all SNAT isoforms, including SNAT4, are expressed in the human placenta.[184] System A activity is present in both the MVM and BM; however, its activity in the BM is markedly lower.[185,186] These observations are consistent with studies using immunohistochemistry, localizing SNAT isoforms to the MVM.[183] Although SNAT1 was reported to exhibit the major System A activity in cultured primary human trophoblasts,[263] these findings are not entirely consistent with recent studies showing that silencing of mammalian target of rapamycin complex 1 and 2 (mTORC1 and mTORC2, respectively) in primary human trophoblasts completely inhibits System A activity and markedly decreases SNAT2 expression in MVM without affecting SNAT1 or SNAT4 expression,[264] implicating SNAT2 as the predominant contributor to System A activity. Additional work is needed to determine the relative contribution of each SNAT isoform to System A activity in vivo and in vitro.

System ASC transports alanine, serine, and cysteine in a Na^+-dependent manner. While ASC activity has been demonstrated in the BM,[186] ASC function in the MVM remains unclear.[185] The expression of ASCT2, which has been implicated as the primary transporter responsible for ASC activity in the human, is very low in the placenta, suggesting that an as-yet-unidentified ASC-like transporter may be responsible for the ASC activity in the placenta. System B^0 is another Na^+-dependent amino acid transporter that is highly expressed at the mRNA level in the human placenta. Although B^0 activity is clearly present in choriocarcinoma cell lines, it remains to be established if this transporter is active also in syncytiotrophoblast plasma membranes.[192] The data also remain controversial with respect to System N activity.[187,188] Na^+-dependent glycine uptake mediated by System Gly has been reported in the MVM.[189]

The β-amino acid taurine (2-aminoethanesulfonic acid) is the most abundant free amino acid in many tissues. Taurine is not incorporated into proteins and plays an important role in bile acid conjugation, defense against oxygen free radicals, regulation of neuronal excitability, and cell volume regulation. Taurine deficiency in fetal life is associated with growth failure, abnormal cellular development, retinal degeneration, cardiac damage, and central nervous system (CNS) dysfunction. The capacity to synthesize taurine is low in the human fetus, and transplacental transfer of taurine is thus the primary source of this important amino acid for the fetus. System β mediates cellular uptake of taurine, Na^+, and Cl^-, and this transporter is highly active in the MVM. In contrast, System β activity in the BM is only 6% of the MVM's activity.[190,191]

The System L amino acid transporter is a sodium-independent exchanger that mediates cellular uptake of essential amino acids, including leucine, methionine, and tryptophan. In fact, because no accumulative transporters that transport essential amino acids are expressed in the MVM, System L exchange of nonessential amino acids in the syncytiotrophoblast cytosol with extracellular essential amino acids is critical for the uptake of essential amino acids across the MVM. This transporter is a heterodimer, consisting of a catalytic light chain, typically LAT1 (large neutral amino acid transporter 1, also known as *SLC7A5*) or LAT2 (also known as *SLC7A8*), and a heavy chain, 4F2hc/CD98 (*SLC3A2*). The heavy chain is believed to be important for trafficking of the light chain to the plasma membrane, where the two subunits form disulfide-bound heterodimers. System L activity has been reported in both the MVM and BM.[185,186,192]

Kudo and Boyd reported that MVM System L activity is due to expression of LAT1,[265] whereas other investigators have suggested that LAT2 is the predominant isoform in the MVM.[266] Lastly, the efflux transporter LAT4 is expressed in the placenta, and is functional in isolated perfused human placental cotyledons, suggesting that LAT4 may also play a role in the efflux of certain essential amino acids across the BM.[193]

Cationic Amino Acids

Cellular uptake of the cationic (or basic) amino acids lysine, arginine, and histidine is driven by the electric potential difference (negative intracellularly) across the plasma membrane. System y^+ is the main transporter for cationic amino acids in the MVM,[194,195] whereas y^+L is likely to be the primary transporter in the BM.[195,196] However, System y^+L activity also has been identified in the MVM,[194,195] and System y^+ activity has been detected in the BM by some but not all investigators.[194,195] Whereas System y^+ only accepts cationic amino acids, y^+L transports neutral amino acids in the presence of Na^+. Whether or not System $b^{0,+}$ activity is present in syncytiotrophoblast membranes remains controversial.[195,196]

Anionic Amino Acids

The anionic (acidic) amino acids glutamate and aspartate are not transferred in the maternal–fetal direction in the in vitro perfused placenta. Furthermore, glutamate is rapidly oxidized by cultured primary human trophoblasts, and there appears to be no net flux of glutamate from the placenta into the umbilical circulation in pregnant women.[267] Collectively, these findings suggest that glutamate is not maternally derived, but originates from the fetal liver. Glutamate may be taken up from both the fetal and maternal circulation into the syncytiotrophoblast, where glutamate is oxidized or converted to glutamine. Consistent with this model, activity for System X^-_{AG} transporters, which mediate cellular uptake of anionic amino acids driven by the Na^+ gradient and associated with co-transport of H^+, have been shown to be present in both the MVM and BM.[171,197]

Regulation of Amino Acid Transporters

The System A transporter has been the primary focus of research into mechanisms regulating placental amino acid transport. System A transporter activity in human trophoblasts is stimulated by insulin, IGF-I, and EGF, and by substrate concentrations.[250] Leptin increases System A activity in primary villous fragments at term. The proinflammatory cytokines interleukin 6 (IL6) and TNFα also stimulate trophoblast System A activity, and the effect of IL6 was shown to be mediated by signal transducer and activator of transcription 3 (STAT3). Adiponectin decreased insulin-stimulated System A amino acid uptake in cultured human trophoblasts by modulating insulin receptor substrate phosphorylation. Furthermore, chronic administration of adiponectin to pregnant mice inhibits placental insulin and mTORC1 signaling, downregulates the activity and expression of System A and L isoforms, and decreases fetal growth.[268] Dexamethasone, a synthetic glucocorticoid, stimulates System A activity in cultured primary human trophoblasts and in term villous explants. Notably, dexamethasone administered to pregnant mice downregulates placental System A amino acid transport,[269] suggesting that the effects of glucocorticoids on System A activity in vitro and in vivo are distinct. Furthermore, in cultured primary human trophoblasts, hypoxia decreases System A activity, which could be explained by a decreased protein expression of the two System A transporter isoforms SNAT1 and SNAT2.[270] Lastly, oleic acid activates System A activity in cultured primary human trophoblasts, an effect mediated by Toll-like receptor 4.[271]

The mTOR signaling pathway responds to changes in nutrient availability and growth factor signaling to control cell growth and metabolism. Rapamycin inhibits mTOR and markedly decreases System A activity in primary human trophoblasts without affecting global protein expression of SNAT isoforms. These findings are consistent with the possibility that mTOR regulates amino acid transporter activity at the posttranslational level. Indeed, inhibition of mTOR using gene-silencing approaches decreases the activity of key placental amino acid transporters in primary human trophoblasts, an effect mediated by modulating the trafficking of specific transporter isoforms between the cell interior and the plasma membrane.[264]

The regulation of placental amino acid transporters other than System A has been insufficiently explored. Studies of the effect of insulin on System L activity in primary human trophoblasts have produced inconsistent results. However, mTOR is a powerful positive regulator of trophoblast System L activity, mediated by influencing LAT1 trafficking to the plasma membrane.[264] The nitric oxide donor SIN1 inhibits taurine transport in MVM vesicles and in villous explants. mTOR increases mRNA levels of the taurine transporter, and stimulates taurine transport in cultured trophoblasts.

Lipids

Dietary fat and fat derivatives are essential for human development,[272] as humans cannot synthesize the diverse types of fat that are essential for development and normal physiology. Fat precursors such as fatty acids are essential for energy storage, membrane phospholipids, signaling molecules (e.g., eicosanoids), and steroid receptor ligands. Sterols such as cholesterol are also crucial during early and late embryonic development.[273] Cholesterol regulates organogenesis by activation of hedgehog

signaling pathways, and is required for fetal growth, organelle membranes, steroid hormone synthesis, and production of bile salts. While the fetus is capable of cholesterol synthesis, most sterol derivatives are transferred to the embryo transplacentally. This transport process involves uptake by the trophoblast, trafficking through the syncytium, basal membrane, and endothelial cells into the fetal circulation (Figure 39.15). As noted in this chapter, there are more data on processes that occur at the level of uptake and trophoblastic transport, and less about efflux and utilization of lipids within trophoblasts.

Triglycerides, low-density lipoprotein (LDL) cholesterol, and apolipoprotein B are significantly increased in the maternal serum and tissues during early pregnancy. Accelerated fetal growth during the second half of pregnancy is associated with maternal lipid catabolism, coupled with relative insulin resistance and increased hepatic production of triglycerides. These triglycerides are available for transplacental transport to the fetus. For sufficient quantities of fatty acids to be absorbed into placental syncytiotrophoblasts, lipoproteins are hydrolyzed by triglyceride hydrolase at the MVM, which releases fatty acids from triglycerides in LDLs and very-low-density lipoproteins.[274] The nonuniform fetal-to-maternal plasma ratios for different types of fatty acids suggest dissimilar rates of transport and metabolism for different fatty acids.

FAT/CD36 (fatty acid translocase and cluster of differentiation 36) is expressed in both the MVM and BM of

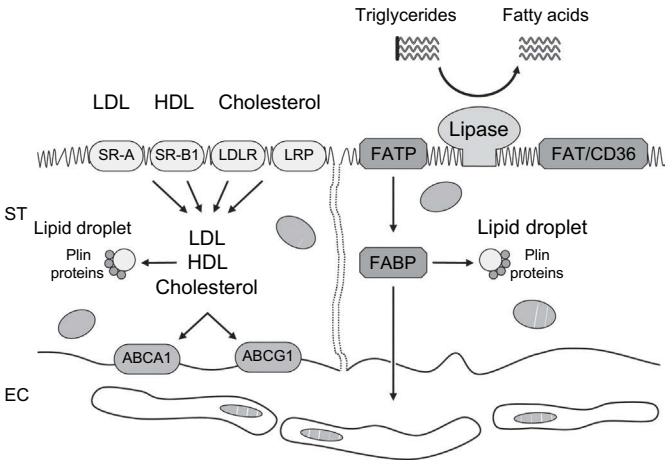

FIGURE 39.15 Lipid trafficking within placental trophoblasts. Triglycerides are cleaved by lipases at the maternal surface of the placenta. Fatty acids are taken up into cells by fatty acid transport proteins (FATPs) and FAT/CD36. These fatty acids are then carried and directed by fatty acid binding proteins (FABPs) to intracellular targets, such as lipid droplets or the nucleus, or are shuttled to the fetal circulation. Cholesterol and lipoproteins are taken up into the syncytiotrophoblast (ST) by LDL receptors (LDLRs), LDL receptor-related proteins (LRPs), scavenger receptor A (SRA), and HDL-binding scavenger receptors B1 (SRB1s). Some cholesterol is retained in the cells and stored in lipid droplets. ATP-binding cassette (ABC) transporters ABCG1 and ABCA1 mediate cholesterol efflux to fetal capillaries (ST: syncytiotrophoblast, EC: Endothelial cells).

trophoblasts,[274] where it binds lipoproteins, long-chain fatty acids, and oxidized LDLs, and facilitates their transport. The six members of the fatty acid transport proteins (FATPs) family regulate fatty acid transport, and are particularly germane at low-fatty-acid concentrations, when diffusion is insignificant. The family includes six integral transmembrane proteins that are expressed in a tissue-specific manner. FATP1–4 and FATP6 are expressed in the human placenta, with subtype-specific expression in the MVM and BM. Intracellular mobilization of fatty acids, eicosanoids, and other lipids within the hydrophilic cytoplasm is orchestrated by fatty acid binding proteins (FABPs),[275] a family of abundantly expressed small (14–15 kD) intracellular transport proteins. FABP1, FABP3, FABP4, FABP5, and FABP7 are expressed in the human placenta and in cultured human trophoblasts. The upregulation of FABP1, FABP3, and FABP4 in hypoxic trophoblasts suggests a role in the fat accumulation observed in the hypoxic placenta. FABPpm is expressed at the microvillous plasma membrane and thereby can preferentially bind and facilitate the uptake of selected fatty acids.[274]

The MVM of human trophoblasts expresses proteins that play a pivotal role in the uptake and trafficking of cholesterol. These include LDL receptors, LDL receptor-related proteins, scavenger receptors A (SRAs), and high-density-lipoprotein (HDL)-binding scavenger receptors BP (SRB1s). Cholesterol is taken up by trophoblasts via internalization of receptor-bound apoB- or apoE-carrying lipoproteins and oxidized LDL, and from SRB1-bound HDL. It is subsequently released on the BM side. The ATP-binding cassette (ABC) transporters, ABCA1 and ABCG1, are regulators of cholesterol efflux. These proteins are also expressed in human placental endothelial cells. Inhibition of either ABCA1 or ABCG1 activity diminishes cholesterol efflux and fetal lipoprotein levels, pointing to a role in regulating the level of lipoproteins in the fetal blood.[276]

Trophoblasts also store lipids within lipid droplets. These dynamic organelles (average size 1–100 μM) are formed within the endoplasmic reticulum, and serve as an intracellular reservoir for neutral lipids, including triglycerides, cholesterol esters, and retinol esters. They also serve to protect the cells from lipotoxicity.[277] The lipid droplets are coated by a phospholipid monolayer and regulatory proteins. These proteins respond to environmental exposures and cellular needs, shuttle lipids from the endoplasmic reticulum to the lipid droplets, and control lipid droplet stability, as well as access and function of lipases.[278,279] Among these proteins, two members of the Plin family of proteins, Plin2 (adipophilin, adipose differentiation-related protein) and Plin3 (tail-interacting protein 47), are most prevalent in human trophoblasts, and likely govern the formation, size, and distribution of trophoblastic lipid droplets and lipid

accumulation. Lipolysis and release of fatty acids by the lipid droplet are accomplished by cytoplasmic lipases, such as hormone-sensitive lipase (HSL) and adipocyte triglyceride lipase (ATGL), which catabolize triacylglycerols to fatty acids and glycerol. Although the processes underlying lipolysis at trophoblastic lipid droplets are incompletely understood, expression analysis suggests that ATGL, and not HSL, is the dominant lipase in trophoblasts, where it stimulates lipid droplet lipolysis. Comparative gene identification-58 (CGI58), also known as α/β-hydrolase domain containing-5 (ABHD5), is a lipid droplet protein that is tethered to lipid droplets via its interaction with Plin proteins. Upon activation, CGI58 translocates to ATGL and activates lipolysis.[280] Whereas ATGL deletion in the mouse does not lead to a placental phenotype, deletion of CGI58 causes fetal growth restriction.[281,282]

Trophoblastic lipid transport and metabolism are under the control of endocrine signals. These include leptin, which is characteristically upregulated in the maternal plasma during pregnancy, likely reflecting leptin synthesis by the placenta. The fetus also produces leptin, and fetal leptin plasma levels correlate with birth size. Leptin is also subject to regulation by other hormones, including insulin, glucocorticoids, and thyroid hormone, suggesting that leptin is a part of the hormonal homeostatic response. Adiponectin has been shown to decrease the expression of lipoprotein lipase in cultured trophoblasts.[283] Resistin and ghrelin are expressed in trophoblasts, yet their role in placental lipid biology remains largely speculative.[284] Lastly, it is noted that several transcription factors that modulate the expression of genes involved in lipid trafficking in trophoblasts and adipose and other tissues, such as peroxisome proliferator-activated receptors and retinoid X receptor alpha, have a central role in placental development and function, supporting the notion that lipid uptake and trafficking are essential for placental function and fetal growth.[285]

Vitamins and Micronutrients

Folate

Cellular uptake of folate is mediated by the folate receptor alpha (FRα), proton-coupled folate transporter (PCFT; SLC46A1), and reduced folate carrier (RFC; SLC19A1), which have been shown to be expressed and active in the human placenta.[286] Placental FRα is predominantly localized to the MVM[286] and mediates folate uptake via receptor-mediated endocytosis. Endocytotic vesicles subsequently travel through the endocytotic pathways (early and late endosomes and lysosomes), during which the interior acidifies, causing the release of folate from FRα. Folate then exits the endosome and lysosome mediated by PCFT, driven by the large proton gradient between the endosome–lysosome and the cytosol. PCFT is highly expressed in the apical plasma membrane of the intestinal epithelium and plays a critical role in folate absorption from the intestinal lumen. In the placenta, PCFT is expressed in several cell types. In the syncytium, PCFT is polarized to the MVM.[286] PCFT cotransports folate and protons, and requires a proton gradient to efficiently transport folate. Because the proton gradient across syncytiotrophoblast plasma membranes is outwardly directed,[162] it is unlikely that PCFT plays a significant role in folate uptake in syncytiotrophoblasts. However, PCFT may be involved in transplacental folate transport by virtue of its role in folate efflux from endosomes and lysosomes. RFC is an anionic exchanger, mediating the cellular uptake of folate in exchange for anions such as organic phosphates. RFC has been proposed to be the major route for cellular folate uptake at physiologic pH. RFC is expressed in the MVM and BM,[286] and likely plays a role in folate uptake across the MVM in exchange for intracellular organic phosphates. The physiological role of RFC in the BM remains to be established. It is likely that ABC transporters mediate folate efflux across the BM. For example, multidrug resistance-associated protein 1 (MRP1), known to transport folate, is highly expressed in the BM.[287]

Vitamin B12

Vitamin B12 is bound to specific carrier proteins, in particular transcobalamin II (TCII). Placental transport has been studied both in vitro and in vivo,[288,289] and takes place via high-affinity TCII–B12 complex receptors.[290] The TCb1R receptor, which mediates cellular uptake of B12, is expressed in the human placenta.[291]

Iron

Iron uptake is critical for the feto-placental unit, as iron deficiency impairs heme synthesis, suppresses mitochondrial energy production, and inhibits cell proliferation. In contrast, excess free iron can cause oxidative damage to membranes, proteins, and lipids. Placental iron transport has been investigated in a range of species (reviewed in Refs 292,293). Diferric (Fe^{3+}) transferrin in the maternal circulation binds to the transferrin receptor in the MVM and is internalized by clathrin-mediated endocytosis. After acidification of the iron-carrying endosome, iron is reduced (Fe^{2+}) and released from the transferrin receptor, which is recycled to the plasma membrane. Efflux of iron from the endosome is believed to be mediated by the divalent metal transporter protein (DMT1, aka SLC11A2). However, other transport mechanisms are likely to play a role in iron trafficking, as mice with homozygous deletion of DMT1 are born with similar iron stores as wild-type controls. Once in the cytoplasm, the iron may be used in biosynthetic pathways or stored (bound to ferritin or as free iron). Alternatively, iron is oxidized by endogenous ferroxidase and transported by ferroportin, also known

as iron-regulated gene (IREG1) or metal transport protein (MTP1),[292,294] across the BM to the fetus. During periods of iron deficiency, the fetus has the capacity to upregulate the transferrin receptor in the MVM and DMT1 in endosomes to ensure adequate transport to the fetus.

Drugs and Xenobiotics

Like many other organs, placental trophoblasts express transporters that regulate placental uptake as well as efflux of drugs and xenobiotics. Unlike other organs, the placenta has the unique role of governing the transport of these drugs into the fetal compartment, and protecting it from adverse effects. In addition to transporter expression, the transfer process depends upon the physico-chemical properties of the drug, placental blood flow, and drug metabolism locally within trophoblasts, or within the maternal or fetal compartments.[295–297] The precise mechanism of action of most placental drug transporters remains unclear. As discussed elsewhere in this chapter, ethical considerations prohibit direct drug transport studies in humans in vivo, and inferences are made from studies in other systems, including ex vivo placental perfusion, cultures of primary human trophoblasts from early or late pregnancy, trophoblast cell lines, trophoblast membrane vesicles, and animal models in vivo (reviewed in Refs 298,299).

Many drug transporters are expressed within the MVM, BM, or endothelial cells within the placenta. These are members of the phospho-glycoprotein family (P-gp: multidrug resistance proteins MDR1 and ABCB1), multidrug resistance–associated proteins (MRP proteins), breast cancer resistance protein (BCRP, aka ABCG2), and other drug and xenobiotics transporters, including organic anion-transporting polypeptides, organic anion transporters, organic cation transporters, monocarboxylate transporters, equilibrative nucleoside transporters, and folate transporters (reviewed in Refs 298,300). Two ABC proteins, P-gp and BCRP, are the best characterized efflux transporters in the placenta and play a critical role within trophoblasts (reviewed in Refs 300–302). P-gp and BCRP are membrane-spanning transporters, which are expressed primarily in the MVM of the syncytiotrophoblast, where P-gp binds a range of organic cations, carbohydrates, chemotherapeutics, antibiotics, and steroids. BCRP overlaps with P-gp in binding a number of endogenous and exogenous drugs and xenobiotics.[303,304] Although the mechanism of action of these two transporters remains unclear, they seem to prevent the entry of drugs into the placenta by effluxing them back into the maternal circulation. These proteins also play a role in transplacental transport of relevant drugs, such as synthetic steroids and glyburide.[301] The pathways that regulate the expression of these transporters remain unclear. While these transporters are known to be modulated by diverse transcription factors, steroid hormones and pathological conditions such as placental infection, hypoxia, and possibly epigenetic mechanisms, the pathways regulating their expression are undetermined. Interestingly, the expression of P-gp declines before term.[301] Lastly, MRPs represent a subfamily of ABC transporters, encoded by genes ABCC1–13. MRPs transport a number of organic anions, and have some overlapping substrates with P-gp and BCRP. Members of this family of transporters are expressed in the MVM, BM, and placental endothelial cells.

The aryl hydrocarbon receptor is a nuclear hormone receptor that heterodimerizes with the ARNT to regulate gene expression in response to diverse drugs. These proteins are expressed in trophoblasts, where they bind many environmental endocrine disruptors that are implicated in placental injury and fetal growth disorders, such as polycyclic aromatic hydrocarbons, polychlorinated biphenyls, and diverse types of cigarette smoke hydrocarbons. Targets for these transcription factors include key placental genes that are involved in drug metabolism, such as cytochrome P450 enzymes CYP1A1, CYP1A2, and CYP1B1; glutathione S-transferase (GST1); UDP–glucuronosyl transferases; and others.[305–307]

The serotonin transporter (SERT) and the norepinephrine transporter (NET) are monoamine transporters attracting more research in recent years, as their role in modulating the action of cocaine and antipsychiatric drugs became apparent. Cocaine, amphetamines, and their derivatives cause increased sympathetic activity, which results in vasoconstriction and decreased uterine blood flow, as well as stimulation of uterine contractile activity. Indeed, both fetal growth restriction and preterm delivery are complications of abuse of cocaine and its derivatives.[308] Both SERT and NET are expressed in the MVM.[309] In the brain, serotoninergic and noradrenergic transporters on presynaptic cells clear the synaptic space from the monoamines, preventing excessive neurotransmitter activity. It is thus assumed that the syncytiotrophoblastic transporters have a similar function, and clearance of serotonin and norepinephrine by the "placental sink" leads to entry of these chemicals into the syncytiotrophoblast, where they can be cleared by the abundant monoamine oxidases.[310] A lack of clearance induced by transporter inhibitors (amphetamines or cocaine) may therefore lead to excess vasoactive substances in the intervillous space, and their adverse consequences.[308]

PLACENTAL TRANSPORT IN COMPLICATIONS OF PREGNANCY

Disorders Associated with Placental Dysfunction

A number of different clinical conditions are associated with placental maldevelopment and dysfunction.

While these conditions have distinctive clinical presentations, their placental histopathological manifestations overlap. Thus, in most cases, placental histological lesions may not be specific enough to define the specific disease associated with placental dysfunction. The most common disorders reflecting placental dysfunction are fetal growth restriction, intrauterine fetal death, and preeclampsia (discussed here). Evidence for placental hypoperfusion characteristic of these clinical conditions, suggesting that they are part of a spectrum of placental pathologies linked to early impairment of spiral artery conversion or late impairment of villous perfusion and trophoblast function.[89,311–313] Hypoperfusion lesions typically appear as clustered apoptotic trophoblasts ("syncytial knots"), disordered villous maturation with subsequent ischemic villous agglutination, and possibly increased intervillous fibrin. These lesions progress with worsened hypoxia, causing further fibrin deposition and atherosis of the decidual arteries. Profound and early impairment of trophoblast invasion and inadequate spiral arterial dilation are associated with spontaneous miscarriages or stillbirths due to premature and disorganized onset of the maternal circulation, whereas less severe deficiencies are associated with intrauterine growth restriction and preeclampsia.[89,314,315] In addition, suboptimal fetal growth, fetal injury, and stillbirths may also reflect abnormalities of the fetal vasculature within the placenta, with fetal vessel thrombi, villous inflammation, or avascular villi.[316,317]

Oxidative stress likely plays a role in the pathophysiology of pregnancy disorders associated with placental dysfunction.[311,318–321] Physiological measurements performed in vivo during the first trimester of human pregnancy indicate that the trophoblast is well adapted to a low-oxygen environment.[64,322] Indeed, it appears that fluctuating oxygen concentrations within the intervillous space caused by intermittent perfusion from the spiral arteries may cause hypoxia–reoxygenation and villous injury.[89,323–325] Oxidative stress with relative hyperoxia or hypoxia is associated with reduced cytotrophoblast proliferation and increased rate of apoptosis. As the trophoblast includes a regenerative layer of cytotrophoblasts, the ultimate consequences of oxidative stress depend on the balance of syncytial degeneration and regeneration.[325]

Among pregnancy disorders that are associated with placental dysfunction, preeclampsia stands out because of its distinctive effect on the mother. Preeclampsia is a pregnancy-specific disease that manifests as hypertension, excessive edema, and proteinuria. When the disease worsens, it causes target organ damage, commonly affecting the kidneys, liver, blood cells and coagulation, cardiopulmonary system, and CNS, where it may manifest as seizures (eclampsia). Preeclampsia is also associated with fetal growth restriction and its sequelae. Preeclampsia is attributed to reduced invasion of extravillous trophoblasts and abnormal vascular remodeling early in pregnancy.[311,319,320] The appearance of preeclampsia only in pregnancy, its abatement shortly after delivery, and the association of preeclampsia with large placental mass and, uniquely, with molar pregnancy, all support the notion that the placenta harbors the cause of preeclampsia. Given the association of preeclampsia with maternal vascular disease, it is speculated that reduced placental perfusion may cause placental injury, and thereby preeclampsia, or predispose the mother to preexisting adverse signals from the placenta.[326]

The reasons for the unique maternal aspects of preeclampsia, despite a placental histopathology that is commonly shared with fetal growth restriction, are puzzling.[327,328] In addition, the vascular-remodeling theory of preeclampsia remains uncertain, as reduced dilation of the distal part of the spiral arteries may not have a major effect on blood flow.[329,330] Conflicting data also exist on secreted products of placental oxidative stress, such as sFlt or PlGF, and their causal role in preeclampsia.[331–333] Interestingly, preeclampsia is characterized by increased release of syncytiotrophoblast microparticles, which are implicated in maternal endothelial cell injury.[319,334–336]

Whereas preterm birth is the most important cause of morbidity and mortality of viable fetuses,[337] the role of the placenta in this disease remains unclear. Among all etiologies of preterm birth, intraamniotic infection and a secondary inflammatory response are established causes of preterm birth. This may manifest as placental inflammation, mainly in the chorionic plate, fetal membranes, and umbilical cord. The association of inflammation with amniotic necrosis, villous inflammation, and thrombosis further adds to the fetal insult.[338,339] Decidual hemorrhage is also common in spontaneous preterm birth.[340] Placental injury associated with fetal growth restriction, preeclampsia, and evidence for poor fetal oxygenation are typically associated with induced, medically indicated preterm birth. The following discussion centers on clinical conditions associated with altered placental nutrient transport, which may contribute to fetal growth abnormalities or fetal injury.

Placental transport functions have been studied extensively in fetal growth restriction associated with placental injury.[172,173] In many of these studies, investigators have determined the activity of transporters in isolated MVM and BM, using plasma membrane protein concentration as the denominator, thereby comparing the transport capacity per unit membrane area of healthy and growth-restricted fetuses (Table 39.3). Thus, changes in the effective placental exchange area are not adequately considered in such studies. Some growth-restricted fetuses are hypoglycemic in utero[159]; however, this appears not to be due to a decreased glucose transport capacity. In contrast, fetal growth restriction due to maternal hypoxemia at high altitude has been associated

TABLE 39.3 Alterations in Placental Transport in Human Fetal Growth Restriction

with decreased expression of glucose transporters in the BM, indicating decreased glucose transport capacity.[341]

System A activity has been shown consistently to be lower in MVM isolated from placentas of growth-restricted fetuses (Table 39.3). Importantly, the most severe cases of fetal growth restriction were associated with pronounced decreases in MVM System A activity. In contrast, System A activity is not altered in villous explants obtained from placentas of growth-restricted fetuses in pregnancies complicated by preeclampsia.[342] Preeclampsia, but not fetal growth restriction without preeclampsia, is typically associated with increased maternal levels of insulin and leptin, which are known to stimulate placental System A activity in vitro.[343,344] Thus, it is possible that the distinct hormonal profile of women with preeclampsia may support placental transport functions in this disease. Homocysteine is a competitive inhibitor of System A transport,[345] and uric acid has been reported to decrease System A activity in villous fragments mediated by intracellular redox-signaling pathways.[346] Thus, elevated maternal serum levels of homocysteine and uric acid, which are often observed in this pregnancy complication, may decrease placental System A activity in vivo.

The activity of transporters of essential amino acids, including System β (transporting taurine) and System L (transporting a range of essential amino acids, including leucine and phenylalanine), is reduced in MVM and/or BM isolated from placentas associated with fetal growth restriction (Table 39.3). These in vitro findings are supported by studies in pregnant women using stable isotopes, demonstrating that placental transfer of the essential amino acids leucine and phenylalanine is reduced in fetal growth restriction at term.[347] In addition, reduced placental capacity to transport amino acids is consistent with studies showing reduced concentrations of amino acids, in particular essential amino acids, in the umbilical vein of growth-restricted fetuses.[267] The activity of MVM lipoprotein lipase, which mediates the first critical step in transplacental transfer of free fatty acids, is also reduced in fetal growth restriction. These findings are in line with clinical studies showing lower fetal–maternal plasma ratios for long-chain polyunsaturated fatty acids in fetal growth restriction.[348]

Placental ion transporters are also subjected to regulation in fetal growth restriction. For example, the activities of Na^+–K^+–ATPase, the Na^+–H^+ exchanger, and lactate transporters are decreased in syncytiotrophoblast plasma membranes isolated from placentas of growth-restricted fetuses. The reduced Na^+–K^+–ATPase activity may increase intracellular concentrations of Na^+, thereby adversely affecting all transport processes dependent on the Na^+ and electrical gradient. Growth-restricted fetuses are prone to develop acidosis in utero, which may be due, in part, to the decreased activity of placental transporters that are critical for the elimination of protons from the fetal circulation. Other ion transporters, however, appear to be regulated quite differently. BM Ca^{2+}–ATPase is upregulated in placentas associated with fetal growth restriction, which may be caused by increased fetal concentrations of PTHrP (38–94),[232] a key regulator of the placental calcium pump.

Obesity

Obesity commonly affects pregnant women worldwide and increases the risk of larger (macrosomic) fetuses, along with related structural and metabolic abnormalities. The mechanisms linking excess maternal adiposity and fetal overgrowth are poorly understood, and the effect of maternal overweight and obesity on placental function remains largely unknown.[349] System A, but not System L, amino acid transport activity is increased in MVM isolated from placentas of obese Swedish women giving birth to large babies.[350] This finding correlated with the activity of placental insulin–IGF-I and mTOR signaling, whereas AMP-activated protein kinase phosphorylation was inversely correlated to birth weight.[350] Using villous fragments, other investigators have reported decreased placental System A activity in overweight or obese Hispanic women giving birth to normal-sized babies.[351] Studying placental transport in the placentas of obese mothers giving birth to normal-sized babies, Dube and coworkers found that placental lipoprotein lipase (LPL) activity and CD36 expression increased, yet placental expression of FATP4, FABP1, and FABP3 decreased.[352]

Additional studies are needed to allow firm conclusions with respect to the impact of maternal obesity on placental nutrient transport.

Diabetes

With the exception of women with type 1 diabetes who develop vascular complications, diabetes in pregnancy, in particular gestational diabetes, is associated with fetal overgrowth. Most studies suggest an increase in placental capacity to transfer nutrients in diabetes associated with fetal overgrowth; however, the data with respect to amino acid transport are less consistent (Table 39.4).

System A amino acid transport activity is reduced and System L transport activity is unaltered in MVM isolated from pregnancies with type 1 diabetes and fetal overgrowth.[172] In contrast, other investigators reported increased MVM System A transporter activity in Swedish women with type 1 diabetes, independent of fetal overgrowth. In addition, placental transport of leucine is increased in women with gestational diabetes. These inconsistent patterns may be related to methodological differences or to variations in study populations. Glucose transport activity and GLUT1 expression in the BM are increased in type 1 diabetes. Because the transport across the BM is likely the rate-limiting step in placental glucose transport, these changes are predicted to increase glucose delivery to the fetus, and they may contribute to fetal overgrowth in type 1 diabetes. Furthermore, the expression of GLUT9 is increased in the MVM and BM isolated from the placentas of women with diabetes,[181] supporting the evidence for increased placental glucose transport capacity associated with this pregnancy complication.

As discussed in this chapter, maternal lipoproteins are the predominant source of fetal fatty acids, likely contributed by the two key membrane-bound lipid hydrolases, lipoprotein lipase, and endothelial lipase.[247] The activity of placental LPL is increased in type 1 diabetes associated with fetal overgrowth. The expression of endothelial lipase is increased in the same conditions.[353,354] In addition, FABP1 expression is upregulated in the placenta in gestational diabetes or preexisting diabetes associated with a large newborn. Similarly, placental expression of FABP4 is elevated in pregnancies of obese women with diabetes.[355] Collectively, these findings suggest an increase in placental supply of lipids to the fetus in pregnant women with diabetes. Considering the complexity of placental nutrient transport as well as the diversity of diabetes phenotypes, additional work in the field is greatly needed.

TABLE 39.4 Alterations in Placental Transport in Maternal Diabetes Associated with Fetal Overgrowth

Transport System	MVM	BM
System A	↑, ↓	↔
System L	↑,[a] ↔	↔

CONCLUSION

Although the placenta forms the critical interface between the fetus and the mother, and is thus essential for the development, survival, and growth of all eutherian embryos, our understanding of placental development and function remains rudimentary. As a rapidly evolving organ, marked differences in placental morphology and function among eutherian embryos may challenge researchers seeking a useful animal model to study the human placenta. Conversely, deciphering evolutionary differences in placental function, when correlated with fetal development and postnatal adaptation, may illuminate important mechanisms underlying the placental support of intrauterine development and the balance between fetal demands and limiting maternal resources.

There are two fundamentally distinct, but not mutually exclusive, models for the regulation of placental transport function in response to developmental, environmental, or pathological influences. The *fetal demand model*, which is supported by several mouse studies, postulates that placental function is primarily controlled by fetal demand.[356,357] In response to maternal undernutrition or restricted utero-placental blood flow, the limited fetal nutrient availability signals to the placenta to bolster placental nutrient transport. This model represents a classical homeostatic mechanism by which the fetus compensates for changes in nutrient availability by regulating nutrient supply (i.e., placental transport) in the opposite direction, thereby correcting for deficiencies. The *maternal supply model*[358,359] suggests that the placenta responds to maternal nutritional cues, resulting in downregulation of placental nutrient transporters in

response to maternal undernutrition or restricted uteroplacental blood flow. Fetal nutrient availability will consequently decrease, resulting in fetal growth restriction. Maternal supply therefore represents a mechanism by which fetal growth is matched to the ability of the maternal supply line to allocate resources to the fetus. Maternal signals conveying nutritional information to the placenta may include metabolic hormones such as insulin, cortisol, leptin, and adiponectin, which are known to be influenced by maternal nutrition and regulate placental transport. Other possible signals to the placenta are oxygen and nutrient levels. Placental mTOR signaling may play a role in integrating these signals and in regulating fetal nutrient availability by modulating placental growth and nutrient transport.[359] In this context, it is noted that key placental transporters for amino acids, lipids, and ions are downregulated in human fetal growth restriction (Table 39.3), which is inconsistent with a homeostatic or fetal demand model for regulation of placental transport. However, most of these studies were performed at term, or in a few cases using tissue obtained from preterm deliveries in the third trimester. It is possible that compensatory changes consistent with fetal demand signals are present earlier in pregnancy, as has been shown in mouse models of growth restriction. Moreover, the distinct upregulation of BM Ca^{2+}–ATPase activity in placentas associated with fetal growth restriction may represent a compensatory activation of the placental calcium transport system in response to increased fetal demand. Published data indicate that placental capacity to transport free fatty acids, and possibly glucose, is increased in diabetic women, particularly in cases of fetal overgrowth. Thus, information gleaned from human diseases such as fetal growth restriction or fetal overgrowth generally supports the *maternal supply model* for regulation of placental transport.

The *maternal supply* and *fetal demand* models likely coexist. Recently, Gaccioli and coworkers proposed that the placenta integrates a multitude of maternal and fetal nutritional cues with information from intrinsic nutrient-sensing signaling pathways to balance fetal demand with the ability of the mother to support the pregnancy by regulating maternal physiology, placental growth, and nutrient transport (Figure 39.16).[360] It is speculated that the evolutionary pressure for the balance between maternal and fetal needs was mainly impacted by maternal undernutrition, which was the common situation throughout human history.[360] Although these regulatory loops may also function in the opposite direction in response to maternal overnutrition, it is possible that the placental responses may not be as readily apparent in maternal obesity or diabetes as they are in maternal undernutrition. Clearly, the relative importance of maternal supply and fetal demand signals for

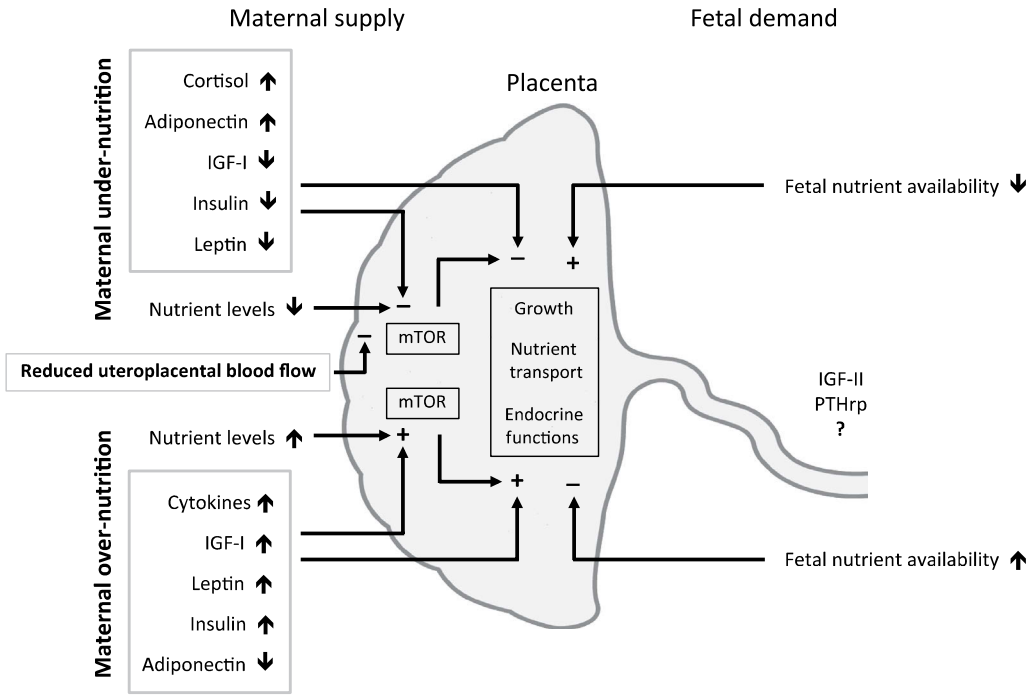

FIGURE 39.16 Maternal supply and fetal demand: an integrated model. The placenta integrates maternal and fetal nutritional signals through intrinsic nutrient sensors, such as mammalian target of rapamycin (mTOR) signaling. These signals then regulate placental growth and nutrient transport to balance fetal demand with the ability of the mother to support pregnancy. Thus, the placenta plays a critical role in modulating maternal–fetal resource allocation, thereby affecting fetal growth and the long-term health of the offspring. See text for detailed explanation. IGF: insulin-like growth factor; PTHrp: parathyroid hormone–related peptide. *Source: Reproduced with permission from Ref. 360.*

the regulation of placental function may differ between species, and depend on the type, duration, and severity of the nutritional perturbation.[360] It is plausible, for instance, that regulation by fetal demand signals is predominant when the nutritional challenge is moderate or brief, whereas regulation by maternal supply may override fetal demand signals if the nutritional challenge is more severe or prolonged. Matching fetal growth to maternal resources in situations of significant maternal undernutrition will produce an offspring that is smaller in size but which, in most instances, will survive and reproduce. Thus, rather than nutrient extraction from the already deprived mother, which will jeopardize the survival of both the mother and her fetus, restricted fetal growth might be the leading strategy.

Gerald J. Pepe

Department of Physiological Sciences, Eastern Virginia Medical School, Norfolk, VA, USA

INTRODUCTION

The placenta differs from virtually all other organs in that it is uniquely formed by the interaction of both maternal and fetal tissues, exhibits an extreme amount of diversity among species, and coordinates and participates in a vast number of functions (e.g., metabolic, endocrine, vascular, and immunologic) that are critical to maternal well-being and fetal development. Our current understanding of the structure, development, and physiologic and endocrine roles of the placenta reflects many years of work by pioneering investigators who challenged existing dogmas using a complement of in vivo and in vitro experimental approaches and technologic methods to test hypotheses.

Notable milestones regarding the structure of the placenta include the studies of (1) William and John Hunter, who independently showed (1774–1794) that the maternal and fetal circulations in the placenta are separate and not continuous and that the "convoluted" (i.e., spiral) arteries of the uterus deliver maternal blood to the placenta; (2) William Carpenter, whose experiments delineated the intervillous space; (3) Ambrosius Hubrecht, who in 1889 defined and named the tissue barrier between maternal and fetal circulations as the trophoblast (nutrition + germ) because of its direct nutritive significance and immediate contact with maternal tissue, blood, or secreted material; (4) Carl Friedlander, who in 1870 described the presence of intravascular cells within the lumen of spiral arteries and commented that "arteries" were only rarely observed, that intravascular cells were multinuclear and might come from the placenta, and that these cells slow down or interrupt maternal blood supply to the placenta; (5) Marcus Duval, who in 1890 confirmed trophoblast invasion into maternal arteries; and (6) William Turner, who in 1876 postulated that the maternal surface of the placenta was a secreting organ that provided nutrients to the fetus and proposed that the widely accepted doctrine that substances including oxygen simply diffuse through the walls of vessels from maternal to fetal blood should no longer be accepted.[1–4]

In the early to mid-1900s, our understanding of placental structure and development, as well as the similarities and important differences between species, was brought forth by the extensive work of Winfield Mossman, Emmanuel Amoroso, Gordon Bourne, James Boyd, William Hamilton, and Allen Enders.[3,4] Concomitant studies by Louis Flexner demonstrated placental transfer of radioactive sodium to the fetus, while Elizabeth Ramsey in collaboration with Martin Donner developed and applied cineradioangiographic techniques in vivo in the rhesus monkey to visualize the pattern of maternal blood flow in the intervillous space. Ramsey's pioneering work demonstrated that unlike the labyrinth placenta of rodents in which the maternal and fetal circulations run in opposite directions and gas exchange occurs via countercurrent mechanisms, in primates, maternal arteries do not carry oxygenated blood all the way to the fetal surface of the organ. Rather, oxygenated blood is delivered to the intervillous space in spurts, or as originally described by Ramsey the "winking and

Knobil and Neill's Physiology of Reproduction, Fourth Edition
http://dx.doi.org/10.1016/B978-0-12-397175-3.00040-5

blinking" circulation, indicating that placental perfusion is uneven,[1] a concept subsequently confirmed by several investigators.

As our understanding of the fine structure and significant vascular and transport functions of the placenta continued to increase, the concept that the placenta might also exhibit endocrine functions was initially suggested by Joseph Halban in 1905, a concept that gained significant support by the discovery of gonadotrophic activity in serum and urine of pregnant women by Ascheim and Zondek in 1927. As studies rapidly progressed to isolate and identify placental-derived protein and steroid hormones, Egon Diczfalusy and Pentti Siiteri using in vivo experimental approaches in pregnant women established in the 1960s the critical concept of a functional maternal–fetal–placental unit that highlighted the interdependence and interactions between the endocrine functions of maternal and fetal endocrine glands (EG) and the placenta. Accordingly, studies of the roles of placental hormones in key aspects of placental development, blood flow, maternal–fetal nutrient exchange, as well as timely maturation and growth of the fetus began to emerge.[3,4]

Today we recognize that the human and nonhuman primate placenta is the site of synthesis of steroid hormones and a diverse complement of peptide and protein hormones that function independently, as well as integral components of paracrine, autocrine, and endocrine control systems. During the past few decades, immunocytochemical, transgenic, and molecular advances have been employed to localize origin, define physiologic roles, and unravel the mechanisms underpinning the action of these hormones within the placenta.

This chapter will summarize the results of these recent studies; the developmental pattern and sites of expression, action, and regulation of the placental hormonal systems; and how they are integrated and function to (1) coordinate pregnancy recognition and maintenance; (2) control development of the placenta, including villous angiogenesis and remodeling of the maternal uterine spiral arteries by extravillous cytotrophoblasts; (3) regulate placental, maternal, and fetal organ systems controlling substrate availability and maternal and utero–fetal–placental vascular function; as well as (4) control the metabolism of hormones (e.g., cortisol–cortisone), thereby coordinating timely maturation of the fetal organ systems important for physiologic function in adulthood. The chapter will also summarize epidemiologic and genetic reports in humans and in vivo studies in nonhuman primate models of human pregnancy that are elucidating regulation, developmental roles, and underlying mechanisms of action of the placental endocrine system and that in humans are often associated with complications of pregnancy, for example preeclampsia, fetal growth restriction (FGR), and increased risk for diseases in adulthood.

PROTEIN HORMONES OF THE PLACENTA

The placenta produces significant quantities of the protein hormones, human chorionic gonadotropin (hCG) and placental lactogen (PL), which exhibit unique patterns of synthesis and regulate physiologic processes that are important to pregnancy. The placenta also synthesizes growth factors, the most physiologically relevant of which are insulin-like growth factor (IGF)-I and -II, transforming growth factor beta (TGFβ), epidermal growth factor (EGF), vascular endothelial growth factor (VEGF), and EG-VEGF. The structures and mechanisms underlying the regulation of the synthesis and actions of hCG and PL have been presented by Ogren and Talamantes[5] in an earlier edition of the *Physiology of Reproduction*. In the present chapter, we provide an overview of the regulation of hCG and PL synthesis and recent developments on the expression and physiological actions of these hormones and the placental growth factors (PlGFs) during pregnancy.

Human Chorionic Gonadotropin

Structure

hCG is a glycosylated protein heterodimer composed of noncovalently bound α and β subunits. Syncytiotrophoblast hCG is composed of a 2-oligosaccharide 92-amino-acid α subunit and a 6-oligosaccharide 145-amino-acid β subunit, exhibits a molecular weight of 37,180, and has a half-life in circulation of approximately 36 h. The highly glycosylated α and β subunits both contain several disulfide linkages that form cysteine knot motifs, which dictate folding of the protein essential for biologic activity and thus binding to the luteinizing hormone–chorionic gonadotropin (LH–CG) receptor, as well as hormone secretion. For example, deletion of any one of the bonds in the β subunit joining cysteines 9 and 90 (9–90), 34–88, or 38–57 decreases, whereas deletion of cysteine 26–110 or replacement of cysteine with other amino acids increases, hormone secretion. The three-dimensional structure of hCG has been determined, and the crystal structure of the deglycosylated protein[6] is depicted in Figure 40.1.

α-HUMAN CHORIONIC GONADOTROPIN

The mature 92-amino-acid α subunit of hCG has a molecular size of 14,500 kDa, of which 17% is contributed by carbohydrate.[7] Disulfide bonds of αhCG join cysteines 7–31, 10–32, 28–60, 59–87, and 82–84.[8] The α subunit also contains two N-linked oligosaccharide chains at asn-52 and asn-78. An α subunit that does not combine with β-hCG (termed a free α subunit) is also expressed by the placenta and detected in maternal serum.[9] The increased

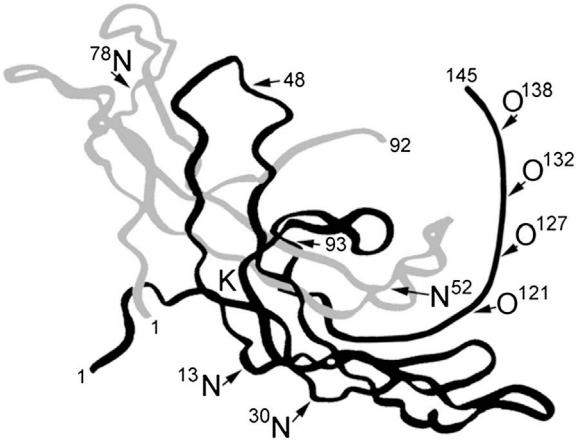

FIGURE 40.1 Crystal structure of deglycosylated regular hCG, as originally determined by Lapthorn et al.[6] and adapted by Cole.[7] The unfolded β-subunit C-terminal peptide is added (missing in crystal structure). It is inferred that this structure is not folded since the sequence comprises primarily a polymer of proline and serine residues. The symbol N indicates the attachment site of N-linked oligosaccharides, and the symbol O the attachment site of O-linked oligosaccharides. Residue β48 is indicated, the site of nicking of hCG (β47–48), and residue β93, the site of cleavage of the β-subunit C-terminal peptide (β92–93). The symbol K indicates the site of the cystine knot structure, four peptides (β1–15, β30–45, β80–100, and β50–65) linked by three disulfide bridges, β34–88, β9–57, and β38–90. The α-subunit is shown in gray, and the β-subunit is shown in black. *Source: Reprinted with permission from Ref. 7.*

size of the N-linked oligosaccharides of free α subunit is thought to be the major factor preventing dimerization with β-hCG.

The α subunit gene is located on chromosome 6q14-q21 and is expressed in the pituitary and placenta.[10] A number of regulatory elements in the 5′ flanking region are important for placental expression and regulation.[11] These include two cyclic adenosine monophosphate (cAMP) response elements (CREs)[12]; a trophoblast-specific upstream regulatory element (URE)[13]; an alpha-activator element (α-ACT)[14]; a junctional regulatory element (JRE)[15]; a CCAAT region[16]; three glucocorticoid response elements (GREs), of which only GRE2 confers glucocorticoid responsiveness[17]; and an element that spans nucleotides (nt) 244 and 213. The CREs bind nuclear proteins, including CREB-327, which is activated after phosphorylation by cAMP–protein kinase A (PKA). The URE also interacts with the CRE, but the mechanisms are not fully known. Although α subunit is also expressed in pituitary cells, expression is regulated by elements that differ from those in the placenta and include a gonadotrope-specific element (GSE).[18]

β HUMAN CHORIONIC GONADOTROPIN

The mature β subunit of hCG is composed of 145 amino acids and is structurally similar to the β subunit of pituitary LH, differing only in the terminal 28 amino acids. Six disulfide bonds of βhCG join cysteines 9 and 90 (9–90), 23–72, 26–110, 34–88, 38–57, and 93–100. The β subunit exhibits a molecular size of 22,200 kDa and contains six oligosaccharide chains, two of which are N-linked to asn-13 and asn-30 and four O-linked to ser-121, ser-127, ser-132, and ser-138. As a consequence, βhCG exhibits extensive structural heterogeneity.

The β subunit of hCG is encoded by a cluster of nonallelic genes (βhCG1, 2, 3, 5, 7, and 8), which includes the LHβ gene located on chromosome 19q13.32 (Figure 40.2(A) and (B)).[11,19–21] The βhCG genes are grouped into type 1 (βhCG7) and type 2 (βhCG3, 5, and 8) and share 97–99% DNA sequence identity.[22] The type 2 βhCG genes encode for the same protein, whereas the type 1 gene encodes a protein that differs by three amino acids, notably replacement of a proline in type 2 by a methionine. Although the βhCG1 and βhCG 2 genes share 85% identity with the other genes in the cluster, they encode a protein of 132 amino acids that exhibits no homology with the β subunit of hCG and that does not correspond to any known protein in the GenBank database.[22] Although all four βhCG type 1 and 2 genes are expressed in placental villous and extravillous trophoblasts (EVTs), βhCG5 and βhCG8 are the most actively transcribed.[19,22] Thus, 60–85% of the total βhCG mRNA extracted from placenta is βhCG5 and βhCG8 (Figure 40.2(A)).[20–22] Studies of the βhCG5 gene indicate that regulatory promoter sequences are located between nt 78 and the transcription start site,[23] with CREs at nt 311-187, nt 44-357, and nt 3700-775.[24] Suppressor activity is also present in the region at nt 287-191,[24] but the regulatory mechanisms and elements involved have not been defined. In addition to synthesis by the placental trophoblast, hCG is also expressed in other tissues, particularly the secretory phase endometrium where the βCG6 and βCG7 subunits are formed.[25] As described by Ogren and Talamantes,[5] structure–function relationships in hCG have focused on assessing subunit contact sites in the αβ dimer, receptor binding, and the role of the disulfide bonds and oligosaccharide chains.

Synthesis and Secretion

hCG is produced by the villous cytotrophoblasts prior to week 6 of gestation and primarily by the syncytiotrophoblast thereafter. Ultrastructural studies indicate that hCG is localized in secretory granules of trophoblast cells and that virtually all of the hormone after it is synthesized is released and not stored. Levels of intact hCG in maternal blood are detectable approximately 1–3 days after implantation, rapidly rise thereafter with peak levels being achieved between weeks 8 and 12 of gestation, and subsequently decline and remain relatively constant after weeks 18–20 (Figure 40.3).[26] hCG is also detected in fetal blood and amniotic fluid, and levels in both compartments show a pattern similar to that in

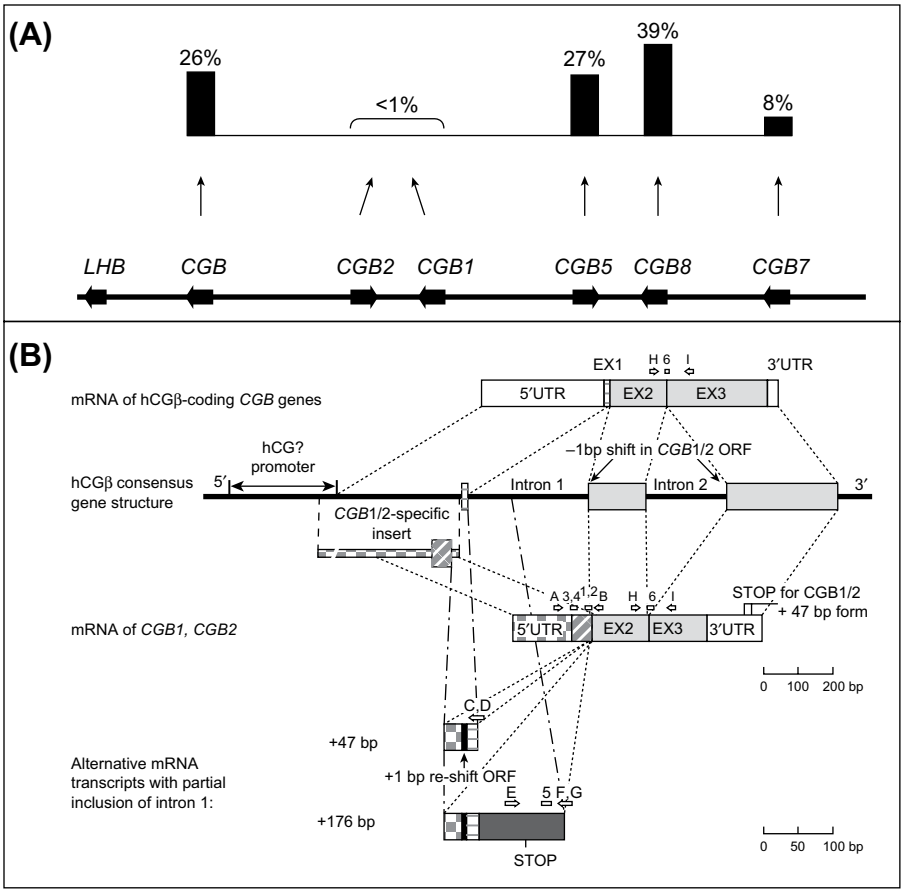

FIGURE 40.2 (A) Schematic presentation of the βLH–βhCG (*LHB–CGB*) gene cluster with genes marked as black wide arrows in the direction of the transcription on sense strand and contribution of each individual βhCG gene to the total mRNA pool. (B) Schematic representation of the structure of the βhCG genes, with coding segments marked on the consensus gene structure with gray boxes, except for the exon 1 for βhCG-coding genes (horizontal stripes) and for *CGB1–CGB2* (diagonal stripes). The 5′UTR of mRNA transcribed from βhCG-coding genes (white box) differs from the 5′UTR for *CGB1–CGB2* (checkered box); the 3′UTR of the two groups is of variable length (white box). Alternative +47 bp *CGB1–CGB2* mRNA forms contain an additional sequence from *CGB1–CGB2*-specific intron 1 (22 bp, black box), including the fragment corresponding to the hCGβ 5′UTR (10 bp, checkered box) and exon 1 (15 bp, horizontal stripes), resulting in a reshift of the *CGB1–CGB2* open reading frame (ORF) to the ORF of hCGβ-coding transcripts. Due to sequence divergence in the 3′UTR of *CGB1–CGB2*, the predicted STOP codons for +47 bp *CGB1* and +47 bp *CGB2* differ by seven amino acids. Alternative transcripts +166 bp (not shown in the figure) and +176 bp contain additional 119 and 129 bp sequences identical to the intronic part of all *CGB* genes (black box). The predicted STOP codon for +166 and +176 bp forms is located at position 355 from the transcription start. *Source: Adapted with permission from Refs 20,21.*

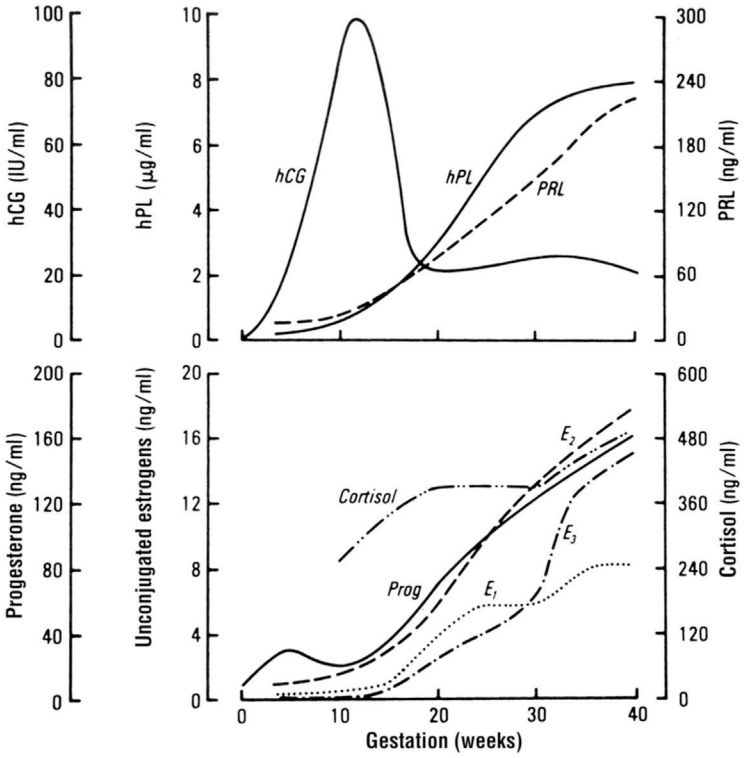

FIGURE 40.3 Serum concentrations of prolactin, human chorionic gonadotropin (hCG), human placental lactogen (hPL), cortisol, progesterone, and unconjugated estrogens during pregnancy. The values have been obtained from several sources in the literature. E_1, estrone; E_2, estradiol; E_3, estriol; PRL, prolactin. *Source: Reprinted with permission from Ref. 26.*

maternal circulation. However, fetal hCG levels are only 3% of those in the mother, whereas levels in amniotic fluid are similar to maternal concentrations during the first trimester, then decline to 20% of that in maternal blood thereafter. Amniotic fluid hCG is thought to originate from direct secretion by trophoblast cells, as well as production by and excretion from the fetal kidney.[27]

It is well established that the profile of hCG in maternal blood is determined by the rate of hCG synthesis and reflects changes in both the number of hCG-producing cells and the synthetic and secretory capacity of individual cells. Thus, the increase in hCG after implantation parallels the increase in trophoblast cell numbers, whereas the decline in hormone production after the first trimester is associated with a decrease in the number of cytotrophoblasts due to fusion of these cells and transformation to the syncytiotrophoblast. The rate of synthesis of hCG and the expression and levels of mRNAs for the α and β subunits, including both type 1 and type 2 βhCG, are greater in trophoblast cells obtained in early than in late gestation.[28]

Maternal blood levels of hCG and other placental-derived proteins, alone or in combination, are altered in and thus may be predictive of several pregnancy complications. For example, in addition to serving as confirmatory of pregnancy, hCG levels are increased in women who develop hypertension and preeclampsia and in Down syndrome, are reduced in early gestation in pregnancies complicated by FGR,[29] and may also serve as a predictor of pregnancy outcome (e.g., preterm birth and fetal demise).[30] Moreover, placental expression of the βhCG genes is reduced in pregnancies with recurrent miscarriage.[21,22] Whereas expression of the βhCG5 and βhCG8 genes is biallelic in healthy pregnancies, monoallelic expression of maternal alleles and hemimethylated gene promoters often characterizes recurrent pregnancy loss.[31] Recent studies have confirmed the existence of more than 70 variants of the βhCG5 and βhCG8 genes.[32] Interestingly, a significant protective effect against miscarriage was associated with two single-nucleotide polymorphisms in intron 2 of both genes and with four variants in the βhCG5 promoter. In contrast, in women with recurrent miscarriage, three nonsynonymous substitutions were identified: a p.Val56Leu mutation in βhCG5 that altered the assembly and functionality of intact αhCG–βhCG heterodimers, a p.Pro73Arg substitution in βhCG8 that altered the conformation of the βhCG subunit, and p.Arg8Trp in βhCG8 that was neutral in a structural–functional context.[32]

Regulation of Synthesis

It is well established that the cAMP–PKA pathway has a pivotal role in stimulating hCG secretion.[33] cAMP, which stimulates PKA and phosphorylation of CREBs essential for binding to CRE in the 5′-flanking region of the hCG genes, increases the mRNA levels of both α and β subunits.[34] Two adjacent *cis*-acting elements that bind a phosphorylated form of CRE-binding protein,[15] GATA-binding proteins,[35] and POU domain class 5 transcription factor 1-modulated ETS (E26)[36] regulate αhCG (CGA) expression by trophoblast. Intracellular cAMP also enhances processing of N-linked oligosaccharide chains, resulting in carbohydrate structures with increased sialic acid content.[37] An elevation in hCG mRNA level is due to an increase in the rate of gene transcription and enhanced stabilization of newly formed RNA.[38] Although activation of the diacylglycerol–protein kinase C pathway by phorbol esters stimulates hCG synthesis, this only occurs after a long lag period following activation of α and β subunit mRNA synthesis. Thus, the physiological role of this pathway remains to be determined, although it has been suggested that synergistic interaction between the PKA and PKC pathways may underpin optimal hCG secretion and release.[5]

Khodr and Siler-Khodr[39] originally showed that the human placenta produced a gonadotrophin-releasing hormone (GnRH) that stimulated hCG production in vitro. Additional studies confirmed placental expression of GnRH receptor and that the receptor was linked to cAMP. However, as previously reviewed by Ogren and Talamantes,[5] numerous other factors alone or in combination have been shown to modulate hCG production and/or mRNA expression by native or transformed trophoblast cells. These include growth factors (e.g., EGF, fibroblast growth factor (FGF), and IGF1), steroid hormones (e.g., cortisol), cytokines (e.g., interleukin 6 (IL6), tumor necrosis factor alpha (TNFα), and TGFβ), other hormones (insulin, oxytocin, and arginine vasopressin), as well as oxygen[40] and agonists of the peroxisome-proliferator activated receptor gamma (PPARγ).[41] Thus, despite intensive investigation, our understanding of the physiological role and potential interaction of the latter factors in regulating the synthesis of trophoblast hCG is incomplete.

Function

The most well-established role of hCG is in the regulation of the maintenance and function of the corpus luteum in early pregnancy. hCG binds to the LH–CG receptor to maintain the life span of, promote luteal angiogenesis within, as well as stimulate progesterone (P_4) and estradiol (E_2) synthesis by the corpus luteum.[42] hCG stimulates luteal P_4 and E_2 production by increasing low-density lipoprotein (LDL) receptor-mediated uptake of cholesterol substrate and increasing the expression of key enzymes, including P450 cholesterol side-change cleavage (P450scc), 3β-hydroxysteroid dehydrogenase (3β-HSD), and aromatase (P450arom), required for steroidogenesis.[43] A second, clearly

established role of hCG is on fetal testis development and function in the first trimester. hCG secreted into the fetus during 8–12 weeks of gestation stimulates testosterone production by the fetal testes,[44] a process essential for differentiation of the internal duct system and external genitalia in the male fetus. hCG has also been shown to stimulate production of relaxin by the corpus luteum, which may act locally to prevent regression of luteal cells, as well as elicit vascular effects in other organs and peripheral tissues.[45]

As reviewed by Rao,[46,47] however, hCG appears to regulate several processes in addition to gonadal function. Thus, hCG produced by the blastocyst also appears to participate in the process of decidualization[48] and development of endometrial receptivity for implantation, in part by controlling expression of factors (e.g., FGF2) that promote cross-talk between the embryo and endometrium[49] and the β-galactoside-binding protein galectin-3.[50] Recent studies show that hCG amplifies IL1 signaling and responsiveness in endometrial stromal cells, leading to the release of angiogenic factors and induction of angiogenesis, thereby coordinating embryonic signaling with endometrial function to promote embryonic growth (Figure 40.4).[51] hCG may also play a role in promoting immune tolerance during human pregnancy[52] by attracting T regulatory cells to the maternal–fetal interface, increasing the number of T cells and their capacity to secrete suppressive cytokines,[53] and enhancing expression of complement regulatory proteins.[54] In addition, hCG binds to its receptor expressed on villous cytotrophoblasts to enhance fusion of these cells, a process that underpins syncytiotrophoblast formation. Thus, it has been proposed that hCG acts in an autocrine manner to control development of the placenta.[55] hCG also stimulated expression of placental leptin[56] and VEGF,[57] uterine angiogenesis,[58–60] and placental expression of the 11β-hydroxysteroid dehydrogenase (11β-HSD)-2 enzyme controlling cortisol catabolism.[61] The high levels of hCG secreted into the maternal circulation during early gestation are associated with a marked reduction in serum thyroid-stimulating hormone (TSH) concentrations, which rebound when hCG levels decline after weeks 12–14 of gestation.[62] Thus, it has been proposed that hCG binds to the TSH receptor and thereby increases maternal thyroid hormone production.[62] Indeed, women with hyperemesis gravidarum or hCG-producing trophoblastic tumors (e.g., hydatidiform mole or choriocarcinoma) often have extremely high levels of hCG and concomitant transient hyperthyroidism.

Recent evidence also indicates that hCG stimulates proliferation[63] and promotes quiescence[64] of uterine myometrial smooth muscle during the second half of gestation. Thus, hCG reduces the amplitude of oxytocin-stimulated uterine contractions by activating large conductance calcium-activated potassium channels of myometrial cells,[64] and it decreases expression and activity of the phosphodiesterase-5 enzyme (PDE5) controlling hydrolysis and thus intracellular levels of cyclic nucleotides (e.g., cyclic guanosine monophosphate (cGMP)) that regulate contractility.[65] Whether the decline in hCG levels late in gestation and/or the apparent decrease in myometrial hCG receptor expression prior to onset of labor[66] facilitates prostaglandin and oxytocin-induced myometrial contractions remains to be determined.

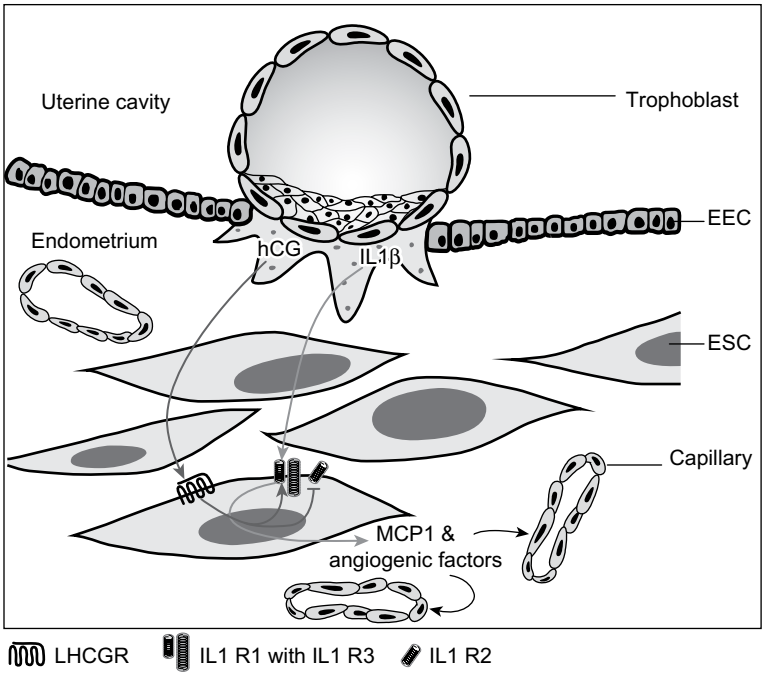

FIGURE 40.4 Hypothesis of hCG and IL1 cross-talk in early pregnancy. Synthesized early by trophoblastic cells, hCG and IL1B act through the endometrial tissue on endometrial stromal cells (ESCs) via their respective receptors (LHCGR, IL1R2, and IL1R1). hCG amplifies IL1 signaling in ESCs, leading to increased cell responsiveness to IL1, the release of angiogenic factors, and the induction of angiogenesis. One of these identified factors is MCP1. EEC, endometrial epithelial cells. *Source: Reprinted with permission from Ref. 51.*

hCG action involves activation of the hCG receptor and induction of cAMP and PKA.[67] Recent studies[68] have shown that cAMP-induced PKA signaling involves binding of the regulatory subunits of PKA to A-kinase anchoring proteins (AKAPs). Such binding ensures specific subcellular compartmentalization of PKA and thus spatial and temporal regulation of PKA signaling events. The AKAPs are composed of a family of more than 50 members that are structurally diverse, but functionally related, proteins that bind to and recruit PKA to locations where it can be accessed by specific regulators and phosphorylate specific substrates. Several AKAPs have been identified in human placenta, including ezrin, AKAP18γ, AKAP350, AKAP70, AKAP95, and AKAP250. The spatiotemporal regulation of PKA signaling by hCG appears to underpin its action (e.g., on placental function).[68] Interestingly, hCG appears to stimulate placental leptin expression through a PKA-independent cAMP and exchange protein activated by cAMP.[69] Moreover, hCG-induced stimulation of the migration and invasion of prostate cancer cells is mediated by activation of extracellular-regulated kinase 1 and 2 (ERK1/2) and matrix metalloproteinase 2 (MMP2).[70] Finally, although hCG and LH act on the same receptor, recent evidence indicates that intracellular signaling may be quantitatively and/or qualitatively different (e.g., hCG is a more potent stimulator of cAMP production).[71]

HYPERGLYCOSYLATED hCG (hCG-H)

Recent evidence indicates that there are five independent hCG variants, each with the same amino acid sequence and differing in the nature and extent of posttranslational processing, which influences protein folding and thus biologic action.[7] The two hCG molecules produced by the placenta are hCG synthesized by the syncytiotrophoblast and hCG-H synthesized by EVTs.[72–74] Additional studies confirmed that EVTs expressed αhCG and βhCG mRNA and that expression was modulated by agonists of PPARγ.[41] The pituitary produces what is now termed sulfated hCG. Malignant cells produce hCGβ and hyperglycosylated hCGβ, which are not linked with the α subunit.[75] A summary of the properties of these five independent variants of hCG is shown in Table 40.1.

Maternal serum levels of hCG-H are actually higher than those of hCG during the first 6 weeks of gestation, peak at about weeks 10–14, and decline thereafter. Several forms of glycosylated hCG, including hCG-H, have been detected in maternal serum, including a specific variant originally termed invasive trophoblast antigen,[75] which is highly expressed in Down syndrome. hCG-H has a molecular weight of 42,800 due entirely to enhanced sugar content (Table 40.1), which leads to incomplete folding of the protein and exposure of sequences otherwise hidden, most notably the cryptic central cysteine knot domain.[7] This structure has also been identified in a number of factors that comprise a cystine knot superfamily that includes VEGF and TGFβ.[76] Accordingly, hCG-H has been shown to bind to and antagonize TGFβ receptors on cytotrophoblast cells, a process underpinning implantation of the blastocyst as well as stimulating angiogenesis through TGFβ receptor activation.[75,76] It has been suggested that hCG-H works with hCG to control differentiation and fusion of new cytotrophoblast cells to form the syncytiotrophoblast and thus placental growth,[73] as well as promote trophoblast migration and invasion in vitro.[7,77] Thus, it has been suggested that a deficiency of hCG-H causes incomplete blastocyst implantation, as well as miscarriage, and thus is a marker for failing pregnancy.[75] Although additional studies remain to be performed, screening of hCG-H alone and/or in conjunction with other factors of placental origin may be critical for early diagnosis of patients likely to exhibit pregnancy complications, notably Down syndrome and preeclampsia.[75]

Placental Lactogen

Structure and Expression

PL, also designated chorionic somatomammotropin (CS), first partially purified in the early 1960s,[78–80] is a member of the growth hormone (GH) family, which also consists of pituitary GH (GH-N) and placental GH variant (GH-V).[81–83] Members of the GH-PL gene cluster are located on chromosome 17 and are very similar in structure.[84] Expression of the GH gene cluster is regulated by a locus control region,[85] which contains hypersensitive sites. These short regions of chromatin become sensitive to DNase cleavage when transcription factors bind to DNA and displace histones within the hypersensitive site.[86] The hypersensitive sites are placental and pituitary specific, and they recruit histone acetyltransferases and deacetylases, which link to transcriptional activation within the GH promoter. Differentiation of placental cytotrophoblasts into the syncytiotrophoblast results in histone methylation of the DNase I-hypersensitive sites III, IV, and V (HSIII–HSV)[87] and acetylation of histones encompassing the entire GH cluster region.[86]

Human PL (hPL) is a nonglycosylated single-chain polypeptide with 191 amino acids and a molecular weight of 22,279. There is over 96% amino acid homology between PL and GH. Two disulfide bonds stabilize the secondary and tertiary structure of PL. Three genes, CSA (designated CSH1), CSB (aka CSH2), and CSL, encode PL and exhibit 94–98% sequence homology in their coding and flanking regions. The CSA and CSB genes encode PL protein differing by a single amino acid,

TABLE 40.1 Properties of the Five Independent Variants of Human Chorionic Gonadotropin (hCG)

Parameter	hCG	Sulfated hCG	Hyperglycosylated hCG	hCGβ	Hyperglycosylated hCGβ
Source of synthesis	Syncytiotrophoblast	Gonadotrope	Cytotrophoblast	Advanced malignancy	Advanced malignancy
Mode of action	Endocrine	Endocrine	Autocrine	Autocrine	Autocrine
Total molecular weight	37,180	36,150	42,800	23,300	27,600
Site of action	LH–hCG receptor	LH–hCG receptor	TGFβ antagonism	TGFβ antagonism	TGFβ antagonism
Peptide molecular weight	26,200	26,200	26,200	16,000	16,000
Molecular weight sugars	10,980	9950	16,600	7300	11,600

Modified from Ref. 7.

while the secreted protein products of the genes are identical.[88–90] The CSL gene contains a G-to-A transversion at the splice site, which prevents pre-mRNA processing and thus expression of CSL protein of the same size as PL. The expression of placental CSA mRNA increases 30-fold and CSB mRNA 10-fold between early and late gestation,[91] suggesting that the CSA gene is more transcriptionally active as placental syncytial development occurs.[92,93] Approximately 90% of CS mRNA is encoded by the CSA gene in the first and second trimesters of human pregnancy.[89,91,94]

Elegant studies have recently been conducted to elucidate the structural events that govern utilization of the transcription start sites of the CSA and CSB genes and the sequence requirements for efficient CS expression in vivo. A 241 bp region located downstream of the CSB gene, which contains hyperacetylated histones H3 and H4, enhances promoter activity in human placental cells.[84,87] Moreover, transcription enhancer factors (TEF), including TEF1 and TEF5, bind to an enhancer element to confer placental-specific CSB expression.[95,96] The difference in transcriptional activity between CSA and CSB enhancer regions has been traced to one or two nucleotide differences in repressor and de-repressor elements.[97,98] Moreover, members of the CCAAT–enhancer-binding protein (C/EBP) and ETS family of transcription factors also differentially modulate CSA and CSB enhancer activities.[99] C/EBP and ETS binding in the CSA enhancer may be significant, since ETS signaling appears to play an important role in development of the placenta.[100] Moreover, by regulating promoter–enhancer complexes and/or chromatin modification, ETS and C/EBP members also may contribute to the expression of CS in the placenta and its lack of expression in the pituitary.[99] The promoter regions of the CSA and CSB genes also bind the transcription factor specificity protein 1 (SP1), which is necessary for transcriptional activation of these genes.[95]

Production

PL is synthesized within the villous placenta, and differentiation of villous cytotrophoblasts into the multinucleated syncytiotrophoblast during the first trimester of human pregnancy results in a striking exponential upregulation of PL production (Figure 40.3).[101,102] The maternal serum levels of PL correlate directly with placental mass. Near term, levels of hPL are approximately 1000-fold higher in maternal (5–10 μg/ml) than in fetal (20–30 ng/ml) circulation, suggesting that PL is differentially secreted from the syncytiotrophoblast into the maternal compartment. The daily production of hPL approximates 1 g, an amount exceeding that of any other protein hormone produced by the placenta. Human PL is stored in and released via exocytosis from Golgi, and the half-life of PL is approximately 20 min.[103]

Regulation of Synthesis

Because PL appears to have an important role in modulating intermediary metabolism within the mother, there has been extensive investigation to determine the effects of components of intermediary metabolism on PL synthesis. Prolonged fasting in the human results in a significant increase in maternal plasma PL levels.[104] Although a decrease in maternal hPL levels with hyperglycemia has been reported,[105] other in vivo and in vitro studies have not shown an effect of glucose on PL secretion.[106,107] Moreover, conflicting results of the relationship of insulin and triglycerides to PL secretion have also been shown in cultures of term placental cells.[108–110] It appears, therefore, that prolonged fasting and hyperglycemia alter the secretion of PL, while short-term alterations in glucose and related intermediary metabolites have little impact on PL release.

Handwerger and colleagues have shown that physiological levels of high-density lipoprotein (HDL), as mediated by apolipoproteins AI and AII, stimulate PL secretion by human trophoblast cultures.[111–114]

Moreover, GH-N[115] and GH-V, which bind to the GH receptor expressed in the placenta[116]; EGF[117]; IGF-I[118]; and the transcription factors PPARγ[119] and activator protein 2[120] stimulate PL secretion in cultures of human placental cells, although the regulatory effects of the growth factors may be related to transformation of cytotrophoblasts to the syncytia. Studies of the role of steroid hormones on placental PL secretion have yielded disparate results. Thus, glucocorticoids, E_2, and P_4 have either increased or no effect on PL release in vivo or in vitro by human placental explants.[110,117,121,122] GH-releasing hormone (GHRH) and the dopamine, acetylcholine, and β-adrenergic neurotransmitters that are present in the placental milieu stimulated, inhibited, or had no effect on PL release in vitro.[123–125] Arachidonic acid and cAMP stimulated the in vitro secretion of PL,[126–128] while oxygen induced expression of the GH cluster genes.[129]

Thus, despite extensive study, a clear picture of the physiological regulation of PL secretion has not been developed. This problem may reflect the widely different in vitro and in vivo experimental approaches that have been employed in this area of placental physiology.

Function

Since the structure of PL is very similar to that of GH and prolactin (PRL), and PL binds with high affinity to prolactin and GH receptors, it is not surprising that PL has effects on intermediary metabolism, growth, and lactogen function. In vitro studies showed that PL stimulated human pancreatic islet beta cell replication and insulin secretion,[130–132] and that overexpression of PL in beta cells increased mitosis and insulin production[133–135] and protected against the development of diabetes in streptozotocin-treated mice.[134,136] Knockout of the prolactin receptor, which is expressed in islet beta cells,[137,138] reduced beta cell mass, proliferation, and insulin secretion and impaired glucose clearance but not insulin sensitivity,[139,140] indicating that lactogen signaling is necessary for pancreatic beta cell development and function. PL and prolactin induced beta cell expression of cyclins A, B, and D and decreased expression of Fox01, FoxM1, cyclin-dependent kinase inhibitors, and the transcriptional coactivator menin that targets the latter inhibitors.[141–143] PL also stimulated the production of growth-promoting serotonin[144] and enhanced beta cell survival[136] in cultures of rodent pancreatic islets. In cultures of beta TC 1 (βTC1) insulinoma cells and human pancreatic islets, PL but not GH promoted cell survival and insulin secretion by rapid activation of the protein kinase B (Akt)–mitogen-activated protein kinase (MAPK) signaling pathway, phosphorylation of Janus tyrosine kinases (JAKs) and signal transducers and activators of transcription (STATs), as well as expression of the homeobox pancreatic duodenal homeobox 1 (PDX1) transcription factor.[132,145] The parallel increase in circulating PL levels and pancreatic beta cell replication during human and rat pregnancy[146,147] is consistent with a role for the lactogens in promoting maternal beta cell replication. Since lactogenic hormones counteract the inhibitory effects of glucocorticosteroids on expression of pyruvate dehydrogenase,[148] which is important to pyruvate metabolism and flux into the Krebs cycle, Freemark and coworkers[149,150] have suggested that lactogenic hormones may maintain beta cell mass and function under conditions of stress and nutrient deprivation to protect against the development of gestational diabetes.

In contrast to these recent findings, earlier studies have shown that PL either increased[151] or had no effect[152] on insulin secretion in vivo and decreased insulin sensitivity in the liver of rodents.[153] Moreover, although PL has been shown to stimulate glucose uptake and oxidation during the fed state consistent with its effects on insulin secretion, PL reduced insulin sensitivity and induced glucose intolerance during fasting in the presence of elevated levels of prolactin and glucocorticoids at mid- to late pregnancy.[151,154] The latter effects, along with an increase in lipolysis,[155] may ensure the utilization of free fatty acids as a source of energy for the mother, while sparing glucose as a primary source of energy for the fetus. Since increased maternal lipolysis and fatty acid re-esterification occur in association with the elevation in PL during advancing human pregnancy,[156] these effects appear to be physiologically relevant. More recent studies, however, have not confirmed the direct lipolytic effects of lactogenic hormones,[157] and thus the role of these hormones in maternal lipid metabolism and insulin resistance is unclear. It also appears that PL and/or prolactin may play a role in maternal hyperphagia and weight gain during pregnancy,[149,158] possibly by inducing hypothalamic neuropeptide Y (NPY) expression.

There is considerable evidence that PL promotes fetal growth, since PL stimulated amino acid uptake and thymidine incorporation by human fetal fibroblasts and skeletal muscle,[159,160] tissues that express PL-binding sites. Because expression of IGF1 and IGF-binding protein (IGF-BP) was simultaneously increased by PL administration,[161] the regulatory effects of PL on fetal tissue growth may be mediated by IGF1. Finally, PL also stimulated proliferation of epithelial cells[162] and ductal growth[163] in the human mammary gland and lactogenesis in laboratory animals.[164]

Growth Hormone Variant

Growth hormone variant (GH-V), first described in 1985,[165] is a glycosylated protein that contains 191 amino acids and differs from GH-N by only 15 amino acids. The GH-V gene undergoes alternative splicing producing a second protein designated GH-V2. GH-V2 accounts for approximately 5% in the first trimester and 15% in the

third trimester of the placental GH-V gene mRNA transcripts. However, hGH-V and hGH-V2 mRNAs account for less than 0.05% of total placenta mRNA at term. GH-V is synthesized by the syncytiotrophoblast, and maternal circulating levels progressively increase, reaching a maximum of 20–60 ng/ml in the third trimester of human pregnancy.[166] Although GH-V is not detectable in the fetus, GH-N is present in relatively high levels, 20–30 ng/ml, in fetal serum.

Regulation of Synthesis and Function

Relatively little is known about the regulation of GH-V synthesis, although triiodotyrosine[167] and the transcription factor AP2[120] increased, while GHRH had no effect[168] on GH-V expression or secretion by BeWo choriocarcinoma cells or primary placental cells. The GH-V promoter is transactivated by the transcription factors myocyte enhancer factor 2 and FoxF1, an effect that may involve coactivation.[169] GH-V binds to the prolactin and GH receptors, and the affinities of GH-V and GH-N for the GH receptor are similar. GH-V exhibited somatotropic[170] and metabolic[171] effects with potency approximating that of GH-N. GH-V is also considered a major mediator of insulin resistance during pregnancy, via its modulatory action on IGF1 expression and insulin action in transgenic mice.[172]

Physiological Relevance and Clinical Correlations of PL and GH-V

Disruption of fetal development (e.g., FGR) during human pregnancy is associated with lower placental PL and GH-V levels or transcripts.[94,149,173,174] In contrast, placental CSA and CSB but not GH-V, mRNA transcript expression, and PL levels were greater in pregnancies with large for gestational age babies.[86,94,175] Thus, PL and GH-V appear to be differentially regulated and expressed in association with altered fetal growth, possibly as a result of polymorphisms or epigenetic modifications in the locus control region, alternative allelic composition of the promoter affecting binding of regulatory transcription factors, or changes in placental trophoblast differentiation.[87,176] It has been postulated that the differential regulation of PL and GH-V in pregnancies with small and large for gestational age babies may provide adaptive maternal and fetal benefits, whereby alterations in PL and GH-V induced by changes in placental sufficiency change the production of insulin and/or IGF1, leading to decreased or increased fetal growth.[177]

Of a total of 11 human pregnancies in which PL was not detectable in maternal plasma, five had low newborn birth weights in the 7th percentile.[149] Deletion of PL and GH-V was associated with either FGR or unaltered fetal growth.[177] As suggested by Freemark,[149] the disparate results on birth weight may reflect compensatory upregulation of the expression of members of the GH family and/or other growth factors in response to PL or GH-V deletion. Decreased plasma levels of PL also occur in pregnancies complicated by preeclampsia and other pathologic conditions, including diabetes mellitus and hypertensive vascular disease,[178–180] most likely because of the decrease in placental mass associated with these clinical conditions. Freemark and colleagues[158] have created a prolactin receptor knockout–GH-deficient mouse model to study the roles of the lactogens and somatotropic hormones in perinatal and postnatal growth and metabolism. Although body weights and plasma glucose were normal in single-mutant mice, double mutants exhibited growth retardation and hypoglycemia, suggesting that lactogens and somatogens act in concert to promote perinatal growth and glucose metabolism.

In summary, despite the effects of PL shown in vitro or in vivo, several studies have shown that women with very low or undetectable levels of hPL (because of partial or complete deletion of the CSA and CSB genes)[181,182] maintained pregnancy and exhibited normal glucose tolerance, insulin sensitivity, lactation, and newborn birth weight.[183–185] The disparate effects of PL on these physiological endpoints may reflect the wide range of experimental approaches, the physiological conditions of and use of nonpregnant as well as pregnant subjects, and variation in the doses and preparations of PL employed in these studies. In addition, PL may act in concert with prolactin, GH-N, GH-V, as well as other growth factors (e.g., IGFs) in regulating metabolic adjustments, pregnancy maintenance, and fetal growth during advancing human pregnancy.

Placental Growth Factors

IGF-I and -II

The IGFs are members of a family of peptides related structurally to insulin. IGF-I and IGF-II share >60% sequence homology, have a molecular mass of approximately 7600 kDa, and, like insulin, are composed of α and β chains connected by disulfide bonds.[186–188] The gene for IGF-I is located on chromosome 12 (12q22–24.1), and transcription is governed by two promoters, one adjacent to exon 1 and the other 5′ to exon 2. The IGF-I gene also has several polyadenylation sites within exon 6. Both promoters regulate transcription at several sites, but they lack "TATAA"-, "CCAAT"-, or "GC"-rich regions. Moreover, the mRNAs derived from promoters 1 and 2 are processed via alternative splicing, which, along with alternative polyadenylation, leads to several IGF-I mRNA transcripts.[189] The gene for IGF-II is located adjacent to the H19 gene on chromosome 11p15.5, and both genes share the same regulatory transcription factors and are imprinted. Genomic imprinting (i.e., the silencing of one copy of an autosomal gene and

expression of the other) is regulated by epigenetic mechanisms, including DNA methylation. Imprinted genes that are paternally expressed (maternally imprinted), such as IGF-II, promote fetal growth, whereas those that are maternally expressed (e.g., H19) act as growth suppressors.[190] Two regions of allele-specific methylation of the human IGF-II gene have been identified.[191] Recent study has shown that loss of imprinting of the IGF-II gene, which as expected was negligible in placentas of women delivering normal-weight babies, was extensive in the placentas of pregnancies with FGR.[192] The authors suggested that loss of IGF-II imprinting in FGR likely contributes to the placental dysfunction that is a major component of the pathogenesis of FGR. However, the factors regulating DNA methylation and silencing of the placental IGF-II gene, and whether loss of silencing is the result or cause of FGR, remain to be determined.[193]

Following release into the circulation or the intercellular space, IGF-I and IGF-II are bound to binding proteins (IGF-BP) that modulate the availability, as well as influence the stability and thus control the activity, of the IGFs. Six IGF-BPs with high affinity for the IGFs have been identified in serum following production by and release from numerous tissues, notably the liver. During pregnancy, the mRNAs for all of the IGF-BPs are expressed by the decidua, trophoblast, and other cells within the placental basal plate. However, IGF-BP3 is the predominant maternal serum IGF-binding protein, binding 70–80% of total serum IGF-I and IGF-II,[194] and levels of IGF-BP3 as well as IGF-BP1 increase with advancing gestation.[195] The physiologic actions of IGFs are controlled by binding to two cell membrane receptors, an IGF-I receptor and an IGF-II receptor.[196] The IGF-I receptor is a heterotetramer that exhibits ligand-activated tyrosine–kinase activity and binds IGF-I > IGF-II > insulin. In contrast, the IGF-II receptor is a monomer that binds IGF-II > IGF-I, as well as mannose-6-phosphate, but does not bind insulin. Site-directed mutagenesis has shown that the IGF-I and IGF-II receptors have two separate binding surfaces and that cross-bridging to the two IGF receptor halves involving residue Glu12 is crucial to receptor activation.[197,198] Both IGF-I and IGF-II receptor signaling involve receptor autophosphorylation and activation of phosphatidylinositol 3-kinase (PI3K), ERK–MAPK, and/or Akt.[199]

Both IGF-I and IGF-II are expressed in the human placenta in addition to other tissues (e.g., liver and adipose).[200,201] The mRNA for IGF-I is detected primarily in the syncytiotrophoblast, whereas IGF-II mRNA is expressed in cytotrophoblasts, the syncytiotrophoblast, EVTs, and placental fibroblasts.[200,202] Placental IGF-I and IGF-II mRNAs are detected as early as week 8 of human pregnancy,[203] and although placental IGF-I mRNA expression appears to decrease between mid- and late gestation,[202,204] there is a marked increase in maternal serum IGF-I and a slight, albeit significant, increase in IGF-II levels with advancing human pregnancy.[205,206] The IGF receptors are localized within the syncytiotrophoblast, as well as the cytotrophoblast and villous stroma.[203,207–209] Although our understanding of the factors controlling placental IGF mRNA expression remains incomplete, the site and level of expression of the mRNAs for, as well as maternal serum levels of, IGF-I and GH-V are positively correlated regardless of pregnancy complication and gestational age.[210] These findings, plus the observation that villous trophoblasts and EVTs express the GH receptor that binds GH-V,[211] suggest that GH-V is a primary regulator of placental IGF-I.[205] Although not secreted into the fetal circulation, the maternal levels of total GH-V, as well as GH-V not bound to GH-binding protein, increase from week 7 until term. Several studies have shown that the rise in maternal serum GH-V is associated with an increase in maternal IGF-I levels, particularly after week 24 of gestation, and highly correlated with fetal growth.[205,206,212] Moreover, placental mRNA expression as well as serum levels of both GH-V and IGF-I are decreased in pathologic human pregnancies (e.g., those with FGR),[166] further supporting a role for GH-V in promoting fetal growth via regulation of IGF-I and presumably actions on placental systems controlling substrate supply to the fetus. Maternal levels of IGF-II also are comparably decreased at weeks 28 and 36 of gestation in FGR pregnancies.[166] However, maternal serum levels of total and free or unbound GH-V were not significantly altered, while maternal and fetal serum levels of IGF1 were lower and IGF-BP3 levels higher in pregnancies complicated by type 1 diabetes.[213] Thus, it would appear that the increase in insulin requirements during pregnancy in type 1 diabetics is not related to GH-V levels.[214]

Gene deletion and other studies have confirmed the importance of IGF-I and/or IGF-II in promoting cell proliferation and survival and placental and fetal growth and development.[188,215–217] For example, mice with deletions of IGF-I and/or IGF-II have pups that are 30–60% smaller than normal.[218,219] However, although neonates of IGF-II knockouts survive and exhibit normal growth after birth, postnatal growth is compromised in IGF-I-deleted animals, the majority of which die before reaching adulthood.[188] While placental growth was normal in IGF-I knockouts, placentas were small and hypoplastic in IGF-II-null animals.[220] Moreover, administration of IGF-I to normal or growth-restricted fetal sheep and guinea pigs increased or restored growth and maturation,[221–224] apparently via upregulating placental nutrient transporters via activation of mammalian target of rapamycin (mTOR),[225] which mediates maternal nutrient availability for fetal growth.[226] In addition, severe FGR was noted in infants with a heterozygous missense mutation,[227,228] or a homozygous mutation within the

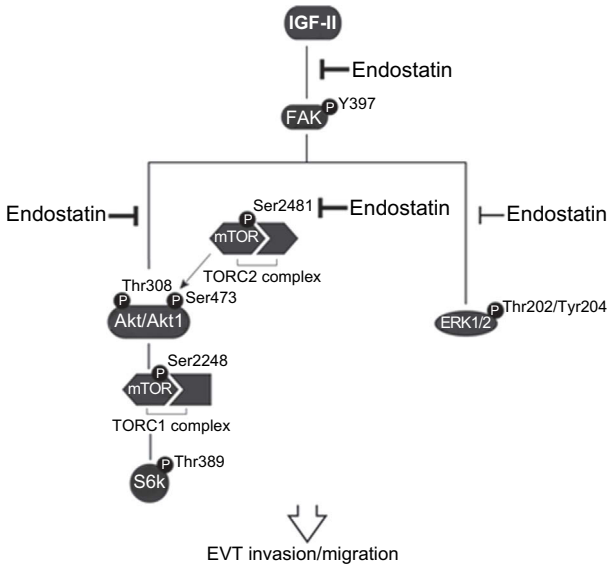

FIGURE 40.6 Proposed model of endostatin-mediated suppression of trophoblast motility. Endostatin exerts broad effects on IGF-II-mediated signaling in human trophoblasts by affecting phosphorylation of FAK–Akt–mTOR–S6K and, to a lesser extent, ERK1/2. Of note, endostatin interferes with both mTOR complexes, TORC1 and TORC2, thereby affecting activation as well as downstream signaling of Akt. However, suppression of the Akt phosphorylated residue at Thr308 suggests additional endostatin targets upstream of Akt, such as FAK. Finally, its main suppressive role in the context of trophoblast invasion was found to be dependent on the expression of Akt1. *Source: Reprinted with permission from Ref. 237.*

kinase[229] or the extracellular fibronectin III[230] domains of the IGF-I receptor. Moreover, null mutation of the Akt1 component of the IGF receptor signaling pathway, as with IGF-II-null mutation, compromised placental, fetal, and postnatal growth.[231] These and other studies support the suggestion that IGF-I has a relatively greater role in fetal growth and development, whereas IGF-II is more important for placental development. However, IGF-I and IGF-II do not act alone in this regard, and highly complex regulatory interrelationships between the IGFs and insulin, thyroid hormone, cortisol, and leptin, as well as nutritional drivers, appear to control placental–fetal growth (Figure 40.5).[217]

In addition to regulating fetal and placental growth, in vitro studies with primary human placental trophoblast and BeWo cells have shown that IGF-I and IGF-II stimulated trophoblast proliferation and survival,[232–234] as well as migration and vessel invasion.[235,236] IGF-BP3 inhibited IGF-I- and IGF-II-induced proliferation of placental trophoblasts by signaling through the TGFβ receptor.[233] Moreover, endostatin, a biologically active fragment of collagen XVIII, inhibited IGF-II-induced placental trophoblast migration and invasion by interfering with the activation of ERK1/2, Akt–mTOR–p70 S6 kinase, and focal adhesion kinase (FAK) (Figure 40.6).[237] Furthermore, although IGF-I did not alter placental artery tone, it reduced the vasoconstrictory effects of a thromboxane mimetic on myometrial arteries,[238] indicating that IGF-I may also modulate delivery of maternal blood to the placenta. Thus, along with their anabolic effects, the IGFs may also promote fetal–placental growth by expanding the placental syncytium and remodeling the uterine arteries to promote maternal–fetal exchange.

TGFβ Super Family: TGFβ

TGFβs are members of a super family of cytokines that includes activins, inhibins, bone-morphogenic proteins, and so on.[239,240] Three isoforms of TGFβ exist, TGFβ1, TGFβ2, and TGFβ3, which are encoded by three different genes. The human placenta expresses mRNAs for TGFβ1 predominantly in the villous placenta, TGFβ2 primarily in the decidua, and TGFβ3 in the villous trophoblasts and EVTs.[241] TGFβ proteins are secreted into the maternal circulation or locally in the maternal–fetal interface, and they are thought to elicit multiple effects on placental function. The TGFβ family members exert biologic actions by binding to the type 2 TGFβ receptor, which initiates interaction with the type 1 TGFβ receptor, forming a dimer that activates receptor serine–threonine kinase activity and induces phosphorylation of the downstream transcription factors SMAD2 (Sma- and Mad-related protein 2) or SMAD3.[242] Both the type 1 and type 2 TGFβ receptors are expressed in human placenta, particularly early in gestation.[243] Because knockout of

either receptor results in severe FGR, it has been suggested that the TGFβ super family plays a role in fetal growth, either directly or via control of placental function.[244] However, placental expression and maternal serum and umbilical cord concentrations of TGFβ1 increase with advancing normal human gestation,[245,246] and they either increase[247] or are unaltered[248] in human pregnancies with FGR; thus, the role of TGFβ1 in fetal growth remains controversial.[209]

In vitro studies have shown that TGFβ1 and TGFβ3 inhibit EVT invasion capacity.[209,249] TGFβ (produced by the decidua) as well as the TGFβ-binding proteoglycan decorin (also of decidual origin) act in a paracrine manner to suppress EVT invasion.[250] The expression and inhibitory effect of TGFβ3 on EVT invasion are enhanced by hypoxia-inducible factor 1 alpha (HIF-1α).[251] TGFβ also mediates the ability of IGFBPs to suppress trophoblast invasive capacity.[252] TGFβ1 and TGFβ3 are elevated in placentas of preeclamptic women,[244,253] and inhibition of TGFβ3 restores the invasive capacity of EVTs isolated in late gestation from placentas of women with preeclampsia.[245,254] However, because studies using placental cells that have been transformed or isolated from women with preeclampsia cannot test cause–effect, it remains to be determined whether the TGFβs play a role in normal placental development and/or become important later in gestation in exacerbating placental dysfunction and thus the complications of diseases characteristic of pregnancy pathologies (e.g., preeclampsia).

TGFβ Super Family: Activin and Inhibin

Activin and inhibin are disulfide-linked heterodimeric or homodimeric protein members of the TGFβ super family originally isolated from gonadal tissue. Activins and inhibins are composed of two different β subunits (β_A and β_B), each encoded by a single gene. The β subunits dimerize, forming activin A (β_A–β_A), activin B (β_B–β_B), and activin AB (β_A–β_B). Inhibins are composed of an α subunit and one of two β subunits (β_A or β_B), giving rise to two functional glycoproteins, inhibin A (α–β_A) and inhibin B (α–β_B). Activin A and inhibin A are expressed in the decidua, syncytiotrophoblast, cytotrophoblast, and fetal membranes.[255] Activin A and inhibin A, as well as follistatin, are the primary placental products formed and secreted into the maternal circulation, and levels of all three increase with advancing gestation and become negligible postpartum.[256] At the cell membrane, activins interact with serine–threonine kinase type 1 and type 2 receptors. Activin bioavailability is blocked by the sequestration of activin by follistatin.

Activin A and inhibin B act in a paracrine–autocrine manner to regulate cell proliferation and differentiation processes in several tissues, including reproductive tissues.[257] Because activin receptors are expressed in the trophoblast, particularly during the first and second trimesters, in villous vascular endothelial cells and fetal membranes late in gestation, and activin stimulates prostaglandin release from amnion cells, roles for activin in placental differentiation, EVT invasion, vascular adaptation of pregnancy, and labor onset have been proposed.[258] Of particular interest is the role of activin A and activin B in modulating inflammatory processes and immunity during pregnancy by regulating the function (e.g., interleukin production) of neutrophils, monocytes, and lymphocytes[259] within gestational tissues.[260] Cross-talk between Toll-like receptor 4 and activins has been shown in animal models of sepsis.[261] Both activin A and inhibin B also differentially regulate expression of human uterine MMPs, and thus cellular remodeling processes involved in decidualization and trophoblast migration and invasion.[249,262] Rosenberg et al.[263] have recently shown that activin A levels declined and inhibin A levels rose in amniotic fluid between normal middle and late human gestation, activin A levels were markedly elevated in women with intraamniotic infection or inflammation independent of amniotic membrane rupture, and activin A was upregulated by the addition of lipopolysaccharide to amniochorion explants. These authors concluded that activin A and inhibin A are dynamic participants in the biological process linked to intraamniotic infection- or inflammation-induced preterm birth. Maternal serum levels of activin A and inhibin A are increased in women with preeclampsia,[264,265] as well as in patients with Down syndrome, those with FGR, and those who deliver prematurely.[258,266] The increase in activin A with preeclampsia may result from the elevation in oxidative stress[267] that accompanies this disease. The combination of maternal serum activin A, inhibin A, and PlGF levels and ultrasound assessment of the uterine artery pulsatility index are predictive of preeclampsia.[268]

Epidermal Growth Factor

EGF, a polypeptide hormone originally isolated from the salivary glands, is a member of the EGF super family composed of heparin-binding EGF-like growth factor (HB-EGF), amphiregulin, betacellulin, epiregulin, epigen, neuregulins1–6 and TGFα. Each of the EGF members activates a family of four receptors, ErbB1–4, also termed HER1–4.[269,270] Receptor activation is very complex and is controlled by the spatiotemporal expression, posttranslational processing, and ectodomain shedding of the ligands, the latter being critical to the interreceptor cross-talk that must be coordinated in response to multiple stimulants.[269]

EGF receptors are expressed in the EVTs and villous cytotrophoblast and syncytiotrophoblast, as well as the decidua, of the human placenta, with expression elevated early and declining with advancing gestation. Maternal serum levels of EGF are also highest in the first trimester and decline with advancing gestation. That EGF and its

receptors play a role in placental development and function is supported by studies showing that pups of mice deficient in EGF are growth retarded, homozygous HER-null mice die in utero due to abnormal placental development, intraamniotic infusion of EGF normalized fetal weight in a rabbit model of FGR, and the EGF receptor is altered in human placentas of pregnancies complicated by FGR.[209] In addition, EGF has been shown to promote trophoblast proliferation and differentiation and inhibit trophoblast apoptosis induced by reactive oxygen species or hypoxia by activating, respectively, PI3K or p38 MAPK and phosphorylation of the B-cell lymphoma 2 associated death promoter.[271,272]

HB-EGF is expressed throughout the course of human gestation in the placenta, including the EVTs and villous cytotrophoblast and syncytiotrophoblast, as well as the decidua.[273] Expression of HB-EGF is particularly high in first-trimester placenta and decidua, although much lower in the syncytiotrophoblast. Interestingly, compared with high expression of HB-EGF in placentas from women who delivered at term or 4–8 weeks prematurely, HB-EGF mRNA and protein expression was negligible in late gestation in placentas from pregnancies complicated by preeclampsia and FGR.[274] The latter pregnancy complications are thought to reflect shallow trophoblast invasion of uterine spiral arteries, and in vitro studies using a variety of cell lines have shown that HB-EGF, as well as EGF, can modulate EVT proliferation, migration, and/or invasion.[273] EGF induces an EVT-invasive phenotype, effects blocked by inhibition of tyrosine kinase activity of HER1, which is expressed in EVTs.[275] Expression of HB-EGF, but not EGF or other EGF-like growth factors, was rapidly upregulated in immortalized EVT cells cultured in a hypoxic (i.e., 2% O_2) environment, and cell survival was dependent on HB-EGF expression and receptor signaling.[276] Moreover, because the level of HB-EGF that was cytoprotective was similar to that released into conditioned medium by first-trimester human trophoblast cultured at 2% oxygen, HB-EGF may play a physiologic role in EVT survival. Interestingly, HB-EGF-mediated signaling also reduced trophoblast apoptosis at term. Therefore, it is possible that the absence of placental HB-EGF expression in preeclampsia may underpin the high incidence of apoptosis noted in these placentas. However, the factors regulating HB-EGF expression in normal and abnormal pregnancy (e.g., preeclampsia) have not been elucidated.

Vascular Endothelial Growth Factor

The VEGF super family is composed of VEGF-A (known as VEGF), VEGF-B, VEGF-C, VEGF-D, VEGF-E, and PlGF. VEGF is encoded from a single gene organized as eight exons separated by seven introns, and alternative exon splicing results in the generation of isoforms composed of (after signal sequence cleavage) 121, 145, 165, 189, and 206 amino acids. VEGF is a potent endothelial cell mitogen and anti-apoptotic factor that stimulates vascular permeability and consequently the formation of new blood vessels via angiogenesis.[277–280] Although new vessel growth and maturation are highly complex and coordinated processes requiring sequential activation of a series of receptors by numerous ligands, VEGF signaling represents a critical early rate-limiting step. Thus, inactivation of a single VEGF allele in mice resulted in significant vascular defects in embryonic tissues and organs, as well as embryonic lethality.[281] Native VEGF is a heparin-binding homodimeric glycoprotein of 45 kDa and the heparin-binding domain provides essential stimulatory cues for angiogenesis. Elimination of this domain in $VEGF_{165}$ results in loss of mitogenic activity, and thus with respect to angiogenesis $VEGF_{165}$ is considered the most physiologically active isomer.

VEGF binds to two structurally related transmembrane tyrosine kinase receptors, the fms-like kinase (Flt-1, or type 1) and kinase-insert domain (KDR/Flk1, or type 2) receptors (Figure 40.7).[280] Both receptors are required for vascular development since homozygous Flt-1 or KDR–Flk-1 defective mice die in utero.[282,283] VEGF-A

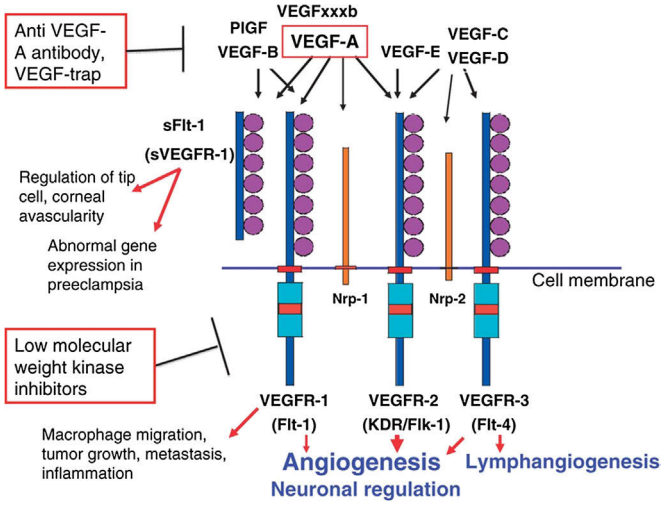

FIGURE 40.7 The VEGF–VEGFR system and its involvement in various physiological and pathological processes. VEGF-A, particularly VEGF165, plays a central role in angiogenesis. VEGFxxxb has recently been reported to act as a natural antagonist to VEGF-A. Three receptors and one soluble form of the VEGFR family members are highly conserved in most vertebrates, except for fish. Major pro-angiogenic signals are generated from VEGFR-2, whereas sFlt-1 maintains physiological corneal avascularity and induces several symptoms in preeclampsia. VEGFR-1 is expressed not only in endothelial cells but also in monocytes and macrophages, and it stimulates angiogenesis, inflammation, and the malignant phenotypes of cancer. Nrp: co-receptors for VEGFs such as $VEGF\text{-}A_{165}$, which increase the affinity between VEGF and its receptors, and the intracellular signaling; VEGFxxxb: an alternatively processed variant form of VEGF-A that is suggested to be an endogenous competitor against VEGF-A. *Source: Reprinted with permission from Ref. 280.*

binds to both receptors, as well as a co-receptor neuropilin 1; VEGF-B only binds to the Flt-1 receptor, which also binds PlGF. VEGF-C and -D bind to another member of this receptor family, fms-like tyrosine kinase 4 (Flt-4, or type 3), and stimulate lymph angiogenesis, while VEGF-E is a KDR–Flk-1 agonist. Results from Flt-1 tyrosine kinase-deficient mice indicate that Flt-1 signaling is important for tumor growth, metastasis, and chronic inflammation (Figure 40.7).[280,284] Upon VEGF or FGF2 activation, the receptor tyrosine kinases initiate a cascade of cellular protein phosphorylations by protein kinases, notably ERK1/2, Akt-1, and/or p38 MAPK, resulting in enhanced proliferation and migration of fetal placental artery endothelial cells.[285] The VEGF-induced signaling mechanisms are highly complex, and an endothelial cell-specific chemotaxis receptor, which is expressed in the placenta, co-localizes with and is required for activation and internalization of the KDR–Flk-1 receptor in endothelial cells.[286] A soluble truncated form of the Flt-1 receptor (sFlt-1), which is generated as a splice variant and contains an extracellular binding domain but lacks tyrosine kinase signaling, has tremendous capacity to sequester VEGF as well as PlGF and thus prevent VEGF interaction with the Flt-1 and KDR–Flk-1 receptors.[287,288]

The mRNAs and proteins for VEGF, Flt-1, KDR–Flk-1, PlGF, and the related angiopoietin 1 and 2 and Tie2 receptor molecules are abundantly expressed by cytotrophoblasts, the syncytiotrophoblast, and/or inner villous stromal cells within the placenta, as well as EVTs, interstitial, and/or decidual cells within the placental basal plate during human,[289–291] baboon,[292] rhesus and marmoset monkey,[293–295] and ovine[296,297] pregnancy. VEGF mRNA expression in villous cytotrophoblasts and vessel density within the inner villous compartment increase with advancing human[298–300] and baboon[292] gestation. As detailed in the section Estrogen, the increase in placental E_2 production with advancing baboon pregnancy stimulates villous VEGF expression and establishment of the villous vasculature.[301] VEGF-A and the Flt-1 and KDR–Flk-1 receptors also appear to be critical for trophoblast function in the extravillous placenta, since the migration and invasive capacity of EVTs were suppressed by blocking VEGF action in cultures of human placental trophoblasts.[302,303] Also as discussed in the section Estrogen in contrast to the E_2-induced increase in VEGF expression by cytotrophoblasts in the placental villous compartment, E_2 decreased VEGF expression by EVTs in the placental extravillous compartment and trophoblast remodeling of the uterine arteries in the decidua basalis during early baboon pregnancy.[304] The authors proposed, therefore, that the increase in E_2 of advancing primate pregnancy controls the extent to which the uterine arteries are remodeled, while concomitantly promoting vascularization of the villous placenta, thereby promoting maternal blood flow to the placenta and thus delivery of substrate to the fetus to stimulate growth. Although the mechanisms of E_2 action on placental VEGF expression remain to be determined, in the rat uterus E_2 enhances VEGF mRNA expression via activation of PI3K and Akt, which facilitates co-recruitment of estrogen receptor alpha (ERα) and HIF-1α to the promoter of the VEGF gene (Figure 40.8).[305]

Several studies have shown that placental expression and serum levels of VEGF and PIGF are lower and the sFlt-1 receptor that sequesters VEGF is higher in human pregnancies complicated by preeclampsia and FGR.[288,306–308] Because the Flt-1 gene promoter contains a hypoxia response element (HRE), the increase in placental hypoxia induced by subnormal uterine artery remodeling in women with preeclampsia may account for the increase in placental sFlt-1 expression,[309,310] and among other consequences also disrupt the permeability of renal glomerular endothelial cells, resulting in proteinuria,[311] a major symptom of preeclampsia. Moreover, Torry and colleagues[312] showed that nitric oxide (NO) generation prevented the rise in sFlt-1, but not VEGF, expression induced by hypoxia in human placental trophoblast cultures, indicating that NO had divergent effects on pro- and anti-angiogenic factors.

In cultures of placental BeWo cells, VEGF activated nuclear factor erythroid 2-related factor-2 (Nrf2), which enhanced transcription of those antioxidant response

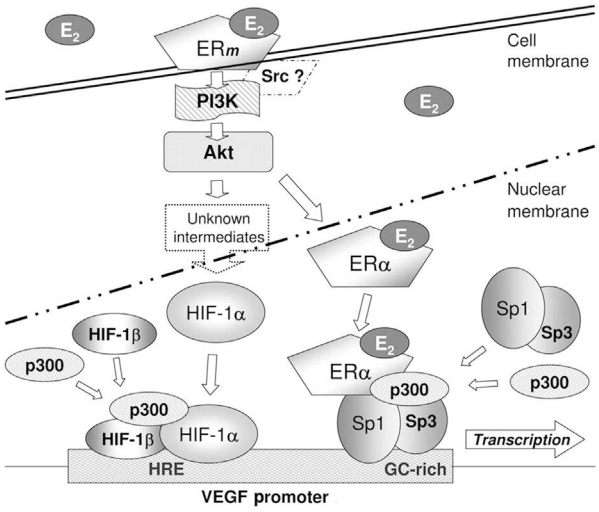

FIGURE 40.8 Model illustrating steps in estradiol (E_2) induction of VEGF expression in the rat uterus in vivo. Previous chromatin immunoprecipitation results indicate that estrogen simultaneously induces the recruitment of both HIF-1 (α and β) to the upstream HRE and ERα to the proximal GC-rich region of the VEGF promoter, probably via interaction with Sp proteins; p300 binds to both transcription factor complexes. The current results show that the activation and recruitment of both HIF-1α and ERα are mediated by PI3K. This may involve activation of a membrane form of the ER (here designated ER*m*), possibly through c-Src. *Source: Reprinted with permission from Ref. 305.*

element safeguard genes (e.g., glutathione peroxidase and heme-oxygenase 1 (HO1)) that are decreased in placentas of women with preeclampsia.[313] The increase in HO1 induced by VEGF also augmented the production of carbon monoxide and HIF-1α, which in a positive feedforward manner further elevated VEGF expression. The authors[313] suggested that a decrease in VEGF bioavailability during preeclampsia results in a decrease in Nrf2 and thus enhanced vulnerability to placental oxidative stress cell damage as well as a further reduction in VEGF.

PlGF has a 42% amino acid sequence identity with VEGFA and is expressed in four isoforms, PlGF1–4, as a result of alternative splicing. PlGF binds specifically to the Flt-1 receptor, and in addition to promoting EVT migration and invasive capacity,[306,307] it has been reported to have both pro- and anti-angiogenic effects.[314] In retinal microvessel endothelial cells, PlGF1 stabilized the VE-cadherin and claudin 5 components of adherens and tight junctions, thereby inhibiting VEGF-induced endothelial cell permeability, a critical early step in angiogenesis.[315]

Endocrine Gland-VEGF

In 2001, Ferrara and colleagues[316] identified a new growth factor that was expressed only in steroid-producing EGs (i.e., the ovary, testis, adrenal, and placenta). Because this protein was mitogenic for EG endothelial cells and exhibited other features characteristic of VEGF (e.g., induction of fenestrations in target cells and upregulation of the gene promoter by hypoxia), it was named EG-VEGF. However, EG-VEGF shares no structural homology with VEGF, but rather is structurally related to a family of peptides termed prokineticins that includes Bv8 protein, also named prokineticin 2 (PROK2).[317,318] The mature EG-VEGF protein is composed of 86 amino acids, including 10 cysteines, and is structurally identical to prokineticin 1 (PROK1). The gene for EG-VEGF–PROK1 is located on chromosome 1p21 and composed of three exons with no known alternative splicing products. Two G-coupled receptors (PROKR1 and PROKR2) bind PROK1 and PROK2 with equally high affinity and mediate a cellular response dictated by the repertoire of G proteins. Activation of the downstream PROK signaling pathways involves MAPK–Akt phosphorylation, phosphoinositol turnover, and mobilization of cAMP or calcium.[318]

EG-VEGF mRNA and protein are detected in the human placenta throughout the course of gestation, and they are localized abundantly in the syncytiotrophoblast and lightly in the cytotrophoblast, but not in the EVTs.[319] Placental expression and maternal serum levels of EG-VEGF peak at 8–9 weeks of gestation and decline thereafter, a pattern very similar to that of hCG. The PROKR1 and 2 receptors are expressed throughout gestation and localized to the syncytiotrophoblast, villous cytotrophoblast, and EVTs.[319,320]

Although expression of EG-VEGF and its receptors can be upregulated by hypoxia, recent studies indicate that hCG may play a role as well.[321] Thus, using placental explants and primary cultures of trophoblast from the first trimester of human pregnancy, Brouillet et al.[321] showed that the cytotrophoblast and syncytiotrophoblast expressed the LH–hCG receptor and that hCG increased mRNA and protein expression of EG-VEGF and PROKR2 in the syncytiotrophoblast and PROKR1 in the cytotrophoblast in a time- and dose-dependent manner. These investigators also cloned the promoter of the EG-VEGF gene and documented the existence of two canonical cAMP response elements (CRE1 and CRE2). Moreover, gene reporter assays with COS7 cells (African green monkey kidney cells) that transiently expressed the luciferase gene under control of the EG-VEGF promoter showed that cAMP rapidly enhanced promoter activity. Thus, cAMP-induced expression of the EG-VEGF promoter occurs at the level of transcription and is mediated via activation of CRE2. Based on these findings, Brouillet et al.[321] have proposed that hCG regulates placental development via control of expression of EG-VEGF and its receptors (Figure 40.9).

It has also been suggested that EG-VEGF may play a role in EVT invasion based on its pattern of secretion and regulation by hypoxia, the marked expression of PROKR2 receptor in EVTs, and the demonstration that maternal serum levels and placental expression of EG-VEGF are elevated in women with preeclampsia.[318] In support of this suggestion, EG-VEGF suppressed the invasive capacity of trophoblasts prepared from normal placentas obtained at 7–12 weeks of gestation or transformed EVT cells.[320] However, it remains to be determined whether EG-VEGF plays

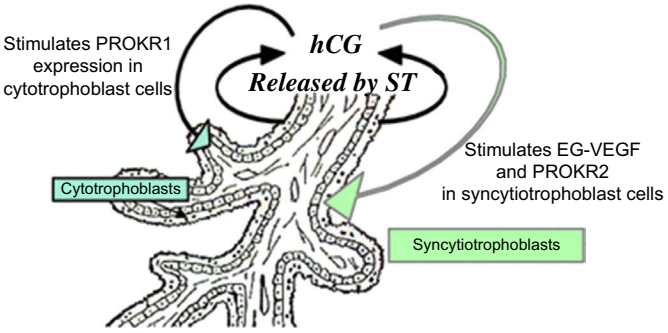

FIGURE 40.9 Proposed model of hCG stimulation of the EG-VEGF–PROKR1 and PROKR2 system in the human placenta during the first trimester of pregnancy. hCG released from the syncytiotrophoblast layer will activate EG-VEGF and PROKR2 expression in the ST layer in an autocrine manner and PROKR1 expression in the cytotrophoblast layer in a paracrine manner. *Source: Reprinted with permission from Ref. 321.*

a physiologic role in regulating EVT invasion or becomes important later in gestation in exacerbating the placental dysfunction characteristic of pregnancy pathologies (e.g., preeclampsia).

It is evident, therefore, that each of the PlGFs (i.e., IGF-I/-II, TGFβ, EGF, VEGF, and EG-VEGF) has been shown by in vitro studies to have the capacity to control placental villous and EVT function, particularly EVT migration and invasive capacity. Future investigation is needed in this area of placental biology to establish the applicability of the role of the PlGFs in vivo during human pregnancy and the manner in which these factors are regulated and interact to regulate placental function.

STEROID HORMONES OF THE PLACENTA

Detailed reviews of the historical perspectives, biosynthetic steps, and characterization of the enzymes involved in the production of placental estrogens and P_4 have previously appeared.[322–326] The present section provides an overview of synthesis and recent developments in the regulation and actions of the placental steroid hormones.

Estrogens

Synthesis

The placenta becomes the primary source of the estrogens at approximately 8 weeks of human gestation, and serum estrone, E_2, estriol, and estetrol levels progressively increase thereafter (Figure 40.3), with total daily production rates of these estrogens at term approximating 40 mg. The placenta does not express the 17α-hydroxylase–17-20-lyase ($P450_{C17}$) gene required for de novo production of the estrogens. However, the fetal zone of the fetal adrenal cortex is a major source of C_{19} steroids, notably dehydroepiandrosterone (DHEA), that are aromatized via the P450 aromatase (P450arom) to the estrogens.[327,328] Because of the importance of the fetal adrenal for placental estrogen synthesis, disorders (e.g., anencephaly) or administration of synthetic corticosteroids that suppress fetal pituitary–adrenocortical function result in a 50% decline in estrone and E_2 and a 90% decrease in estriol levels.[329,330] The maternal adrenal provides the C_{19} steroids for the remaining 50% of estrone and E_2 formation during pregnancy. The concept of a functional fetal–placental unit for estrogen biosynthesis in human pregnancy provided the basis in the past for measurement of maternal serum estriol levels to assess fetal well-being and placental uptake of DHEA to evaluate placental function.

Within the fetal adrenal cortex, DHEA is synthesized de novo from cholesterol, derived primarily by receptor-mediated uptake of LDL, and then sulfurylated and delivered to the placenta as DHEAS or, after 16-hydroxylation in the fetal liver, as 16-0H-DHEAS (Figure 40.10). DHEAS is converted to DHEA and 16-OH-DHEAS to 16 OH-DHEA via a sulfatase expressed in the placenta. DHEA is converted to Δ^4-androstenedione via Δ^5-3β-hydroxysteroid dehydrogenase–isomerase (3β-HSD), and a single P450arom enzyme; anchored to the endoplasmic reticulum and encoded by the CYP19A1 gene located on chromosome 15q 21.1; aromatizes Δ^4-androstenedione to estrone, testosterone to E_2, and 16-OH-DHEA to estriol. The CYP19A1 gene contains five different transcriptional start sites and individual promoters for tissue-specific expression in the placenta and other tissues. The placenta utilizes exon 1.1 for the transcription start site that binds the Sp1 transcription factor.[331] P450arom catalyzes the oxidative demethylation of C_{19} steroids to yield C_{18} steroids with an aromatic A-ring. The crystal structure of P450arom has been characterized and in the crystal aromatase molecules are uniquely linked by head-to-tail intermolecular interaction via a loop between helix D and helix E of one aromatase molecule that penetrates the heme-proximal cavity at the next molecule, forming in tandem a polymeric aromatase chain.[332,333] The interconversion of estrone and E_2 and of Δ^4-androstenedione and testosterone is catalyzed by 17β-hydroxysteroid oxidoreductase (17β-HSD).

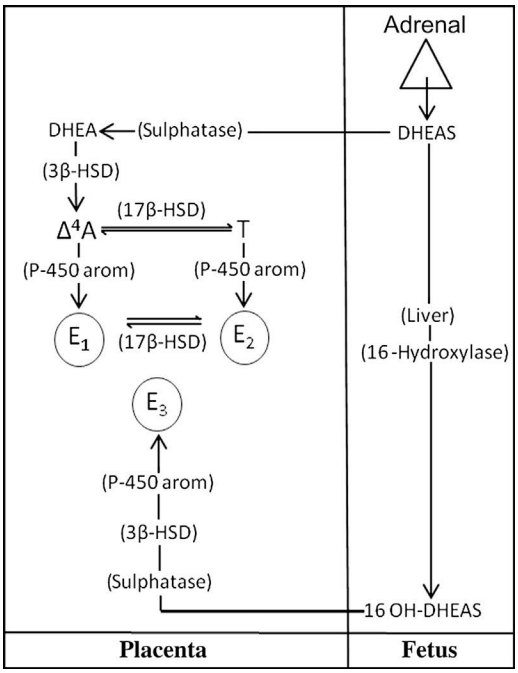

FIGURE 40.10 Estrogen biosynthesis in the fetal–placental unit during human pregnancy. DHEA, Dehydroepiandrosterone; DHEAS, DHEA sulfate; Δ^4A, Δ^4-androstenedione; T, testosterone; E_1, estrone; E_2, estradiol; E_3, estriol.

Several different 17β-HSD isoforms exist, which differ in structure, substrate specificity, and co-factor use. The interconversion of estrone and E_2 is catalyzed by 17β-HSD-1, located on chromosome 17q11–q21, and interconversion of testosterone and Δ^4-androstenedione is catalyzed by 17β-HSD-2, and both 17β-HSD-1 and -2 are expressed in the placenta.

Regulation

Since the fetal zone of the fetal adrenal cortex is a major source of DHEA and other C_{19}-steroid precursors that are aromatized to the estrogens in the placenta, the regulation of the fetal cortical zone is paramount to placental estrogen production. Therefore, as previously reviewed,[334–336] ACTH and other factors, including growth factors, that stimulate fetal adrenal DHEAS synthesis indirectly increase placental estrogen production. In addition to ACTH, corticotrophin-releasing hormone (CRH) secreted by the placenta has the capacity to stimulate fetal adrenal DHEAS production directly[337,338] and thus placental estrogen formation. Moreover, placental CRH and its related peptide urocortin 1 (Ucn1), acting via the CRH receptors (CRHR1 and CRHR2) that are expressed in the placenta[339] and that activated Gs–Gq PKA and Gi–Gq PKC signaling pathways,[340–342] enhanced E_2 and decreased P_4 formation by cultured human placental trophoblasts (Figure 40.11).[342–345] Since placental CRH and Ucn1 levels increase[346,347] and the ratio of plasma P_4 to estriol decreases[348] near term, it has been suggested that CRH and related peptides may be involved in the initiation of labor (see Chapter 42).

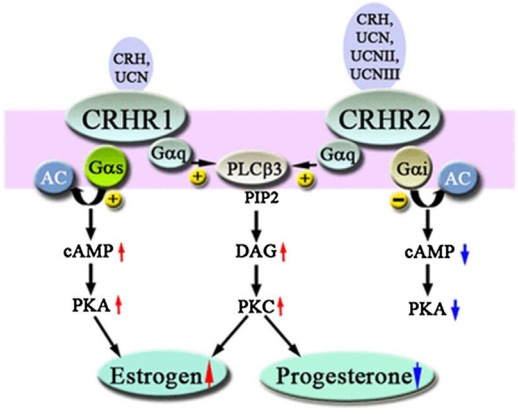

FIGURE 40.11 Scheme illustrating the proposed regulation of estrogen and progesterone production by CRH and its related peptides in human placenta. CRHR1 primarily couples to Gs and Gq protein. When CRH or UCN binds CRHR1, it stimulates the AC–cAMP–PKA and PLC–PCK signaling pathways, which stimulates estrogen production. CRHR1 activation can inhibit progesterone production via the PLC–PKC signaling pathway but not by the AC–cAMP–PKA signaling pathway. When CRHR2 is activated by UCNII and UCNIII as well as UCN and CRH, it induces Gαi and Gαq activation and then stimulates the PLC–PCK signaling pathway, which stimulates estrogen production and inhibits progesterone production. *Source: Reprinted with permission from Ref. 342.*

The capacity for placental aromatization increases with advancing gestation, and cAMP plays an important role in stimulating expression of the P450arom enzyme.[349–351] Cortisol has also been shown in human trophoblast cell cultures to increase the expression of P450arom by activating the cAMP–Sp1 pathway.[352] Moreover, in vitro differentiation of human cytotrophoblasts to the syncytiotrophoblast and the associated induction of P450 aromatase–CYP19A1 are upregulated in a 20% O_2 environment and prevented by 2% O_2, suggesting regulation by O_2-modulated transcription factors such as mammalian achaete-scute homologous protein 2 (Mash2)–achaete-scute complex homolog 2 (ASCL2).[353,354] In addition, the human placental trophoblast expresses the estrogen receptor alpha (ERα)[355] and an estrogen response element–like sequence that modulates the induction of CYP19 promoter 1.1 activity by E_2.[356] The human placenta also expresses the orphan nuclear estrogen-related receptor gamma (ERRγ),[357] which transgenic mouse studies suggest may regulate ion transport channels[358] and genes involved in angiogenic and calcium transfer pathways,[359] and which is selectively upregulated during trophoblast differentiation. ERRγ induces CYP19A1 and is downregulated by HIF-1α in placental cell culture.[360] Therefore, Mendelson and colleagues[360] have proposed (Figure 40.12) that early in gestation, when the placental environment is hypoxic, elevated levels of HIF-1α inhibit ERRγ transcription and thus CYP1A gene expression and cytotrophoblast differentiation into the syncytiotrophoblast. It is further proposed that after week 9 of gestation, the increase in placental vascularization increases O_2 availability and decreases HIF-1α, which causes upregulation of ERRγ and induction of CYP19A1 transcription. The resulting increase in E_2, in turn, is proposed to activate ERα, which may functionally interact with ERRγ and other transcription factors to further upregulate CYP19A1 expression.

Function

The placenta produces micromolar amounts of the estrogens during human pregnancy and, as presented in the accompanying Chapters 42 and 43 of this text and in earlier reviews, it is well established that E_2 has an important role in preparing the endometrium for implantation, the cascade of events leading to the induction of labor,[361] and the maternal cardiovascular changes of pregnancy.[362,363]

ER knockout mice have been used to characterize the role of E_2 in reproduction in rodents.[364] However, the human placental trophoblast also expresses ERα and ERβ,[355,365] providing a mechanism for E_2 action in

this organ during human pregnancy. For example, the morphological differentiation of human villous cytotrophoblasts into the syncytiotrophoblast is stimulated in vitro by E_2.[366,367] E_2 also stimulates trophoblast expression of leptin,[368–370] which along with other factors promotes trophoblast differentiation.[371] Using the baboon as a nonhuman primate model for the study of human pregnancy, the authors have shown that E_2 also controls several other important aspects of placental and fetal development. Remodeling of the uterine spiral arteries is extensive during the first trimester of human pregnancy, whereby EVTs migrate to, invade, replace the endothelial and smooth muscle lining of, and thus transform the uterine arteries into low-resistance high-capacity vessels to promote blood flow to the placenta and thus development of the fetus. Impaired vessel remodeling underlies the etiology of preeclampsia,[372] which results in maternal and neonatal morbidity and mortality, while excessive remodeling that occurs in placenta accreta impairs essential vasoregulatory processes after delivery.[373,374] Although there is a rapid rate of uterine artery transformation early in gestation when E_2 levels are low, prematurely elevating E_2 levels in early baboon pregnancy, by shifting the normal rise in E_2 from the second to the first trimester via maternal E_2 administration, suppressed trophoblast invasion and remodeling of the uterine spiral arteries[375] and disrupted uteroplacental blood flow dynamics at term.[376] The decline in vessel transformation was associated with a decrease in the expression of placental EVT VEGF and the α1β1 and α5β1 integrins thought to be involved in trophoblast migration.[304,377] Thus, VEGF and certain integrins may mediate the E_2-induced suppression of uterine vessel transformation. The lack of a direct effect of E_2 on HTR8-SV neo trophoblast migration and invasive capacity, as shown in vitro,[378] seems consistent with E_2 acting via other factors. The authors[379] have proposed, therefore, that the low levels of ovarian E_2 in early pregnancy promote VEGF expression and EVT remodeling of the uterine arteries (Figure 40.13), whereas the normal rise in E_2 thereafter suppresses and thus controls the extent to which the uterine vessels are remodeled. E_2 administration in early rat pregnancy also suppressed development of the uterine spiral arteries,[380] although the endocrine interrelationships between the mother, placenta, and fetus are different in rodents and in humans and nonhuman primates. The E_2-induced suppression of uterine artery transformation in early baboon pregnancy appears translationally relevant to the human, since elevated levels of E_2 in early in vitro fertilization human pregnancy are associated with a fivefold increased risk of developing preeclampsia,[381] in which subnormal trophoblast uterine artery remodeling is a hallmark feature. In the second trimester of baboon pregnancy, the normal rise in E_2 concomitantly promoted placental villous VEGF expression and blood vessel development,[301,382] as it does in myometrial microvascular endothelial cells.[383] Thus, E_2 differentially regulates placental EVT and villous VEGF expression and consequently coordinates uterine artery remodeling and villous angiogenesis to ensure blood flow to and vascularization of the villous placenta to promote fetal development.

During the second half of baboon pregnancy, E_2 stimulates the receptor-mediated uptake of LDL as cholesterol substrate for and activity of the P450scc enzyme catalyzing the synthesis of P_4 by the placental trophoblast.[384–386]

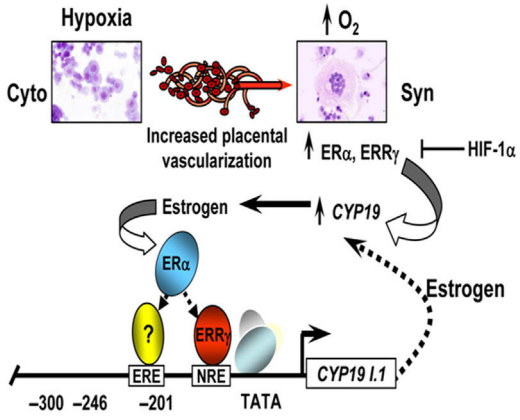

FIGURE 40.12 Model of hCYP19 regulation in human trophoblasts. This figure is reproduced in color in the color plate section. Early in gestation, the placenta is relatively hypoxic; the elevated levels of HIF-1α inhibit ERRγ transcription via interaction with a response element (HRE) in the ERRγ promoter. This, together with hypoxia-mediated induction of basic helix–loop–helix factors ASCL2 and USF1/2, blocks syncytiotrophoblast differentiation and hCYP19 gene expression. After the ninth week of gestation, increased placental vascularization results in increased oxygen availability to the trophoblast cells. The consequent decrease in HIF-1α levels and the expression of other inhibitory transcription factors cause upregulation of ERRγ and induction of hCYP191.1 transcription. The increased estrogens produced, in turn, activate ERα, which may functionally interact with ERRγ and other activating transcription factors to further upregulate hCYP19 expression. *Source: Reprinted with permission from Ref. 360.*

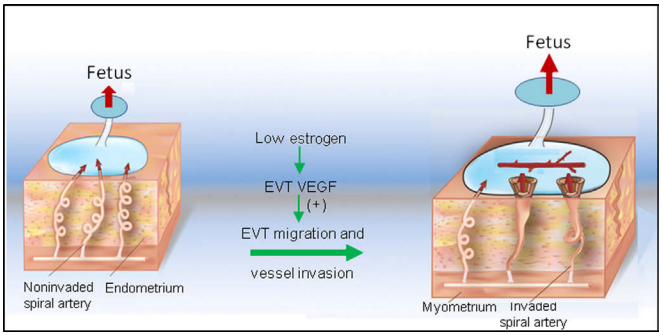

FIGURE 40.13 Proposed role of low estrogen levels in early primate pregnancy in promoting VEGF expression and extravillous trophoblast (EVT) migration and invasion–remodeling of the uterine spiral arteries.

In addition to regulating syncytiotrophoblast expression of the 11β-hydroxysteroid dehydrogenase 1 and 2 (HSD1/2) enzymes responsible for controlling transplacental cortisol–cortisone metabolism, as discussed in the section 11β-Hydroxysteroid Dehydrogenase (11β-HSD) and Cortisol–Cortisone Metabolism, the increase in E_2 of advancing baboon gestation downregulates cyclin D1 expression within[387,388] and thus the growth of and production of C_{19} steroid estrogen precursors by the fetal zone of the fetal adrenal cortex, apparently in a feedback manner to control E_2 levels within a physiological range.[389] As highlighted by Kaludjerovic and Ward,[390] the E_2-induced alteration of fetal adrenocortical maturation may translate to the human and be elicited by exposure to environmental estrogens as mediated by epigenetic changes.

Wood and colleagues[391,392] have shown that E_2 increases activity of, and ACTH secretion within, the fetal hypothalamic–pituitary axis during ovine pregnancy, possibly via modulating fetal brain prostaglandin biosynthesis.[393] Thus, Wood has proposed that the interplay of placental E_2 and the fetal hypothalamic–pituitary–adrenal (HPA) axis may have a role in the initiation of labor in the human.[392]

Development of the pool of ovarian follicles essential for reproductive function in adulthood in the human is established in utero and in the baboon fetus, in which the levels of E_2 were suppressed throughout the second half of pregnancy by maternal administration of the aromatase inhibitor letzozole, the number of ovarian follicles was reduced by 50%,[394] and the majority of the remaining follicles contained oocytes that exhibited both vacuolization and disrupted mitochondria.[395] The disruption of fetal ovarian follicle formation by E_2 suppression was not due to subnormal serum FSH levels or ovarian FSH receptor expression.[396] However, the number and height of oocyte microvilli were decreased,[395] the subcellular localization of the ezrin and ezrin-binding protein 50 proteins critical for microvillus formation were altered,[397] and the intraovarian activin–inhibin ratio was decreased[398,399] by E_2 deprivation. Each of these changes, along with ovarian follicle formation, was restored by concomitant E_2 and letrozole treatment. The authors[379,400] have proposed, therefore, that E_2 promotes formation of the stockpile of healthy ovarian follicles within the primate fetus (Figure 40.14) and that this developmental process is critical for the timely onset of puberty and reproductive function after birth.[401] The human fetal ovary also contains the mechanisms required to respond to E_2, and Fowler and colleagues[402] have proposed that E_2 also plays a role in primary follicle formation in the human fetus, a postulate that is consistent with the abnormal ovarian follicle development that occurs in women with P450arom deficiency.[403]

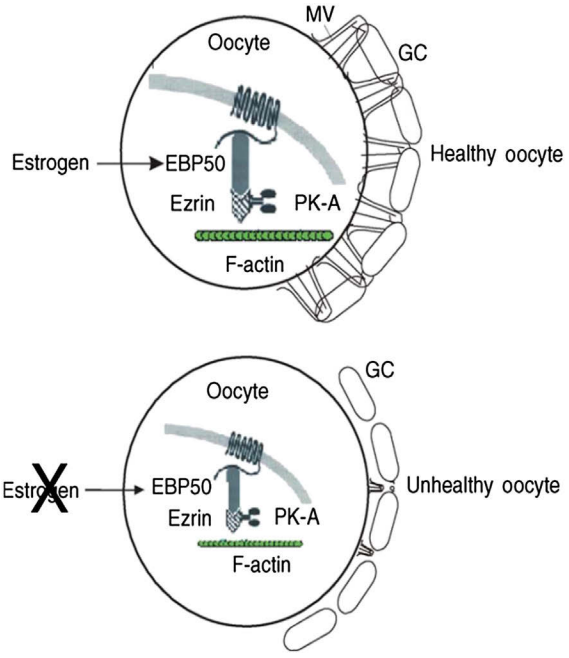

FIGURE 40.14 Proposed role of estrogen on fetal ovarian oocyte microvillus (MV) formation and interaction with granulosa cells (GCs) essential for oocyte health and function and thus long-term survival. During primate pregnancy, estrogen promotes the expression and subcellular location of the ezrin and ezrin binding protein 50 (EBP50) proteins that are critical for attaching to F-actin and thus microvillus formation. *Source: Reprinted with permission from Ref. 400.*

E_2-deficient pregnant baboons,[404] P450arom or ERα knockout mice,[405–408] and P450arom-null humans[409,410] exhibit a disruption in testis morphology; germ cell, efferent ductule, and epididymal development; and/or infertility, showing that E_2 also has an essential role in promoting fetal testis development and fertility in adulthood.

Null mutation of P450arom in human pregnancy[411–413] and administration of the aromatase inhibitor letrozole during baboon pregnancy[414] also result in insulin insensitivity and glucose intolerance in the offspring, indicating that E_2 in utero programs mechanisms within the fetus that are important for normal insulin action after birth. Placental E_2 deficiency in human pregnancy also impairs the pubertal growth spurt, skeletal maturation, and accrual of bone mass in both men and women.[403,415,416]

Progesterone

Synthesis

The placenta also becomes the principal source of P_4 at approximately 8 weeks of human pregnancy, and P_4 levels increase to 150–175 ng/ml at term (Figure 40.3) and a production rate of over 200 mg/day. De novo synthesis of cholesterol from acetate and cholesterol

esterification within the placenta are limited, whereas the receptor-mediated uptake, utilization, and metabolism of LDL by the placental syncytiotrophoblast via the classical LDL pathway account for the major proportion of placental P_4 production.[417] The apolipoprotein component of LDL and cholesteryl esters are then hydrolyzed to form free cholesterol. Placental mitochondrial transport and binding of cholesterol are not mediated via steroidogenic acute regulatory protein (StAR), which is not expressed in the placenta. However, MLN64 protein, which is structurally closely related to StAR,[418] has the ability to transport cholesterol between membranes of and stimulate pregnenolone synthesis by isolated placental mitochondria.[419] Cholesterol is converted to pregnenolone via the P450 cholesterol side-chain cleavage (P450scc) enzyme attached to the matrix side of the inner mitochondrial membrane. This process involves hydroxylation and oxidative scission of the C20-22 bond of 20,22-dihydroxycholesterol. A single P450scc protein, termed CYP11A1, lies on chromosome 15q23–q24 and is composed of nine exons that span 30 kb. Unlike in the adrenal and gonad, expression of P450scc in the placenta does not require steroidogenic factor 1 (SF1), but CP2 proteins[420,421] and zinc finger protein TReP-132[422] mediate placental P450scc expression. P450scc functions as a terminal oxidase in a mitochondrial electron transport system, whereby electrons from NADPH are accepted by an adrenodoxin reductase flavoprotein associated with the inner mitochondrial membrane. Adrenodoxin reductase transfers the electrons to an iron–sulfur protein, adrenodoxin, which is located in the mitochondrial matrix and acts as an electron shuttle to donate the electrons to cytochrome P450scc. Tuckey et al.[419,423,424] have shown that the reduction of adrenodoxin by adrenodoxin reductase is a rate-limiting step for electron transport to P450scc in the placenta. A 3β-HSD enzyme catalyzes the conversion of pregnenolone to P_4 and DHEA to Δ^4-androstenedione. Placental 3β-HSD type 1 is located on chromosome 1p13.1 and is a microsomal monomer peptide of 42,000 Da located in both mitochondrial and microsomal fractions. Dehydrogenase and isomerase activities of 3β-HSD are inseparable and catalyze both C_{19} and C_{21} Δ^5 to Δ^4 steroid reactions using NAD^+ as cofactor. It appears that placental 3β-HSD is in excess and thus not rate limiting for P_4 synthesis.

Regulation

Placental P_4 biosynthesis depends on the LDL receptor-mediated uptake of substrate LDL; however, placental P_4 synthesis does not appear to be acutely regulated. cAMP chronically stimulates expression and activity of P450scc,[425,426] adrenodoxin,[425] LDL receptors,[427] and P_4 secretion[428] in a dose-dependent manner in cultures of human cytotrophoblasts, an effect that requires the catalytic unit of protein kinases, which may regulate gene transcription.[425] PKA and phosphotyrosine phosphatase D1 are associated with the syncytiotrophoblast mitochondrial membrane by an anchoring kinase cAMP protein-121, and PKA inhibitor H89 suppressed P_4 synthesis.[429] As discussed here, the reduction of adrenodoxin is a rate-limiting step for electron transport to P450scc, and cAMP has been suggested to have a role in regulating placental adrenodoxin.[324] Placental mitochondrial P450scc activity in humans[417] and P450scc mRNA activity in baboons[430] increase with advancing gestation, and, as discussed here, E_2 stimulated the LDL uptake and P450scc activity steps involved in placental P_4 formation during baboon pregnancy.

Function

As presented in Chapter 38 in this book on implantation, P_4 has an essential role in promoting endometrial decidualization, implantation, and glandular function in the early establishment of pregnancy. Transgenic mouse studies show that P_4, signaling through progesterone receptor (PR) isoforms A and B as modulated by COUP (chicken ovalbumin upstream promoter) transcription factor 2 nuclear receptor and Heart- and neural crest derivatives expressed protein 2 transcription factor, is critical for decidualization and implantation.[431] P_4 also suppresses the maternal immune system and inflammatory processes at the maternal–fetal interface to promote pregnancy maintenance and implantation of the conceptus,[432,433] as presented in Chapter 41. P_4 also suppressed the migration and invasive capacity of HTR8–SV neo trophoblast cells in vitro[378] by inhibiting MMP2 and MMP9 activities,[378,434] and thus has the potential to control EVT vessel invasion in early pregnancy. As detailed in Chapter 42 on parturition, P_4 has a pivotal role throughout pregnancy in suppressing myometrial contractility and labor. Finally, transgenic mouse studies indicate that PR action is essential for lobuloalveolar proliferation and growth of the mammary gland,[431] but suppresses secretory activity of the breast until after delivery when placental P_4 is lost.[435]

Physiological Relevance and Clinical Correlations

The results of P450arom deficiency in human pregnancy, administration of aromatase inhibitor during nonhuman primate pregnancy, and developmental and in vitro studies demonstrate the fundamentally important role that placental E_2 plays during human and nonhuman primate pregnancy. These studies collectively have shown that E_2 controls implantation, placental EVT and villous development, transplacental corticosteroid metabolism, fetal adrenal and gonadal development, metabolic and cardiovascular dynamics, and the initiation of labor. Although the incidence of P450arom deletion in human pregnancy seems rare, it is possible that cases of aromatase deficiency may have been overlooked

because of the need for E_2 during implantation and early placental development and the lethality in its absence. Because pregnancy and fetal development appeared normal in cases of human placental sulfatase[436] and aromatase[403,416,437] deficiency, it has been concluded[326,403] that estrogen is not needed for normal fetal development and the physiology of pregnancy. However, the difficulty of conducting comprehensive investigation of physiological and developmental processes and mechanisms during human pregnancy limits the conclusions that can be drawn from the clinical studies. Most importantly, detailed follow-up studies of the offspring delivered from estrogen-deprived human and nonhuman primate pregnancy are needed to fully establish the importance of E_2 in utero on fetal organ system development and the impact on physiological processes and metabolic function after birth.

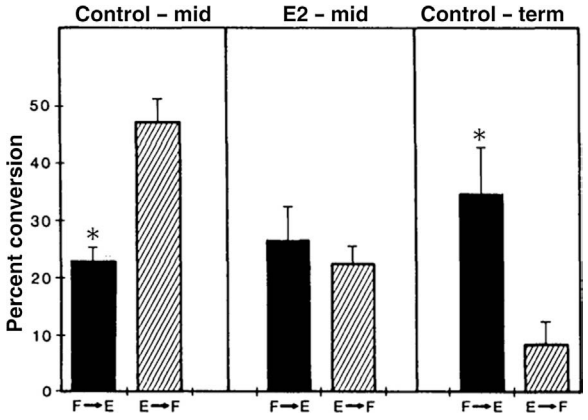

FIGURE 40.15 Transuteroplacental conversion of cortisol (F) to cortisone (E) and of E to F in untreated control baboons on gestation days 100 (midgestation) and 170 (term) and in baboons treated daily with E_2 between days 70 and 100 (midgestation). 11β-Hydroxysteroid Dehydrogenase (11β-HSD) and Cortisol–Cortisone Metabolism

Developmental Pattern of Cortisol–Cortisone Metabolism in the Primate Placenta

It has long been known that the placenta in late gestation in the human[438] and nonhuman primate[335] actively metabolizes cortisol to cortisone. Because cortisol binds to the glucocorticoid receptor, whereas cortisone does not and is inactive, it has generally been thought that the major if not sole role of the primate placenta is to protect the fetus from the relatively high concentrations of biologically active cortisol present in maternal circulation.[335] While the latter is indeed a major function of the placenta, as discussed in more detail in this chapter, Pepe and Albrecht[439,440] showed that the primate placenta also exhibits the capacity to form cortisol from cortisone. Moreover, during early to midgestation, placental formation of cortisol from cortisone is substantial and exceeds the oxidation of cortisol to cortisone. Thus, the pattern of placental glucocorticoid metabolism is altered from preferential reduction of cortisone to cortisol at early to midgestation, a time in pregnancy when the fetus and fetal adrenal cannot synthesize their own cortisol, to preferential oxidation in late gestation (Figure 40.15). It has been proposed, therefore, that the placenta by controlling the formation of cortisol from cortisone dictates the levels of cortisol that arrive in the fetal circulation, consistent with the prevailing theory of the importance of the maternal–placental hormonal milieu in programming fetal organ system development.[335]

It has also been shown that E_2 regulates placental cortisol–cortisone metabolism.[440,441] Thus, the developmental change in placental corticosteroid metabolism from preferential reduction of cortisone to cortisol at midgestation to oxidation of cortisol to cortisone at term was prevented in baboons in which E_2 production was suppressed and induced prematurely at midgestation by E_2 administration (Figure 40.15). In contrast, the oxidation–reduction of cortisol–cortisone in maternal tissues was not altered during the course of pregnancy or by E_2.[442] Thus, estrogen specifically modulates metabolism in the syncytiotrophoblast as confirmed by studies showing that the conversion of cortisol to cortisone by cultures of baboon syncytiotrophoblast obtained at term exceeds that of cells of midgestation and is increased in trophoblast cells from mothers treated at midgestation with E_2. It would appear that E_2 regulates placental glucocorticoid metabolism via interaction with ER expressed in the primate trophoblast.[442]

Regulation of 11β-HSD-1 and -2 Expression in Human and Baboon Placental Syncytiotrophoblast by E_2

In tissues such as the liver, cortisol metabolism is catalyzed by an 11β-HSD enzyme that exhibits both oxidative and reductive capacity and utilizes $NADP^+$–NADPH as co-factor. Although $NADP^+$-dependent 11β-HSD enzyme activity is demonstrable in the baboon[443] and human[444] placenta, the authors[439] were the first to show that 11β-HSD-catalyzed oxidation of cortisol to cortisone in homogenates of human and baboon villous trophoblast was much greater when NAD^+ was used as co-factor. Subsequent studies confirmed that NAD^+ is the preferred co-factor for the 11β-HSD enzyme catalyzing cortisol oxidation in the human placenta.[445] Collectively, these findings were consistent with the original suggestion of Monder and Shackleton[446] that there are multiple (iso) forms of 11β-HSD. Indeed, it has since been confirmed that there are two 11β-HSD

enzymes catalyzing cortisol–cortisone metabolism[447,448] and that these proteins are the product of two different genes.[449,450] The enzyme originally purified from rat liver[451] and termed 11β-HSD-1 is an $NADP^+$–NADPH-dependent oxido-reductase that behaves primarily as a reductase in part due to its higher affinity for cortisone. In contrast, 11β-HSD-2, which has been purified from human placenta,[452] is an NAD^+-dependent enzyme that only oxidizes cortisol to cortisone.

The 5′-flanking regions of the human and baboon genes encoding the 11β-HSD proteins[449,453–455] are >95% homologous, and the syncytiotrophoblast is a predominant site of expression of the mRNA and protein for both 11β-HSD-1 and -2.[456,457] Because 11β-HSD-1 can function as an NADPH-dependent reductase, the expression of 11β-HSD-1 in syncytiotrophoblast provides the molecular basis for the extensive reduction of cortisone to cortisol across the primate placenta during early to midgestation.[443] The syncytiotrophoblast expression of 11β-HSD-2 is consistent with the extensive capacity of the placenta to oxidize cortisol to cortisone.[335]

Studies have shown that the mRNA and protein levels of 11β-HSD-2, as well as 11β-HSD-1, in the syncytiotrophoblast increase with advancing gestation in the baboon and human.[456,458] Moreover, syncytiotrophoblast microsomal NAD^+-dependent 11β-HSD enzyme activity at midgestation was increased fourfold in baboons treated with E_2 and decreased at term in estrogen-suppressed animals.[442] The upregulation of 11β-HSD-2, and also 11β-HSD-1, in the syncytiotrophoblast appears to involve a direct ER-dependent action of E_2 on the promoter of these two genes.[454] Thus, in JEG-3 cells transfected with the 5′-flanking regions of the baboon 11β-HSD-1 or 11β-HSD-2 genes, basal promoter activities of both genes were increased by E_2 in the presence but not absence of a co-transfected ER. Consistent with these observations, Burton et al.[459] demonstrated that the mRNA and protein levels of 11β-HSD-1 and -2 in rat uterus were abolished by ovariectomy and restored by E_2 replacement.

The E_2-dependent upregulation of 11β-HSD-2 is consistent with increased transplacental oxidation of cortisol to cortisone at term.[443] However, the concomitant upregulation of 11β-HSD-1 mRNA, protein, and enzymatic activity with advancing gestation is surprising and presumably reflects a role for factors and/or processes in addition to upregulation of enzyme expression. One of the unique features of the syncytiotrophoblast is that it is a polarized cell composed of a maternal-facing microvillus brush border and a basal membrane (BM) juxtaposed to the fetal vasculature. Moreover, cells of other tissues in which 11β-HSD-2 is expressed (e.g., the colon and cortical collecting duct of the kidney)[457] are also polarized with different enzymes located in the luminal and BMs. The same appears to be the case for 11β-HSD-1 and -2 in the human and baboon placenta.[460] Thus, 11β HSD-1 is localized primarily in the syncytiotrophoblast microvillus membranes (MVMs) and is present, but in much lower amounts, in more internal regions, including the BM. In contrast, 11β-HSD-2 is localized to the cytosol and BM but not present in the MVM. Most interestingly, the ratio of 11β-HSD-2 to 11β-HSD-1 proteins in the BM is increased twofold between mid- and late gestation, an increase that is regulated by E_2.[461] It would appear therefore that the differential localization and increased levels of these two enzymes provide the biochemical–architectural basis for the E_2-dependent change in placental metabolism of cortisol–cortisone with advancing gestation. Consistent with this hypothesis, Burton et al.[462] have shown that 11β-HSD-1 and -2 expression is markedly different in the basal and labyrinth zones of the rat placenta. Finally, while E_2 has a pivotal role in establishing the extent and site of expression of these two enzymes, other factors apparently then function at discrete periods of gestation to fine-tune enzyme expression. Thus, human placental 11β-HSD-2 expression has been shown by in vitro studies to be upregulated by glucocorticoids, hCG, prostaglandins, and other factors that activate cAMP[463] and downregulated by hypoxia[464] and calcium.[465] Although study of the regulation of 11β-HSD-1 has been more limited, expression appears to be modulated by glucocorticoids and gene promoter activity downregulated in human epidermoid cancer 2 cells by growth hormone and IGF1.[466]

Impact of E_2-Regulated Placental Cortisol–Cortisone Metabolism on Fetal Development

In humans and nonhuman primates, the transitional zone of the fetal adrenal gland does not develop the 3β-HSD enzyme required to synthesize cortisol de novo until very late in gestation. Thus, throughout the majority of gestation, fetal adrenal cortisol production is negligible. In contrast, as judged by anatomical correlates of function, and the ability to secrete ACTH and CRH, the baboon and human fetal hypothalamus and pituitary gland develop the ability to function relatively early in gestation. Thus, development of the fetal adrenal appears to be "out of phase" with that of the hypothalamus and pituitary, yet by term the HPA axis has become functionally integrated.[442] Although cortisol is detectable in the fetus throughout the course of gestation, it is now well established that essentially all of the cortisol in fetal blood before midgestation is of maternal origin, whereas by late gestation >50% originates from hormone produced by the fetal adrenal.[443] Therefore, the authors[467] proposed that the placenta, via metabolism of cortisol–cortisone, dictates the qualitative and quantitative pattern of these corticosteroids arriving within the fetus, and consequently indirectly regulates the timing of maturation of the fetal HPA axis. As seen in Figure 40.16, because placental metabolism in early to midgestation

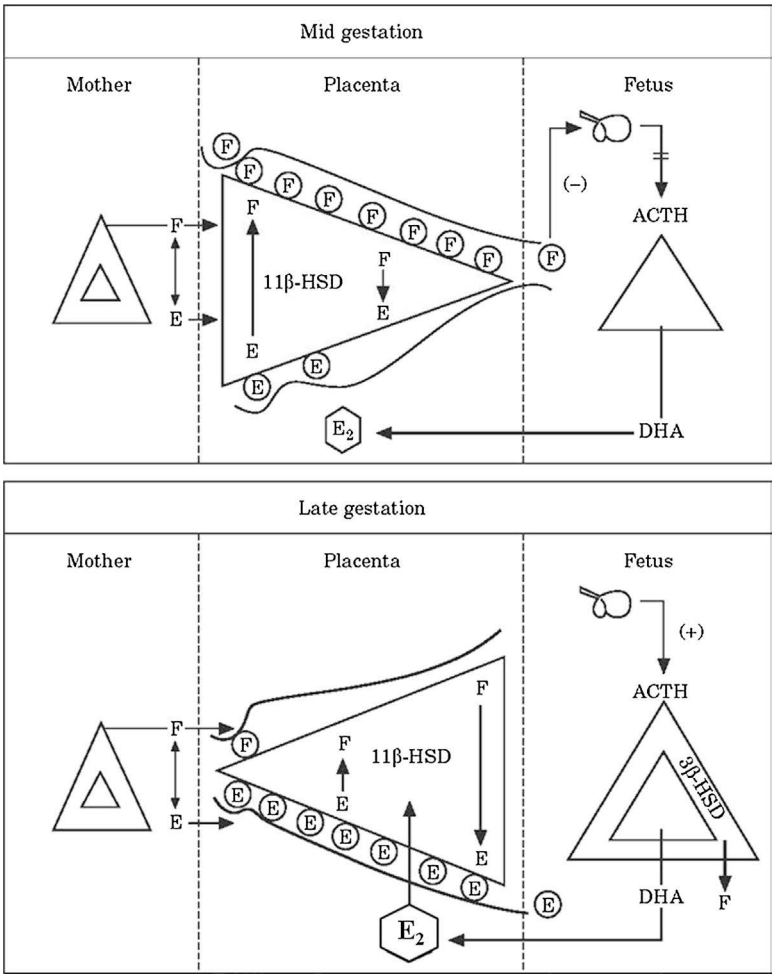

FIGURE 40.16 The role of estrogen (E_2) on placental 11β-HSD-catalyzed metabolism of cortisol (F) and cortisone (E) and regulation of the fetal pituitary–adrenocortical axis at mid- and late gestation in the baboon. During early to midgestation, E_2 levels are low and placental 11β-HSD-catalyzed metabolism of maternal glucocorticoids favors the formation and transfer of F to the fetus, which suppresses fetal pituitary ACTH production and development of the fetal adrenal transitional zone and thus F synthesis. With advancing gestation, the increase in E_2 enhances placental 11β-HSD-induced oxidation of maternal glucocorticoids to E, which decreases the amount of F arriving at the fetus; this results in increased fetal pituitary ACTH production, which induces 3β-HSD expression in and development of the fetal adrenal transitional zone and thus de novo F production by the fetus. 3β-HSD, Δ^5-3β-hydroxysteroid dehydrogenase. *Source: Reprinted with permission from Ref. 467.*

favors the formation of cortisol, the primary maternal corticosteroid arriving within the fetal circulation would be biologically active cortisol, which would suppress fetal pituitary ACTH production, thereby preventing maturation of the fetal adrenal transitional zone and the ontogenesis of cortisol production. With advancing gestation, the E_2-induced placental syncytiotrophoblast localization of 11β-HSD-1/-2 and increase in placental conversion of maternal cortisol to biologically inactive cortisone would be expected to decrease the concentration of maternal cortisol arriving across the placenta into the fetus, resulting in fetal pituitary ACTH release and maturation of the fetal adrenal gland. In support of this hypothesis, the expression of proopiomelanocortin mRNA and ACTH in the fetal pituitary,[468] mRNA–protein levels and activity of 3β-HSD and $P450c_{17}$, and protein kinase A activity in and the ontogenesis of de novo cortisol production by the baboon fetal adrenal were greater at term than at midgestation, and they increased prematurely at midgestation by treatment with E_2, which induced placental oxidation of cortisol to cortisone.[442] Subsequent studies in various rodent models confirm the earlier studies in the primate to support the important role of placental 11β-HSD enzymes in development of the fetal HPA axis.[469] For example, in mice, 11β-HSD-1 mutation leads to attenuated negative feedback of the HPA axis response to stress,[470] whereas mutation of the 11β-HSD-2 gene leads to hypertension, excess mineralocorticoid activity, and increased anxiety in adulthood.[471] Moreover, pharmacologic inhibition of 11β-HSD-2 during rodent pregnancy leads to molecular and neurological changes within the HPA axis associated with increased stress response and anxiety in adulthood.[472]

Physiological Relevance and Clinical Correlations

The placental 11β-HSD-dependent regulation of the fetal HPA axis is also likely operative during human pregnancy, as recently reviewed.[473] For example, consistent with the latter postulate, women with hypoadrenalism (e.g., Addison's disease) can maintain pregnancy without corticosteroid treatment,[474] ostensibly because of premature activation of the fetal HPA axis in utero in the absence of placental transport of maternal cortisol. Moreover, in low-birth-weight babies born at 27 weeks gestation, those with lower placental 11β-HSD-2 activity

had a more severe early postnatal clinical course and lower blood pressure and were more likely to receive glucocorticoid supplementation, consistent with decreased adrenal function.[475] Studies in humans have documented that placental[476] and fetal tissue[477] 11β-HSD-2 gene expression and activity are reduced in pregnancies complicated by FGR. However, placental expression of 11β-HSD-1, in addition to 11β-HSD-2, is reduced in babies born small for gestational age,[478] and umbilical cord blood levels of cortisol are low in FGR newborns.[479] Thus, while protection of the fetus from excess maternal cortisol, via placental 11β-HSD-2, appears to be an important factor in FGR, lower expression of 11β-HSD-1, which has not been investigated as extensively, might be equally important to compromised fetal growth and development. It is important to note that reduced expression of 11β-HSD-2 in FGR and growth restriction in pregnancies complicated by preeclampsia reflect measurements in late gestation. Interestingly, it has recently been shown that placental 11β-HSD-2 expression is actually elevated in the first trimester in pregnancies at risk for preeclampsia based on Doppler flow analyses.[458]

The importance of placental glucocorticoid metabolism to fetal well-being is further emphasized in animal experiments[480] and in human studies showing that stress experienced by the mother during pregnancy is associated with increased risk for adverse effects in the offspring, including anxiety,[481] attention deficit hyperactivity disorder,[482] and cognitive defects.[483] Moreover, placental 11β-HSD-2 expression was lower in mothers with maternal prenatal anxiety, presumably due to increased maternal adrenal cortisol production.[484] It has also been shown that cognitive and behavioral development was impaired in the offspring of mothers who consumed high levels of licorice, which contains glycyrrhetinic acid, an inhibitor of 11β-HSD-2.[485,486]

PLACENTAL HYPOTHALAMIC-LIKE NEUROPEPTIDE AND PEPTIDE HORMONES

It is well established that the placenta expresses key components of the hormonal systems that characterize the hypothalamic–anterior pituitary axis, including CRH–proopiomelanocortin (POMC)–ACTH, GnRH–LH–hCG, GHRH, and somatostatin, as well as the posterior pituitary (i.e., oxytocin). The placenta is also a source of several neuropeptides (e.g., kisspeptin, NPY, and neurokinin B (NKB)) and vasoactive peptides (e.g., endothelin 1, adrenomedullin (AM), calcitonin gene-related peptide (CGRP), and parathyroid hormone-related peptide (PTHrP)) that modulate other hormone systems that are important to successful pregnancy. The expression, regulation, and multiple actions and interactions of the placental hypothalamic-like hormones were reviewed by Petraglia and colleagues in the last edition of the *Physiology of Reproduction*.[255] In addition, reviews of the placental neuroendocrine system and roles in pregnancy and of pregnancies complicated by placental pathologies have also recently been published.[487–490] Thus, in this section, we present an overview of these hormones and recent advances on their regulation and roles in pregnancy and placental function.

CRH and Urocortins (Ucn)

The CRH–Ucn family of peptides is produced in the placenta and includes CRH, Ucn1, Ucn2, and Ucn3. The gene for CRH is located on chromosome 8 and contains a CRE, one-half of an estrogen response element, and two TATA boxes. The human Ucn gene is located on chromosome 2p23-p21, and putative regulators include a TATA box, GATA-binding sites, a POU domain, and a CRE. The free or biologically active levels of CRH and the Ucns are controlled primarily by a CRH-binding protein (CRHBP) also synthesized in the placenta. Importantly, in contrast to the marked increase in placental expression and maternal serum levels of CRH with advancing gestation, expression and levels of CRHBP decline sharply in the last 2–4 weeks of gestation,[491] presumably enhancing the bioavailability of CRH and Ucns.

CRH and Ucns exert their actions by activating one of two CRH receptors, CRHR1 (CRH and Ucn1) or CRHR2 (CRH, Ucn1, Ucn2, and Ucn3). Both receptors belong to the G protein-coupled receptor (GPCR) superfamily. The CRHR1 gene is located on chromosome 17q21.31 and expressed as eight splice variants, whereas the CRHR2 gene is located on chromosome 7q14.3 and transcribes three splice variants. The CRHRs are expressed in the syncytiotrophoblast, myometrium, amnion, and chorion.[492] CRH is expressed in the cytotrophoblast, syncytiotrophoblast, and intermediate trophoblast, while Ucn2 and Ucn3 are expressed by the syncytiotrophoblast, decidua, and EVTs.[493,494] The factors that control and thus increase (e.g., glucocorticoids, norepinephrine, and prostaglandins) or suppress (P_4) placental CRH production comparably influence hypothalamic CRH, with the exception of cortisol, which interestingly does not suppress but rather enhances placental CRH expression.[495] E_2 acting via ERα has been shown to upregulate CRHR gene expression in the syncytiotrophoblast, and activation requires a functional CRE.[496]

Placental CRH stimulates fetal pituitary ACTH expression[497] and via ACTH and/or a direct action increases fetal adrenal DHEA and DHEAS levels and thus placental estrogen synthesis, as well as cortisol production in late gestation.[337] As discussed in the section Steroid Hormones of the Placenta, CRH may also act directly

on the placental trophoblast to promote E_2 and decrease P_4 biosynthesis.[342] Because the rise in CRH after weeks 16–18 of gestation is more rapid in women who deliver preterm[498,499] and slower in those who deliver late, it has been proposed that CRH acts as a biologic clock to control the length of pregnancy and thus the timing of birth.[487,500–502] The mechanisms by which CRH and/or Ucn may control the timing of birth are unknown, although CRH and Ucn2 modulate myometrial contractility,[503] and the expression of the CRHR1 is upregulated in the human myometrium at the time of labor.[504] Ucn2 acting via CRHR2 regulates the PKC–MAPK–ERK signaling pathway and myosin light chain phosphorylation,[505] as well as large conductance calcium-activated potassium channels[506] in the human myometrium. Recent studies also indicate that the inducible nuclear transcription factor NFkB (or kB) also may play a role in modulating lipopolysaccharide- and TNFα-induced placental CRH transcription and labor.[507,508] Thus, TNFα, which is elevated by Ucn2,[509] activates interleukin 1 receptor-associated kinases, which complex with TGFβ-activated kinase ubiquitin-conjugating enzymes to activate an IkB kinase–NFkB essential modulator complex. The latter then phosphorylates an NFkB inhibitor releasing NFkB, which travels to the nucleus where it stimulates CRH transcription.

Glucocorticoids also increase the synthesis and nuclear translocation of the noncanonical NFkB pathway and consequently CRH expression in the human placenta.[508] Glucocorticoids[510] and CRH[511] also regulate placental trophoblast expression of the GLUT1 and GLUT3 transporters responsible for placental transfer of glucose to the fetus.[512] Additional investigation is needed to determine whether glucocorticoids act directly, or indirectly via placental CRH and placental transfer of substrates such as glucose, to disrupt programming of fetal growth and development. CRH–Ucn may also be involved in or interact with the pathways associated with preterm delivery due to infections,[513] as well as control EVT invasion and activation of Fas ligand-induced apoptosis in placentas of pregnancies complicated by preeclampsia.[514] Maternal serum CRH levels are increased and CRHBP decreased in pregnancies complicated by preeclampsia, and measures of maternal CRH and CRHBP may be predictive of the risk for development of preeclampsia.[499]

CRH at relatively high concentrations can also act on vascular smooth muscle and endothelial cells to increase peripheral vasodilation and thus lower arterial blood pressure.[515] Although a physiologic role for CRH on maternal cardiovascular function remains to be determined, it has been shown that the hormone is a potent dilator of and thus may contribute to the regulation of the uteroplacental circulation and vascular tone.[516]

In addition, CRH and Ucn stimulate processing of placental POMC and thus expression of ACTH, β-endorphin, and α-MSH.[517] Placental ACTH is localized primarily to the cytotrophoblast in the first trimester and the syncytiotrophoblast thereafter, and expression and levels of placental ACTH increase with advancing gestation. However, placental ACTH does not appear to contribute significantly to maternal ACTH levels. Thus, placental ACTH either acts locally and/or is secreted into the fetus where it has been shown to interact with a family of five melanocortin receptors (MC1R–MC5R) expressed by various fetal tissues to potentially modulate fetal development in rodent models.[518] Moreover, the placenta synthesizes the opioid peptides, enkephalin and dynorphins 1–8 and 1–13.[255,519] Maternal serum levels of enkephalin are similar in pregnant and nonpregnant women, whereas levels of dynorphin are elevated primarily late in gestation. Although maternal levels of β-endorphin have been shown to either increase or not change during pregnancy, placental expression is increased by the stress of delivery.[255] While the specific roles of these opioids on placental function remain to be elucidated, the mu (μ), kappa (κ), and delta (δ) receptors that bind the endorphins, enkephalins, and dynorphins are expressed on placental cell membranes.[520] The κ receptors appear to have the highest affinity for the opioid peptides and thus elicit the most potent effects on aspects of placental function, which include release of hCG in culture.

Gonadotrophin-Releasing Hormone

GnRH is a decapeptide synthesized by the hypothalamus, and two isoforms, GnRH1 and GnRH2, are expressed by human placental cytotrophoblasts and the syncytiotrophoblast.[39] The gene for GnRH1 is located on chromosome 8p11.2–p21 and encodes a 92-amino-acid precursor protein that contains the GnRH decapeptide as well as a signal sequence, a GKR-processing sequence, and a GnRH-associated peptide.[488,521] The gene for GnRH2 is located on chromosome 20p13, is 70% homologous to the GnRH1 gene, and encodes a pre-prohormone and comparable signal and GKR sequences and a decapeptide that differs from GnRH1 in three amino acids. Both GnRH isoforms signal via activation of the GnRH receptor 1 (GnRHR1), which has been localized to human placental cytotrophoblasts, the syncytiotrophoblast, and the decidua.[522,523] The gene encoding GnRHR1 is located on chromosome 4q13.2–21.1 and encodes a GPCR that lacks an intracytoplasmic COOH terminal tail important for receptor desensitization as well as internalization and recycling. A second GnRHR isoform (GnRHR2) has been isolated and the gene localized to chromosome 1q12. However, this receptor does not appear to be functionally active

in humans, and thus GnRH1 and -2 signal through GnRHR1.

Although levels of GnRH appear to be unchanged during the course of gestation, placental mRNA and protein expression of GnRHR1 mirrors that of βhCG and thus increases progressively during the first 8–9 weeks and decreases progressively thereafter.[522] Those factors that increase the release of GnRH from the hypothalamus (e.g., depolarizing and cAMP stimulatory agents, activin A, and E_2) also stimulate placental GnRH secretion.[524] A number of factors appear to regulate GnRHR1 expression, notably GnRH1, activin, and inhibin, and response elements for these factors have been identified in the promoter region of the gene.[255,488]

Placental GnRH regulates βhCG expression,[525] and GnRH1 appears to be the more physiologically relevant in this regard as it has a much higher affinity for GnRHR1 and can stimulate hCG secretion for up to 24 h.[526] GnRH may also have a role in decidualization in early pregnancy, since it induced apoptosis in human decidual stromal cells, an effect mediated by growth arrest DNA damage-inducible gene 45α and MAPK signaling.[523] GnRH1 and GnRH2 also may play a role in EVT invasion[527] via modulation of MMPs.[488,528,529]

Kisspeptin

Kisspeptins comprise a family of proteins derived from the Kiss1 gene, which when translated yields a 145-amino-acid peptide known as kisspeptin 145 or Kiss1. Kiss1 can be further transformed to yield Kiss14, Kiss13, and Kiss10 and the 54-amino-acid peptide metastatin (kisspeptin 54) originally shown to inhibit cancer metastasis.[530] Kiss1 mRNA and protein are highly expressed by the placental syncytiotrophoblast, cytotrophoblasts, and decidua.[531] The kisspeptin receptor, formerly known as the orphan G protein-coupled receptor (GPR54), is expressed in the human hypothalamus and the placenta.[531,532] Placental Kiss1 and GPR54 mRNA levels are elevated in the first trimester and markedly increased in both preterm and postterm, as well as preeclampsia pregnancies,[533–535] while plasma kisspeptin levels exhibit a progressive rise during normal pregnancy.[536]

Kisspeptin modulates GnRH neuronal excitability, function, and expression and thereby influences the hypothalamic–pituitary–gonadal axis and the onset of puberty. Thus, subjects with loss-of-function mutation of the GPR54 have idiopathic hypogonadotropic hypogonadism.[530,532,537] Within the placenta, however, Kiss1 has also been shown to inhibit migration of trophoblast cells in culture,[538] and placental trophoblast kisspeptin expression is low in women with a history of recurrent miscarriage.[531] Recent studies have described the signaling events that are activated by Kiss10 interaction with GPR54 and that apparently involve interaction and cross-talk with the EGF receptor.[539]

Neuropeptide Y

NPY is a 36-amino-acid peptide that is abundantly expressed in the decidua, fetal membranes, and placental cytotrophoblast and intermediate trophoblast,[540] as well as the central and peripheral nervous system. Maternal serum levels of NPY are greater in pregnant than nonpregnant women and remain relatively stable or increase slightly during gestation.[487] Serum NPY levels drop rapidly postpartum, and thus the placenta appears to be a major source of NPY in maternal serum. The two NPY receptor subtypes, NPY1R and NPY3R, are localized to placental syncytiotrophoblast microvilli.[541]

NPY appears to have a role in stimulating placental trophoblast CRH synthesis and release[540] by modulating the phospholipase C–inositol triphosphate receptor axis and calcium calmodulin kinase II activity.[542] NPY may also participate in the regulation of several physiologic processes, including stimulation of food intake, inhibition of insulin release, modulation of gastrointestinal motility, basal secretion of pituitary LH,[543] and cascade of events leading to labor and delivery, although its roles in these processes during pregnancy remain to be clearly defined. However, maternal NPY levels are increased in preeclampsia[544] and, like changes in maternal leptin and other adipokines, may represent a compensatory response in the presence of placental dysfunction.

Oxytocin

Oxytocin is a 9-amino-acid peptide that is transcribed from the oxytocin gene located on chromosome 20p13. Oxytocin is synthesized by or released from the supraoptic nucleus and PVN of the hypothalamus, the axons of which terminate in the posterior pituitary gland. Oxytocin is also produced in the placental syncytiotrophoblast, decidua, amnion, and chorion.[545] Oxytocin mRNA levels in intrauterine tissues are increased in association with spontaneous labor.[545] Maternal serum oxytocin concentrations exhibit a circadian rhythm and are highest at night coinciding with nocturnal spontaneous uterine activity. E_2 appears to be a major regulator of oxytocin expression, particularly in the decidua and chorion.[546] Placental oxytocin expression is also increased by placental CRH, as well as activin and prostaglandins,[547] factors that are part of the cascade of events that appear integral to parturition. The oxytocin receptor is abundantly expressed in myometrium and other intrauterine cells, including the decidua and chorion leavae, where levels are increased by E_2 and decreased by P_4.[548] However, the relative contribution of placental oxytocin to the onset of

labor, particularly the relationship to pituitary oxytocin release during the expulsive phase, is unclear.

Chromogranin A

Chromogranin A is a 49-kDa glycoprotein of the neuroendocrine system that is typically increased by stress, including hypoxia.[489,549] Chromogranin A is colocalized within and co-released from storage granules along with NPY and catecholamines.[549] During pregnancy, chromogranin A is also expressed by the trophoblast, decidua, and fetal membranes, and maternal serum levels exhibit a progressive rise with advancing human gestation.[550]

Plasma chromogranin A levels are higher in the fetus than in the mother and are elevated by the process of spontaneous labor.[551] Therefore, it has been postulated that chromogranin A may inhibit catecholamine and NPY release to counteract the vasoconstrictory effects of the latter peptides at the time of delivery.[551]

Neurokinin B

The placenta also expresses NKB, which belongs to the tachykinin family of signaling peptides, such as substance P, that function in the central nervous system as excitatory neurotransmitters for nociception.[552] The 10-amino-acid NKB peptide is abundantly expressed by the syncytiotrophoblast and secreted into the maternal circulation,[553] where levels increase with advancing gestation.[554] The 3G protein-linked NKB receptors (NKBR1–3) are also expressed in human placenta and umbilical vein endothelial cells, as well as hypothalamic neurons.[555]

Mutation of the genes encoding either NKB or NKBR3 causes normosmic isolated hypogonadotropic hypogonadism (niHH), indicating the importance of NKB in human reproductive function and development.[556–558] In contrast to the infertility associated with the null mutation of NKBR3 (Tacr3$^{-/-}$) in humans,[552] Tacr3$^{-/-}$ mice exhibit normal fertility.[559] Consistent with the role of NKB on the hypothalamic–pituitary–gonadal axis in humans, Plant and coworkers[560] showed that administration of NKB to gonadectomized rhesus monkeys elicited robust GnRH-stimulated LH pulses. NKB has also been shown to modulate other physiologic processes, including water homeostasis,[561] pulmonary inflammation,[559] and cognition.[562] NKB may also enhance placental vasodilation via a receptor-mediated mechanism independent of nitric oxide. Finally, maternal levels of NKB are increased in women with preeclampsia, which could reflect a compensatory increase to compromised uteroplacental blood flow.[553]

Monoamines

The placenta also expresses the enzymes that catalyze the synthesis, as well as metabolism, of epinephrine, norepinephrine, dopamine, and serotonin.[563,564] Moreover, receptors and transporters for these factors are localized in the placental trophoblast and altered in pregnancy complications, including preeclampsia.[563]

Endothelin (ET)

Endothelins (ETs) are 21-amino-acid peptides produced by several cell types (e.g., fibroblasts and macrophages, and notably endothelial cells). Three isoforms, ET1–3, have been identified and are encoded by three separate genes. ET1 is synthesized as a 212-amino-acid pre-peptide, which is processed to a 38-amino-acid precursor (Big ET1) that is subsequently cleaved into the mature ET1 by a specific ET-converting enzyme, termed ECE1.[565] PreproET1 mRNA and ET1 protein are synthesized by placental endothelial cells, as well as villous trophoblast and amniotic epithelium.[566] ECE1 is expressed in endothelial cells lining the vessels of the maternal basal plate and fetoplacental vessels.[567,568] Placental ET1 receptor expression appears to be highest in early gestation.

ET1 is a potent vasoconstrictor of the human placental vasculature and thus in conjunction with other factors likely plays a role in control of uteroplacental blood flow.[569] There also is considerable evidence that placental ET has a role in the pathology of preeclampsia.[570] For example, placental ET1 expression[571] and circulating ET1 levels[572,573] are higher in women with preeclampsia. Granger and colleagues[574–577] have used the reduced uterine perfusion pressure (RUPP) rat as a model for preeclampsia. In the RUPP rodent, which exhibits hypertension, renal injury, proteinuria, and endothelial dysfunction, the ischemic placenta produced factors that increased vascular ET1 production, and ET1 mediated the onset of hypertension induced by administration of TNFα or the soluble Flt-1 VEGF receptor.[574]

Adrenomedullin

AM is a 52-amino-acid peptide with homology to CGRP. Human AM is processed from preproAM and proAM via enzymatic amidation. Originally discovered in 1993 in human adrenal pheochromocytoma, AM mRNA and protein are also expressed in the syncytiotrophoblast, villous cytotrophoblast, EVTs, and chorio decidua.[578,579] Maternal levels of AM are threefold higher in pregnant than nonpregnant women and rise during the course of human gestation.[580]

Homozygous AM$^{-/-}$ mice produce embryos with little vascularization of the yolk sac and fetal death

at midgestation caused by cardiovascular defects.[581] Administration of an AM antagonist caused FGR and defective blood vessel development in the placental labyrinth.[582] AM decreases vasomotor tone in isolated perfused placental vessels previously constricted with thromboxane.[583] Thus, AM may participate in the maintenance of low resistance of the placental vascular bed by binding to a GPCR, stimulating the nitric oxide cGMP pathway in endothelial cells, and activating cAMP in smooth muscle cells.[584] Although AM mRNA expression in the trophoblast, amnion, and chorio decidua was increased in patients with preeclampsia,[585] maternal AM levels were unaltered, increased, or decreased in other studies of pregnancies with preeclampsia.[586]

Calcitonin Gene-related Peptide

CGRP, a 37-amino-acid neuropeptide originally shown to influence nociception and modulation of the autonomic system, also exhibits potent vasodilatory effects.[587] CGRP mRNA and protein are expressed in the syncytiotrophoblast, villous vascular endothelial cells, EVTs, and decidua.[588–590] CGRP is secreted into the maternal circulation, where levels progressively increase with advancing gestation.[589] CGRP acts via a seven-transmembrane GPCR, which is modified by receptor activity-modifying proteins (RAMP1–3), and is localized to the placental syncytiotrophoblast microvillous and BMs, as well as the EVTs and the myometrium, where levels are highest prior to labor.[255]

Homozygous CGRP receptor-null mice exhibit cardiovascular defects, hydrops fetalis, and embryonic death at midgestation,[591] indicating the importance of CGRP for embryonic and fetal development. A major function of CGRP in pregnancy appears to be modulation of uteroplacental vasoactive tone.[592] Interestingly, in pregnant rodents, the induction of hypertension by administration of L-NAME, which blocks nitric oxide production, was prevented by concomitant administration of CGRP.[593] Moreover, Yallampalli and colleagues[590] and others[594] have shown that CGRP induced human vascular endothelial cell proliferation and migration and capillary-like tube formation in a dose- and time-dependent manner. The authors[590] suggested, therefore, that CGRP has a role in placental angiogenesis and neovascularization. It has also been suggested that CGRP may play an important role in the etiology and/or progression of preeclampsia, although maternal CGRP levels were either decreased[588,589] or unaltered[595] in preeclampsia.

Parathyroid Hormone-related Peptide

PTHrP is a 141-amino-acid protein that shares substantial sequence homology with parathyroid hormone (PTH). PTHrP was originally purified from tumors associated with hypercalcemia, and thus circulating levels are typically low except in such clinical conditions. Following enzymatic cleavage, several forms of the protein exist, including PTHrP1–34 and 67–86. PTHrP1–34 protein is expressed in the syncytiotrophoblast, whereas PTHrP67–86 is expressed primarily in endothelial cells of placental villous capillaries.[596] Maternal serum levels of PTHrP are elevated in pregnancy and appear to be maximal in late gestation. PTHrP binds to the PTH receptor, which is also expressed in the placenta and myometrium.

PTHrP-deficient mice show a reduced maternal–fetal calcium gradient and skeletal dysplasia, and they die at birth,[597] in contrast to PTH-null mice in which placental calcium transfer was unaltered.[598] In rats in which fetal growth was reduced by uteroplacental restriction, fetal and placental calcium homeostasis was disrupted and placental PTHrP expression increased, presumably to compensate for impaired placental function.[599] Finally, PTHrP also elicits a potent vasodilatory effect on the uteroplacental circulation and inhibition of uterine contraction.[592,600]

ADIPOKINES

Over the past decade, several factors, including leptin, adiponectin, resistin, and ghrelin, have been isolated from adipose and other tissues and shown to be important to metabolic homeostasis and satiety. In addition to PL (discussed in this chapter), these factors, termed adipokines, also play an important role in the metabolic adaptations that characterize human pregnancy, notably the increase in maternal insulin resistance with advancing gestation. A review of the expression, physiology, and interaction of these adipokines in controlling food intake, metabolism, and insulin sensitivity has been published.[601] Therefore, our emphasis will be to summarize the nature, expression, and metabolic role of these factors in pregnancy; their potential impact on placental function; and their secretion in pregnancies complicated by FGR, obesity, and hypertension or preeclampsia.

Leptin

Leptin is a 146-amino-acid, 16 kDa protein hormone, discovered in 1994,[602] that regulates food intake, energy expenditure, and metabolism and thus body weight.[603] Originally thought to be primarily the product of adipose tissue,[602] leptin is also expressed by the placenta as well as numerous other tissues, including muscle, liver, brain, and ovary.[604–606]

The actions of leptin are modulated by the leptin receptor, which is a member of the cytokine receptor superfamily that includes receptors for interleukins,

prolactin, growth hormone, and erythropoietin.[607,608] As a consequence of differential splicing, there are four known isoforms characterized by the length and sequence of the cytoplasmic terminal and classified as long (HLR_L) or short (HLR_S), the latter composed of isoforms with cytoplasmic regions of 5, 15, or 67 amino acids.[607,608] In all receptor isoforms, the extracellular ligand-binding and transmembrane domains are identical, as are the first 29 amino acids of the cytoplasmic region. All isoforms contain a "box 1" region involved in binding JAKs. However, the long form also has a "box 2" site that binds STAT, and thus only HLR_L activates JAK–STAT. HLR_{S15} activates and thus signals via MAPK.[608,609] Finally, soluble receptors (sol-HLRs) generated by proteolytic cleavage of membrane-bound HLRs are released into and thus detected in the peripheral circulation.[610] Because these soluble receptors can sequester and thus reduce the availability of leptin, they are thought to play a functional role in the leptin resistance characteristic of some forms of obesity as well as pregnancy.[605]

Maternal serum concentrations of leptin are elevated very early in gestation and continue to rise throughout the remainder of pregnancy, peaking during the second and third trimesters.[611–613] That the placenta is a major source of maternal circulating leptin is supported by studies showing that leptin mRNA and protein are expressed in placental syncytiotrophoblast throughout gestation, as well as by the cytotrophoblast in early gestation, and that maternal serum levels become elevated before any increase or change in maternal adiposity and return to baseline rapidly after delivery.[605,611,612,614,615] Placental leptin mRNA levels are much higher in early than late gestation and thus, as discussed further here, placental leptin expression and maternal serum levels appear to be regulated by the hormonal milieu of pregnancy and not by trophoblast mass.[605] Maternal adipose, however, remains a source of leptin in pregnancy. Thus, regardless of the stage of gestation, maternal leptin levels are considerably higher in overweight pregnant women (Body Mass Index (BMI) > 26 kg/m^2), whereas placental leptin expression is similar in obese and lean women.[601]

In addition to expression of HLR by maternal tissues (e.g., HLR_L in the hypothalamus and HLR_S in the liver and adipose), the placenta as well as the amnion, chorion, and umbilical vasculature express mRNA and protein for both HLR_L and HLR_S. Receptors are expressed throughout the course of gestation, and proteins are localized to the syncytiotrophoblast, the EVTs, and fetal vascular endothelial cells.[616] Levels of the sol-HLR in maternal serum appear to be elevated in pregnancy. As a consequence, the concentrations of maternal unbound leptin remain elevated but are not further increased during the second and third trimesters.[617] Therefore, it has been suggested that the level of leptin available to bind HLR_L in the maternal hypothalamus is not further increased and/or that this very high level of leptin downregulates hypothalamic HLR_L expression and function.[605]

Leptin is encoded by the *lep* gene located on chromosome 7q31, and transcription in adipose is increased by glucocorticoids, insulin, and E_2 and decreased by β-adrenergic agonists.[618,619] In addition to a TATA box, three motifs including C/EBP sites and an SP1 site, as well as consensus half sites for ER and a hypoxia response element (HRE) in the promoter, contribute to leptin transcription.[619] Although the same promoter is used by adipose and placenta, the placenta utilizes a specific enhancer composed of three protein-binding elements (PLE1–3) 1.9 base pairs upstream and localized within a medium reiteration frequency repeat (MER11) element of the *lep* gene.[618] Interestingly, MER11 elements are often found in the human genome but are not present in the murine genome, which likely explains why the human but not the murine placenta expresses leptin mRNA.[619] It is important to note that the proteins binding the PLE3 motif in the *lep* gene are placenta specific. Moreover, E_2 appears to be the major regulator of placental *lep* gene expression[606,620,621] and likely functions via both nuclear and membrane-associated ERα-induced MAPK and Akt pathways (Figure 40.17).[369,370] In addition, as discussed in the section on hCG, Maymo and colleagues[369,371] and others[622] have shown that hCG stimulates placental leptin expression in a complex manner mediated by cAMP, MAPK,

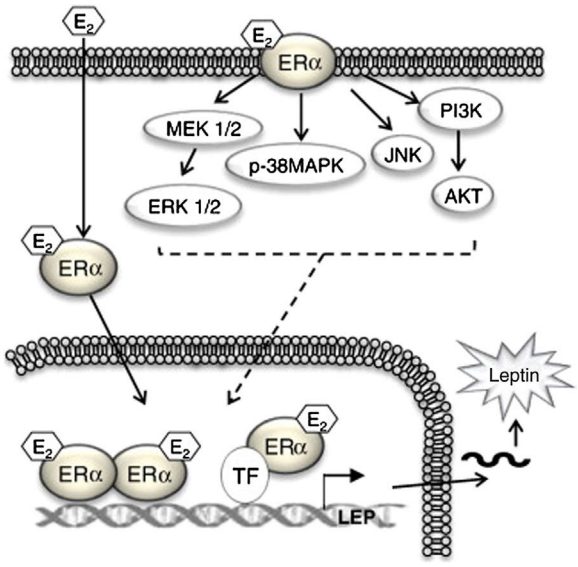

FIGURE 40.17 Proposed model of estradiol (E_2) mechanisms involved in induced leptin expression in trophoblastic cells. E_2 action involves nuclear and membrane-associated estrogen receptor alpha (ERα). The activation of several signaling pathways in response to E_2 regulates leptin expression. Another transcription factor (TF) could also be involved. *Source: Reprinted with permission from Ref. 370.*

and cAMP–Epac signaling pathways. Finally, placental leptin mRNA levels are elevated by glucocorticoid[623] and hypoxia[624,625] and thus *lep* gene expression may also be responsive to HIF-1α.[619,626]

Tissue-specific regulation of leptin expression is also known to be epigenetically mediated through DNA methylation at a tissue-specific region in the *lep* gene promoter.[619,627,628] Moreover, there is an inverse relationship between DNA methylation in this region and gene expression. For example, in adipose, DNA methylation is low and leptin gene expression high, whereas in liver DNA methylation is high and *lep* gene expression low. Thus, the degree of methylation of the *lep* gene in the placenta could also play an important role in leptin expression in normal pregnancy, as well as in pregnancies complicated by FGR, diabetes, and preeclampsia.[619,627]

In addition to regulation of satiety, leptin has other metabolic functions, including the suppression of pancreatic β cell insulin secretion, enhancement of adipocyte glucose utilization and lipolysis, increase in insulin sensitivity, and uptake of sugar by the small intestine. However, leptin appears to participate in other physiologic processes as well, including angiogenesis, hematopoiesis, and osteogenesis, as well as in neuroendocrine, immune,[606,629] and reproductive function (e.g., puberty, oocyte maturation, and implantation).[605]

Importantly, the primary physiologic role of leptin to suppress food intake is reduced during pregnancy, presumably to assure nutrient availability for fetal growth and maternal metabolic homeostasis. The hyperphagia of pregnancy is associated with or caused by leptin resistance and disruption of the leptin receptor signaling pathway in the hypothalamus and/or changes in placental hormone (e.g., PL secretion).[630] In addition to effects on maternal tissues, leptin has been shown to modulate several aspects of placental function, including stimulation of proliferation and suppression of trophoblast apoptosis, upregulation of syncytiotrophoblast system A sodium-dependent neutral amino acid transport activity critical to fetal growth, as well as enhancing placental lipid catabolism, nitrous oxide production, and the secretion of hCG, prostaglandins, and pro-inflammatory cytokines.[606,615,631–634]

Adiponectin

Adiponectin is a 248-amino-acid, 30 kDa protein that enhances insulin sensitivity and reduces hepatic glucose production, and thus hypo-adiponectinemia is typically associated with insulin resistance.[635,636] Although this metabolic hormone is abundantly and almost exclusively produced by adipose, several studies have shown that the placenta also expresses adiponectin mRNA.[601,615,636] The full-length protein (fAD) consists of an N-terminal sequence, a collagen domain, and a C-terminal globular domain and can multimerize to form several stable low-, medium-, and high-molecular-weight complexes. Importantly, fAD is processed to generate a 16.5 kDa truncated globular protein (gAD) that is an active form of adiponectin.[636] Low plasma adiponectin levels that are characteristic of diseases, such as type 2 diabetes and gastric cancer, not only reflect reduced adipose gene expression but also are often associated with single-nucleotide polymorphisms (SNPs) in the adiponectin gene located on chromosome 3q27.[637]

The adiponectin receptors, ADIPOR1 and -R2, are expressed in multiple tissues. ADIPOR1 is ubiquitously expressed but predominates in skeletal muscle and binds gAD with high affinity. In contrast, ADIPOR2 is primarily localized to liver and has higher affinity for fAD than gAD.[638] The human placenta also expresses mRNA for both receptors, although only the ADIPOR2 protein has been detected and localized to the syncytiotrophoblast.[615,639] In humans, maternal serum adiponectin levels are elevated very early in gestation and then decline and remain relatively constant throughout the remainder of pregnancy. Serum levels in maternal circulation during the second half of gestation are comparable to or slightly lower than respective values in nonpregnant women.[640–642] In contrast, adiponectin levels in the fetus are markedly increased and correlated with gestational age.[643] Fetal adipose, as well as cells of skeletal muscle and intestinal wall, express adiponectin, which is thought to facilitate fetal growth via its ability to increase insulin sensitivity.[644]

As recently reviewed,[615,636] the physiologic roles of adiponectin on placental function remain to be definitively established. However, in vitro studies have shown that adiponectin can decrease trophoblast proliferation; enhance hCG secretion; promote trophoblast MMP expression, angiogenesis, and cell migration; modulate inflammation; as well as increase basal system A activity and antagonize insulin-stimulated system A activity and phosphorylation of the insulin-receptor substrate.[636,645–647] Interestingly, lower DNA methylation of the adiponectin ADIPOQ gene promoter on the fetal side of the placenta was correlated with high maternal glucose and adiponectin levels and lower DNA methylation on the maternal side of the placenta associated with a higher insulin resistance index.[648] The authors suggested that these placental epigenetic adaptations have the potential to induce sustained glucose metabolism changes in the mother and offspring later in life. Finally, recent studies have also shown that insulin signaling and insulin-regulated amino acid transporter expression and activity were attenuated in placentas of pregnant mice chronically infused with fAD.[649]

Resistin

Resistin, a protein hormone composed of two 92-amino-acid disulfide-linked polypeptides, impairs adipose cell glucose uptake, increases blood glucose levels, and thus decreases insulin sensitivity.[650,651] Originally isolated from adipocytes in animal models and in nonfat cells of adipose depots in humans, resistin mRNA and protein are also expressed by the human placenta and localized to the syncytiotrophoblast and EVTs in early gestation and the syncytiotrophoblast in late gestation.[652] Maternal serum levels in the first and second trimesters are relatively constant and comparable to values in nonpregnant women. However, resistin levels and placental mRNA expression are increased by the third trimester.[653] Because adipose resistin expression remains unchanged during pregnancy,[629,653] placental production is likely a major source of resistin in the maternal circulation where in conjunction with PL this factor is thought to play an important role in the marked increase in insulin resistance with advancing gestation.[601] The factors controlling expression of the gene encoding resistin, which is localized to chromosome 19p13.2, remain to be elucidated.

Studies have shown that resistin increases migration and invasiveness of BeWo cells via upregulation of MMP2 activity and expression, as well as suppression of tissue inhibitors of metalloproteinases 1 and 2 (TIMP1/2).[654] Resistin enhances endothelial cell tube formation as well as expression of VEGF, the VEGF receptors, and MMP1 and -2, and thus may also play a role in villous angiogenesis.[615,654]

Ghrelin

Ghrelin is a 28-amino-acid peptide hormone produced by mucosa cells of the stomach as well as other tissues, including the intestine, pancreas, kidneys, and placenta.[655] Ghrelin circulates bound to lipoproteins, and about 5–10% of the hormone has a fatty acid modification (octanoate residue) at serine 3 catalyzed by the enzyme ghrelin-*O*-acyl-transferase. Acyl ghrelin (AG) binds to the growth hormone secretagogue receptor (GHS-R1a) to elicit stimulation of pituitary GH secretion as well as appetite. Once in blood, active ghrelin is rapidly deacylated by enzymes that cleave the octanoate residue to form des-acyl-ghrelin (DAG), which accounts for up to 90% of the hormone circulating in plasma.[656] Recent studies suggest that DAG acting via pathways yet to be identified alone and/or in conjunction with AG stimulates adipogenesis. Importantly, hyperglycemia and insulin resistance are independently associated with a decrease in ghrelin expression.

In pregnancy, ghrelin (AG plus DAG) levels in maternal serum and mRNA expression in placenta are highest in early to midgestation, decline after the second trimester, and remain relatively low during the third trimester.[657,658] It also appears that maternal levels of AG decline in late gestation.[659,660] Although maternal levels of ghrelin are not significantly correlated with BMI or insulin levels, the decrease in serum ghrelin after midgestation occurs when maternal weight and fasting insulin levels (i.e., insulin resistance) are increasing.[658]

The placenta expresses the functional GHSR1a ghrelin receptor, and in placental JEG3 cells ghrelin stimulated proliferation and decreased caspase 3 activity as well as the production of progesterone, but had no effect on hCG expression.[661] The factors regulating placental ghrelin expression remain to be elucidated. However, it has been shown that women carrying the 51Q allele of the ghrelin gene have a fivefold lower risk of developing gestational diabetes.[662] 51Q is also protective against metabolic syndrome where glucose intolerance is a factor.[663] Presumably, the R51 residue is a site for proteolytic cleavage to produce mature ghrelin, and the 51Q allele apparently leads to lower blood levels of ghrelin. Thus, the protective effect of 51Q may reflect decreased levels of ghrelin, which would facilitate and/or permit increased pancreatic release of insulin.

Adipokine Expression in Pregnancy Complications

Preeclampsia

Maternal serum leptin levels are increased in pregnancies complicated by preeclampsia.[601,641,664,665] This increase was similar in obese and nonobese mothers,[665] and presumably reflects increased production of leptin by the placenta.[641,666,667] Maternal leptin levels and placental mRNA are further increased in preeclamptic pregnancies complicated by FGR[665,668] and small for gestational age neonates.[669] Upregulation of placental leptin expression in preeclampsia may reflect a compensatory response of and need for increased nutrient delivery to an underperfused placenta[641] and/or increased *lep* gene transcription in response to hypoxia and HIF-1α.[619] Moreover, recent studies have shown that CpG sites downstream of the transcription start site of the placental *lep* gene are significantly hypomethylated in pregnancies complicated by early-onset preeclampsia.[619] In addition, because *lep* gene expression was less skewed and thus more biallelic, it appears that the loss of normal monoallelic expression associated with hypomethylation in early-onset preeclampsia may lead to overall increased *lep* gene expression. Interestingly, however, hypomethylation was not detected in placentas of patients with late-onset preeclampsia or in normotensive women with FGR.[619]

Maternal levels of adiponectin and resistin are either increased[641,665,670] or decreased[642,653] in preeclamptic pregnancies. The differences in adiponectin may reflect

maternal body weight and BMI, since preeclamptic women with normal BMI have elevated adiponectin, whereas obese women presumably with exaggerated insulin resistance have decreased adiponectin.[642,671] Although resistin levels appear to be independent of BMI, differences in preeclamptic women may reflect dysfunction in other maternal organs (e.g., kidney).[672] Finally, the role and regulation of placental and adipose expression of these factors in preeclampsia remain to be determined.

Gestational Diabetes Mellitus (GDM)

It is generally accepted that the expression and maternal serum levels of leptin, adiponectin, resistin, and ghrelin are dysregulated in pregnancies complicated by gestational diabetes mellitus (GDM).[673–675] However, results are inconsistent and presumably reflect differences in maternal BMI and the extent and/or time (during or before pregnancy) of onset of metabolic dysfunction.[601] Thus, a number of studies clearly indicate that maternal leptin levels as well as placental leptin mRNA expression are increased in women with GDM, while others have shown that leptin was either reduced or unchanged.[676,677] Similarly, while risk of development of diabetes in pregnancy is increased in patients in which adiponectin levels are reduced in early gestation, maternal adiponectin levels in the second half of gestation were unaltered or increased in GDM.[677–679] Interestingly, using glycemic clamp procedures, Gibson et al.[680] showed that maternal leptin and adiponectin levels were not altered by insulin or glucose in GDM pregnant women studied in the second and third trimesters. In these same patients, however, levels of DAG but not AG were decreased by glucose and insulin. These findings contrast with studies showing that maternal AG levels are unaltered, whereas those of DAG are elevated, in patients with GDM. Finally, maternal levels of resistin, which increase normally in late gestation, have been shown to be similar, further elevated, or decreased in GDM.[681–684]

In summary, with advancing gestation placental expression and maternal serum levels of leptin, resistin, hPL, and placental GH increase, whereas those of adiponectin and ghrelin decrease, an overall pattern of hormone expression that would facilitate maternal satiety and decrease insulin sensitivity to ensure adequate maternal nutrient (e.g., glucose) supply to the fetus for growth and maternal adipose deposition for maternal metabolic homeostasis. Leptin and adiponectin may also act via their respective receptors expressed in placental cells to regulate aspects of trophoblast function, including expression and/or activity of nutrient transporters important to fetal growth.

Furthermore, it appears that placental *lep* gene transcription, mRNA levels, and maternal serum concentrations are elevated in pregnancies complicated by preeclampsia and further increased in preeclamptic patients with FGR independent of maternal BMI, presumably as a compensatory response to and increased nutrient need of an underperfused placenta and/or hypoxia. Although changes in adiponectin and resistin may also be associated with preeclampsia, results are equivocal and confounded by the apparent impact of BMI as well as renal function on expression of these adipokines. Finally, while evidence clearly shows dysregulation of leptin and adiponectin as well as resistin and ghrelin in GDM, results are highly variable and attributable to the impact of confounding variables, including BMI, the extent of diabetes, the timing of diabetes onset before and/or during pregnancy, as well as potential pregestational treatment modalities. Clearly there is need for additional studies to establish the impact of these multiple adipokines during normal pregnancy and in GDM.

CONCLUSION

Research in placental biology during the past few decades has substantially advanced our understanding of the structure, temporal, and cell-specific expression, actions, and regulation of well-established (e.g., hCG) as well as more recently identified (e.g., adipokines) hormones during pregnancy. The latter investigation, coupled with highly novel technologies to examine cell signaling and gene structure, modification, and function, have further increased knowledge of the mechanisms underpinning the expression, action, and potential involvement of placental hormones in normal as well as abnormal pregnancies. However, it is apparent from examination of these studies that, in many instances, a clear picture does not exist of how the multiple hormones expressed by the mother, placenta, and fetus interact to control pregnancy maintenance, fetal development, and maternal–fetal homeostasis.

An example of this gap in knowledge in placental endocrine biology is how well-established hormones such as PL and IGF interact with more recently identified peptides (e.g., leptin) to control maternal and fetal intermediary metabolism, homeostasis, and growth. Moreover, there is lack of clarity about whether and how the numerous factors recently implicated by in vitro approaches regulate in vivo placental EVT migration, invasion, and remodeling of the uterine arteries. Another challenge in placental endocrine research is to clearly establish how placental E_2, P_4, and the placental hypothalamic-like neural peptides (e.g., CRH and oxytocin) interact in a gestational stage-specific manner to control uterine function critical to the initiation of labor. Follow-up studies of the consequences of alterations in placental and fetal function by experimental paradigms,

or as associated with problem pregnancies, on development of the offspring are also needed.

Several experimental models have been employed to study placental endocrine function and hormone action. Transgenic mouse studies have enabled discovery of the impact of loss of gene function on fetal and organ system development. However, there are significant differences between rodents and humans in placentation, hormone biosynthesis, and endocrine interaction between the mother, placenta, and fetus. Moreover, there appear to be major differences during rodent and human pregnancy in the effect of placental hormones on organ maturation (e.g., the role of placental NKB on gonadal development and function and the ontogeny of and import of placental E_2 on ovarian follicular development).

Epidemiologic and genetic studies of abnormal human pregnancy have yielded important advances on the association and potential impact of changes in placental hormone production on fetal development. However, the very low incidence of genomic defects (e.g., P450arom deficiency) in many cases in human pregnancy and the difficulty for ethical reasons in performing human research limit ability to comprehensively assess physiological and developmental impact. Moreover, although changes in placental function have been shown to be associated with disease states (e.g., preeclampsia), it is difficult to discern whether these alterations precede and thus are involved in the etiology or are the result of the pathological condition, and thus conclusions on cause and effect cannot be made. Emphasis also needs to be made on quantifying protein levels on specific cell populations within the highly heterologous placenta. In vitro approaches with primary and transformed human placental cells are extremely valuable in dissecting out molecular mechanisms and signaling pathways that underlie hormone action and receptor biology. However, with cell culture there is always the potential problem of cell differentiation and applicability in vivo to the human situation.

In vivo studies with nonhuman primates that exhibit patterns of maternal–placental–fetal hormone production, interaction, and development qualitatively similar to those in the human offer valuable and significant opportunities to investigate endocrine interactions and their impact on development of the fetus in utero and of offspring after birth, and most importantly to translate findings to the human. However, the relatively high cost of conducting nonhuman primate research limits its widespread use.

While there is no simple solution to address the limitations inherent to any experimental model in vitro, rodent, nonhuman primate, and human approaches provide individual advantages and, when combined with ever emerging technological advances, provide the best opportunity to advance the concept put forth by Egon Dicszfalusy some 50 years ago, namely, that the maternal–fetal–placental systems function as a unit in which there is interdependence and interaction between the endocrine functions of maternal and fetal EGs and the placenta.

Acknowledgments

INTRODUCTION

The principal role of the immune system is to monitor and defend the integrity of the organism. Immune cells act to recognize and usually repel invaders of all types, from microorganisms to tumors and artificial tissue transplants, so as to prevent disease and contamination of host genetic material. Yet this powerful defense system is overcome during pregnancy in mammals where the fetus is gestated internally. This arrangement, known as viviparity, provides maximum protection from environmental hazards but introduces a critical requirement for circumvention of immune rejection. The embryo and the gestational tissues formed after implantation express "foreign" antigens, including some encoded by major histocompatibility (MHC) genes derived from the disparate maternal and paternal chromosomes. By virtue of deriving 50% of its MHC genes from the genetically nonidentical father, the conceptus is thus termed "semiallogeneic" in relation to the mother. Spermatozoa and oocytes also express specific antigens that can provoke autoimmune responses under some conditions. With these hallmark indicators of "nonself" origin, the male and female gametes and all of the conceptus-derived tissues therefore present a serious challenge to the female immune response.

The surprising ability of mammalian females to permit introduction and survival of genetically different cells during implantation, and to nurture the developing fetus throughout the course of pregnancy, has intrigued immunologists for half a century or more. The mechanisms in place for preventing maternal immune attack on the fetus are generally successful since species continue to propagate. Our knowledge of this special immunological relationship is now substantially advanced, but there are pieces of the puzzle still missing. The imperative for research in this field remains strong, considering the major health burden attributable to reproductive conditions including infertility, miscarriage, preeclampsia, and preterm birth, all of which are thought to be at least partly attributable to origins in the maternal immune response. An emerging area is the immune contribution to early life origins of offspring health—that is, how inflammatory disturbances in the maternal–fetal immune relationship can program development of diseases that become evident after birth, ranging from asthma and allergy to metabolic and cardiovascular disorders, and even mental and cognitive dysfunction.[1]

A Brief History

Various theories have been advanced to explain why maternal immune rejection does not occur, and our understanding of the immunology of pregnancy has grown and shifted substantially over the last 70 years. Three interrelated hypotheses concerning physical separation of the fetus and immune system, attenuated antigenicity of the fetus, and systemic maternal immune suppression formulated by the renowned transplantation immunologist Peter Medawar[2] were the first attempt to formally address the issue. Although these ideas informed and guided research in reproductive immunology through the latter half of the twentieth century,[3] ultimately none have withstood the test of time as a sufficient explanation.

In broad terms, discussions concerning the nature of the immune response to pregnancy have centered around

Knobil and Neill's Physiology of Reproduction, Fourth Edition

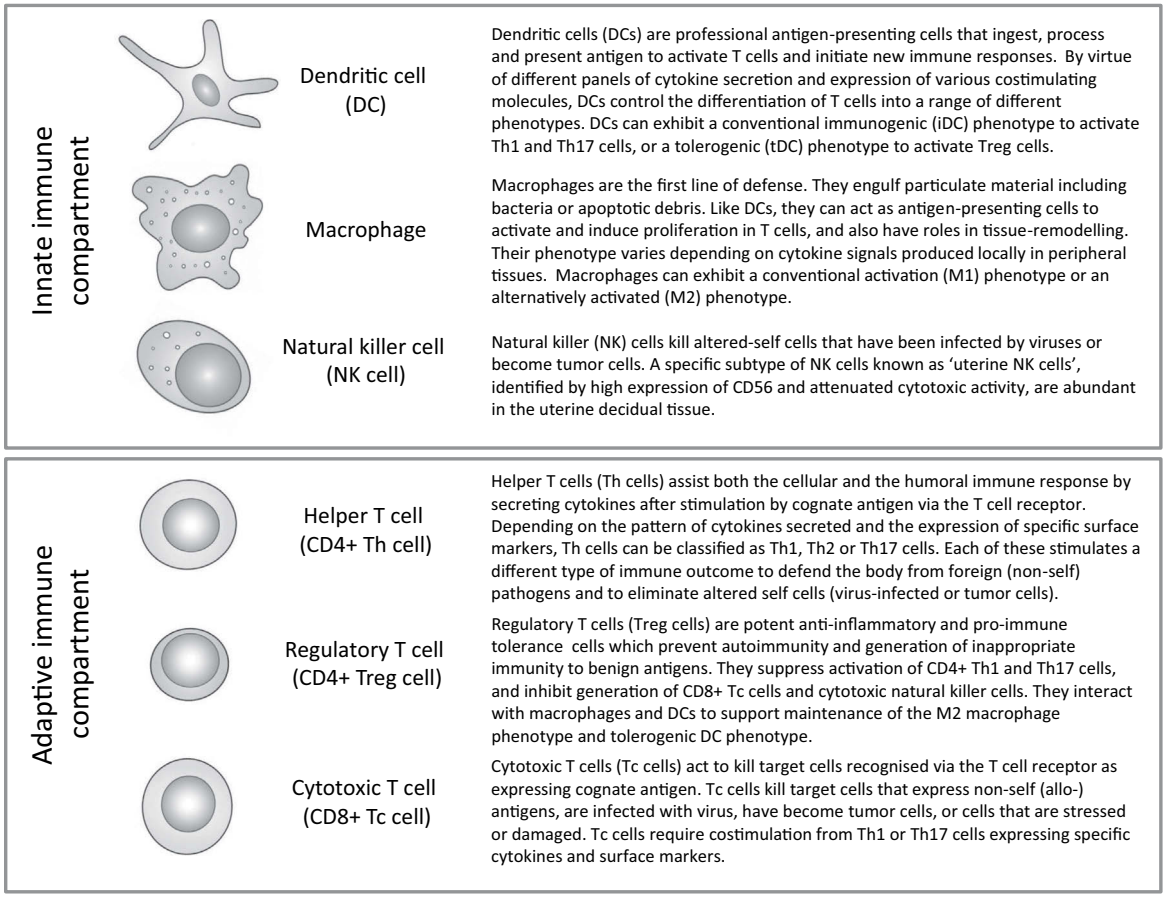
the extent to which the "innate" and "adaptive" immune compartments and their component elements of the immune response are central players. Innate and adaptive immunity are distinguished by their involvement of different leukocyte lineages and separate evolutionary origins. The *innate immune system* is an evolutionarily ancient system consisting of cells that are always present and ready to mobilize and engage with foreign material immediately upon first encounter. The main cellular components of the innate immune system relevant to pregnancy are macrophages, dendritic cells, and natural killer (NK) cells (Box 41.1). The *adaptive immune system*, on the other hand, is a more recently evolved and more sophisticated system of defense involving a repertoire of lymphocytes, which by a mechanism of somatic gene recombination, can express a diverse array of receptor systems with great specificity against individual foreign entities. Components of the adaptive immune system are normally silent; however, when activated, these components "adapt" to the presence of foreign agents by activating, proliferating, and creating potent mechanisms for neutralizing or eliminating the initiating agent. There are two types of adaptive immune responses: humoral immunity, mediated by antibodies produced by B lymphocytes; and cell-mediated immunity, mediated by T lymphocytes. Cells of the adaptive immune response most relevant to pregnancy are the cytotoxic T lymphocytes (Tc cells) marked by CD8 expression, and helper T

BOX 41.1

LEUKOCYTE CELL LINEAGES WITH KEY ROLES IN THE MATERNAL IMMUNE RESPONSE TO PREGNANCY

Leukocyte cell lineages with key roles in the maternal immune response to pregnancy can be assigned to the innate immune compartment (DCs, dendritic cells; macrophages; NK cells, natural killer cells) or the adaptive immune compartment (helper T cells, Th cells; cytotoxic T cells, Tc cells; regulatory T cells, Treg cells). A brief description of the function of each leukocyte lineage is given.



lymphocytes (Th cells) and regulatory T cells (Treg cells), both marked by CD4 expression (Box 41.1).

In the late 1980s Tom Wegmann put forward the formative "Th1/Th2" hypothesis of pregnancy success,[4,5] which influenced reproductive immunology research substantially through the 1990s. This hypothesis was founded in an understanding emerging in the early 1980s, that Th cells can be categorized as Th1 cells, which produce inflammatory cytokines, or Th2 cells, which produce anti-inflammatory cytokines (details are given later in the chapter). Reflecting on observations that T-cell activation can facilitate pregnancy success, together with observations of placental cytokine synthesis and responsiveness, he hypothesized that fetal–maternal immune compatibility might arise from a systemic deviation in the maternal immune response away from potentially destructive Th1 immunity and towards benign Th2 immunity. Because of its manifestation as antibody-mediated rather than cell-mediated immunity, the Th2 response is compatible with fetal survival while Th1 responses appear detrimental. Ultimately it has emerged that the Th1/Th2 hypothesis is an oversimplification of the true state of affairs. Although the principle of immune deviation away from Th1 holds value, Th2 immunity is clearly not a required aspect of maternal acceptance of the fetal allograft.

In contrast to Wegmann's emphasis on T cells and cytokines, other investigators have focused on the extent to which the innate and adaptive compartments of the immune response participate as contributing forces in determining pregnancy success. Drawing on the special anatomical relationship between the placental and maternal tissues in women, the peculiar characteristics of human placental trophoblasts, most notably their altered expression of human leukocyte antigen (HLA) proteins and the vital contribution of an unusual population of NK cells to placentation, Ashley Moffett-King, Joan Hunt, and others have encouraged the view that the immune adaptation to pregnancy is a unique response centered in the innate immune compartment, involving NK cells as opposed to an adaptive response involving T lymphocytes.[6,7]

Current Understanding

In the most recent decade, an integrated model has emerged, acknowledging that both the innate and adaptive immune compartments are involved in the maternal immune adaptation required to avert rejection of the conceptus.[8,9] Importantly, current theories accommodate long-standing evidence that maternal lymphocytes are not ignorant of the embryo, but instead are actively primed to recognize conceptus antigens, as indicated by the presence of activated T cells and antibodies in the blood of pregnant women.[10–12] The most powerful experimental evidence for this comes from T-cell transgenic mice where it is possible to track T cells that specifically react with fetal alloantigens.[13] Recent studies clearly demonstrate that a state of active immune tolerance in the adaptive immune compartment must exist at implantation to prevent antigen-specific immunity towards the invading conceptus.[14] Regulatory T (Treg) cells, a special subset of T cells, have emerged as central players in mediating this tolerance.[15,16] Treg cells are powerful inhibitors of inflammatory type 1 (cell-mediated) immunity that also interact with macrophages and dendritic cells, NK cells, and other cells of the innate and adaptive immune response to suppress inflammatory activation and maintain immune quiescence.[17]

Thus current understanding holds that preventing fetal immune rejection involves a combination of strategies, with multiple overlapping and complementary mechanisms operating for the protection of the fetus. These strategies relate to attenuation, suppression, or evasion of different compartments and different phases of the immune response. Some key aspects of the immune response are circumvented, while others are engaged and persuaded towards immune acceptance, or "tolerance," in order to actively permit the intimate associations between maternal cells and gametes or embryos that characterize oocyte maturation and embryogenesis, implantation, and placental development. Figure 41.1 illustrates the critical point that both mother and fetus cooperate to create the immunological environment that allows fetal growth and development.

The maternal aspect of the fetal–maternal interface features pathways that: (1) diminish the likelihood of activativing adaptive immunity; (2) ensure any immune activation is skewed towards immune tolerance, as opposed to immune rejection; and/or (3) facilitate the tissue remodeling required to support placental development and function. A specific chemokine gene expression profile in decidual cells affords a unique "gatekeeper" role of this tissue in governing leukocyte recruitment. Those leukocytes permitted access to the maternal decidua are associated not only with immune regulation but also feature populations such as uterine NK (uNK) cells that promote structural changes in the decidual vasculature to support placental invasion and development. The macrophages, dendritic cells, and Treg cells that mediate adaptive immune tolerance and inhibit immunity to conceptus antigens in pregnancy also influence vascular dynamics through their potent capacity to suppress inflammation. Soluble molecules that establish and maintain the maternal–fetal interface as a site of immune competence (cytokines and chemokines) and others that have immunosuppressive and immune-deviating properties (hormones and prostaglandins) are also important for sustaining the unique

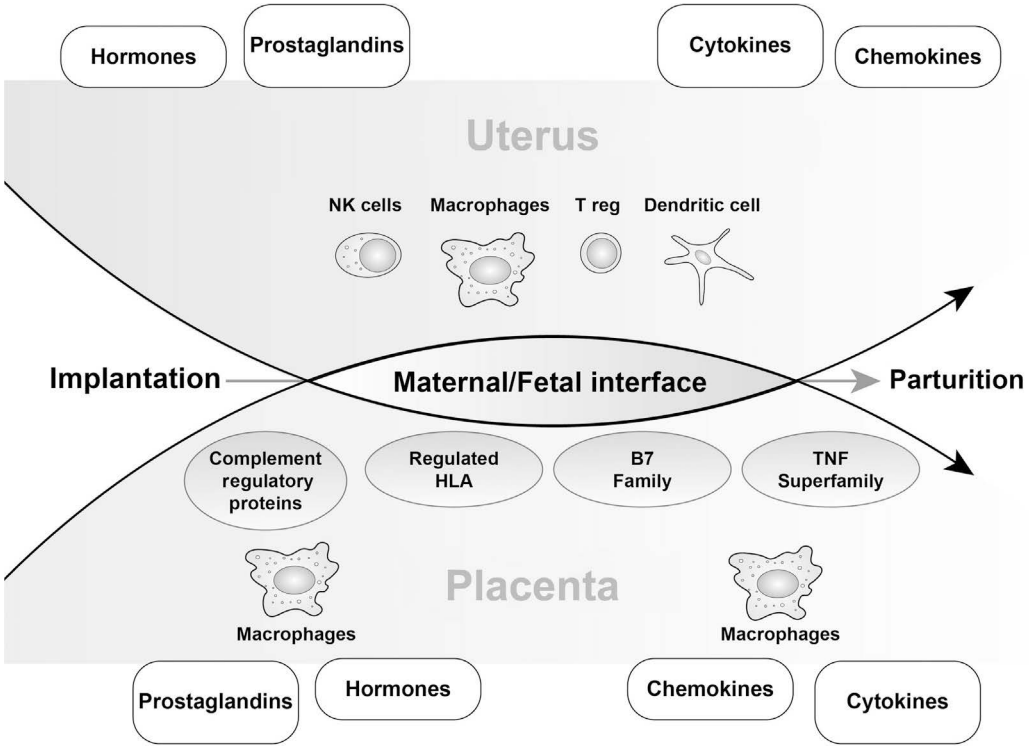


FIGURE 41.1 Multiple mechanisms underlie maternal tolerance of the fetus. Both maternal and fetal mechanisms contribute to successful gestation of the genetically different fetal semi-allograft. Mothers revise the roster of the different leukocyte lineages (macrophages, dendritic cells, NK cells, lymphocytes; see Box 41.1) in the decidua to disallow residence of most antigen-specific immune cells. Production of soluble immune-regulatory molecules including hormones, prostaglandins, cytokines, and chemokines from both uterine and placental cells occurs; the placenta and extraplacental membranes produce many of the same immune-suppressive molecules but also display specially selected members of multi-gene families that bypass or inactivate immune cells. NK cells, natural killer cells; Treg, CD4+ regulatory T cells; HLA, human leukocyte antigen family; TNF superfamily, tumor necrosis factor superfamily; B7, B7 peripheral membrane protein co-stimulator family.

features of the maternal tissues that interact directly with the fetal-placental unit.

Fetal and particularly placental tissues contribute novel mechanisms that include but are not limited to the unique physical structure of the placenta; its restricted expression of MHC transplantation antigens that normally mediate graft rejection; secretion of cytokines, hormones, and soluble MHC antigens that deviate immune responses away from inflammation and towards immune tolerance; high expression of proteins that suppress lymphocyte activation and kill activated lymphocytes; and display of other proteins that protect against cytotoxic antibodies.

In broad terms there are common mechanisms operating in all mammals, but considerable variation exists among species, which relates to different reproductive strategies as well as the structure of the gestational tissues and the extent of their integration and invasion into the mother's uterus and blood supply. The most diverse and sophisticated mechanisms are evident in humans, where maternal and fetal cells intermingle in a type of placentation called hemochorial, and where single pregnancies are the rule. Many of the same evasive strategies prevail in nonhuman primates such as the monkey and the baboon, where placentation is also hemochorial and single pregnancies are usual. In other mammalian species, these two conditions are rarely met; maternal and fetal cells are less intimately associated or multiple fetuses are the rule rather than the exception. Yet many of the mechanisms that ensure successful human pregnancy are present to a greater or lesser degree in these other species, thus broadening the range of informative experimental models and providing insights on the molecular basis of the strategies allowing successful reproduction. In particular, mice are an important experimental model with the benefit of a powerful toolbox of immunological reagents and resources, including many transgenic and knockout genetic models and intervention strategies that allow investigators to define critical molecular and cellular pathways. The value of mouse models is evidenced by the many pathways identified in mice that in turn have proven to be operative in primate and human systems.

In this chapter, features of the female reproductive organs and specific strategies that protect against immune-mediated embryonic loss are described. While the focus is the human, mice and other animals are discussed in the context of comparative biology and/or

their provision of important insights. Key concepts are that:

- Both the mother and the fetus contribute to successful pregnancy.
- Multiple immune evasion and tolerogenic mechanisms are deployed.
- Immune adaptations to permit internal habitation of the fetus depend on ovarian steroid hormones and are initiated prior to and concurrently with implantation.

Major features include specific structural elements of the ovary and uterus that support immune accommodation of the gametes and conceptus; characteristic features of the leukocyte subpopulations that access the uterus and decidua; production of immune suppressive and pro-tolerogenic molecules by both maternal cells and fetal trophoblast cells; restrictions on fetal trophoblast expression of the MHC molecules that provoke graft rejection; and a critical role for T-regulatory cells, which suppress inflammation and inhibit generation of effector T-cell populations capable of harming the fetus. Collectively, these strategies comprise a complex series of mechanisms that permit implantation and facilitate survival and progression of semi-allogeneic pregnancy, while contributing to the quality control processes that maximize reproductive investment and promote a healthy outbred population.

IMMUNOLOGICAL FEATURES OF THE NONPREGNANT UTERUS

In terms of immune competence, the cycling uterus closely resembles other mucosal tissues whose surfaces are exposed to environmental agents and pathogens. But unlike other tissues, the uterus of a reproductive-aged woman undergoes extensive and predictable remodeling due to responsiveness to ovarian steroid hormones, which coordinate preparation each cycle for potential embryo implantation and pregnancy. This remodeling includes substantial changes in the immune cell component, such that the maternal immune adaptation for pregnancy can be viewed as commencing even before conception and embryo implantation.

Hormones and Leukocytes in the Cycling Uterus

Uterine cells expressing specific hormone receptors respond dramatically to cyclic changes in the levels of steroid sex hormones circulating in the blood. As a consequence, major tissue alterations occur in an ordered and chronologically predictable manner. These events are reviewed in detail elsewhere in this volume (see Chapters 24, 25 and 38). In brief, in the early proliferative phase that follows menstruation, estradiols predominate and stimulate proliferation and partial differentiation of the endometrial epithelial cells. At approximately the time of ovulation, estrogens decline and progesterone from the corpus luteum targets the mesenchymal cells of the endometrium to initiate the changes required for receptivity for embryo implantation.

An important aspect of this cycle is that leukocytes respond to the same hormones. There are cycle-related fluctuations in circulating leukocytes in the peripheral blood, and these reflect more overt changes in the reproductive tissues, largely by virtue of regulation of expression of the cytokines and growth factors produced by hormone-stimulated endometrial cells,[18] and also by direct effects.[19] Thus, the hormone-driven cyclic changes include alterations in the immune cell populations in the stroma of the endometrium and changes in their functions that in turn faciliate endometrial receptivity and the possibility of embryo implantation and pregnancy. These changes impact susceptibility to infection with less protection in the progesterone-dominated phase. Dependency of these leukocyte changes on specific sex hormones has been extensively tested and verified. For example, it has long been known that estrogens stimulate an influx of macrophages and other leukocytes into the mouse uterus[20] and that human NK cell populations depend on progesterone for maintenance and proliferation.[6,21]

In the human uterus, both T and B lymphocytes are established in lymphoid aggregates in the uterus just as they are at other mucosal surfaces.[22] Endometrial T cells outnumber B cells, and exhibit a range of different phenotypes. In women, most endometrial T cells express the conventional α/β form of the T-cell receptor (TCR), while fewer cells express the γ/δ form typical of mucosal tissues.[23] The majority express the Tc marker CD8 as opposed to the Th marker CD4, and in addition to their location within aggregates adjacent to glands, they can be found in intraepithelial locations, or scattered singly in the endometrial stromal tissue.[23]

Most importantly for reproductive competence, the uterus contains a large proportion of Treg cells, which have important anti-inflammatory and tolerance-inducing properties. Animal and human studies both reveal variation over the course of the nonpregnant cycle, suggesting ovarian hormone regulation of uterine Treg-cell populations, with a notable estrogen-induced increase at the time of ovulation.[24–26] Rising progesterone levels in the luteal phase are involved in sustaining and expanding the Treg-cell populations, potentially acting via nuclear progesterone receptors[27] to elicit memory T-cell markers, which indicate a committed antigen specificity, and to stabilize their suppressive phenotype.[28]

Macrophages and dendritic cells, which both have key functions in antigen presentation and in governing

the nature of the adaptive immune response, are distributed throughout the endometrial stroma and are numerous in the connective tissue in the myometrium.[20,29] The endometrial stroma also contains large numbers of NK cells, which express a unique phenotype specific to the uterus,[30] including markers that vary with the cycle.[31] The leukocytes in the cycling uterus, including the NK cells,[32] have key functions in host defense, but they are also involved in the extensive tissue remodeling, breakdown, and repair associated with structural changes in the endometrium over the cycle. The decidual response, which commences in the implantation-receptive secretory phase, appears to be facilitated by leukocytes, particularly uNK cells[33] and dendritic cells.[34] Near the end of the cycle, mast cells are particularly prominent[35]; these cells appear to have a specific function in driving menstruation.[36]

Cytokine Regulation of Leukocytes in the Cycling Uterus

The behavior of leukocytes in the endometrium is controlled in large part by the cytokines and chemokines present in the local microenvironment. Different cytokine genes show different spatial and temporal expression patterns, suggesting their independent regulation or sequential activation, by mechanisms that are not fully defined but are likely to involve cross-talk between cytokine transcription factors and steroid hormone receptors. In situ hybridization and immunohistochemical studies demonstrate that uterine epithelial cells lining the luminal cavity and comprising the endometrial glands secrete an extensive repertoire of cytokines. Although leukocytes are often assumed to be the principal source of tissue cytokines, in the endometrium, the range and output of cytokines synthesized by uterine epithelial cells generally meets or exceeds that of the leukocyte compartment.[37]

Control of cytokine production by uterine epithelial cells is principally regulated by the ovarian steroids estrogen and progesterone. These hormones interact with agents introduced into the uterus, including seminal fluid and microbial agents, thereby provoking cytokine production by epithelial cells through Toll-like receptors and other signaling pathways. Estrogens drive synthesis of several important pro-inflammatory cytokines in uterine epithelial cells, giving rise to similar patterns of cytokine production in the peri-ovulatory period in the rodent and human uterine epithelium. Several estrogen-regulated cytokines, including colony stimulating factor-1 (CSF1), granulocyte-macrophage CSF (GM-CSF, CSF2), and tumor necrosis factor (TNF), all increase in abundance over the course of the proliferative phase,[37] together with estrogen-induced interferon-γ (IFNγ).[38] Another key factor involved in mediating immune defense in the uterus is interferon-ε (IFNε), which is induced by estrogen in uterine epithelial cells each menstrual cycle. In mice, IFNε has a major role in protection from *Chlamydia* and herpes simplex virus-2 infection.[39]

By contrast, progesterone has an anti-inflammatory effect on epithelial cell cytokines, suppressing production of GM-CSF, interleukin (IL)-1, and several chemokines. It also acts directly on immune cells with effects similar to those of corticosteroids; at high levels progesterone may act through the glucocorticoid receptor (GR) to downregulate production of inflammatory cytokines.[19,40] In women, a secretory phase decline in GM-CSF, and further increase in CSF1, TNF, and leukemia inhibitory factor (LIF), match patterns occurring early in murine pregnancy.[41–44] This suppression of pro-inflammatory cytokines by progesterone after ovulation is one of the first steps each cycle towards preparing endometrial receptivity and initiating immune adaptation for possible embryo implantation and pregnancy.

Cytokines, in particular the chemokine subfamily,[45] play an integral role in regulating leukocyte recruitment and persistence, by orchestrating the molecular events that promote extravasation of specific populations of leukocytes from the peripheral blood and positioning within the tissue. Attachment and transmigration of leukocytes across the endothelial cell barrier, followed by their movement through the tissue and accumulation in various sites, occurs in response to chemokine gradients. Both steroid hormones and products of the embryo regulate chemokine expression in endometrial epithelial cells and stromal cells.[46,47]

Tightly regulated synthesis of a group of at least nine prominent chemokines is implicated in precisely regulating the spatial and temporal fluctuations in each endometrial leukocyte lineage, with combinations of chemokines at different cycle stages targeting different leukocyte lineages. In this manner, distinct chemokine expression profiles during the mid-luteal phase compared with the premenstrual period can account for the uNK cell recruitment required for pregnancy as opposed to the macrophage, eosinophil, and neutrophil recruitment implicated in tissue breakdown and menstrual shedding.[48] For example, progesterone enhances expression of the chemoattractants IL-8 and CCL2 (monocyte chemotactic protein-1, MCP1), as well as the uNK cell chemokines CXCL10 (IP10) and CXCL11 (ITAC), during the window of implantation.[47,49] A further change in chemokine synthesis occurs in the mid-secretory phase as the endometrium attains receptivity for embryo implantation.[50] Chemokines required for recruitment of Treg cells, including CCL19 (macrophage inflammatory protein-3β, MIP3β) and CCL5 (RANTES), are also expressed in the mid-secretory phase.[51,52] In mice, a similar elevation is induced by seminal fluid exposure at coitus.[53]

Infection can dramatically impact the populations of leukocytes found in the uterus. The absolute numbers and relative proportions of lymphocytes, particularly CD4+ T cells, are increased in the reproductive tracts of pathogen-infected mice and women suffering from sexually transmitted disease,[54,55] with the precise numbers and phenotypes depending on the nature of the pathogen and the stage of progression of the disease. The altered immunological environment and elevated inflammation linked with bacterial and/or viral infection of reproductive tissues is crucial to the pathophysiology of infertility in many women.

Immunology of Oocyte Development

As the ovum develops within the follicle, it is physically sequestered away from immune cells circulating in the blood and residing in the ovarian stroma. The ovary is relatively deficient in T and B lymphocytes but contains an abundant population of macrophages, cells that play critical roles in folliculogenesis, tissue restructuring during ovulation, and both formation and regression of the corpus luteum.[56] Ovarian macrophages generally exhibit features of an alternatively activated mode, presumably as a consequence of exposure to progesterone and progesterone-induced cytokines, which together inhibit classical macrophage activation.[57] Within the developing corpus luteum after ovulation, macrophages have a key role in secreting pro-angiogenic factors that are essential for the rapid angiogenesis that underpins progesterone synthesis and support of pregnancy.[58] In addition, ovarian macrophages phagocytose debris to facilitate removal of atretic follicles and exhausted corpora lutea.

The physical barrier provided by granulosa cells and a basement membrane protect the ovum and prevent immune cell access during follicle development. Both the oocyte and its surrounding zona pellucida express immunogenic molecules foreign to the mother. Although neither the zona nor the ovum stimulates immunity in healthy women, autoimmune ovarian disease results from operational failure of the immune regulatory mechanisms required for normal tissue homeostasis.[59,60] Autoimmunity to oocyte antigens can be induced experimentally by treatment with antibodies to zona pellucida,[61] or by removal of the thymus shortly after birth, but this can be prevented by passive transfer of T lymphocytes from spleens of normal adult mice.[62] The protection-conferring population are now known to be Treg cells, which are actively educated to suppress immunity to zona-pellucida antigens within the lymph nodes draining the ovary.[63] Elegant experiments comparing male and female donors of Treg cells show the antigen-specific nature of the Treg suppressive activity and the necessity for the persistent presence of the cognate tissue antigen in generating the ovary antigen-specific Treg cells.[62]

A second, critical mechanism of protection of the ovary against autoimmune disease is deletion of ovary-reactive T cells undergoing development within the thymus. Failure of this mechanism occurs experimentally in mice with functional deletions of the autoimmune regulator (*Aire*) gene, and naturally in women suffering autoimmune polyendocrine syndrome type I (APS-I), in which the *AIRE* gene contains function-nullifying mutations.[64–66] Normally, this transcriptional regulator promotes expression of genes within the thymus, where T-cell development occurs, that are otherwise restricted to specific tissues.[64] Expression of these tissue-restricted antigens in the thymus ensures that immature self-reactive T cells, which arise frequently and at random during T-cell development, encounter the antigen and consequently are deleted.[67] Thus, in the absence of functional AIRE, self-reactive T cells targeting many endocrine organs, including the ovary, escape thymic elimination and erroneously leave the thymus. These deviant cells are then aberrantly activated upon encounter with the antigen in the periphery, even notwithstanding normal numbers and development of Treg cells. The fallout of AIRE deficiency is fulminant ovarian autoimmune disease, characterized by T-lymphocyte infiltration and production of autoantibodies targeting granulosa cells, luteal cells, and oocytes. Ultimately, this leads to complete loss of germ cells and infertility.[60]

Regulation of expression of the HLA antigens in oocytes may also be important. Oocytes lack the highly immunogenic class Ia (HLA-A, B) and class II (HLA-D) major histocompatibility (MHC) antigens,[68,69] and instead transcribe a gene in the class Ib family, HLA-G, whose protein products are not highly immunogenic[70] and instead elicit immunosuppressive and tolerogenic responses.[71] The unique features of the HLA antigens are discussed in greater detail below.

The Female Immune Response to Seminal Fluid at Coitus

The female response to paternal antigens begins at the time of insemination, after transmission of seminal fluid at coitus. Semen contains transplantation antigens, which as described in detail below, can be recognized by a host or recipient as foreign and elicit potent immune responses. MHC molecules are associated with sperm, seminal leukocytes, and/or desquamated genital tract epithelial cells, with a substantial concentration of the immunosuppressive MHC molecule, HLA-G5, within the extracellular fraction.[68] These and other seminal fluid antigens are the same as those that will later be expressed by the conceptus and gestational tissues if pregnancy ensues following coitus. Low frequency

of recombination within the MHC locus and preferential expression of paternal MHC expression in certain placental cells[72] increases the homology between paternal MHC antigens in the seminal fluid and conceptus tissue.

Seminal fluid contains signaling molecules that interact with estrogen-primed epithelial cells lining the female reproductive tract to activate expression of an array of cytokine and chemokine genes. This results in leukocyte recruitment and activation of innate and adaptive immune events in a sequence that resembles an inflammatory cascade.[73,74] This post-coital leukocytic response has been described in mice[75–77] as well as in pigs, rabbits, sheep, and several other mammals.[78–81] The female response to seminal fluid is thought to have a fundamental role in reproduction, because seminal fluid-signaling proteins linked with immunity and defense are present in such diverse organisms as flies, mosquitos, crickets, honeybees, rodents, and primates.[82]

Immune changes induced by seminal fluid facilitate preparation of the female reproductive tissues for pregnancy through clearance of debris and pathogens and providing an immune environment that ensures that surplus sperm do not elicit anti-sperm immunity. At least in some species, this pathway is also linked to activation of a state of active immune tolerance towards male transplantation antigens that will be shared after conception by the semi-allogeneic embryo.[73,74] The full effect of seminal fluid on female immune parameters is best characterized in the mouse, where within hours of mating, macrophages, dendritic cells, and granulocytes are recruited into the endometrial stroma and lumen.[77,83,84] Through a process of cross-presentation by female dendritic cells in lymph nodes draining the genital tract, seminal fluid antigens activate and expand inducible Treg cell populations.[26,85] These Treg cells subsequently circulate through the blood and boost the pool available for migration into the endometrium so as to assist in generating immune tolerance of the conceptus at implantation.[53]

The extent to which seminal fluid may elicit related effects on fertility is less well defined in women. After transmission at coitus, seminal fluid induces an inflammation-like response in the cervical tissue of women. This is characterized by extensive infiltration of macrophages, dendritic cells, and memory lymphocytes into the epithelial and deeper stromal tissues,[86] as well as a neutrophil exudate into the cervical canal.[87] This leukocyte infiltration is accompanied by elevated expression of *CSF2*, *IL6*, *IL8*, and *IL1A* as well as a wide array of other chemokine and cytokine genes.[86] The cervical response requires contact between seminal fluid and the female tissues, since condom-protected intercourse does not elicit comparable changes in gene expression and leukocyte recruitment.[86]

The inflammatory response to seminal fluid depends on seminal plasma factors originating in the seminal vesicle gland,[76] notably the potent immune-deviating cytokine transforming growth factor-β (TGFβ), which is synthesized in the latent form and activated in the female tract after ejaculation.[88] The TGFβ content of semen is extraordinarily high in all mammalian species so far studied, approximately five-fold that of serum, and comparable to colostrum, the most potent biological source of TGFβ known.[89] Similar data from rodents and primates indicates the likely conservation of this signaling pathway across mammalian species. Microarray and in vitro studies show that TGFβ is a critical male–female signaling agent in regulating the immune response to seminal fluid at coitus in women, but is not the only agent.[90] A second family of factors that interact with TGFβ in human seminal fluid signaling are the E-series prostaglandins, which are present in high concentrations in seminal plasma and mediate immune regulatory functions.[91,92]

A key role for seminal fluid TGFβ in inducing tolerogenic Treg cells after coitus is supported by experiments where exogenous TGFβ was found to boost vaginal Treg cell numbers and to alleviate fetal loss in the CBA/J × DBA/2J abortion-prone mouse model.[93] This potent immune-deviating molecule thus explains why seminal plasma is necessary for Treg-cell activation and promoting tolerance to paternal alloantigens at implantation.[26] However, the success of artificial reproduction technologies where pregnancy is initiated without female tract contact with seminal plasma suggests that while seminal fluid may contribute to promoting immune adaptation for pregnancy, it is not essential. Pregnancy is indeed possible after artificial insemination, or in vitro fertilization (IVF) and embryo transfer without seminal fluid exposure in rodents and livestock species, but the progression to pregnancy and fetal growth parameters in this situation can be compromised.[94] In women, lack of prior intercourse with the conceiving partner over several months prior to conception increases the likelihood of preeclampsia and fetal growth restriction,[95] and this may be linked to reduced abundance of Treg cells reactive with partner HLA antigens (see below).

Immunology of Preimplantation Embryo Development

Following ovulation and until fertilization, the ovum and its protective covering, the zona pellucida, traverse the fallopian tube (oviduct). Like the uterus, the oviduct is richly endowed with resident immune cells and secretes a remarkable array of cytokines.[96–98] The growth and development of the pre-implantation embryo as it traverses the female reproductive tract is influenced by the cytokines and growth factors secreted

into the luminal compartment from oviduct and uterine epithelial cells during the pre-implantation period. Embryos express cytokine receptors from conception until implantation; multiple cytokines exert different effects on cell number and viability, gene expression, and developmental competence.[99] The biological effects of several growth factors and cytokines targeting the pre-implantation embryo have been reviewed previously.[100–104] Experiments involving the addition of exogenous cytokines to embryo culture, neutralizing ligand or receptors, or using mice with null mutations in cytokine genes have shown that several factors including GM-CSF, CSF-1, LIF, heparin-binding epidermal growth factor (HB-EGF), insulin-like growth factor-I (IGF-I), and IGF-II promote blastocyst development, while others including TNF and IFNγ exert potent inhibitory effects. The exposure of embryos to the correct array of cytokines during development may be essential for later fetal and placental development and long-term health of offspring.[105]

In most women, there is no evidence for immune rejection of the ovulated egg or early cleavage-stage embryo. The pre-implantation embryo is potentially more susceptible to immune rejection than the oocyte because it expresses a wider array of immunogenic molecules, including "foreign" (paternal) allogeneic antigens. The assumption is that the zona pellucida and adherent granulosa cells provide protection and that T cells would not have ready access to the embryo until implantation. But since the HLA-A, -B, and -D antigens that would stimulate rejection remain unexpressed by the external trophoblast layer of embryonic cells,[68] the capacity of the maternal immune system to recognize the foreignness of the embryo would be limited regardless of the zona pellucida.

Nonetheless, clinicians report that 50% or more of potential pregnancies fail.[106] Inadequate development of the pre-implantation embryo, as well as insufficient receptivity of the endometrium, contribute to this high rate of implantation failure. Reproductive immunologists fully recognize the contributions of genetic disorders to these losses but postulate that some of the unexplained infertility might be due to failure of the fallopian tube to provide sufficient growth factor support for the pre-implantation embryo[104] or to inadequate immune protection mechanisms in the fallopian tube.[107,108]

Since cytokine secretion by the oviduct and uterus can reflect the presence of a range of inflammatory and nutritional stressors in the female, the cytokines released by the oviduct may provide signals that embryos sense and adapt to the pervading environment, or alternatively undergo demise due to the unfavorable conditions.[109] Additionally, dysregulated expression of oviductal cytokines combined with altered immune cell populations and impaired embryo-tubal transport has been implicated as an underlying cause of ectopic pregnancy.[98]

Another immunoevasive strategy is production of immune suppressive molecules by the pre-implantation embryo. For example, both oocytes and embryos transcribe and translate membrane-associated and soluble isoforms of HLA-G, respectively called HLA-G1 and HLA-G5.[69,110,111] HLA-G5 is present in the media of in vitro cultured embryos, and high levels signal capacity of the embryo to implant and develop successfully in patients undergoing assisted reproductive technologies.[69,112–114] Abundance of secreted HLA-G and the ultimate success of in vitro fertilization may also be related to HLA-G genotype.[112,115] Although HLA-G5 is known to exert profound immune cell suppression (reviewed by Hunt et al.[71]), its expression in the embryo could be related to an immune suppressive function, to facilitation of normal embryonic developmental processes, or both: embryos with HLA-G mRNA exhibit an increased rate of cleavage.

A further potential immune cell modulator secreted by the human embryo is human chorionic gonadotropin (hCG). This polypeptide hormone is released prior to implantation, although it is not usually present in sufficient amounts for identification in pregnancy detection kits at this early time. hCG binds to receptors on decidual macrophages[116] and acts to induce a tolerogenic phenotype in dendritic cells through induction of 2,3-indoleamine dioxygenase (IDO).[117] The effects of hCG are also elicited through induction of immune regulatory cytokines in endometrial cells, which exert direct effects on both developing embryos and the endometrial immune response.[118] Through direct effects on lymphocytes as well as cytokine-induced immune deviation exerted via tolerogenic dendritic cells, hCG suppresses the cytotoxic activity of T cells and instead promotes Treg-cell recruitment into the implantation site.[119]

IMMUNOLOGY OF EMBRYO IMPLANTATION

The Decidual Response

As the embryo attaches and then invades into the endometrium, progesterone levels surge and in response, dramatic changes take place in the local environment to accommodate and respond to the infiltrating conceptus-derived cells. A key event in the maternal reaction to embryo implantation is the decidual response of the endometrium. In women, this commences in the superficial endometrium in the latter half of the menstrual cycle under the influence of progesterone. In mice and several other species it occurs contemporaneously with, and in response to, embryo implantation into the

anti-mesometrial side of the uterus. Decidualization is a transformation in uterine stromal cell phenotype signals that involves complex interactions between ovarian steroid hormones, growth factors, and cytokines,[120,121] and potentially specific leukocyte populations including NK cells and dendritic cells.[33,34] Accompanying the decidual response is a dramatic change in the uterine extracellular matrix (ECM), which provides a structural framework for trophoblast invasion and supports an increase in vascular permeability and tissue edema.[120] In turn the decidual response alters resident leukocyte populations, as a consequence of the altered ECM affecting leukocyte adhesion, migration, and differentiation, acting in concert with direct effects of decidual transformation on chemokine synthesis.[50]

The Leukocyte Response to Implantation

The leukocytes present at the time of embryo implantation are specifically equipped: (1) to facilitate the decidual transformation; and (2) to deal with the initial challenge of invading embryo-derived trophoblast cells.[33] Under the influence of progesterone, the resident leukocytes become programmed by local cytokines and conceptus-derived signals into immune inhibitory profiles consistent with transition into the immune-privileged environment required to sustain semi-allogeneic pregnancy.[122,123] This pro-tolerogenic behavior in leukocytes is essential to protect and support the initial phase of placental morphogenesis when the genetically dissimilar, highly specialized cytotrophoblast cells from the implanted blastocyst advance directly into regions where these leukocytes reside (Figure 41.2).

Although the nonpregnant, cycling uterus is home to several subpopulations of leukocytes with the ability to initiate an antigen-specific immune response, major modifications are made in the uterine leukocyte populations concurrently with implantation to reduce the likelihood of anti-fetal immunity (reviewed in Refs 8, 9, and 124). The pregnant uterus is effectively reprogrammed from a mucosal site where Th1- and B-lymphocyte immunity is facilitated into a site where innate immune cells predominate and T-cell immunity is suppressed. Yet this early establishment phase when trophoblast cells first breach the epithelial surface of the uterus is most vulnerable to failure as a consequence of immune attack or insufficient endometrial support, with >50% of human embryos estimated to be lost at this time.[106] Antigen-specific immunity towards conceptus antigens, if present in the mother, could comprise a significant danger to ongoing development of the semi-allogeneic fetus.

The most prominent leukocyte subpopulations that persist in the peri-implantation uterus are NK cells and antigen-presenting cells that include macrophages and dendritic cells. B cells and many T cells disappear from the decidualizing endometrium,[23,125] leaving immune suppressive, anti-inflammatory regulatory T cells as the major remaining T-cell subset.[126] Treg cells are relatively enriched, whereas Th2 cells remain proportional

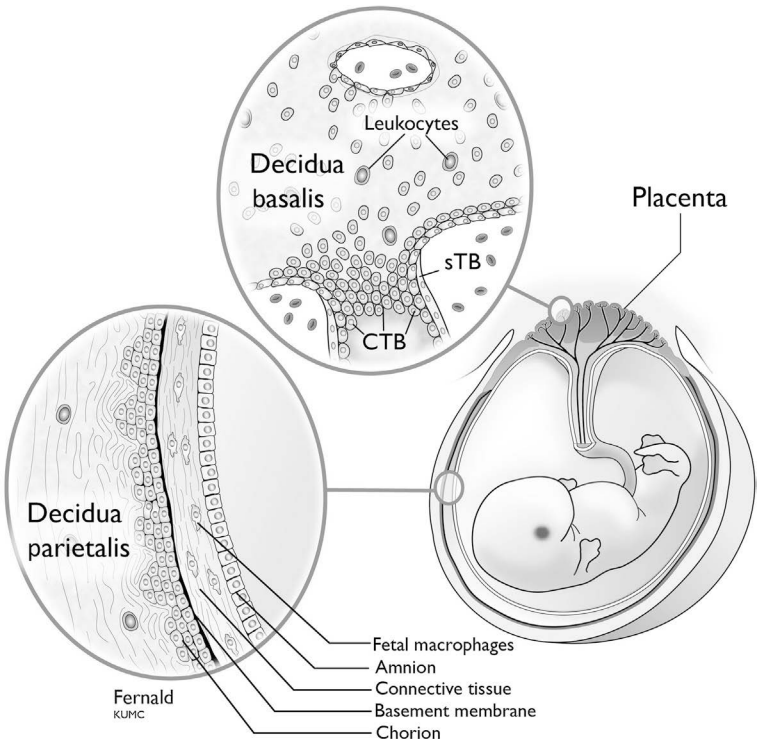

FIGURE 41.2 Anatomy of the maternal–fetal interface. The fetus is entirely surrounded and encased by placental and chorion membrane trophoblast cells. Maternal cells and fetal cells are intermixed in the decidua basalis, the site of attachment of the placenta to the uterus (upper insert) and between the chorion membrane and decidua parietalis (left insert). CTB, cytotrophoblast cells; sTB, syncytiotrophoblast.

to Th2 cells in the blood. Levels of Th1 and Th17 cells, on the other hand, are substantially diminished compared with levels in peripheral blood.[127,128] As a consequence of the cellular changes and their programming for anti-inflammatory rather than inflammatory responses, the pregnant uterus is a site where support of embryonic development rather than maintenance of host defense is favored. This is in contrast to the cycling uterus where defensins and other antimicrobials are abundant.[129] Because infections are less vigorously controlled in the pregnant than in the cycling uterus, a common consequence may be infection-associated preterm labor.[130]

Genetic models allowing depletion of specific leukocyte lineages show several leukocytes are essential for a normal decidual response and embryo implantation in mice. Although the data cannot be directly extrapolated to humans, the mouse models provide important leads for exploration of mechanisms and pathways in women. Dendritic cells,[34] macrophages,[58] and Treg cells[15] are all essential for implantation and progression of pregnancy. Dendritic cells and macrophages are essential regardless of fetal MHC disparity, consistent with critical roles in non-immune as well as immune-regulatory functions. When dendritic cells are depleted from *Cd11c-Dtr* mice, by administration of low-dose diphtheria toxin to transiently remove DT receptor-expressing $CD11c^+$ cells, formation of the decidua and ensuing placental development is terminated.[34] When macrophages are depleted from *Cd11b-Dtr* mice, where low-dose diphtheria toxin depletes DT receptor-expressing $CD11b^+$ cells, embryo development proceeds to the blastocyst stage but implantation fails. This is because macrophages are critical for the development of the vascular network within the corpus luteum that allows progesterone secretion and underpins endometrial receptivity.[58] Treg cells are absolutely essential for semi-allogeneic pregnancy but are less important for syngeneic pregnancy, underscoring their critical role for maternal tolerance of fetal MHC antigens.[15] Perhaps surprisingly, NK cells are not essential for pregnancy,[30] although in the absence of these cells decidual vasculature remodeling is compromised and placental development is impaired. The precise roles of these individual leukocytes are detailed in the section Immunology of Pregnancy: The Maternal Contribution later in the chapter.

GENETIC DISPARITY AND THE IMMUNOLOGICAL PARADOX OF PREGNANCY

The Fetal Semi-Allograft: Self–Nonself, and the Danger Theory

Following implantation, there is explosive growth of embryonic and extraembryonic tissues, the latter of which quickly begin to interdigitate with the maternal decidua in a manner that leads to juxtaposition between genetically disparate cells unparalleled in any other physiological situation. Because of the range of antigens expressed by the growing fetus and placenta that are foreign to the mother together with the expansive physical contact between the two, there is, conceivably, an immunological threat to the survival of the fetus even greater than that of the oocyte and pre-implantation embryo. These antigens include molecules derived from paternal genes as well as tissue-specific molecules that are unexpressed in other types of cells. Importantly, these antigens do not generally evoke an adverse immune response; in a healthy pregnancy, maternal cells do not attack fetal or placental cells, and antibodies in the maternal blood with specificity for fetal/placental surface antigens do not cause trophoblast death.

The "self–nonself" paradigm of transplantation immunity[2] has been helpful in shaping thought and informing experimental analysis of how the fetus, and particularly the placenta, evade maternal immune rejection in pregnancy. Transplantation theory would predict that foreign antigens expressed by the fetal-placental unit should act as "transplantation" antigens, which would stimulate graft rejection by recipient immune cells. In humans the major transplantation antigens are the HLA antigens, which are subdivided into class Ia (HLA-A, -B, and -C), class Ib (HLA-E, -F, and -G), and class II (HLA-D) (discussed in detail below). Consideration of the role of these antigens in transplant rejection led to discovery that a major adaptation that permits semi-allogeneic pregnancy is that placental trophoblast cells strictly regulate HLA gene expression and select for those that are least immunogenic (reviewed by Loke and King[131]). It seems clear that preventing maternal overreaction to fetal-placental antigens is important, since in addition to tightly controlled expression of HLA by trophoblast cells, the pregnant uterus and placenta contain an abundance of overlapping and complementary immunoprotective mechanisms. Although T lymphocytes generated in the thymus that bear TCRs specific for all foreign MHC are exceptionally numerous, in mice it seems cytotoxic T cells programmed for response to paternally inherited antigens are effectively barred from entering the decidua following implantation. A central mechanism by which this occurs was recently revealed using experimental murine models: epigenetic alterations preventing expression of essential T cell-recruiting chemokine genes take place in decidual cells, preventing entry of T cells even in the presence of strong systemic inflammatory signals.[132]

The "Danger Model" of immunity, originally put forward by Polly Matzinger,[133] has also informed thinking on the immune response to pregnancy. This model proposes that immune responses are not initiated by degree

of foreignness of an antigen to the host per se, but rather by its capacity to initiate tissue damage. When applied to pregnancy, the Danger Model would predict that because paternally inherited fetal antigens—and indeed any fetus, embryo, or oocyte antigens—constitute no risk to the mother, maternal T lymphocytes programmed to respond to these antigens should not be activated.[134] This is in contrast to immune responses generated against antigens associated with microbial pathogens, where conserved ligands or molecular motifs called pathogen-associated molecular patterns (PAMPs) (e.g., lipopolysaccharide (LPS) and viral nucleic acids) avidly bind to pattern recognition receptors (PRR). Pattern recognition receptors include Toll-like receptors (TLRs), C-type lectin receptors, NOD-like receptors, and RIG-I-like receptors, and are expressed on leukocytes and many "nonprofessional" immune cells, including cells in the placenta (reviewed by Takeuchi et al.[135]). Ligand activation of PRR as a result of microbial infection stimulates a potent inflammatory response and promotes immunity. Upon necrotic or ischemic injury to tissues, endogenous damage-associated molecular patterns (DAMPs) can also bind to PRR and generate inflammation and immunity. With respect to normal pregnancy, it is likely that a lack of PRR ligands and thus failure to elicit "danger" signals reinforces other active and passive mechanisms by which immune rejection of the conceptus is avoided. Conversely, ischemic or necrotic damage to fetal-placental tissues in pathological pregnancies may promote inflammation as a result of DAMP/PRR signaling, further endangering pregnancy.[136]

Structural Features of the Human Maternal–Fetal Interface

The complex architecture of the gestational tissues and their anatomical and physical relationship with the mother is perhaps the single most crucial determinant of the immunological success of pregnancy. Most notably, the placenta and associated extraplacental membranes are principal players in promoting a peaceful immunological coexistence between the mother and fetus during pregnancy. Many types of placental cells participate in this arrangement, particularly the various populations of trophoblast cells. Trophoblast cells arise from the trophectoderm, the outermost layer of the blastocyst, and are normal occurrences only in pregnancy. On the whole, trophoblast cells comprise the single fetal cell type that interfaces with maternal blood and decidua (Figure 41.2). As such, these cells define the nutritional, endocrinological, and immunological interface between the mother and the fetus. These unique cells thus have a major impact on both local and systemic immunological processes in the mother, and this impact is tied to their anatomical positions within the placenta, their manner of self-renewal and turnover, and by their expression of paternally inherited alloantigens together with tightly regulated expression of immunologically relevant modulators.

Early Development of the Placenta and Extraplacental Membranes

Almost immediately upon implantation, the trophectoderm initiates a complex program of differentiation, ultimately giving rise to several structurally and functionally distinct trophoblast subpopulations. Archival tissue sections from human implantation sites suggest that trophectoderm-derived trophoblast cells promptly expand by proliferation, the outermost cells fusing to form a syncytium. From this point onwards, a "trophoblast shell" encases the inner cell mass, which concurrently initiates formation of embryonic and extraembryonic tissues. This basic anatomical arrangement between embryo and trophoblast persists for the duration of pregnancy: the embryo and fetus remain entirely sequestered from the mother by layers of trophectoderm-derived trophoblast cells (Figure 41.2).

After implantation, the precursors to all trophoblast cells in human placentas are the villous cytotrophoblast cells. Avascular chorionic villi separated by lacunae form and surround the embryo. By six weeks, the villi deepest within the uterine wall are invaded, as a result of chorioallantoic fusion, by extraembryonic mesoderm. Mesodermal and trophoblastic elements undergo branching morphogenesis to form mature, vascularized chorionic villi and the definitive placenta. Within the villi, cytotrophoblast cells proliferate and differentiate along one of two pathways. First, they can fuse to the outermost syncytiotrophoblast layer of the chorionic villi, effectively donating and replenishing fresh cytoplasm, macromolecules, and organelles. Alternatively, proliferating cytotrophoblast cells may break through the syncytiotrophoblast, exit the villus, and migrate into the decidua in formations of defined columns. These columns serve to physically anchor the placenta to the decidualized endometrium, which at its location beneath the placenta is called the decidua basalis. The migrating extravillous trophoblast emanating from the columns differentiate further, subdividing into those located in the decidual stroma (interstitial cytotrophoblast cells) and those lining the maternal spiral arteries (endovascular cytotrophoblast cells). The presence of endovascular cytotrophoblast cells signifies completion, at around 12 weeks of gestation, of the important transformation of the maternal endometrial spiral arteries from narrow, constricted vessels into broad conduits that supply the placenta with ample maternal blood at low pressure (reviewed by Burton and Jaunaiux[137]).

Whereas the deeper, vascularized chorionic villi progress to create the definitive placenta, the more superficial

villi, opposite the site of placental growth, are never invaded by mesoderm, and instead regress to form the chorion membrane. The chorion membrane is one stratum of four, collectively called the extraplacental membranes. From the fetal to maternal aspect, the membranes are comprised of amnion, which encompasses the amniotic cavity wherein the fetus resides and develops; two connective tissue layers; chorion; and maternal decidua capsularis (Figure 41.2). The mesodermally derived connective tissue between the amnion and chorion is replete with fetal macrophages. Atop the chorion lies the decidua capsularis, which, as the fetus and amniotic fluid expand and obstruct the uterine lumen, becomes progressively thinner and eventually fuses to the decidua parietalis. While the placenta grows to occupy up to one-third of the perimeter of the maternal–fetal interface, the extraplacental membranes constitute the remaining area. Together, these structures comprise a chimeric unit of two intact but genetically distinct entities, an arrangement that in physiology is entirely unique to pregnancy.

Syncytial Shedding: Knots, Microvesicles, and Exosomes

As well as whole cells, fragments and vesicles that range from nanometer scale to large multinucleated syncytial knots are shed into the maternal circulation (Figure 41.3) (reviewed by Redman and Sargent[138]). The smaller vesicles have been classified as plasma membrane-derived microvesicles. These bleb from the cell surface and measure up to 1 μm in diameter. Additionally, exosomes, which are 50–150 nm, are derived intracellularly from multivesicular bodies. Syncytial knots may represent collections of effete or apoptotic nuclei that arise as a consequence of physiological regeneration of the syncytium: hypothetically, as villous cytotrophoblast cells fuse and replenish the syncytium, effete nuclei cluster and are released into the maternal blood together with aged cytoplasm and other organelles.[139] Although the origin and function of syncytial knots is controversial,[140–142] it is clear that an abundance of fetal material accesses the maternal blood during pregnancy.

Further, placentally derived vesicles, small and large, may transport fetal antigens and/or immunomodulatory proteins to maternal organs. Where the shed material ultimately alights likely depends, at least in part, on their size. Knots, which measure up to 100 μm, can become trapped within the first capillary bed they encounter upon exiting the uterine vein, which is in the lung.[143,144] Small sized microvesicles can pass through the capillary beds and readily circulate within maternal blood.

Although it is important to note that the majority of microparticles in maternal blood originate from maternal platelets,[138] the placental contribution of exosomes and microvesicles undoubtedly changes the maternal immunological milieu. Circulating placental exosomes, identified by their expression of placental alkaline phosphatase, are found in maternal blood and contain biologically active components including Fas ligand and MHC class II antigens that can influence expression of T-cell activation markers.[145] Chorionic villous explant-derived exosomes generated in vitro similarly retain immunosuppressive proteins possessed by their syncytiotrophoblast and villous cytotrophoblast parents. Among these proteins are the HLA and B7 family proteins, syncytin-1, and biologically active NKG2D ligands.[146–148] These features may be shared by extravillous trophoblast cells, as these cells too appear to be high producers of exosomes that can influence macrophage function and differentiation.[149–151]

In addition to exosomes, larger microvesicles have been shown to elicit inflammation by maternal endothelial and immune cells.[138] Further, both microvesicles and exosomes have important implications for the adaptive immune response to fetal antigens in pregnancy. This material can impact maternal endothelial cells to influence their activation status and cytokine expression, and are likely also to be taken up and processed by maternal antigen-presenting cells in peripheral lymphoid organs. Depending on whether the originating trophoblasts are necrotic or apoptotic, either tolerogenic or immunogenic responses could be elicited.[138,152] Thus in vivo, similar placental immunomodulatory pathways could influence both the innate and adaptive maternal immune response to pregnancy.

Maternal–Fetal Cell Coexistence and Exchange

In species such as humans, rodents, and nonhuman primates where placentation is hemochorial, fetal cells invade deeply into maternal tissue and are in direct contact with maternal cells, where they would be expected to be at considerable risk of immunological attack. The most intimate associations between these genetically disparate cells are in the decidual stroma, where fetal cells intermingle with maternal cells, first in the maternal spiral arteries undergoing remodeling, and then in the chorionic villi, which are awash with maternal blood from the end of the first trimester onwards. At each of these sites, interstitial, endovascular, and chorionic cytotrophoblast cells neighbor maternal decidual, endothelial, and blood cells and readily coexist without evidence of inflammation. Ultimately, most of the vascular endothelial cells proximal to the placenta are entirely replaced by the endovascular trophoblast cells, and all syncytiotrophoblast cells are bathed in maternal blood. Thus, each trophoblast population has developed strategies for advancing and differentiating within the potentially immunologically hostile maternal tissue, while

demonstrating complete resistance to cytotoxic cells and other potentially destructive immune mediators circulating in maternal blood and tissues.

Beyond the maternal–fetal interface, maternal cells remain mainly in maternal tissues and fetal cells in fetal tissues. This is not an absolute separation, however, and there is compelling evidence that fetal cells traffic into peripheral maternal tissues, and maternal cells into peripheral fetal tissues (Figure 41.3). Termed fetal and maternal microchimerism, respectively, a proportion of these microchimeric cells survive following pregnancy and can reside alongside their familial host cells for substantial periods—even decades—influencing one another in unexpected ways.

That fetal microchimeric cells survive in the mother is likely due to several factors, including a failure to express a sufficient density of the MHC antigens to trigger graft rejection, a lack of "danger" signals, and active tolerogenic mechanisms. The origins and functions of the itinerant cells remain obscure, but both beneficial and detrimental effects on maternal health have been proposed. For instance, fetal microchimerism may stimulate maternal scleroderma, a graft-versus-host disease-like autoimmune disorder, and/or contribute to altered risk of rheumatoid arthritis.[153–155] Whether or not, and how, the microchimeric cells influence maternal autoimmune disease most likely depends on the genetic relationship between mother and fetus: both HLA genes and potential autoantigens are likely to be important (reviewed by

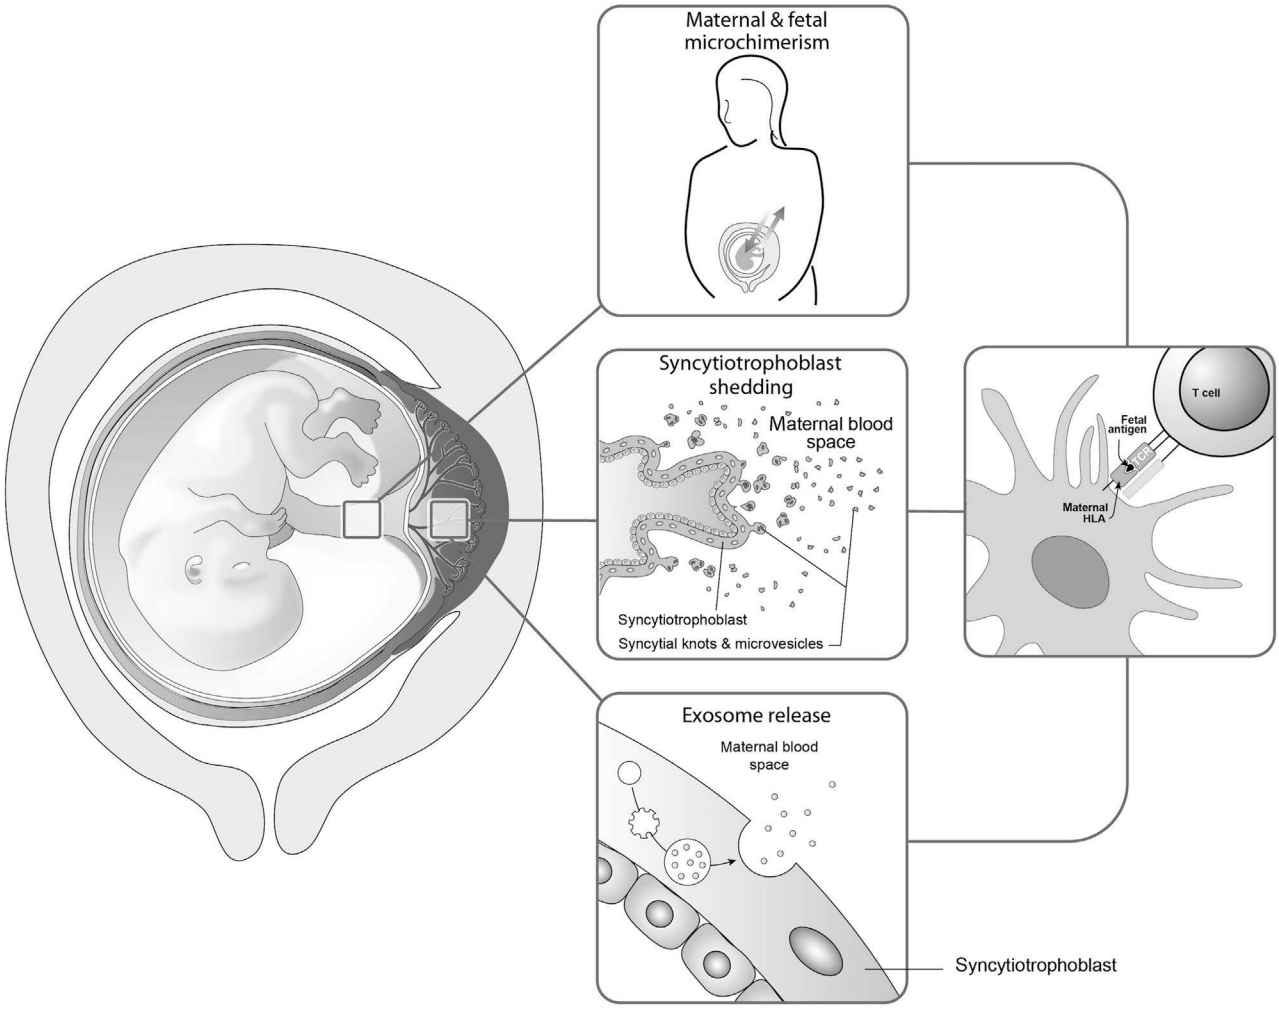

FIGURE 41.3 Microchimerism and exchange of fetal–maternal material across the placental barrier. A small number of fetal cells circulate systemically in the maternal blood, and conversely, maternal cells are present in the fetal circulation (upper insert). In addition to intact cells, substantial amounts of subcellular material are shed from placental syncytiotrophoblasts in the form of fragments ranging in size from large multinucleated syncytial knots and microvesicles (middle insert) to nanoscale-sized exosomes (lower insert). This shed material is thought to provide antigens that can be presented by maternal antigen-presenting cells and other immune-regulatory signals that influence the maternal immune response in a systemic manner (right insert). *Source: Reprinted from Placenta 32 (Supplement B, Trophoblast Research vol. 25), M. Petroff: Fetal antigens: identity, origins and influences on the maternal immune system, S176-S181, Copyright 2011, with permission from Elsevier.*

Nelson[155]). Additionally, the fetal cells might comprise a reservoir of stem cells for organ regeneration and repair and/or participate in sustaining long-term tolerance in the mother to fetal antigens.[156–158]

In humans[159] and in mice,[160] maternal microchimerism also occurs: small populations of maternal cells are found in fetal tissues, and these persist after birth and into adult life. Understanding resistance of maternal cells to fetal attack is less paradoxical than the reverse situation; indeed it seems unsurprising that maternal cells remain unharmed in the fetus, as the fetal immune system is still undergoing development: antigens encountered by the fetal/neonatal immune system are recognized as "self" and are tolerated. Furthermore, there is more recent evidence in humans that maternal cells traffic across the placenta and access the fetal lymph nodes, resulting in induction of Treg cells that promote fetal tolerance to maternal antigens.[161] Thus, it is likely that both centrally (in the thymus) and peripherally (in the lymph nodes), fetuses develop potent, perhaps lifelong tolerance to non-inherited maternal antigens (NIMAs) due to maternal microchimerism.

Maternal Awareness of Fetal Antigens

Despite the altered antigenicity and lack of "danger" stimuli associated with pregnancy, it is now well established that the adaptive immune compartment is also engaged as part of the normal maternal immune response to pregnancy. It has been known for decades that some pregnant women make antibodies towards fetal HLA antigens—indeed, serum from pregnant women is a rich source of anti-HLA immunoglobulin originally used for HLA typing.[10,70] More recently, it has become clear that activated T cells reactive with fetal HLA are detectable in the peripheral blood[162] and decidua of pregnant women.[11] Importantly, the presence of antibodies and immune cells appears entirely consistent with healthy pregnancy and birth, and likely occurs to some extent in most women.[11,162,163] This shows that maternal lymphocytes are not ignorant of the embryo, but instead are actively primed to recognize conceptus antigens including paternal MHC.

Strong evidence for maternal immune awareness of fetal antigens is evident in mice, where T-cell transgenic models have been very informative.[13,14] In these model systems, which are now commonly used to study the adaptive immune response to pregnancy, endogenous or transferred T cells have been clearly shown to interact with natural or genetically introduced conceptus antigens.[13] In healthy pregnancy, the T-cell response ranges from activation and proliferation to anergy and deletion, but when T cells are inappropriately activated, rejection of the fetus in an alloantigen-dependent manner can occur.[15]

Together, these considerations underscore the complexity of the issues at play in the maternal immune response to pregnancy. The consensus view at the time of writing is that despite several strategies to diminish the antigenicity and immunogenicity of placental tissue in contact with maternal blood, ultimately an adaptive immune response to pregnancy is detectable. In the last 5 to 10 years, this has refocused research on the question of how maternal immune awareness in the adaptive compartment can be reconciled with pregnancy success. In outbred animals such as humans, it may be that no one individual strategy is an absolute requirement and that considerable redundancy exists between multiple overlapping mechanisms of suppression and tolerance. The following sections will discuss the range of fetal and maternal strategies that are believed to contribute.

IMMUNOLOGY OF PREGNANCY: THE MATERNAL CONTRIBUTION

During early placental development, a range of adaptations in the local and systemic maternal immune environment contribute to accommodating the invading conceptus tissues for the duration of pregnancy. This permissive response to pregnancy is driven initially by progesterone released by the corpus luteum and then by progesterone and other factors released from the placental trophoblast cells (see below for details). Progesterone and placental hormones sustain a specific local cytokine profile, and these soluble factors combine to support specific immune cell phenotypes in the decidua. These cytokine and leukocyte parameters conspire to suppress inflammation and generate a mother's functional immune tolerance of conceptus tissues, which persists from implantation until late gestation when parturition commences. As well as regulating the immune response, immune cells at the site of maternal contact with conceptus-derived placental trophoblasts participate in the tissue remodeling and particularly the changes to the maternal vasculature that enable adequate placental access to the maternal blood supply required to support optimal fetal development.

Immunological features of the pregnant uterus have been extensively reviewed.[9,164,165] The change of leukocyte subpopulations such that cells of the innate immune system predominate and T-cell cytotoxicity is diminished, is of critical importance. Although small numbers of T lymphocytes are present throughout gestation, these are mainly Treg cells. NK cells and mononuclear phagocytes are the predominant subgroups of immune cells in the pregnant uterus.

The maternal portion of this interface depends on a signaling circuit wherein the hormone progesterone constitutes the major force in reconstructing the uterus

into an anti-inflammatory and immune-privileged site. Progesterone interferes with the NFκB pathway to inhibit production of pro-inflammatory molecules,[166] and together with the elevated estrogens characteristic of pregnancy drives cells of the innate immune system into suppressive profiles characterized by diminished production of inflammation-associated cytokines.[167,168] Suppressed NFκB reduces expression of the Th1 transcription factor T-bet,[166] which likely explains the profound effect of progesterone in skewing T lymphocytes towards production of IL-10 and IL-4.[169] Thus, macrophages, NK cells, and the few T lymphocytes remaining in the decidua exhibit anti-inflammatory patterns of cytokine secretion under the direction of this powerful hormone influence.

Additionally there are systemic consequences for pathogenesis of various disease states, due to the altered immune environment in pregnancy. The reduction in activity of pro-inflammatory cytokines and natural killer cells, inflammatory macrophages, and helper T-cell type 1 (Th1) cells, combined with elevated Treg cell activity and production of anti-inflammatory cytokines, reduces the severity of diseases caused by inflammatory responses (such as arthritis and multiple sclerosis) and increases the severity of diseases that are mitigated by inflammatory responses (such as influenza and malaria).[167]

The Cytokine Response to Pregnancy

Following the initial uterine inflammatory response in the peri-conceptional phase, progesterone-induced anti-inflammatory cytokines such as TGFβ, IL-10, CSF1, and LIF gain prominence. Their synthesis in luminal and glandular epithelial cells drives nearby maternal immune cells into an immunosuppressive mode. Although the pregnant uterus produces several cytokines with immunosuppressive properties, IL-10 and TGFβ have been identified as of critical importance from an immune perspective.[170,171] The prominence of IL-10 synthesized by macrophages as well as epithelial cells was first shown in pregnant mice[5] and is a feature of the human decidua as well.[172] This cytokine not only directs T lymphocytes away from cytotoxic activity but also elicits macrophage production of HLA-G[173,174] in a feed-forward pathway that culminates in their release of the key immune suppressive cytokine, TGFβ.[175]

In mice, endogenous TGFβ is supplemented by TGFβ delivered in the male seminal fluid[176]; in rats, the cytokine is synthesized in diverse uterine cells[177]; and in women, TGFβ may be produced in uterine macrophages as a consequence of encounter with placental HLA-G5.[175] The TGFβ, together with IL-10, serves to induce specific phenotypes in local leukocytes that include alternatively activated M2 macrophages and tolerogenic dendritic cells. These ultimately prevent activation of cytotoxic immunity in the uterus. In this effort, the uterine cytokines are critically aided by direct effects of progesterone and prostaglandin E_2 (PGE_2), both of which target leukocytes directly and are highly anti-inflammatory and immunosuppressive.[168,178,179]

Studies in cytokine-null mutant mice enable the specific functions of individual cytokines to be discriminated from those with redundant roles, and the specific function of individual cytokines to be defined. Notably this strategy has identified a critical role for LIF in inducing maternal endometrial receptivity, particularly the decidual response that is essential for embryo implantation.[180] IL-11, which is in the same cytokine family as LIF and signals through related gp130-associated receptors, is also critical for the decidual response and implantation success.[181] The cytokine CSF1 was the first identified as being required for normal fertility.[182] Despite its function as a regulator of uterine macrophages, infertility is mainly the consequence of CSF-1 effects on normal ovulation and estrous cycle progression.[183] In contrast, other cytokines such as IL-10 are dispensable for pregnancy unless an inflammatory insult is administered, when mice deficient in this cytokine experience substantially elevated susceptibility to miscarriage,[184] which is at least partly due to altered NK cell activity.[185] Each of these same cytokines are synthesized in response to progesterone in the decidual tissues of early human pregnancy and has been implicated as contributing to the immune adaptation sustaining pregnancy.[186]

The Innate Immune Response to Pregnancy

Some of the most profound changes in pregnancy are reflected in local and systemic populations of leukocytes classified as comprising the innate immune response. The individual subsets of key innate cell populations are considered individually below.

Uterine NK Cells

Uterine NK cells (uNK cells) are the most prominent leukocyte in the early human decidua.[187] Compared with NK cells in the blood, the majority of uNK cells in the decidua are noteworthy for their unusual structural and functional characteristics and attenuated surface marker expression.[6,188] In women these cells have a defined chronological profile where the cells are numerous during the first two trimesters, comprising 20–40% of the decidual stromal cells, and then decline to undetectable levels as parturition approaches (reviewed in Refs 6 and 21). Human uNK cells are small cells of the lymphoid lineage that contain distinct granules and express a pattern of cell surface markers, $CD56^{bright}CD16^{-}$, which distinguishes them from NK cells in the blood, most of which are $CD56^{dim}CD16^{+}$. In the mouse and rat, the uNK cells are readily identified throughout pregnancy by their exceptionally large size and abundant granules.[188] The life-cycle

and cytokine regulation of the mouse uNK cell has been extensively documented, and includes degranulation in the last trimester and replenishment from the spleen in an IL-15-dependent manner (reviewed in Ref. 30).

NK cells are traditionally known for their surveillance function; in most mucosal sites, NK cells recognize and kill infected and abnormal cells. Unlike other mucosal NK cells, uNK cells do not readily kill target cells despite having reservoirs of killer molecules such as granzymes and TNF in their granules.[189] Failure to readily exhibit killing function is in part their response to decidual cell-derived signals that include CCL2, which induces suppressor of cytokine synthesis-1 (SOCS1) and suppresses perforin synthesis.[190] The cytokine profiles of the uNK cells are generally consistent with their functional differences to blood NK cells. These produce both Th1-type cytokines such as IFNγ and IL-18 that are associated with inflammation and cell activation, and Th2-type cytokines such as IL-10.[191]

NK cells recognize and destroy aberrant host cells on the basis of host cell failure to exhibit normally expressed HLA, or expression of NKG2D receptors such as MHC class I polypeptide-related sequence-A and -B (MICA/MICB).[192] Avoiding NK cell lysis may be one reason why cytotrophoblast cells migrating into the uNK-replete decidua exhibit cell surface MHC class I antigens. The HLA-C, HLA-E, and HLA-G molecules expressed by human trophoblasts are likely to have intrinsic protective capacity. In particular, interactions between trophoblast cell HLA-E and uNK CD94/NKG2 inhibitory receptors cause loss of killer function in human uNK cells.[193] Although HLA-G can modulate immune responses in blood NK cells, decidual NK cells are less responsive.[194] HLA-C is also present on extravillous trophoblast cells, and this polymorphic HLA class Ia molecule appears particularly important for interactions with uNK killer cell immunoglobulin-like (KIR) receptors, as explained in detail below.[195]

The general principle that uNK activities are beneficial to pregnancy is well accepted, mainly as a consequence of studies in genetically modified mice, where a range of elegant genetic strategies have been utilized to define their roles. Deficiency of uNK cells reveals a key role for these cells in modification of the maternal vasculature via production of IFNγ,[196] which in turn promotes placental growth and development.[197] Additionally these cells have pro-angiogenic functions in generating the more extensive decidual vasculature that accompanies placental development.[198] However, despite considerable experimentation, the roles these cells play in human pregnancy remain unclear.[199] In particular, the possibility that uNK cells contribute to "quality control" of the implantation process[200] requires further investigation. This might be achieved through their influence on commitment to decidualization versus menstruation,[33] or NKG2D-mediated elimination of conceptus tissue under nonconducive circumstances such as viral infection.[185,201] The commitment to exert cell-mediated killing activity against trophoblasts is also influenced by macrophage, dendritic cell, and Treg cell-derived signals, principally involving modulation of suppressive TGFβ and TLR-derived danger signals.[202,203]

Decidual Macrophages

Macrophages are a consistent feature of the decidua throughout the course of pregnancy. They average 15–20% of the decidual stromal cells in women,[124,204] where they are frequently located close to invading cytotrophoblast cells, adjacent to the uterine glandular epithelium, and proximal to uterine blood vessels. As with macrophages in other locations, these cells are highly versatile and multifunctional, with extraordinary capacity to alter their phenotype and behavior in response to environmental signals. They are thought to be critical to host defense, uterine tissue remodeling and homeostasis, and local immune modulation (reviewed in Refs 122, 197, and 205).

In human decidua, the cells are ubiquitous and make valuable contributors to defense, being fully capable of phagocytosis and destruction of microorganisms. In mice, macrophages are less abundant in the decidua, and this is believed to contribute to loss of resistance to infections such as *Listeria monocytogenes* in pregnancy.[206] The human decidual macrophages are activated, as evidenced by their expression of HLA class II, CD11c, and CD86 antigens (reviewed in Ref. 71), and therefore appear capable of presenting microbial or other exogenous antigens to T lymphocytes. Yet decidual macrophage cytokine profiles indicate that the cells are programmed into an immune suppressive, alternatively activated (so-called M2) mode, producing powerful immunoinhibitory cytokines such as IL-10 and TGFβ1,[172,175] presumably in response to M2-inducing TGFβ and PGE_2 synthesized in other endometrial cells.[207] In the mouse, macrophages themselves are a source of PGE_2,[179] a molecule with profound immunosuppressive properties, but human decidual PGE_2 appears to arise from endometrial stromal cells that have differentiated into decidual cells.[206] Decidual macrophages are reported to express B7-H1,[208,209] an inhibitory member of the B7 family of costimulatory molecules, indoleamine dioxygenase (IDO, as well as ILT-3, DC-SIGN, and MS-1 (reviewed in Refs 7, 11, and 97)), all of which are markers associated with immune modulation characteristic of an M2 suppressive profile.

Like M2 macrophages involved in fetal development, decidual macrophages are believed to contribute to trophoblast invasion and placental development through their secretion and regulation of a range of matrix metalloproteinases and other proteases, growth factors, chemotactic

molecules, cytokines, and a range of matrix components. These agents, the precise patterns of which are fine-tuned by local microenvironmental signals, afford macrophages key roles in the tissue restructuring and angiogenesis that are central to placental development.[205] Decidual macrophages are also highly competent in the induction and effective clearance of apoptotic cells, which in the uterus would be necessary to accommodate the expanding fetus as pregnancy progresses.[210]

Under certain conditions such as intrauterine infection or preeclampsia, the environmental factors that support alternatively activated decidual macrophages are overcome by TLR-mediated danger signals and the cells instead assume a pro-inflammatory profile.[205,211] In preeclampsia, decidual macrophages produce TNF, which has toxic effects on migrating trophoblast cells and might account for the diminished numbers of viable cytotrophoblast cells in the preeclamptic decidua.[212] In gram-negative infections, the decidual macrophages produce extraordinarily high levels of TNF, other inflammatory cytokines, and PGE_2, which ultimately induce preterm labor (reviewed in Refs 213–215).

Decidual Dendritic Cells

The decidua contains another type of innate immune cell, the dendritic cell (reviewed in Refs 216 and 217). The principal function of dendritic cells is to regulate the adaptive immune response through a specialized capacity to take up, process, and present antigens to T lymphocytes, and to govern the activation response of T cells through powerful immune-regulatory activity. Although fewer in number than macrophages, dendritic cells are ontologically related; a large proportion of dendritic cells in the uterus exhibits characteristics consistent with a myeloid origin. Decidual dendritic cells fall into two broad categories: $CD83^+$ mature dendritic cells, which comprise approximately 1% of decidual stromal cells,[218] and $CD83^+$ immature macrophage/dendritic cells.

Like decidual macrophages, mature $CD83^+$ decidual dendritic cells exhibit an immunosuppressive phenotype and features of so-called "tolerogenic dendritic cells".[219] Tolerogenic dendritic cells control the activation and expansion of Treg cells and are crucial for maintenance of immune tolerance and prevention of autoimmune disease.[220] This subset is characterized by attenuated expression of co-stimulatory molecules CD80 and CD86, and absence of the Th1-inducing cytokine IL-12.[220] Expression of IDO is another defining feature of tolerogenic dendritic cells. IDO expression allows dendritic cells to directly activate resting Treg cells for potent suppressor activity, and appears to be crucial for converting $CD4^+CD25^+FOXP3^+$ Treg cells from $CD4^+CD25^-$ T cells and promoting their suppressive activity.[221]

Various immature dendritic cells populations are present in the decidua, including a unique DC-$SIGN^+$ $CD14^+CD83^-$ population that exhibits high proliferative activity and close physical association with uNK cells.[222] These cells fail to stimulate resting T cells and preferentially activate inducible Treg cells.[223] The DC-$SIGN^+$ cells switch their phenotype in response to inflammatory cytokines, differentiating into mature $CD83^+$ dendritic cells capable of activating T-cell immunity.[222] DC-SIGN is utilized for immune evasion by several viral and bacterial pathogens, and binding alters both cytokine production and antigen presentation in ways that benefit the pathogen.[224] Thus, DC-$SIGN^+$ cells are implicated as central players in the development of the pregnant uterus as an immune privileged site benefiting the fetus.

Certain decidual cytokines, including TGFβ, IL-10, GM-CSF, granulocyte-CSF (G-CSF), and IL-4, are linked to differentiation of tolerogenic dendritic cells that consistently induce $CD4^+CD25^+$ Treg cells.[225] The glycan-binding protein galectin-1 is an additional key regulator of tolerogenic dendritic cells capable of inducing Treg cells.[226] HLA-G also directs induction of tolerogenic dendritic cells, acting by ligating the LILRB2 receptor to disrupt the HLA class II–mediated antigen presentation pathway.[227] These tolerogenic properties of HLA-G are linked with Treg cell induction and in part are mediated through endogenous HLA-G synthesis within decidual DC-SIGN+ dendritic cells.[223]

Recent studies indicate that uNK cells have an instrumental role in controlling the tolerogenic phenotype of decidual dendritic cells. In mice, acute NK ablation using a diphtheria toxin-mediated transgenic approach switches dendritic cells to an immunogenic function.[228] As in mice, human decidual dendritic cells interact closely with NK cells,[229] but the relevant NK-cell derived signals are yet to be identified.

The Adaptive Immune Response to Pregnancy

In the immune system, T lymphocytes can be broadly categorized into CD8+ cytotoxic T cells (CTLs) and CD4+ T helper cells (Th cells). Th cells can be further stratified into Th1 cells, which produce inflammatory cytokines; Th2 cells, which produce anti-inflammatory cytokines and promote B lymphocyte development; Th17 cells, which are pro-inflammatory and affect antipathogen immunity and graft rejection; and Treg cells, which are anti-inflammatory and immune-suppressive (Figure 41.4). While differentiation of Th1 and Th2 cells is generally viewed as irreversible, the more recently described Th17 and Treg cells are less stable and there is greater plasticity for movement between these two phenotypes when environmental conditions change.[230]

At a systemic level, cytotoxic T lymphocytes generated in the thymus that bear TcR specific for foreign MHC are

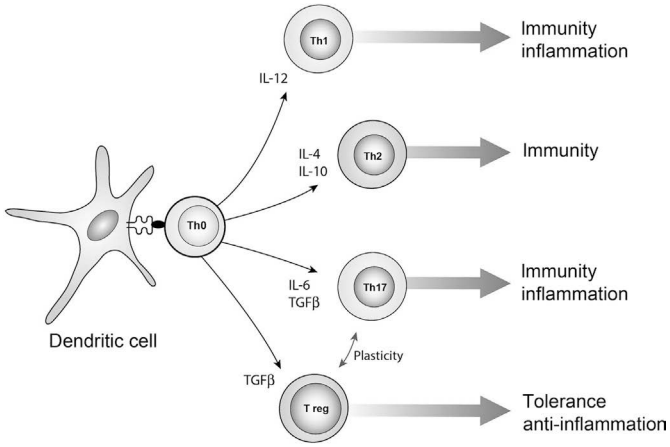

FIGURE 41.4 Funtional differentiation of Treg cells. The microenvironmental context in which naive CD4+ Th0 cells encounter their cognate antigen is a principal determinant of their differentiation fate and development into Treg cells as opposed to Th1, Th2, or Th17 cells. Treg cells confer immune tolerance and suppress inflammation while Th1, Th2, and Th17 cells mediate protective immunity and are linked with inflammation. Signals originating from the dendritic cell presenting antigen to the Th0 cell, as well as the relative concentrations of key cytokines in the immediate vicinity, are instrumental. IL = interleukin; Th1, Th2, Th17 = T-helper type 1, type 2, and interleukin 17-producing Th cell; TGF = transforming growth factor.

exceptionally numerous, but T cells programmed to kill cells bearing paternal MHC antigens are essentially eliminated from the decidua following implantation. Various theories have been advanced to explain the mechanisms by which this local skewing in T-cell phenotype occurs. After discovery of the first division in Th cell phenotype between Th1 and Th2 phenotype in the 1980s, Wegmann and co-workers put forward the proposal that pregnancy could be considered a Th2-type phenomenon.[5] In normal pregnancies, Th2 cytokine levels are high at the maternal–fetal interface, and antibody responses in the mother are strong. Cells of the innate immune system residing in the pregnant uterus and their Th2-type cytokines undoubtedly contribute to this state, but a substantial body of evidence indicates that placental cells are the primary source of the immune-deviating cytokines that program T cells, principally through their actions on the dendritic cells and macrophages that induce and control T-cell phenotypes.

Although appealing in its simplicity, the concept of a Th2 bias in pregnancy is an oversimplification, and it is clear that many Th1-type cytokines, such as IFNγ and TNF, have important roles in homeostasis of the pregnant uterus and placenta.[231] Indeed it now seems the key point is that detrimental Th1 and Th17 cells are suppressed, rather than Th2 cells promoted. Th1 and Th17 cell-mediated responses are dampened by placental anti-inflammatory cytokines such as TGFβ and IL-10 as well as progesterone and prostaglandins, whereas Th2-regulated antibody responses may be maintained and even elevated by two nonapoptosis-inducing TNF superfamily ligands produced in placentas, BAFF (also known as BlyS [B lymphocyte stimulator], TALL-1, THANK, zTNF4) and APRIL (a proliferation-inducing ligand)[232] (Figure 41.5).

Infections can overcome the immunosuppressive environment at both the local and systemic levels, with generation of high levels of Th1-type responses.[211,213,215] This defense against pathogens may be a lifesaving response for the mother, but devastating effects can be incurred by the fetus, with the pro-inflammatory shift to Th1 and Th17 responses identified as a key trigger for preterm labor.[233] The major cellular element in the maternal decidua T-cell population responsible for suppressing Th1 and Th17 cells under normal circumstances is Treg cells.

T Cells

In women, T lymphocytes comprise about 10% of the leukocytes in the decidual tissue of early pregnancy, and the majority of these are CD8+ with a relatively smaller population of CD4+ helper T lymphocytes. The precise phenotypes and specific cytokine expression profiles of decidual T cells have been explored, and considerable heterogeneity is evident.[234,235] Their antigenic specificities also remain unknown, but the majority of those expressing γ/δ TCRs incorporate gene segments that indicate potential recognition of a wide array of self and/or trophoblast antigens.[236,237] Activated T cells reactive with fetal HLA are detectable in the peripheral blood[162] and decidua of pregnant women.[11] A high degree of MHC mismatch between maternal and fetal HLA increases the numbers of these cells.[11,162,163] Experiments using reagents to evaluate the reactivity of TCRs expressed by T cells shows that at least half of all pregnant women have T cells with specificity for fetal epitopes, and these retain a functional memory phenotype throughout pregnancy without causing harm to the fetus.[238]

A similar scenario is evident in mice, with T lymphocytes increasing substantially in pregnancy such that α/β and γ/δ TCR+ T cells comprise up to 20% of total lymphocytes in midgestation decidua.[239] Specificity for paternal class I MHC antigens is detected among CD8+ T cells in lymph nodes draining the uterus, although evidence of downregulated TCR expression suggests functional unresponsiveness in these cells.[14]

To some extent, T-cell responses to alloantigens in pregnancy may have benefits for pregnancy outcome. For example, mice mated with MHC-disparate males have greater numbers of fetuses than inbred mice, and the fetuses are heavier, potentially due to greater placental access to maternal nutrients from increased dilation

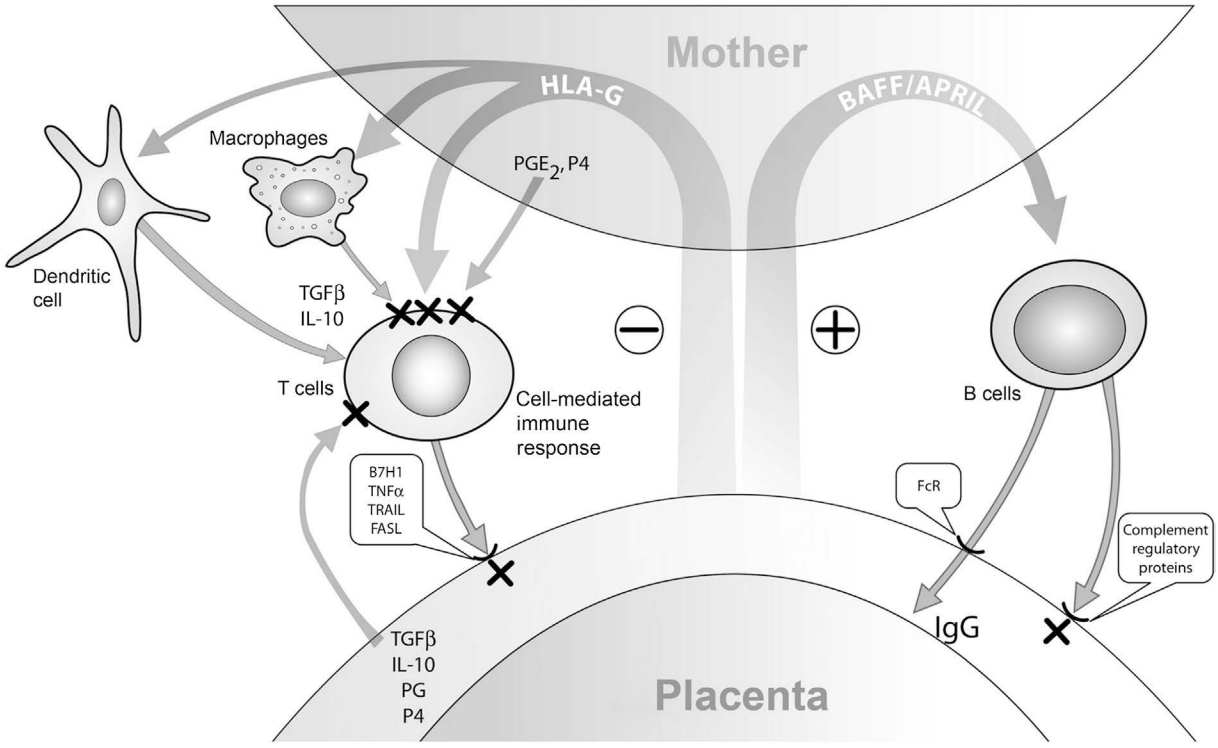

FIGURE 41.5 Placental contribution to tolerance. In this scheme, HLA-G along with immunosuppressive cytokines, prostaglandins, and progesterone, inhibit maternal cell-mediated immunity. Effector cells are impaired by special adaptations on the placental syncytiotrophoblast that include expression of inhibitory cytokines. Antibody-mediated immunity may be promoted by nonapoptosis-inducing members of the TNF superfamily of ligands, BAFF and APRIL. Cytotoxic antibodies directed to placental antigens are inhibited by expression of the complement regulatory proteins on syncytiotrophoblast while beneficial IgG is transported into the fetus.

of maternal uterine blood vessels.[240] In humans, intervals between pregnancies are lengthier when mothers and fathers are genetically similar.[241] The practice of immunizing potential mothers with their husband's or third-party leukocytes is based on the concept of boosting adaptive immunity to paternal MHC antigens, but double-blind studies show this is not a useful technique and may even be dangerous.[242] Because of poor pregnancy outcomes, the practice is prohibited in the United States by the Food and Drug Administration except under approved experimental protocols.

Regulatory T Cells

The most functionally important T cells in the decidual tissue may be immune suppressive T_{reg} cells, defined as $CD4^+CD25^+$ cells expressing the signature transcription factor FOXP3. This special subset of T cells is now believed to play a central role in mediating immune tolerance in pregnancy.[15] Treg cells are powerful inhibitors of inflammatory immune events and type 1 (cell-mediated) immunity.[17] They are critical for preventing immunity to self-antigens as well as exogenous antigens.[243,244] Their suppressive function is essential in tissues containing proteins and other antigenic structures that are not identified as self because of their tissue-restricted expression or occurrence late in development. This is also the case in mucosal and epithelial surfaces, where environmental agents are regularly encountered and tolerance of nondangerous foreign entities is essential to homeostasis and function. This unique capacity to suppress responses to tissue-specific antigens and alloantigens strongly suggests that Treg cells are able to perform a key role in pregnancy tolerance. It is therefore not surprising that $CD4^+CD25^-$ T lymphocytes are now widely believed to be critical suppressor cells that sustain semi-allogeneic pregnancy.[15]

Initially, suppression of activation and proliferation of $CD4^+$ T cells was thought to be the principal function of Treg cells.[245] However, Treg cells are now known to inhibit proliferation and cytokine production in both $CD4^+$ and $CD8^+$ T cells,[246] to suppress B-cell proliferation and immunoglobulin production,[247] to inhibit cytotoxic function of NK cells,[248] and to inhibit maturation and inflammatory activation of antigen-presenting cells including dendritic cells and macrophages.[249–251] Adoptive transfer of wild-type Treg cells but not Treg cells from TGFβ-null mutant donors into nude mice suppresses NKG2D expression and NK cell cytotoxicity, showing the key role for TGFβ in mediating this suppressive function.[248] In dendritic cells, the actions of Treg cells in maintaining tolerogenic dendritic cells and suppressing formation of immunogenic dendritic cells require diverse cell–cell

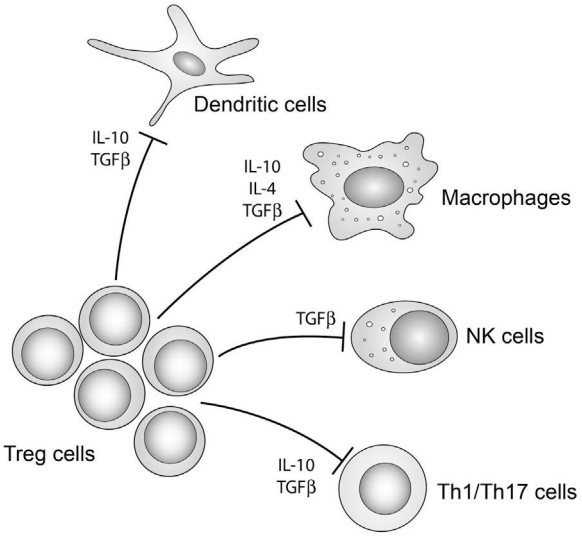

FIGURE 41.6 Suppressive pathways of Treg cells. Treg cells act to exert their immune regulatory and anti-inflammatory effects through inhibiting proliferation and cytokine production in both $CD4^+$ and $CD8^+$ T cells, suppressing cytotoxic function of NK cells, and inhibiting maturation and inflammatory activation of dendritic cells and macrophages. contacts involving CD223 (lymphocyte-activation gene 3, LAG-3), neuropilin-1, and cytotoxic T-lymphocyte associated protein 4 (CTLA-4), which downregulates CD80 and CD86 co-stimulatory molecules. Other soluble signals include IL-10 and TGFβ.[252] Thus, Treg cells can target several stages of the innate and adaptive immune response, spanning the events of lymphocyte activation and proliferation, through to effector function (Figure 41.6). Each of these anti-inflamamtory and immune suppressive functions contributes to their key role in maintaining semi-allogeneic pregnancy.

There are two different pathways of Treg generation. "Natural" Treg cells (nTreg cells) are derived in the thymus, via a selective process based on the TCR structure and its affinity for self-structures expressed in thymic epithelium. Adaptive or "inducible" Treg cells (iTreg cells), which are most important in pregnancy, are produced within peripheral tissues by a mechanism that generates Treg cells with TCRs that recognize antigens restricted to specific peripheral tissues, none of which are present in the thymus.[244] Inducible Treg cells are critical for controlling immunity against foreign antigens that are innocuous, against which aggressive responses would be inappropriate. Under normal circumstances these include reproductive antigens, such as those expressed by the developing conceptus, sperm, or oocytes.

In order to proliferate, become mature, and exert suppressive activity, Treg cells must interact with antigen presented by tolerogenic dendritic cells, in the context of specific immune-deviating environmental signals[62,245] (Figure 41.7). Appropriate cytokines are particularly important for fate commitment of naïve Th0 cells into Treg cells, as opposed to Th1, Th2, or Th17 phenotypes. TGFβ is one critical cytokine, well known for its immune suppressive and anti-inflammatory actions.[253] When TGFβ is present at the time of TCR-antigen ligation, naïve Th0 cells are directed away from the default pathway that generates T cells without suppressive capabilities.[243,244] Instead, these cells differentiate into a suppressor T-cell phenotype and express *Foxp3*.[254] TGFβ can also drive proliferation of mature Treg cells by modulating the function and signaling capabilities of dendritic cells.[255] In vitro experiments show that PGE_2 may synergize with TGFβ to enhance the generation and inhibitory capacity of human $CD4^+CD25^+$ Treg cells.[256]

Once activated and fully functional, Treg cells can interact with other cells in their local vicinity to exert suppression in an antigen-nonspecific manner. Several different and redundant effector mechanisms are responsible for this suppressive activity.[257] Ligation of Treg surface molecules, namely CTLA-4, membrane-bound TGFβ, and CD223, mediate contact-mediated suppression,[257] and this is achieved by competitive sequestration of IL-2 from neighboring T cells.[245,258] Treg cells act to sustain and strengthen a suppressive immune environment by secreting TGFβ and IL-10, which further expands the Treg cell response,[259] and condition dendritic cells to express IDO and maintain a tolerogenic phenotype[221,260] (Figure 41.7).

With their unique capacity to suppress responses to tissue-specific antigens and alloantigens, Treg cells are eminently suited to perform critical functions in mediating tolerance to reproductive antigens in pregnancy. Indeed, inducible Treg cells were discovered almost 10 years ago to have key roles in suppressing maternal immune attack against the conceptus,[15] and since then have been implicated in suppressing autoimmunity to other reproductive and gamete-specific antigens expressed by sperm and oocytes.[261,262] The absolute requirement for Treg cells in semi-allogeneic pregnancy was first demonstrated in experiments where complete T-cell populations or populations depleted of $CD4^+CD25^+$ Treg cells were transferred into pregnant T-cell deficient mice.[15] In the absence of Treg cells, semi-allogeneic fetuses were uniformly rejected, while genetically identical (syngeneic) fetuses generally survived.[15] Passive transfer of CD25-reactive PC61 monoclonal antibody to deplete $CD25^+$ cells in vivo provided further support for an essential role for Treg cells in maternal tolerance of semi-allogeneic fetuses.[263,264] Fetal loss and fetal growth impairment is similarly seen in mice when maternal Treg cells are depleted by diphtheria toxin-mediated killing of CD25-expressing cells.[265] In this latter study of syngeneic pregnancies, only male fetuses were lost, revealing the critical importance of maternal

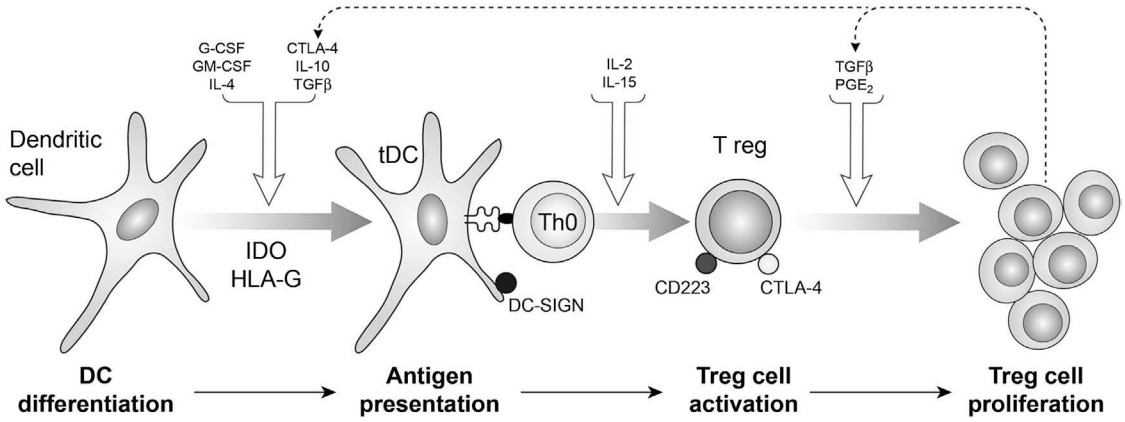

FIGURE 41.7 Suppressive pathways of Treg cells. Tolerogenic dendritic cells, together with regulatory cytokines and other immune-deviating agents, control Treg cell activation and proliferation. Cytokines G-CSF, GM-CSF, IL-4, and IL-10, together with IDO and HLA-G, regulate dendritic cell differentiation into a tolerogenic phenotype. IL-2 and/or IL-15, acting at the site of antigen presentation by tolerogenic dendritic cells, are required for Treg cell activation and proliferation. TGFβ and PGE_2 drive further rounds of proliferation of mature Treg cells. Treg cells release IDO, IL-4, and IL-10 to amplify effects on dendritic cells and Treg cell generation. Treg-mediated tolerance to antigens encoded by the Y chromosome.

In women, Treg cells comprise approximately 14% of $CD4^+$ cells in early decidua.[126] The decidual Treg cells are phenotypically similar to those in other locations, with expression of intracellular CTLA-4, GITR, and OX40, all of which are markers for this subset. The frequency of $CD4^+CD25^+$ cells in the peripheral blood is increased during early pregnancy,[266] suggesting that cells circulating in blood may migrate into the uterus to increase their numbers during pregnancy. The numbers and suppressive function of these cells in the human decidua are related to the extent of HLA-C mismatch,[11] providing a potential explanation for why MHC disparity between the fetus and the mother can improve pregnancy outcome.[240]

Changes in Treg cell populations are a very early event in the maternal immune adaptation to pregnancy. Rising progesterone levels at the time of embryo implantation are implicated in sustaining and expanding Treg cell populations beyond the estrogen-regulated populations present at ovulation. In vitro, progesterone has been shown to convert $CD4^+CD25^-$ T cells into $CD4^+CD25^+$ Treg cells. This conversion has been demonstrated in vitro using the progesterone antagonist RU486 and in vivo, using progesterone-treated ovariectomized and pseudopregnant mice, suggesting that progesterone expands Treg populations via nuclear progesterone receptors.[27] Progesterone may act to stabilize the Treg cell phenotype and inhibit conversion into pro-inflammatory Th17 cells exposure by inhibiting expression of the IL-6 receptor.[28]

In mice, within two days following mating, an expanded Treg cell pool is detectable in lymph nodes draining the uterus. Similar but less profound changes are seen in the spleen and distal lymph nodes.[15,26,267] In addition to the effects of ovarian hormones, experiments employing tetramer-based strategies to identify T-cell receptor specificity have revealed that pregnancy expands Treg cells with specificity to fetal antigen.[268] As in humans, expression of paternal and other pregnancy-specific antigens in the placenta leads to a greater increase in Treg cell numbers, and is associated with enhanced specific suppression of antipaternal alloantigen reactivity.[267,269] This pre-implantation increase in Treg cells is accompanied by paternal alloantigen-specific functional tolerance, which can be measured as hyporesponsiveness in the Th1 immunity required to elicit a delayed type hypersensitivity response to paternal MHC, or to reject tumor cells expressing paternal MHC.[26]

This early expansion of Treg cell populations in lymph nodes is accompanied by accumulation of $FOXP3^+$ cells and elevated *Foxp3* mRNA expression in the uterus.[15,53] Treg cell recruitment in the uterus during the pre- and peri-implantation period is linked with glandular and luminal epithelial cell production of the Treg cell chemokine CCL19, which acts through the CCR7 receptor to regulate Treg cell recruitment and retention in peripheral tissues.[53] Other chemokines are likely to be involved in attracting Treg cells into the implantation site. Activation by paternal antigens confers expression of chemokine receptor CCR5 on Treg cells, and CCR5 is implicated in sequestering activated, antigen-specific Treg cells in the gravid uterus.[269]

Compelling evidence that Treg cells are most critical at the implantation phase of pregnancy as opposed to later stages comes from Treg cell depletion experiments, which show that semi-allogeneic pregnancy cannot

commence unless sufficient Treg cells are present in the uterus. Passive administration of antibody reactive with CD25 prior to implantation on day 2.5 post-coitum results in implantation failure, while depletion on days 4.5 or 7.5 post-coitum does not terminate pregnancy but instead increases the rate of later fetal resorption. Conversely, depletion in the mid- and late gestation phase of pregnancy does not adversely affect ongoing fetal development.[270]

Confirmation that paternal antigen-specific Treg cells are inducible as opposed to natural Treg cells comes from studies showing their generation depends on the Foxp3 enhancer gene, conserved noncoding sequence-1 (CNS1).[271,272] Increased rates of fetal resorption in CNS1-null mutant females mated with allogeneic males but not syngeneic males confirms that inducible Treg cells modulate maternal responses to paternal alloantigens in gestational tissues.[271] The fact that the CNS1 enhancer emerged in eutherian mammals, where placental tissue is closely interdigitated with maternal tissue, indicates that the CNS1-dependent pathway of extrathymic Treg generation may have arisen under selective pressure to enforce tolerance towards paternal alloantigens and allow viviparous reproduction to evolve.[271]

Chemokines and Selective Decidual Leukocyte Recruitment

Regulated patterns of chemoattractive chemokines synthesized by decidual cells and trophoblast cells in the early developing placenta, together with specific pathways of lymphocyte recruitment, are responsible for the distinct patterns of leukocyte populations present at the fetal–maternal interface.[46,51,273–275] For example, CCL3 (monocyte inflammatory protein-1, MIP1α) has been identified as a major product of cytotrophoblast cells that attracts monocytes and NK cells into the human uterus,[273] whereas IL-8 attracts neutrophils and other leukocyte populations.[276] Interestingly CCL3 is also implicated in facilitating cytotrophoblast cell differentiation,[274] a finding that illustrates the multifunctional nature of immune-regulatory molecules at the fetal maternal interface.

The subsets of lymphocytes recruited into decidual tissue are further restricted by virtue of lymphocyte homing mechanics. All lymphocytes are programmed during their development to follow specific migration pathways through the body that enable antigen-specific immune responses to be concentrated at certain sites. Directed migration, or "homing," into mucosal tissues is controlled by expression of distinct patterns of adhesion molecules on the lymphocyte cell surface, which mediate differential recognition and adherence to endothelium in mucosal sites. The molecular regulation of T-lymphocyte homing into the decidua may be influenced by local microdomains evident within the implantation site, with differential expression of adhesion molecules among local vessels.[277] One example of this is mucosal vascular addressin (MAdCAM-1), which is found in only a proportion of vessels at the leading edge of trophoblast invasion in women, and is otherwise absent from the reproductive tract.[278]

Certain chemokines are involved in recruitment of the Treg cells that are essential for embryo implantation. Accumulation of these cells commences prior to implantation, with experiments in mice implicating estrogen-induced expression of chemokines that target the CCR5 chemokine receptor, including CCL3, CCL4, and CCL5.[24] In the pre-implantation phase, expression of the Treg chemokine CCL19 increases in uterine glandular and epithelial cells in women.[52] In mice, exposure to seminal fluid acts to elevates CCL19 expression.[53] CCL19 acts through the CCR7 receptor to regulate Treg cell retention in peripheral tissues such as the pregant uterus.[279]

The specific patterns of chemokine expression are in part controlled by epigenetic silencing of decidual tissue expression of chemokines that recruit certain T-cell lineages.[132] A mechanism involving repressive histone marks that actively prevent decidual cell synthesis of specific chemokines involved in cytotoxic Th1 cell recruitment, including CCL5 as well as CXCL9, CXCL10, and CXCL11, prevents access of Th1 cells into the decidua in a fail-safe mechanism to ensure that potentially aggressive T cells cannot reach placental tissue. A consequence of this altered chemokine silencing may be to increase the susceptibility of the decidua to infection. Since CXCL10 is also only focally expressed in the human decidua,[280] it is possible that a similar silencing mechanism operates in women.

IMMUNOLOGY OF PREGNANCY: THE FETAL CONTRIBUTION

Sites of Fetal Contact with Maternal Cells

An important mechanism by which the fetus avoids eliciting maternal immune rejection is by tightly controlled expression of immunostimulatory and immunosuppressive molecules. The need for specific immunomodulators is dictated by the anatomical positioning of the trophoblast subpopulation. The direct supply of arterial blood to the placenta throughout the latter two-thirds of pregnancy means that the potential for contact between the syncytiotrophoblast and circulating lymphocytes is constant, and that the syncytiotrophoblast is conceivably the most vulnerable to the maternal immunological milieu. Studies in the mouse have documented both hormone-mediated and fetal antigen-specific curtailment of central T- and B-cell production

during pregnancy, but the mother maintains peripheral immunocompetence and overall levels and functionality of circulating lymphocytes remain intact.[281,282] Further, as reviewed above, the stroma of the decidua basalis is replete with maternal immune cells, constituting about 40% of total cellularity, and extravillous trophoblast cells exiting cell columns stream into the decidua here in vast numbers. Similarly, the chorion membrane resides in direct apposition to decidua cells, and maternal leukocytes can be found at this location throughout pregnancy. Lastly, it has become increasingly clear that yet another maternal–placental–fetal interaction exists within the periphery. As described above, the placenta releases copious quantities of microvesicles directly into the maternal blood, and fetal cell trafficking results in long-term microchimerism in the mother. These vesicles and cells carry both fetal antigens and immunomodulatory proteins directly to maternal lymphoid organs and other tissues. Thus, the varying maternal compartments in which feto-placental cells and vesicles reside necessitate site-specific tailoring to cope with maternal immune cells to which they are exposed.

Regulated Expression of Immunomodulatory Molecules by Trophoblast Cells

HLA Molecules

The major transplantation antigens first identified for their dominant roles in graft rejection are known as the human leukocyte antigens (HLAs). The telomeric end of human chromosome 6p21 (mouse chromosome 17) contains a cluster of these genes (Figure 41.8) (reviewed in Refs 71, 283, and 284). Within this cluster are 16 HLA class I genes, only six of which are transcribed or translated.[285] The class I genes that are expressed by cells are subdivided into the highly polymorphic class Ia, which includes HLA-A, -B, and -C genes, and the weakly polymorphic class Ib genes, which include HLA-E, -F, and -G genes. HLA class II (HLA-D) genes are also highly polymorphic. Regulation of the genes encoded by the three groups differs greatly, being highly cell- and tissue-specific as well as related to the differentiation and activation states of cells. The antigens are functionally versatile, driving either immunostimulatory or immunoinhibitory pathways. In particular, when released in the soluble form, these antigens are perceived as immunosuppressive rather than immunostimulatory (reviewed by Zavazava[286]).

The HLA class I genes are expressed biallelically, such that the protein products of both maternally derived and paternally derived HLA are present on individual cells. Class Ia antigens exist as membrane-bound molecules on the surface of most nucleated cells, but can also exist in the serum in a variety of soluble isoforms (reviewed by Campoli and Terrone[287]). Their expression is not cell type-restricted; HLA-A, -B, and probably also -C are expressed by essentially all somatic cells. These antigens are unique markers of individual identity as each gene is highly polymorphic, with thousands of alleles each.[285]

By contrast, products of the class Ib genes are held in common among most individuals. The numbers of alleles are low for HLA-E and HLA-F, and the number of proteins with differing amino acid compositions are 5 and 4, respectively. To date, 50 alleles of HLA-G encoding 16 distinct proteins have been identified.[285]

TROPHOBLAST REPRESSION OF HLA EXPRESSION

Several decades of investigation have shown that syncytiotrophoblast cells may either fail entirely to express HLA antigens or may select specific genes with special nonimmunogenic properties for expression (reviewed in Refs 71, 283, and 284). The antigens that trophoblast cells never express in vivo are HLA-A and -B, which in other contexts are highly effective stimulators of acute graft rejection. Trophoblast cells also effectively repress expression of HLA class II antigens,[288] which are used for stimulation of the T-helper cell subset. Although some types of cells can be induced to express HLA class Ia and class II antigens, trophoblast cells in placental explants cultured in vitro cannot.[289] When released from the architectural environment of the normal placenta, purified trophblast cells can be induced to express

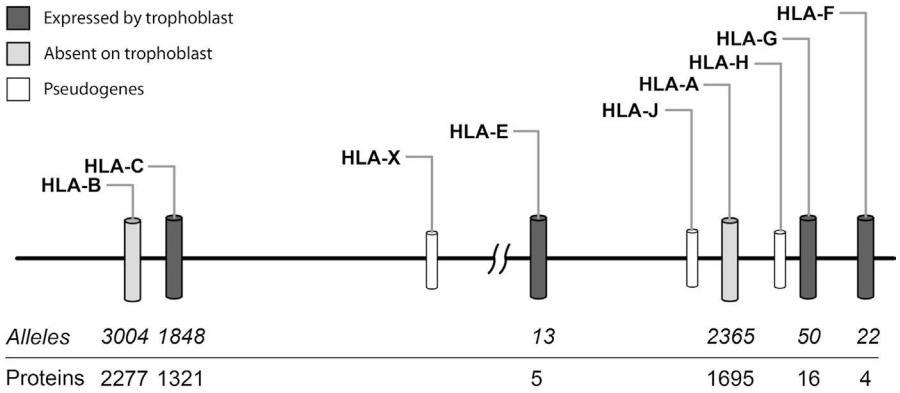

FIGURE 41.8 The human major histocompatibility on chromosome 6. The HLA class I genes, which are telomeric to HLA class II, include HLA class Ia (HLA-A, -B, -C) and Ib (HLA-E, -F, -G), and trophoblast cells strictly regulate the expression of each of these genes. Three of the 10 known, unexpressed HLA pseudogenes are shown. Each of the class I genes differ significantly in the numbers of alleles known and proteins expressed (bottom panel). HLA, human leukocyte antigen.

class I HLA with inflammatory cytokines,[290] suggesting that elements within the placenta have a major role in regulating expression of HLA in trophoblast cells. This robust repression of HLA-A, -B, and class II molecules prevents trophoblast cells from participating in antigen presentation and from comprising direct targets of $CD8^+$ and $CD4^+$ T cells. Thus, this mechanism has long been recognized to be a major pathway whereby the placenta passively escapes maternal immune rejection.

TROPHOBLAST HLA-C

Human extravillous trophoblast cells express one class Ia molecule, HLA-C, and all three class Ib molecules. The HLA-C gene is polymorphic, and could stimulate maternal antifetal acquired immunity if paternal alleles differed from maternal. As discussed above, trophoblast HLA-C may be recognized by maternal cells, and provoke the need for an immunosuppressive Treg response.[11] Thus allelic disparity at the HLA-C locus is not usually a causal factor in infertility or termination of pregnancy. While increased infiltration of paternal HLA-C-specific T cells into the maternal–fetal interface is associated with higher allelic disparity, these cells may be kept in check by corresponding increases in local Treg cells.[11]

Accumulating evidence suggests that HLA-C has a trophic function in placentation, specifically by promoting uNK cell participation in remodeling the uterine spiral arteries—the critical supply line delivering maternal blood to the developing placenta. Experimental evidence supporting this idea has been growing for more than 15 years, starting with the seminal findings of failed spiral artery remodeling in mice lacking NK cells.[291] The narrow, smooth muscle-bound decidual arteries in these mice is reminiscent of the restricted spiral artery remodeling found in pregnancy disorders such as preeclampsia and intrauterine growth retardation.[292,293] Successive studies using mouse models, purified cells ex vivo, and in vitro models have demonstrated that uNK cells display a unique synthesis profile of pro-angiogenic growth factors, trophoblast migration-promoting chemokines, and smooth muscle cell disrupting factors.[196,294–297] Further, extravillous trophoblast and uNK cells appear to engage in bidirectional cross-talk. A principal trophoblast-derived factor in engaging uNK cells appears to be HLA-C, recognition of which uNK cells are biased towards.[298] Epidemiologic evidence supports this model: Hiby and co-workers have reported that combinations of genotypes of maternal killer inhibitory receptor (KIR) and fetal HLA-C that should, at the molecular level, encourage NK activation, act to reduce risk of preeclampsia and pregnancy failure.[299–301] Thus, a growing body of literature supports the concept that activation of uNK cells through trophoblast HLA-C stimulates production of cytokine and growth factors, which in turn promotes trophoblast migration and disarrangement of smooth muscle cells encircling spiral arteries. Although the cellular and molecular mechanisms of these genetic associations are as yet undefined, further studies seeking to reveal the role of placental HLA in maternal spiral artery remodeling are warranted, including those using murine models.[240]

CLASS IB HLA: HLA-E, HLA-F, AND HLA-G

The other HLA class I antigens expressed by trophoblast cells are HLA-E, -F, and -G. The importance of HLA-E is discussed above in the section on uNK cells. Although there was originally much confusion regarding the specific class I HLA that signaled inhibition of uNK cells, it is now clear that HLA-E, which binds to the CD94/NKG2 receptor, is of prime importance in preventing uNK cells from killing their normal targets.[193] However, HLA-G might yet prove of value in this setting because the uNK cells express both leukocyte immunoglobulin-like receptor B1 (ILT2 or LILRB1) receptors and KIR2DL4, which signal inhibition through different pathways. Figure 41.9 shows the potential immune cell targets of trophoblast cell HLA-G antigens and the receptors known to bind the specific antigens. HLA-F is also present on invading cytotrophoblast cells,[302,303] but its binding patterns and activities remain unknown.

The physical properties of HLA-G are unique; two of these profoundly influence its regulation and functions. First, the gene has a large deletion in its promoter region that precludes enhancement of expression by the usual modulators, i.e., interferons and TNF. Second,

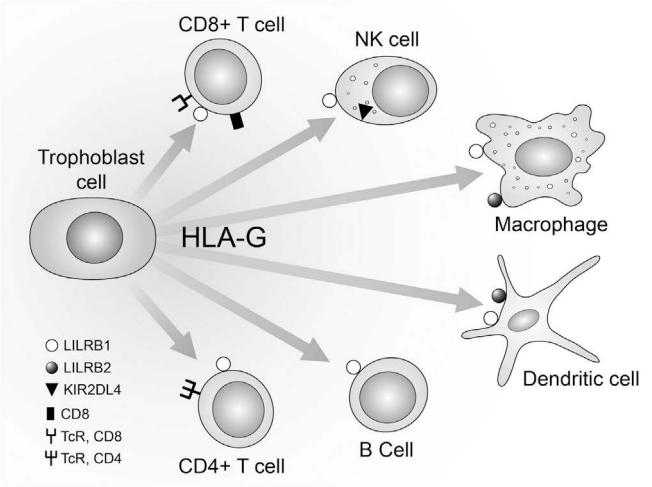

FIGURE 41.9 Trophoblast HLA and immune cell interactions. Each subpopulation of leukocytes expresses its own pattern of receptors for HLA class I, which permits diversity in responses. Note that the leukocyte immunoglobulin-like receptors (LILR) comprise a large family, and that individual leukocyte subgroups express specific members such as TCR (T cell receptor), ILT (immunoglobulin-like transcript), or KIR (killer inhibitory receptor).

the HLA-G transcript is alternatively spliced to yield seven different messages, of which four are predicted to encode membrane-bound proteins and three are predicted to encode soluble proteins (reviewed in Refs 71, 283, and 284).

The placental expression patterns for HLA-G have been extensively investigated and reviewed.[71,304] HLA-G was first identified on the term chorion membrane and on cytotrophoblast cell columns in early pregnancy. The invasive interstitial and endovascular cytotrophoblast cells remain HLA-G$^+$. Further, individual isoforms derived from the HLA-G gene by alternative splicing have varying expression patterns. The membrane-bound isoform that is derived from the full-length message, HLA-G1, appears on invasive cells, but smaller isoforms that may be either membrane bound or soluble (HLA-G2 and -G6) are also prominent on the extravillous cytotrophoblast cells.[69] By contrast, a second soluble isoform, HLA-G5, is ubiquitous in placentas and membranes taken from all three trimesters of pregnancy.[305]

The membrane-bound form that has been most thoroughly studied is the full-length protein, HLA-G1. This isoform is present on invading cytotrophoblast cells in columns distal to the placental villi, on interstitial and endovascular trophoblast cells, and on some cells remaining in the term chorion membrane. HLA-G1 and its soluble counterpart, HLA-G5, can exist as free heavy chains or as heterodimers, each in association with β2-microglobulin. This latter form further homodimerizes via disulfide linkage between the heavy chains; dimerization confers increased affinity and bioactivity for its LILRB1 receptor.[306–309] Its target could be uNK cells through LILRB1 and/or KIR2DL4 receptors; LILRB1 and LILRB2 molecules likely mediate HLA-G interaction with T cells and macrophages, respectively (Figure 41.9). HLA-G can inhibit antigen-spectific cytolysis by cytotoxic T cells and NK cells,[310] as well as CD4 T-cell alloproliferative responses and cytokine production.[311,312] HLA-G also could modulate T-cell activity indirectly through its LILRB2-mediated actions on dendritic cells.[313] Interestingly, HLA-G1-transfected antigen-presenting cell lines have been shown to display enhanced levels of receptors such as KIR2DL4, LILRB1, ILT3, and LILRB2,[314] which could comprise a feed-forward pathway for secretion of cytokines or alteration of other antigen presenting cell activities.

The functions of HLA-G5 might be similar to those of HLA-G1, as their structures are identical except that HLA-G5 is missing the transmembrane and cytoplasmic domains and is therefore a soluble protein. Binding of HLA-G5 to receptors on leukocytes has profound effects, and these are exerted through multiple pathways. HLA-G5 stimulates death of phytohemagglutinin (PHA)-treated lymphocytes through the Fas/FasL cell death pathway, reduces expression of lymphocyte CD8α, a co-receptor involved in linking CTL with antigen-presenting cells, and drives mononuclear phagocytes into an immunosuppressive profile where the cells produce high levels of TGFβ (reviewed in Refs 7, 11, and 67). Soluble HLA-G appears to be selective in its enhancement of suppressive cytokines; there is no relation, for example, between levels of HLA-G and IL-10 in serum.[315] The first report of binding of HLA-G to macrophages indicated a preference for LILRB2, but studies in U937 cells, a histiocytic cell line, indicate that both the LILRB1 and the LILRB2 receptors on these phagocytes bind HLA-G5.[175]

Evidence is accumulating for functional distinctions among the isoforms. The argument for similar functions is supported by the finding that in the absence of HLA-G1 and -G5 due to a deletion in the HLA-G gene, women have demonstrable HLA-G proteins in their placentas and produce viable offspring.[316–318] These results are consistent with the idea that other isoforms provide functional compensation. Although initially controversial, several studies show that these are not only present in placentas but are functional.[305,310,319,320]

The argument for isoform-specific functions is supported by the report that HLA-G2/G6 is expressed exclusively in the extravillous cytotrophoblast cells distal to the villus whereas HLA-G5 is ubiquitously expressed in villous and extravillous cytotrophoblast cells and is prominent in syncytiotrophoblast and maternal blood at term.[305,321] At this point in time, the major isoform-specific distinction supported by experimental evidence is concentration-dependency; HLA-G5 is a significantly more effective stimulator of certain responses such as production of TGFβ by macrophages[175] than is HLA-G6 (reviewed in Ref. 71). However, macrophage-like cells demonstrate a significant preference for binding the HLA-G6 isoform via their LILRB1 receptors whereas binding of the HLA-G5 isoform is performed equally by LILRB1 and LILRB2,[175] suggesting that discrete, receptor-driven, isoform-specific functions may yet be uncovered. The functions of HLA-G2, HLA-G3, and HLA-G4 remain poorly explored with the exception of a report from Riteau and co-workers showing that as with HLA-G1, all of these isoforms protect transfected cells from effector cell lysis.[310,320] The expression and fuction of HLA-G7 remains unknown.

B7 Family Co-stimulatory Molecules

T cells require two signals from antigen-presenting cells to become fully activated. As well as the antigen-specific signal provided through T-cell receptor ligation with HLA-peptide complex, a second signal, the co-stimulatory signal, is required. Co-stimulation is antigen nonspecific and is provided by the interaction between co-stimulatory molecules expressed on the membrane of the antigen presenting cell and the T cell. One of the best characterized co-stimulatory

molecules expressed by T cells is CD28, which interacts with B7-1 (CD80) and B7-2 (CD86) on the membrane of antigen-presenting cells (reviewed by Greenwald et al.[322]). Without the co-stimulatory signal, naive lymphocytes, instead of becoming activated in response to the antigen/HLA complex, may become tolerized and anergic to subsequent stimulation.[323] With both signals, however, naive lymphocytes are primed to respond to antigenic stimulus, and the result is proliferation and cytokine production. Conversely, B7-1 and B7-2 may down-modulate T cell activation through the CTLA-4 receptor, which serves to shut off the immune response. The limitation of expression of B7-1 and B7-2 to professional antigen-presenting cells ensures that only cells presenting foreign antigen, and not cells expressing only self-antigen, can elicit an immune response.

There are currently seven known members of the B7 family, at least five of which are transcribed and translated in the human placenta.[208] There are also five known CD28 family molecules. Depending in part on the receptor–ligand combination, these interactions have either inhibitory or stimulatory action on immune cells.[324,325] In contrast to the restricted expression of B7-1 and B7-2 on antigen presenting cells, other members of the B7 family have a broader range of distribution, at least at the level of mRNA, and many cells can express these proteins upon induction by inflammatory stimuli.[326,327] Uniquely, all human trophoblast cells abundantly and constitutively express the B7 protein, B7-H1 (or PDL1); its cognate inhibitory receptor, PD-1, is abundant on decidual $CD8^+$ and $CD4^+$ T cells, including $CD4^+CD25^+FoxP3^+$ Treg cells.[328]

The cellular distribution of the more recently described members of the B7 family on both antigen-presenting cells within lymphoid organs and on parenchymal cells in the periphery reflects their ability to modulate T-cell activation at both the priming and the effector stages. Due to the absence of class Ia HLA on trophoblast cells, this protein most likely modulates effector activity of T cells in the placenta. In vitro, trophoblast B7-H1 shifts cytokine production by activated human decidual T cells towards a Th2 profile.[208,328] Whether the B7-H1/PD-1 pathway is requisite for semi-allogeneic murine pregnancy is controversial; while a requirement for maternal B7-H1 has been reported, results are inconsistent among investigators; furthermore the B7-H1 receptor PD-1 is not mandatory.[329,330]

2,3-Indoleamine Dioxygenase

In 1998, Munn et al. presented evidence in a mouse model suggesting that inhibition of tryptophan metabolism by placental cells via production of IDO comprises a major strategy for protecting the embryo from maternal immune cell attack.[331] The experiments described a system in which chemical inhibition of IDO, an enzyme which removes tryptophan from the environment and is a known inhibitor of cell proliferation, caused fetal rejection at gestation day 10 that was entirely restricted to semi-allogeneic pregnancies. More recently, the group of investigators who generated the first report on placental IDO demonstrated that in the mouse placenta, IDO is located in trophoblast giant cells.[332]

Evaluating the role of IDO in human pregnancy is difficult because women deficient in this ubiquitous enzyme are unknown. Studies on human placentas and decidua have yielded conflicting results, with placental endothelial cells, isolated stretches of syncytiotrophoblast, placental mesenchymal cells, extravillous cytotrophoblast cells, and placental macrophages identified as positive by immunohistochemistry.[333,334] Whether human decidual macrophages are IDO positive or negative remains in doubt, but stage of gestation may be important.[172,335] Many other types of leukocytes, including eosinophils,[336] dendritic cells,[337] and Langerhans cells,[338] also express IDO, but none has been investigated in pregnancy. The assortment of results and their probable contributions to human semi-allogeneic pregnancy have been discussed by Entrican.[339]

Evaluating IDO functions in mice is also difficult. In contrast to their predictions, Baban and co-workers found that mice with genetic deficiencies in IDO have entirely normal pregnancies.[332] The investigators postulated that other mechanisms of immune suppression compensated for lack of IDO, but the experiments could also be interpreted to mean that IDO is not an immune modulator in pregnancy. Bonney and Matzinger[134] expanded the Danger Theory to this concept, raising the question of whether or not, in the original experiments,[331] the IDO-reducing chemical simply damaged fetal cells which then emitted the danger signals associated with dead and dying cells. These signals stimulated an influx of paternal antigen-specific and antigen-nonspecific leukocytes that ultimately destroyed the placenta and fetus. In summary, while intriguing, the importance of this molecule to the immunology of pregnancy remains to be clearly established.

TNF and TNF Receptor Superfamilies

The Fas/FasL pathway was first implicated in maternal–fetal tolerance more than 15 years ago when the death-inducing ligand was found in human trophoblast cells and its receptor on decidual leukocytes.[340] It was soon posited as a mechanism to deter access of leukocytes into the decidua: matings of FasL-deficient *gld* mice, in which both fetus and mother lack functional FasL, gave small litter sizes and substantial fetal resorption accompanied by infiltration of leukocytes into the placenta.[341] Although later studies revealed a likely strain-dependency of this effect, data in human in vitro models substantiate the initial hypothesis. FasL-expressing human

primary trophoblast cells were found to kill nonspecifically activated leukocytes through ligation of cell surface Fas receptor.[342] FasL is also expressed within the decidua, and maybe co-opted for use in removal of endothelial and/or vascular smooth muscle cells during spiral artery remodeling.[343]

Initially assumed to be expressed at the cell surface, FasL is now known to be contained within vesicles in the cells and released via association with exosomes.[145,343] This is true for both interstitial trophoblast cells and syncytiotrophoblast, consistent with the idea that it can act both locally at the maternal–fetal interface, and systemically following secretion from the chorionic villi. Indeed, FasL is found in association with exosomes in maternal peripheral blood, and in mice, is required for deletion of fetal antigen-specific T lymphocytes.[345] Mechanistically, Fas/FasL may be an intermediary for several immune privilege-promoting molecules including HLA-G and hCG, as it plays at least a partial role in death induced by these molecules.[346-348] Fas receptor is on decidual CD4+ and CD8+ leukocytes, and inverse positioning of FasL-positive decidual cells and Fas receptor on leukocytes. Fetal FasL is necessary for deletion of fetal antigen-specific T cells in the mouse.[349]

There are many other members of the TNF superfamily and TNF receptor superfamily: 19 and 29 to date, respectively, and each may play a specific, equally significant role in maternal–fetal immunology. Many are transcribed and translated in the human placenta,[350,351] and can be detected as soluble factors in human pregnancy serum. Like FasL, TRAIL (TNF-related apoptosis-inducing ligand) is highly expressed by trophoblast cells, is released into maternal serum, and is toxic to leukocytes bearing its receptors.[352,353] Similarly, APRIL (a proliferation-inducing ligand), BLyS (B lymphocyte stimulator), and CD30L are present.[232] Provocatively, trophoblast cells often express receptors for TNF superfamily proteins, but have intact mechanisms for resistance to apoptosis induced by these ligands. Thus, trophic functions of these proteins in promoting trophoblast survival or function are probable and indeed confirmed for the flagbearer member of this family, TNF, in both human and mouse models (reviewed by Haider and Knofler[354]).

TNF family proteins may also play a role in modulation of antibody-mediated immunity during pregnancy. While researchers have focused mainly on the problem of how cell-mediated responses are diminished, the question of how antibody levels become elevated in pregnant women has not been thoroughly investigated. Yet this question is of great importance, as newborns need a broad spectrum of antibodies for protection from newly encountered environmental pathogens. While mothers continually generate antibodies that circulate in the blood, studies using transgenic mice have shown that production of B cells capable of producing antifetal antigen antibodies is dramatically deterred.[282] Ultimately, noncytotoxic IgG antibodies are delivered to the fetal circulation via special neonatal Fc receptors on syncytiotrophoblast,[355,356] an event paramount to passively immunizing the fetus and neonate against microbial infection.

The placenta is actively involved in promoting synthesis of immunoglobulin. Human trophoblasts produce two nonapoptosis-inducing TNF superfamily ligands, BAFF and APRIL, with the capacity to sustain B-lymphocyte viability (Figure 41.5).[232] An unfortunate consequence is that mothers with antibody-mediated autoimmune disorders may suffer more during pregnancy. These ligands are elevated in women with autoimmune diseases, and have been suggested to comprise a major underlying defect in their homeostatic mechanisms.

The superabundance of maternal antibodies might be expected to have detrimental effects, as some could be cytotoxic to the placenta and extraplacental membranes. Yet placental destruction via antibody-mediated immunity does not take place in normal pregnancies. Mammalian placentas have installed an effective protective mechanism to prevent their destruction by complement-activating cytotoxic antibodies. Human placentas display an array of complement regulatory proteins that interfere with complement deposition and consequent toxicity.[355] Mice display only one of the complement regulatory proteins, and a knockout mouse model has shown definitively that in the absence of this protein, the placenta is destroyed.[357]

IMMUNOLOGICAL ORIGINS OF PREGNANCY DISORDERS

The evidence for associations between immune disturbances and various clinical complications of pregnancy is now overwhelming. Unexplained infertility, recurrent spontaneous miscarriage, preeclampsia, and preterm delivery are all linked with altered immune parameters. One caveat with assigning an immunological origin has been to recognize the distinction between causal events and those that are a consequence of fetal loss; this is particularly difficult to dissect in human clinical conditions. Notwithstanding, the links between altered immune parameters in at-risk women and many of the perturbations shown in mice to cause infertility and pregnancy loss are compelling. In broad terms, a consistent emerging theme is that a shift away from the anti-inflammatory, pro-tolerance environment of normal pregnancy is a risk to ongoing pregnancy success. This can occur due to a range of challenges mediated by exogenous or endogenous pro-inflammatory agents, or perturbed or insufficient anti-inflammatory protective mechanisms.

It is notable that the demise of protective mechanisms linked with attenuated progesterone signaling is the natural precedent of parturition and delivery at term. This raises the prospect that the immune response of pregnancy may be linked with the timing and success of the birth process (see Chapter 42). In support of this, the percentage of $CD3^+$ decidual lymphocytes that express markers of Treg cells are significantly decreased in deciduas in spontaneous vaginal delivery compared to elective caesarean section.[267,358] This implies a potential role for Treg cells in the pro-inflammatory changes during late stages of pregnancy, and prompts speculation that their decline near parturition might be a causal factor in fetal expulsion from the maternal tissues when gestation is complete. However, the premature conversion of Treg anti-inflammatory to pro-inflammatory activity at less than 36 weeks of gestation can have important, lifelong consequences. This has prompted substantial recent efforts to understand how the immune system contributes to preterm labor and related pregnancy complications.

Placental Responses to Infection

As the fetoplacental unit grows, the chorionic villi become increasingly complex and numerous, expanding to accommodate the needs of the growing fetus. The syncytiotrophoblast constitutes the single largest physical interface between mother and fetus—estimated to be up to $12\,m^2$ at term[359]—and this large surface area is essential for many critical functions that include bidirectional transport of nutrients and waste between the mother and the fetus, production of pregnancy-specific hormones, and protection against environmental toxicants.[360] Given this enormous area and particularly the anti-inflammatory and immune suppressive environment conferred by the Treg cells and other agents of maternal tolerance, the gestational tissues in the decidua should be vulnerable to microbial colonization. Indeed it seems remarkable that infection in pregnancy is not more common.[361] Fortunately, the syncytiotrophoblast and villous cytotrophoblast cells serve as a structural and functional barrier to placental and fetal infection by systemically distributed pathogens in maternal blood. The trophoblast layers serve as a first-line of defense against fetal via expression of receptors that recognize bacterial and viral products, including TLR2, TLR3, TLR4, and TLR7/8. The proposition that trophoblast cells contribute critically to resistance to infection by acting as a component of the innate immune system was first put forth by Pollard.[362] These investigators demonstrated in mice that these cells produce chemoattractants to promote a uteroplacental immune response in response to systemic *L. monocytogenes* infection.

The human placenta also may contribute systemic and paracrine mechanisms in its resistance against microbes. Exosomes emanating from the placenta carry the placenta-specific C19MC microRNAs, mirroring the profile of both trophoblast and pregnancy serum-derived microRNAs.[363] These microRNAs have recently been discovered to confer resistance of target cells to infection by a variety of clinically important viruses.[364] This newly described function of placental exosomes may prove to be an important antimicrobial defense mechanism for both mother and fetus.

Deficiency in Treg Cells

Several studies link compromised function or diminished Treg cell populations with complications of pregnancy that originate in defective implantation or placental dysfunction.[16] In broad terms, insufficient Treg cells are likely to dispose towards increased inflammation and, potentially, development of Th1 and Th17 cell subsets (Figure 41.10). In preeclampsia, $CD4^+CD25^{high}$ T cells are significantly reduced in the peripheral blood and decidual tissue compared to women with healthy pregnancies.[365] Changes in decidual Treg cells together

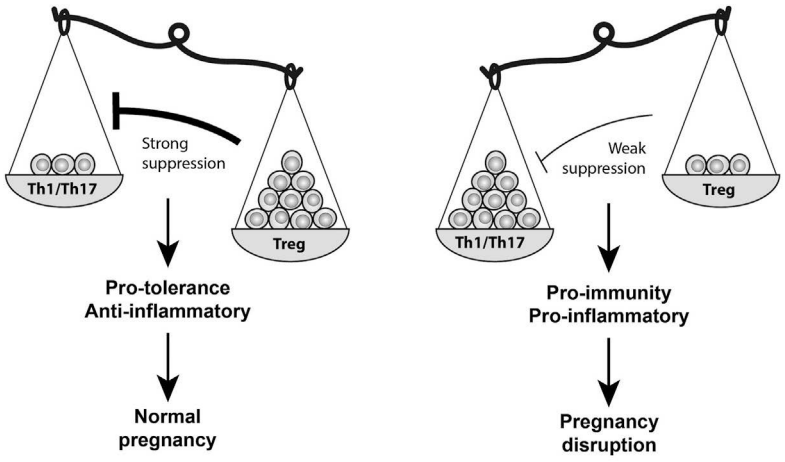

FIGURE 41.10 Treg and reproductive dysfunctions. Deficiencies in Treg cell numbers and/or suppressive function are associated with reproductive disturbances including infertility, recurrent spontaneous abortion, and preeclampsia in women. Current understanding is that adequate Treg cell numbers and function acts to suppress inflammation as well as Th1/Th17-mediated cytotoxic attack on the semi-allogeneic conceptus, but Treg cell depletion leads to insufficient suppression and increased inflammation, with Th1/Th17-mediated fetal loss.

with an elevation in the proportion of pro-inflammatory Th17 $CD4^+$ T cells are reported to be most notable in early-onset severe preeclampsia.[366] These observations are consistent with the idea that an imbalance in the reciprocal functions of regulatory and effector T cells contributes to this disease.[367] Notably, inducible Treg cells, as opposed to natural Treg cells, are diminished in preeclampsia; this may originate in reduced capacity for CD14+DC-SIGN+ antigen-presenting cells to drive Treg cell differentiation.[223]

In miscarriage, reduced immunosuppressive capability may be due to insufficient expansion of Treg cell populations, leading to numerically fewer Treg cells as well as Treg functional deficiency. Both decidual and peripheral blood $CD4^+CD25^{high}$ T cells are diminished when measured after spontaneous abortion compared to induced abortions.[368] Women experiencing repeated miscarriage have a reduced frequency of Treg cells among the peripheral blood $CD4^+$ pool as well as lower suppressive capacity when compared with fertile women.[25] There is also evidence of elevated susceptibility to IL-6 trans-signaling, which can mediate abnormal suppressive function and disposition to Th17 conversion.[369] Low levels of circulating Treg cells in early pregnancy are predictive of miscarriage risk.[370] Conversely, levels of IL-17-producing T cells in the peripheral blood and decidua are increased with signs of imminent miscarriage.[371,372]

Primary unexplained infertility is also associated with reduced endometrial expression of *FOXP3* mRNA,[373] suggesting that impaired differentiation and/or sequestration of Treg cells into the decidua even prior to conception may affect achievement of pregnancy. There is evidence that some chronic disease states that impact systemic immune function such as in asthma,[374] allergy[375] autoimmune disease,[376] and HIV infection,[377] can alter immune adaptation to pregnancy and may specifically reduce Treg cells.

Dysfunction in uNK Cells

Various studies have suggested that there are changes in the numbers, phenotype, and/or function of uNK cells in women who repeatedly miscarry or experience unexplained infertility. Analysis of leukocytes from the nonpregnant endometrium of women who have experienced three or more miscarriages showed an increase in the number of CD56dim CD16+ cells and a decrease in the normal CD56bright CD16- uNK cells.[379] It has been suggested that this shift in the balance of NK phenotypes represents a hostile environment for implantation that is inconsistent with healthy pregnancy progression. Similar findings were reported for midsecretory endometrium in infertile women prior to unsuccessful IVF cycles, compared with successful IVF cycles.[379] Altered activation phenotypes in uNK cells are also evident in decidual tissues recovered at the time of miscarriage.[23,169,380] However, whether this is a causal feature or simply a consequence of the inflammatory events leading to miscarriage, is difficult to determine.

Disturbances to HLA-G

Relationships and potential associations between HLA-G and poor reproductive capacity have been extensively investigated, with mixed results that may be dependent upon diagnostic criteria and/or technical differences in the studies. Data from women with unexplained recurrent miscarriage[381–383] relates the condition to variation in the HLA-G promoter region.[382] Yet Patel and coworkers report that HLA-G on cell membranes is not associated with idiopathic recurrent pregnancy loss.[384]

Preeclampsia has been intensively studied; this disease is marked by abnormal invasion of cytotrophoblast cells into the decidua,[385] suggesting some role for HLA-G, which appears prominent in invasive cytotrophoblast cells. Levels of HLA-G may be reduced in the invasive cells of preeclamptic women.[386,387] Recent studies focusing on HLA-G alleles[388] and isoforms,[389] or combinations thereof,[317] and associations with preeclampsia[390] are present in the scientific literature. Le Bouteiller has reviewed some of the recent observations on HLA-G and preeclampsia.[391] Little attention has been paid to intrauterine growth retardation, perhaps because there is evidence that this condition is not associated with loss of the ability of a mother to synthesize HLA-G1 and HLA-G5.[389]

In summary, specific DNA sequences, whether in the promoter or coding region, appear to control the amounts of HLA-G[392] that are produced. Reduced levels may be associated with disease, yet when the changes result mainly in reduction of specific isoforms, other isoforms may substitute and compensate, permitting pregnancy to proceed.

Although HLA-G was originally believed to be expressed only by human trophoblast cells, this is clearly not the case. HLA-G is also expressed in human macrophages[174] and expression is linked to activation of the macrophages by IFNγ. This was subsequently verified in another laboratory where HLA-G5 was identified in activated monocytes using cell ELISA spot assays.[393] There are many additional reports suggesting a role for inflammation in driving expression of HLA-G. It remains to be determined what the functions of the HLA-G molecules may be in nontrophoblastic cells, but evidence in transplant patients suggests that this molecule, which was first identified as a natural immunosuppressant in pregnancy, may exert protective effects in patients undergoing heart transplants.[394]

CONCLUSION

The last half-century of research effort to understand the immunological enigma posed by semi-allogeneic pregnancy has brought extraordinary advances and revelations. Multilayered and sophisticated strategies for allowing semi-allogeneic pregnancy have been identified and triaged into those that appear essential and others that support and strengthen a healthy coexistence. Importantly, this knowledge is providing a new prism through which to understand the origins of many disorders of pregnancy that can have devastating consequences for children and their families, as well as high societal and health care costs. It seems reasonable to expect that future lifestyle strategies and drug therapies to suppress inflammation, through enhancing tolerogenic antigen-presenting cell functions and/or boosting Treg cell numbers, will ultimately emanate from the emerging understanding of the immune response to pregnancy.

There are several important research questions still to be resolved. Key knowledge gaps are the principal pathways and determinants by which the balance of tolerogenic versus immunogenic leukocytes are activated in a healthy pregnancy, and the most common pathways by which this is disturbed in women with reproductive disorders. A picture in which several environmental and genetic determinants may converge to induce inflammatory stress and shift this balance, is emerging. It seems likely that future research will focus on how dietary factors and micronutrients, obesity, the maternal intestinal and vaginal microbiome, stress, infection, and environmental chemicals may all compromise the immune response to pregnancy through elevating inflammation. Other challenges are to define the significance of HLA antigen dissimilarity or sharing in aberrant leukocyte activation, and the role of progesterone among other molecular mediators in T-cell and NK-cell differentiation. The importance of the immune response as a sophisticated quality control system and how this relates to infertility and miscarriage incidence needs to be resolved. Critically, a solution for preeclampsia can only arise once we fully understand how NK cells, Treg cells, dendritic cells, and macrophages all interact to control placental vascular development in the early phase of placental development. Charting the sequence of events and critical factors that cause leukocytes to become activated, be recruited into gestational tissues, and initiate parturition at the end of gestation is a major challenge that promises important insight into preterm labor and options for its prevention.

Until these issues are resolved and a better understanding of the fundamental biology underlying the maternal immune response in pregnancy is available, it will be essential to remain cautious with unproven experimental interventions such as administration of anti-inflammatory and immune suppressive agents. This is particularly the case for infertility treatments where the risk-benefit analysis of experimental treatments in otherwise healthy, reproductive-aged women is ethically challenging compared to patients suffering terminal illness or a debilitating autoimmune condition.

Furthermore, immunologists have found that the natural situation of pregnancy comprises an excellent model for defining how tumors usurp immune rejection and for devising new strategies that might improve the success rate for transplantation of organs and cells. Traditional therapies have focused on the host, with administration of cytotoxic drugs to the tumor-bearing patient, and modulation of host immune responses in graft recipients. Yet pregnancy immunology has taught experimentalists and clinicians that both the host and the invading tissue cooperate to develop a protected environment. Now, therapies are being devised wherein host immune cells attacking tumors are redesigned to meet the challenge of tumor evasive strategies, and gene-modulated organ and tissue grafts are being constructed to mimic pregnancy-like host tolerance.

INTRODUCTION

Parturition—the process of birth—is fundamental to viviparity and a pivotal event in the mammalian reproductive cycle. The goal of this chapter is to synthesize current understanding of the physiology and pathophysiology of human parturition from the perspective of (1) the uterus and its functional tissue types: the myometrium, cervix, decidua, and fetal membranes; (2) the hormonal interactions that control the myometrium, cervix, decidua, and fetal membranes; (3) the physiologic interactions that trigger parturition and determine birth timing; and (4) the evolutionary biology of human parturition and the specific and unique selective pressures in the hominid lineage that influenced the extant physiology and pathophysiology of human birth.

The process of parturition is similar in all viviparous species and culminates in the forceful emptying of the uterus to safely deliver the conceptus. Historically, the central role of the hormone progesterone, as necessary to maintain pregnancy and block the onset of labor, has been recognized for more than 70 years. This "progesterone block" hypothesis, originally proposed by George Corner in the 1940s[1] and later refined by Arpad Csapo in the 1950s,[2] remains a cornerstone of parturition physiology. Subsequent in vivo studies in sheep by Liggins and colleagues in the 1960s established activation of the fetal hypothalamic–pituitary–adrenal axis as the driver of withdrawing progesterone (removing the block) and initiating parturition.[3–5] Findings in the sheep, however, proved problematic to extrapolate to human parturition, as systemic progesterone withdrawal, a fall in circulating serum progesterone, does not occur in women before the onset of labor. Similarly, advances in the use of genetically altered mice in the period from the mid-1990s to the present have delineated the pathway for parturition in this species, which again is distinct from human parturition in endocrine regulation characteristics.[6,7] With current advances in genomics and high-dimensional gene expression, protein, and metabolite profiling, greater attention has been given to studying humans and nonhuman primates.

Nonetheless, key conserved events in the parturition process are present across viviparous species. Pivotal among these are (1) transformation of the uterine smooth muscle (myometrium) from a quiescent to a highly excitable state, wherein it contracts forcefully and rhythmically to become the engine for birth; (2) remodeling of the extracellular matrix (ECM) of the cervical stroma such that the walls of the cervix distend in response to the contractions of labor to open the cervical canal and allow the conceptus to be moved into the vagina; and (3) weakening and rupture of the fetal membranes (the amnion and chorion) in response to paracrine interactions initiated by inflammation in the adjacent decidua (the endometrium of pregnancy). The synchronization of these events, referred to as active labor, occurs over a relatively short time and usually at term, which is the

Knobil and Neill's Physiology of Reproduction, Fourth Edition

optimal time for birth considering adequate fetal maturity for survival outside the uterus and maternal physical, metabolic, and behavioral constraints for birthing and sustaining the neonate. The physiology and pathophysiology of human parturition will be considered from the perspective of the key functional components (i.e., the myometrium, cervix, decidua, and fetal membranes) of the gravid uterus and how their activities are controlled and coordinated to maintain pregnancy, facilitate birth, and nurture the neonate.

The gravid uterus is controlled by hormones generally classified as uterotropins and uterotonins. Uterotropins (e.g., estrogens and progesterone) establish the phenotype of the uterus by affecting its overall growth, contractile capacity, biomechanical integrity, and inflammatory status. Uterotonins (e.g., prostaglandins (PGs), which are 20-carbon unsaturated fatty acids that exert a spectrum of signaling effects on inflammation, smooth muscle function, and cellular metabolism[8–11]; and oxytocin (OT)) are hormones that directly stimulate or repress myometrial contraction and play critical roles at parturition by inducing the contractions of labor and cervical dilation. For most of pregnancy, pro-gestation uterotropins stimulate the growth of the uterus needed to accommodate the conceptus, and promote myometrial quiescence, closure of the cervix, and inflammatory quiescence at the maternal–fetal interface between the decidua and the fetal membranes. For parturition to occur, the effects of pro-gestation uterotropins (especially progesterone) diminish and the uterus is transformed to the laboring state through the combined effects of pro-labor uterotropins (mainly estrogens and PGs) and stimulatory uterotonins, especially prostaglandin F2 alpha ($PGF_{2\alpha}$), prostaglandin E2 (PGE_2), and OT. During this process, the myometrium becomes highly contractile and excitable to produce the coordinated and forceful contractions of labor in response to $PGF_{2\alpha}$ and OT. At the same time, the ECM of the cervix remodels in response to PGE_2, causing the tissue to become thin, soft, and distensible such that it dilates in response to increased intrauterine pressure induced by each contraction. Eventually, the cervix dilates wide enough to allow passage of the conceptus into the birth canal. Biochemical changes in ECM also occur at the fetal–maternal interface, due to inflammation in the decidua, to cause weakening and rupture of the adjacent fetal membranes (the amnion and chorion). Inflammation in the myometrium, cervix, and decidua is also a major component of the parturition processes and precedes the onset of active labor. The complex interplay between specific uterotropins, uterotonins, and proinflammatory hormones in the myometrium, cervix, and decidua that induce and mediate parturition will be discussed in this chapter.

The success of pregnancy is dependent on the appropriate timing of parturition. Ideally, birth should occur at a stage in gestation when the fetus is physiologically prepared for life outside of the uterus. In addition, specific physiological and behavioral processes (e.g., lactation) of caregivers are functional to ensure neonatal survival. Through natural selection, term gestation would have adapted in response to specific selective pressures in each viviparous lineage to maximize reproductive efficiency within the context of each species' overall reproductive strategy and environmental niche. This evolutionary perspective explains the remarkable diversity in parturition timing among viviparous species. Full term for human pregnancy is at the 40th completed week of gestation (calculated from the first day of the mother's last menstrual period). At this time, the probability of the fetus and mother surviving the parturition process is at its apex, with the risk for neonatal and/or maternal morbidity and mortality increasing exponentially the further from term that birth occurs (whether preterm or postterm). It is hypothesized that the extant timing mechanism for human parturition that causes term to occur at around the 40th week evolved through natural selection acting in response to a specific set of traits unique to the hominid lineage, the most influential of which is thought to be encephalization (a large brain). The fossil record shows a clear increase in brain and head size in progressive hominid species and reflects the potent selective pressure of encephalization. Herein, we explore how the physiology of human parturition was shaped by our unique natural history.

HUMAN EVOLUTION AND BIRTH TIMING

Perhaps no greater evolutionary selective pressure exists than to optimize reproductive outcomes by enhancing both maternal and fetal survival during parturition. The solution to optimizing reproductive fitness integrates multiple factors, including maternal habitus, fetal size, litter size, uterine shape, nutrient access, and other influences specific to each viviparous species. Thus, the mechanisms that promote reproductive fitness are likely to be unique to each organism. As completely sequenced genomes for the mouse, chimpanzee, and human became available, consistent with the notion of evolutionary pressure shaping pregnancy outcomes, genes involved in reproduction were among the most divergent groups.[12,13]

For human pregnancy, relatively recent evolutionarily events have likely impacted birth timing. According to the current fossil record, hominid brain size, and therefore head size, began to increase around 1 million years ago and has remained constant for at least the last 100,000 years.[14–17] This was, in part, mediated by an increase in the rate of brain growth during

fetal development that would have caused a progressive increase in the size of the fetal head at term. The large fetal head size at term poses two potential problems for infant and maternal survival. First, the size of the fetal head could reach the limit imposed by the pelvis, and, therefore, the advantages of encephalization would have been negated by the costs of neonatal and maternal loss due to difficulties at birth (Figure 42.1). The passage of the fetal head is further compromised by a relatively narrow maternal pelvis due to constraints that otherwise facilitate bipedalism. This relationship, the "obstetrical dilemma," results in significantly less obstetric capacity, that is, space between the infant head and maternal pelvis, in humans as compared to our nearest evolutionary relative, the chimpanzee.[15] Second, the large and rapidly growing human fetal brain consumes substantial energy resources from the mother. An alternative model to the relative size of the "obstetrical dilemma" is the "metabolic crossover hypothesis"[18] or the "energetics of gestation and growth hypothesis,"[19] which posits that the inability to provide adequate energy to the developing fetus results in "starvation" signals that initiate a cascade of events that ultimately culminates in labor and delivery.

The fact that encephalization continued in hominids suggests that natural selection solved the problem of cephalo-pelvic disproportion at term. One possible solution was to select for birth-timing mechanisms that cause the fetus to be born before its head becomes larger than the pelvic outlet. Indeed, human brain size at birth is less than 30% of its final adult size, while chimpanzee brain size is 50% of adult size.[20,21] The less developed human brain at birth could reflect relative changes in the timing for brain growth during development, a relative shortening of human gestation prior to parturition, or both. Recent allometric scaling and character tracing studies analyzing the ratio of neonatal brain or body size in comparison to the length of gestation indeed suggest that human gestation has been shortened relative to that of other primates.[22] One prediction of a relatively short human gestation is that the human neonate would be less mature at birth than other primates. This prediction is clearly evident. Human infants are cognitively, sensorily, and motorically less developed than neonatal chimpanzees and other primates,[23–25] a pattern described as secondary altriciality, due to the relative immaturity in the context of a long gestation in absolute time. The extant mechanism for human birth timing, however, is not ideal, as reflected by the difficulty of human parturition due mainly to the large fetal head and the relatively high incidence of pregnancy failure due to preterm or postterm birth. As natural selection operates at the population level over multiple generations, it could be argued that the present physiology

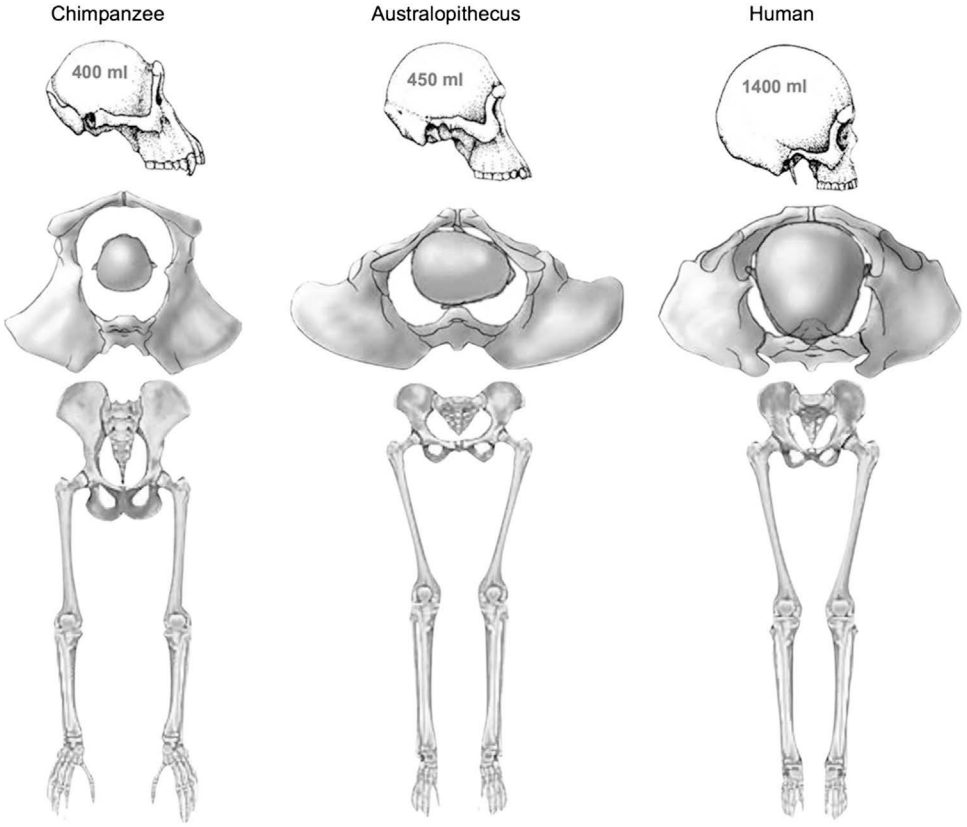

FIGURE 42.1 Changes in the cephalo-pelvic ratio through primate evolution. Relationship between the pelvic anatomy and the size of the fetal head at term in the human and chimpanzee, and an estimate of the cephalo-pelvic relationship of Australopithecus (2–4 million years ago) derived from the fossil record. *Source: Adapted from Rosenberg and Trevathan.*[15]

exists because the overall benefits of a birth-timing mechanism that favors encephalization outweigh the costs of reproductive failure (i.e., neonatal and maternal loss) due to preterm and postterm parturition. Whether preterm birth itself is uniquely human is also an area of current investigation. A potential corollary of the overall shortening of human gestation at term is that human pregnancy would be predisposed to terminate prematurely because of recent genomic changes that on average improve outcomes.[22,26] One recent study on captive chimpanzees suggests that the potential for infection-related preterm birth may have arisen prior to the human–chimpanzee evolutionary divergence,[27] but evidence of spontaneous preterm birth for chimpanzees in the wild has not been obtained. Interestingly, because of differences in pelvic shape, Neanderthal mothers did not have as severe constraints on delivery of the fetal head at term despite having the same fetal head size as anatomically modern *Homo sapiens*.[21,28] These considerations, more than of historical interest, foster new approaches for elucidating mechanisms for birth timing. Using comparative genomics across species, the signature for rapid evolution of genes specifically in the human genome can be used as a method to identify new components of the pathway leading to parturition.[22,29] Indeed, many of the established components of pregnancy maintenance and parturition, such as the progesterone receptor (PR), the estrogen receptor (ER), matrix metalloproteinase 8 (MMP8), the OT–neurophysin I precursor, and the prostaglandin E receptor 4 (PGEP4) receptor, show rapid evolution in their coding regions in humans.[22,30]

THE GRAVID UTERUS

The uterus is the principal organ of pregnancy and parturition. In the nongravid state and during most of the first trimester of pregnancy, the human uterus is a hollow, pear-shaped, muscular sack connected at its base to the upper end of the vaginal vault by the cervix, the narrow cylindrical portion of the lower uterine segment. The cervical cavity connects the uterine and vaginal cavities, and for most of pregnancy is blocked by a mucus plug that separates the sterile intrauterine environment from microorganisms in the vagina. The uterine wall consists mainly of smooth muscle cells to form the thick myometrium, which is the principal site of uterine growth during pregnancy and at parturition becomes the engine for birth. The inner lining of the uterus comprises the decidua, derived from the endometrium through the process of decidualization (discussed further in this chapter). The decidua is in close physical proximity to the chorion and amnion and is the maternal component of the physical fetal–maternal interface. It persists throughout pregnancy to form the physical barrier between the fetal chorionic tissue and the mother and is shed with the placenta and fetal membranes at birth.

The Parturition Process

Pregnancy and parturition involve specific activities by the myometrium, cervix, decidua, and fetal membranes that can be divided into four phases.[31]

Phase 0—establishment and maintenance of pregnancy: Pregnancy is established when the blastocyst implants into the endometrial stroma. During this process, the endometrium undergoes a complex morphologic transformation known as decidualization to form the specialized endometrium of pregnancy known as the decidua (see the section The Decidua and Fetal Membranes section). The decidua forms a physical and biochemical barrier between the fetal and maternal tissues that facilitates maternal immune tolerance of the allogeneic fetal graft. During Phase 0, the myometrium is maintained in a relaxed and quiescence state and grows to accommodate the enlarging conceptus. At the same time, the cervix remains rigid and unyielding, and its canal is closed by a mucus plug. The regulatory processes occurring within the decidua and myometrium required for Phase 0 are each dependent on progesterone (as discussed in this chapter).

Phase 1—preparation for labor: This phase represents the beginning of parturition and may start weeks prior to the onset of active labor. It involves changes in the gene expression in myometrial and cervical cells that, respectively, increase myometrial contractility and cause the cervix to become soft and compliant. In addition, tissue-level inflammation, indicated by increased infiltration and activation of macrophages and neutrophils and increased production of proinflammatory cytokines, occurs in the myometrium, cervix, and decidua.

Phase 2—labor and delivery: Active labor is defined as repetitive forceful uterine contraction associated with progressive dilation of the uterine cervix and rupture of the fetal membranes, and it occurs as a direct consequence of phenotypic changes in the myometrium, cervix, and decidua induced during Phase 1. In addition, the myometrium and cervix are exposed to increasing amounts of PGs, especially $PGF_{2\alpha}$, due to tissue-level inflammation, and increased OT secreted from the decidua and maternal pituitary. The combined effects of increased myometrial contractile efficiency, excitability, and uterotonin exposure and responsiveness cause the contractions of labor. In the cervix, increased exposure to PGE_2 combined with progesterone withdrawal, increased estrogen responsiveness, and tissue-level inflammation cause remodeling of the ECM that softens the cervical wall, leading to dilation

and effacement in response to the contractions of labor. Eventually, the cervix dilates enough to allow the contractions of labor to force the conceptus into the vaginal canal. Inflammation in the decidua also causes ECM remodeling in the adjacent fetal tissues that weakens the membranes, leading to rupture in response to increased intrauterine pressure.

Phase 3—hemostasis and involution: Immediately after the uterine contents are expelled, the myometrium undergoes a sustained and forceful contraction (mainly in response to OT), which helps constrict the spiral arterioles to facilitate postpartum uterine hemostasis. This contraction is critical to avoid a potentially lethal postpartum hemorrhage through the vascular lakes once occupied by the placental villi. During the first 3–6 weeks after birth, the myometrium gradually reverts to the nongravid state, and the cervix remodels and reverts to the narrow and rigid state. The decline in estrogen and progesterone levels after birth causes myometrial cells to atrophy, the vasculature of the uterus to regress, and blood flow to the uterus to be reduced. Within 3 to 5 months, cyclic activity of the endometrium reestablishes and the uterus is prepared for another pregnancy.

Thus, the physiology of human parturition centers on the hormonal mechanisms that control the growth and contractile properties of the myometrium, the biomechanical integrity of the cervix, and the immunologic and hormonal activity of the decidua.

The Myometrium

The human myometrium is composed of specialized smooth muscle cells called myometrial cells, which are arranged in randomly oriented interconnected bundles within an ECM of collagen, elastin, proteoglycans, and adhesion molecules such as laminin and fibronectin. The myometrium accounts for the majority of the uterine mass, and the remarkable growth of the uterus during pregnancy is due mainly to hyperplasia and hypertrophy of myometrial cells. Animal studies suggest that growth of the myometrium during pregnancy occurs by myometrial cell hyperplasia during the first half of pregnancy, referred to as the proliferative phase, and then myometrial cell hypertrophy and ECM remodeling during the latter half of pregnancy, referred to as the synthetic phase.[32–36] The myometrium also is highly compliant during most of pregnancy, and late in gestation is markedly distended by the conceptus. Thus, by term, the gravid uterus is endowed with a large number of hypertrophied and distended myometrial smooth muscle cells with the potential of generating the force needed to expel the conceptus.

Growth of the gravid uterus is thought to be regulated by the combined uterotropic actions of progesterone and estrogens produced by the maternal ovary or placenta, depending upon the time in gestation and the species, and locally produced growth factors such as epidermal growth factor and insulin-like growth factor I.[37,38] Growth of the myometrium can also be affected by mechanical distention. During the third trimester, the rate of fetal growth exceeds that of the uterus, leading to increased stretch of the myometrium. Animal and cell culture experiments suggest that signaling pathways activated in response to stretch cause myometrial cells to undergo hypertrophy and produce a less compliant ECM.[39,40] Increased myometrial stretch late in pregnancy is also thought to contribute to the cohort of signals that trigger labor (as discussed in this chapter).

Myometrial cells contract by converting chemical energy from the hydrolysis of adenosine triphosphate (ATP) into mechanical energy via the formation of rapidly cycling cross-bridges between actin and myosin, causing the filaments to slide over each other and shorten the cell.[41,42] The process is triggered by increased levels of intracellular free calcium (Ca^{2+}). Ca^{2+} binds with and activates calmodulin, which in turn activates the myosin light-chain kinase (MLCK) enzyme. MLCK phosphorylates the light chain of myosin, leading to activation of its ATPase activity.[41,43] The subsequent hydrolysis of ATP by myosin ATPase provides the energy for actin–myosin cross-bridges to form and slide against each other. Thus, myometrial cell contractility is controlled by events that affect the level of intracellular free Ca^{2+}. This is achieved by electrical or humoral mechanism through voltage- and ligand-gated Ca^{2+} channels, respectively. Myometrium is an excitable tissue in which contraction can be induced by an action potential in response to membrane depolarization that opens voltage-gated Ca^{2+} channels, especially the L-type Ca^{2+} channel, leading to an influx of extracellular Ca^{2+} that increases intracellular free Ca^{2+} and triggers the contractile machinery.

Quiescence of the gravid uterus is dependent on the resting membrane potential of myometrial cells, which establishes basal myometrial cell excitability. This is affected by the large-conductance Ca^{2+}-activated potassium (K^+) channel (BK), which facilitates the passive efflux of K^+ down its electrochemical gradient, leading to cell membrane hyperpolarization and decreased excitability.[44–50] The BK channel is activated (opened) by a depolarization in membrane potential and by an increase in intracellular free Ca^{2+}[51,52] and plays a major role in the relaxation phase of a typical contraction. In myometrial cells, BK channels are activated by relaxatory uterotonins.[53,54] BK subunit expression is decreased in association with the onset of labor.[55] Pharmacologic blockade of the BK channel depolarizes myometrial cells, increases intracellular free Ca^{2+} levels, and increases the frequency and amplitude of phasic contractions.[44]

Humoral control of myometrial contraction is mediated by the activation of intracellular signaling

pathways that stimulate the release of Ca^{2+} from intracellular stores through ligand-gated Ca^{2+} channels in the sarcoplasmic reticulum and on the cell membrane. Stimulatory uterotonins such as OT and $PGF_{2\alpha}$ induce contraction by first activating cognate G protein–coupled receptors linked to Gαq (the alpha subunit of heterotrimeric G protein q). Gαq activates phospholipase C (PLC), which in turn catalyzes the formations inositol 1,4,5-triphosphate (IP3) and diacylglycerol (DAG).[56–59] IP3 binds to the ligand-gated Ca^{2+} channel to induce the release of stored Ca^{2+} from the sarcoplasmic reticulum, and DAG activates protein kinase C (PKC), which augments L-type Ca^{2+} channel activity.[58–61] The net effect is a sustained increase in intracellular free Ca^{2+}.

Relaxatory uterotonins (e.g., PGI_2, beta-adrenergic receptor activators, and nitric oxide (NO)) suppress contractile activity by inhibiting Ca^{2+} mobilization and inhibiting the activity of specific kinases in the contractile apparatus.[62] These effects are mediated mainly by the cyclic adenosine monophosphate (cAMP)–protein kinase A (PKA) signaling pathway. In general, relaxatory uterotonins bind G protein–coupled receptors linked to $G\alpha_s$ (the G_s alpha subunit). $G\alpha_s$ activates membrane-bound adenylate cyclase, which catalyzes the formation of cAMP. cAMP activates PKA, which decreases intracellular Ca^{2+} mobilization by inhibiting IP3-induced release of Ca^{2+} from the sarcoplasmic reticulum, inhibiting L-type Ca^{2+} channel activity, and stimulating the sequestration of Ca^{2+} into intracellular stores. PKA also inactivates MLCK and PLC and stimulates BK channel expression. Thus, the cAMP–PKA signaling pathway exerts potent relaxatory effects on the myometrium. Myometrial cell relaxation also is induced by NO, a highly diffusible signaling molecule involved in many physiological and pathological processes.[63–67] NO activates soluble guanylate cyclase, which catalyzes the formation of cyclic guanosine monophosphate (cGMP). cGMP activates PKG, which functions in a similar way as PKA to repress intracellular free Ca^{2+} mobilization and the activity of MLCK and PLC. cGMP causes relaxation in vascular smooth muscle, but it is highly inefficient in the myometrium, and there is some controversy as to its role in maintaining uterine relaxation and mediating relaxatory actions of NO in myometrial cells.[68] NO is produced by the conversion of L-arginine into L-citrulline and NO, which is catalyzed by various isoforms of the nitric oxide synthase (NOS) enzyme. In the human uterus, NOS protein and mRNA are low and not correlated with the stage of gestation or the onset of labor, suggesting that endogenously produced NO is not a modulator of myometrial contractility in human parturition.[69]

A novel, recently described mechanism for maintenance of uterine quiescence involves progesterone-mediated induction of caspase-3 activity.[70] In the uterine myocyte, active caspase-3 degrades contractile proteins. Decreased progesterone signaling late in gestation reduces anticontractile caspase-3 actions and may promote labor. Interestingly, the myocyte, while inducing caspase-3 action, which is normally apoptosis promoting, simultaneously elevates antiapoptotic pathways to avoid myocyte cell death.[71,72]

The myometrium lacks neural connections, and an electrical pacemaker system has not been identified in the uterus. Nonetheless, actions potentials propagate between neighboring myometrial cells and myometrial cell bundles to synchronize contractions temporally and spatially across the entire uterus. Contraction synchrony is achieved by intercellular communication through specialized channels, known as gap junctions, that facilitate electrical and metabolic coupling between adjacent myometrial cells.[73] Small molecules, including ions, amino acids, and second messengers, flow between cells through gap junctions, and the development of spatially and temporally coordinated Ca^{2+} waves can also be mediated through gap junctions.[74] For most of human pregnancy, gap junctions between myometrial cells are scant, and the muscle produces only weak and uncoordinated contractile activity.[75,76] Late in gestation and in association with the parturition process, expression of gap junction alpha-1 (GJA1; also known as connexin 43) increases in human myometrium, leading to an increase in the number of gap junctions between myometrial cells, and this coincides with the development of the coordinated forceful contractions of labor.[73,76–81] In mice, ablation of GJA1 expression in the myometrium disrupts parturition and prolongs pregnancy.[82,83] Expression of genes encoding gap junction subunits and the assembly of functional gap junctions in myometrial cells is increased by estrogens and PGs and decreased by progesterone.[84,85]

Thus, myometrial contractility is controlled by processes that affect (1) intracellular free Ca^{2+} levels; (2) electrical excitability, determined by the resting membrane potential; (3) responsiveness to uterotonic hormones mediated by the level of cognate receptors and the activity of associated signaling cascades that affect Ca^{2+} mobilization and myosin ATPase activity; and (4) the extent of gap junction electrical and biochemical coupling of myometrial cells and myometrial bundles. These processes are affected by uterotonic and uterotropic hormones.

The two contractile states of the gravid uterus, quiescence and laboring, are established by the combined actions of uterotropic and uterotonic hormones (Figure 42.2). Uterotropic hormones, especially progesterone and estradiol, affect contractile capacity by modulating the expression of genes in myometrial cells that encode factors collectively referred to as contraction-associated proteins (CAPs). Some important

CAPs include receptors for uterotonic hormones (e.g., OT receptor (OTR), $PGF_{2\alpha}$ receptor (FP), and PGI_2 receptor (IP)); enzymes involved in PG biosynthesis (PG endoperoxidase type 2 (PTGS2)) and metabolism (15-hydroxyprostaglandin dehydrogenase (HPGD)); ion channels, especially the L-type Ca^{2+} channel and the BK channel; and gap junction proteins, especially GJA1.

For most of pregnancy, the myometrium is maintained in a quiescent state (i.e., Phase 0) due to the relaxatory actions of progesterone. In addition, the myometrium undergoes remarkable growth to accommodate the developing conceptus and prepare for its role as the engine for birth at the end of pregnancy. Proliferation and hypertrophy of myometrial cells during Phase 0 are thought to be induced by the combined effects of estrogens (estradiol, estrone, and estriol) and uterine wall distention imposed by the growing conceptus. Estrogens also promote expression of the type B progesterone receptor (PR-B), which mediates the relaxatory actions of progesterone.[86] Thus, for most of pregnancy, the net effects of progesterone and estrogens are myometrial quiescence and growth.

Weak and uncoordinated contractile activity, known clinically as Braxton-Hicks contractions or contractures, occur during Phase 0 and may increase in frequency and intensity near term. Contractures are not powerful enough to move the conceptus or dilate the cervix, and likely reflect basal excitability of the myometrium in response to increased distention. The switch in myometrial contractility from contractures to contractions is a hallmark of Phase 1 and is due to a phenotypic change in the contractile capacity of the myometrium in preparation for the onset of active labor (i.e., Phase 2).

In all species, the transition from Phase 0 to Phase 1 can be induced by progesterone withdrawal (as discussed in this chapter). In this regard, two functions of progesterone in the physiology of pregnancy become critical: (1) the mechanism by which it promotes myometrial uterine quiescence, and (2) the mechanism by which its withdrawal induces labor. The general consensus is that progesterone promotes myometrial relaxation by

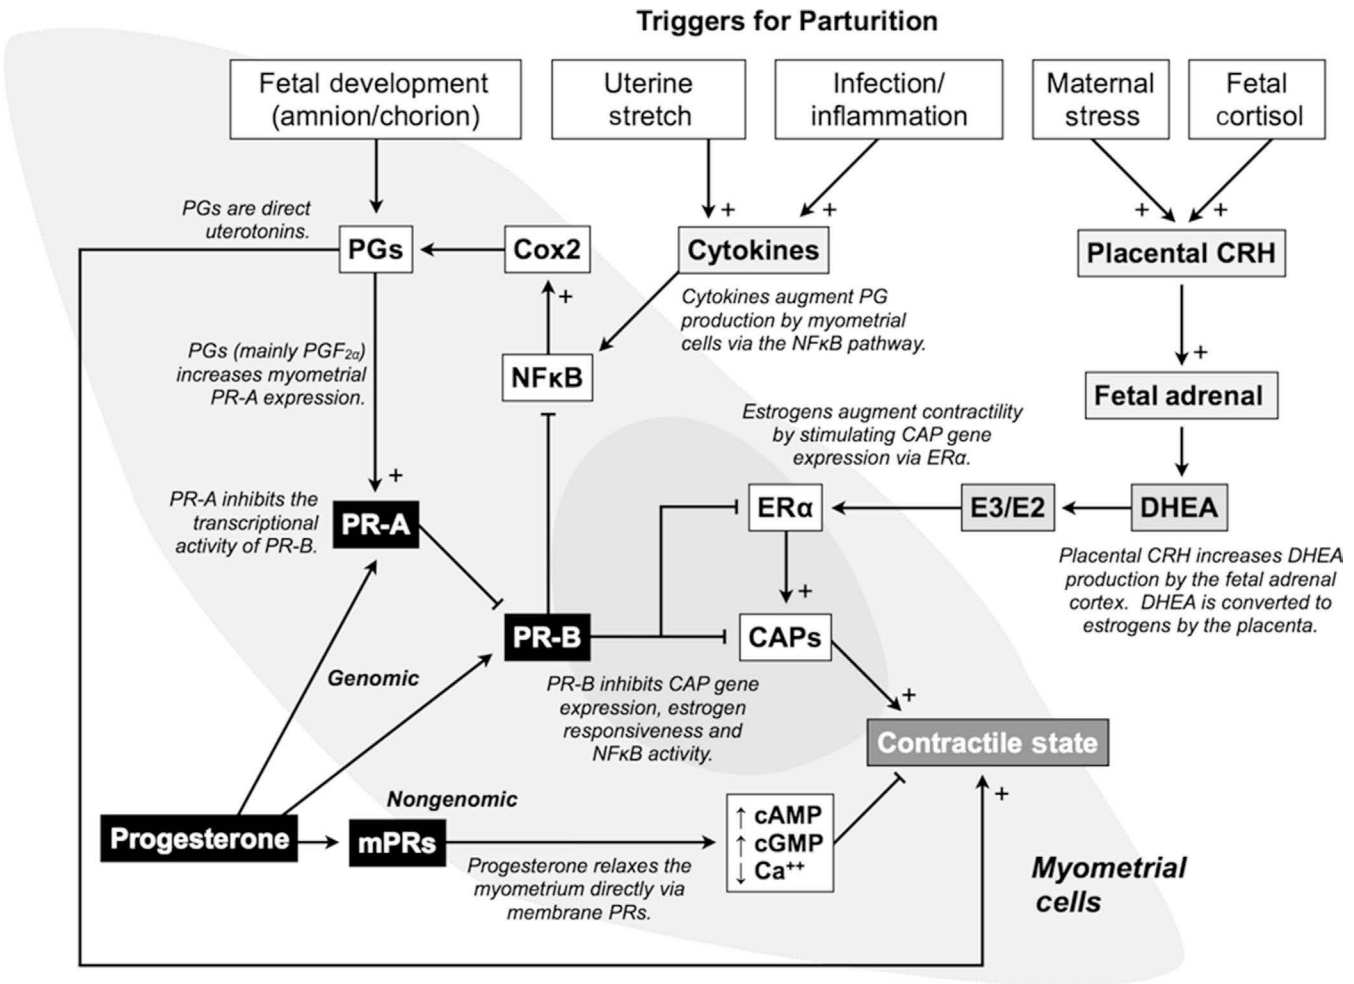

FIGURE 42.2 Hormonal pathways regulating myometrial contractility.

inhibiting the expression of genes encoding pro-labor stimulatory CAPs. It also blocks the capacity for estrogens to increase expression of stimulatory CAPs by inhibiting expression of estrogen receptor alpha (ERα). The assumption is that progesterone specifically blocks the pro-labor actions of estrogens but does not affect the pro-growth actions of estrogens. This may be because the pro-growth actions of estrogens on the pregnancy myometrium are mediated via an extranuclear mode of ERα action, whereby ERα interacts with cytoplasmic signaling molecules to initiate the mitogen-activated protein kinase (MAPK) pathways that augment cell proliferation and hypertrophy.[87] Upon progesterone withdrawal, genomic actions of ERα are activated to augment expression of stimulatory CAP genes, leading to increased myometrial excitability and contractility. Thus, the switch to Phase 1 and eventually Phase 2 is mediated by the combined and functionally linked effects of progesterone withdrawal and estrogen activation.

The phenotypic transition to the laboring state also involves increased myometrial excitability due to relative myometrial cell depolarization, increased sensitivity to uterotonins due to increased myometrial cell expression of cognate receptors (especially OTR and FP), increased local PG production due to tissue-level inflammation and increased expression of PG synthetic enzymes (especially PTGS2), and increased electrical coupling between myometrial cells due to increased gap junction formation as a result of increased GJA1 expression. Thus, the quiescent state is actively achieved by the dominant relaxatory actions of progesterone and tropic actions of estrogens, and transition to the laboring state is caused by progesterone withdrawal and estrogen activation and increased responsiveness to stimulatory uterotonins. The mechanism of action of key uterotropins and uterotonins in the parturition process is discussed further in this chapter.

The Cervix

The cervix is the cylindrical extension of the lower uterine segment that connects the uterus with the upper end of the vagina (for reviews, see Refs 88,89). It contains a central canal that links the uterine and vaginal cavities, and as such serves as the gateway between the uterus and the vagina. In the nonpregnant state, the cervical canal is narrow and open to allow menstrual discharge and entry of sperm. During most of pregnancy, the cervical canal remains narrow (i.e., competent) to contain the conceptus in the uterus, and it is closed by a mucus plug to separate the uterine and vaginal cavities. For birth to occur, the cervical ECM is remodeled, causing the tissue to become soft and distensible. This causes the central canal to widen and allow the conceptus to pass into the vagina. Contractions of labor cannot produce birth if the cervix is rigid and closed, whereas an open cervix (i.e., cervical incompetency) can lead to birth even without myometrial contractions. Thus, the cervix serves a key mechanical role during pregnancy to either contain and protect the conceptus in the uterus or allow its passage into the vagina. The biomechanical integrity of the cervix is therefore crucial for the success of pregnancy, and its control is a key part of the parturition process.

Cervical anatomy can be divided into three components: (1) the ectocervix that projects into the vagina and is lined by epithelial cells, (2) the endocervix that forms the lining of the cervical canal, and (3) stromal fibroblasts that form the body of the cervix that connects to the myometrium. The main role of the endocervical epithelial lining is to prevent vaginal microorganisms from entering the uterine cavity. The main function of the stromal fibroblasts is to produce a collage-rich ECM that confers rigidity to regulate the size of the cervical canal.[88]

During pregnancy, endocervical epithelial cells proliferate and form endocervical glands and crypts that extend and branch deep into the fibrous connective tissue of the cervical wall. By late in the third trimester, endocervical glands occupy ~50% of the entire cervical mass. The glands secrete an antibacterial mucinous substance that plugs the cervical canal. The endocervical epithelial cells also secrete defensins and mediate inflammatory responses that inhibit bacterial proliferation. At certain stages of pregnancy, the cells produce high levels of PG synthetic enzymes,[90] and they secrete cytokines and chemokines (especially interleukin 8 (IL8))[91] and protease inhibitors[92–94] that affect the integrity of the stromal ECM and therefore the mechanical properties of the cervix. During the early stages of pregnancy, the volume of cervix occupied by endocervical glands increases and is directly associated with the length of the cervical canal.[95] After midgestation, the cervical gland area begins a gradual decline that correlates with progressive cervical softening and shortening of the cervical canal.

The cylindrical wall of the cervix is composed mainly of endocervical fibroblasts and a relatively low number (10–15%) of myometrial cells.[88,89] The endocervical fibroblasts produce a dense and rigid fibrous ECM composed of type I and type III collagen in conjunction with the structural proteins, elastin and fibronectin, hyaluronate, and various proteoglycans such as versican and decorin. The unyielding ECM keeps the cervical canal narrow for most of pregnancy by resisting tensile forces generated by the myometrial contractions that exert a circumferential upward pull on the cervical wall; increased intrauterine pressure, especially late in pregnancy when the conceptus enlarges and myometrial contractions become more frequent; and the general downward force of gravity on the uterine contents. ECM rigidity is determined by the orientation and length of collagen fibers. In general,

closely parallel collagen bundles with fiber lengths of at least 20 μm augment tissue rigidity, whereas short collagen fibers in a disarrayed configuration decrease tissue rigidity. Biomechanical properties of the cervix during human pregnancy can be divided into four phases: *softening, ripening, dilation, and repair*.[96]

Cervical softening: During the first few months of human pregnancy, the cervix is rigid and unyielding. Cervical rigidity, however, progressively decreases after midgestation without losing tensile strength. This process is mediated primarily by restructuring of the fibrillar collagen architecture. The process also involves increased vascularity and edema, hypertrophy of cervical stroma, and hypertrophy and hyperplasia of the cervical glands, and is generally related to cervical growth.

Softening of the cervical ECM causes gradual thinning of the cervical wall and shortening of the cervical canal (i.e., the distance between the uterine and vaginal openings). Late in the softening phase and usually near term, the cervical canal may dilate by up to 3 cm and the cervical plug may be lost. Although cervical softening does not compromise tensile strength, the structural changes can affect the timing of parturition. Ultrasonography monitoring of the cervix during pregnancy has shown that aberrant softening that excessively shortens or deforms the cervical canal is a strong predictor of preterm birth.[97] This may cause an untimely breach of the cervical barrier to opportunistic microbial invasion from the vagina to the amniotic cavity that triggers the parturition cascade and causes preterm birth.

Animal studies have indicated that relaxin produced by the placenta, chorion, and decidua is a major regulator of cervical softening.[98] Relaxin promotes cervical softening in rats, mice, and guinea pigs.[99–102] In relaxin-deficient mice, defects in cervical remodeling during pregnancy are associated with difficult parturition.[103] In the absence of relaxin, cervical softening during pregnancy is deficient but cervical growth is not affected.[104] Progesterone and estrogen appear to modulate the actions of relaxin on the pregnancy cervix, possibly by affecting relaxin receptor levels or signaling.[105]

Another factor that may regulate cervical softening is thrombospondin 2 (TSP2). Mice deficient in TSP2 have increased cervical softening at midgestation but normal parturition at term,[106] suggesting that, at least in mice, premature cervical softening does not affect the timing of parturition. This is in contrast to clinical observation showing that shortening of the cervix at 18–22 weeks of gestation, presumably due to excessive softening, is strongly predictive of preterm birth, especially if accompanied by funneling of the membranes.[107,108]

Thus, the general consensus is that gradual cervical softening with maintained structural integrity represents an adaptation of the cervix to pregnancy, and likely is part of the cervical growth process. This process appears to be independent of parturition-associated changes in the cervix that are needed for delivery of the conceptus. Although cervical softening may not be part of the parturition process per se, it may affect the timing of parturition by affecting susceptibility to intrauterine infection. Effects of softening during pregnancy on the mechanical and biological competence of the cervix are therefore critical factors in the trajectory toward parturition.

Cervical ripening: Cervical ripening occurs late in pregnancy and involves major changes in the structure and composition of the cervical ECM leading to a loss of structural integrity and tensile strength.[109,110] The process of cervical ripening is an early event in the parturition cascade and precedes the onset of active labor by several weeks. During ripening the cervix becomes soft, thin, and easily distensible, and its load-bearing capacity decreases. The dramatic biomechanical change is caused primarily by a decrease in the concentration and organization of collagen in the ECM. Modification of the collagen architecture is mediated by an increase in hydrophilic glycosaminoglycans, especially decorin, which binds to collagen fibers and disrupts fibrillar organization,[111,112] and increased expression of hyaluronate,[113–115] which weakens the interaction of collagen with fibronectin and increases the gap between collagen fibers by attracting water into the interfibrillar space, thereby increasing cervical hydration and collagen dispersal.[89,109,114–116] Water imbibition also increases collagen solubility and susceptibility to digestion by extracellular MMPs, especially collagenase. The net effect is increased dispersal and disorganization of shortened collagen fibers. As described in this chapter, short and disarrayed collagen fibers increase tissue softness, pliability, and distensiblity.

Progesterone promotes cervical competency and prevents ripening. Various mechanisms for the effect have been identified. Progesterone inhibits collagen breakdown by increasing the expression of tissue inhibitor of metalloproteinase 2 (TIMP2) and inhibiting the expression and activity of MMPs by endocervical fibroblasts.[117–120] In addition, progesterone antagonizes estrogen-induced collagenase expression by endocervical fibroblasts.[121,122] Progesterone also inhibits hyaluronate synthesis in human endocervical fibroblasts by inhibiting expression of the hyaluronan synthase 2 gene.[123,124] A decrease in hyaluronate would prevent water imbibition and collagen dissolution and therefore maintain ECM rigidity. Consistent with progesterone withdrawal at parturition, hyaluronate levels in the cervix increase prior to the onset of parturition,[125] possibly due to the combined effects of progesterone withdrawal and stimulation by estrogens and PGs. In all species studied so far, treatment with PR antagonists at any stage of pregnancy promotes cervical ripening.[126–130] Sensitivity

of the cervix to RU486 (mifepristone)-induced ripening increases as pregnancy nears term, suggesting that the capacity for progesterone to maintain cervical competence decreases as pregnancy progresses.[131]

Cervical ripening is an inflammatory process that involves infiltration of activated myeloid cells into the cervical stroma.[132–135] Induction of tissue-level inflammation in the cervix is thought to initiate a positive-feedback cycle that augments the inflammatory state, leading to increased accumulation of ECM degradative activity. Progesterone is thought to counteract that process by inhibiting the responsiveness of endocervical fibroblasts to proinflammatory cytokines.[136]

PGs are important regulators of parturition (as discussed in this chapter) and play a pivotal role in cervical ripening. Clinical ripening of the cervix leading to the induction of labor is routinely performed by treatment with PGE_2 or synthetic analogs (e.g., misoprostol) administered locally (intracervically or vaginally) or intravenously (IV).[137–141] Based on ECM composition, PGE_2-induced ripening is indistinguishable from spontaneous ripening and is effective at all stages of pregnancy.[142] PGE_2 ripens the cervix, at least in part by modulating glycosaminoglycan expression by endocervical fibroblasts via its interaction with the type 4 PGE2 receptor.[143,144]

Estrogenic actions in the cervix are also thought to promote ripening by augmenting collagenase expression in endocervical cells.[121,122] Estrogens also increase mucus secretion by endocervical epithelial cells and promote the formation of endocervical glands and cervical growth.[145] These pro-gestational actions are likely due to the modulation of estrogenic actions on the cervix by progesterone. Upon progesterone withdrawal, however, estrogenic effects on the cervix promote ripening via increased collagenase expression.

Cervical dilation: Cervical dilation occurs at the time of active labor and involves dramatic thinning (effacement) of the cervical wall such that it virtually dissolves into the lower uterine segment. At this stage, the cervical resistance to tensile force collapses, and in response to the contractions of labor and pressure from the presenting fetal part (usually the head), the cervix dilates to open the central canal and allow passage of the conceptus into the vagina.

Dilation is associated with increased expression and tissue-level activity of MMPs, especially collagenase. Dilation also involves a massive influx of leukocytes into the cervical stroma, and these inflammatory cells are a major source of collagenase.[146] Immune cell infiltration is promoted by the potent chemokine IL8, whose levels increase dramatically in the cervix of women during labor and after delivery.[147] Cervical dilation also involves increased production of hyaluronate in response to progesterone withdrawal. Hyaluronate softens the cervical ECM and augments tissue-level inflammation.[123,125]

Cervical repair: Repair and recovery of the cervix back to the competent state occur in the immediate postpartum period. This process involves the inhibition of proinflammatory pathways, cessation of collagen dissolution, and promotion of collagen synthesis and reestablishment of the collagen architecture to confer rigidity. Relief of mechanical stretch also may contribute to inhibiting proinflammatory signaling pathways. The hormonal control of cervical repair and recovery is not clearly understood, but it is likely to involve local paracrine interactions that inhibit inflammatory pathways and the re-establishment of cycling estrogenic and progesterone effects on cervical growth.

The Decidua and Fetal Membranes

The fetal membranes, composed of the amnion and chorion, together with adjacent decidua of maternal origin, provide a dynamic site for regulation of both myometrial activity and fetal maturation. Essential functions for these tissues include paracrine signaling between the mother and fetus to initially limit the potential for the onset of the characteristic changes associated with the onset of labor before term, a barrier function to retain amniotic fluid and prevent invasion of the fetal compartment with circulating biochemical signals and potential microbial pathogens, and, finally, the key to the parturition process, controlled membrane rupture to promote efficient expulsion of the fetus and placenta.[148,149]

The structure of the fetal membranes at term arises as the result of sequential morphological events that begin at implantation. Embryo implantation occurs as the blastocyst transverses a disrupted endometrial cell surface, such that the blastocyst occupies an interstitial location in the uterus.[150] The endometrium that comes to surround the implanted blastocyst forms the early decidua. The decidua is initially regionalized as the decidua basalis, between the blastocyst and the myometrium, and the decidua capsularis, filling the overlying area through which the blastocyst penetrated the uterine wall.[151] The endometrial lining on the uterine surface opposite the implantation site is designated the decidua vera. In human pregnancy, the expansion of the conceptus leads to fusion of the amnion and chorion with the decidua vera, and the decidua capsularis degenerates.[150] The cytotrophoblast cells of the chorion directly contact the maternal decidual cells (Figure 42.3). While initially filling only a portion of the chorionic cavity, the amnion expands to enclose the developing embryo and physically oppose the chorion by the 12th week of human gestation. The chorion and amnion, while opposed to one another through pregnancy, remain separable layers that allow distinct patterns of disruption during membrane rupture, as is described in greater detail in the discussion on membrane rupture in this section.[152] Interestingly, the

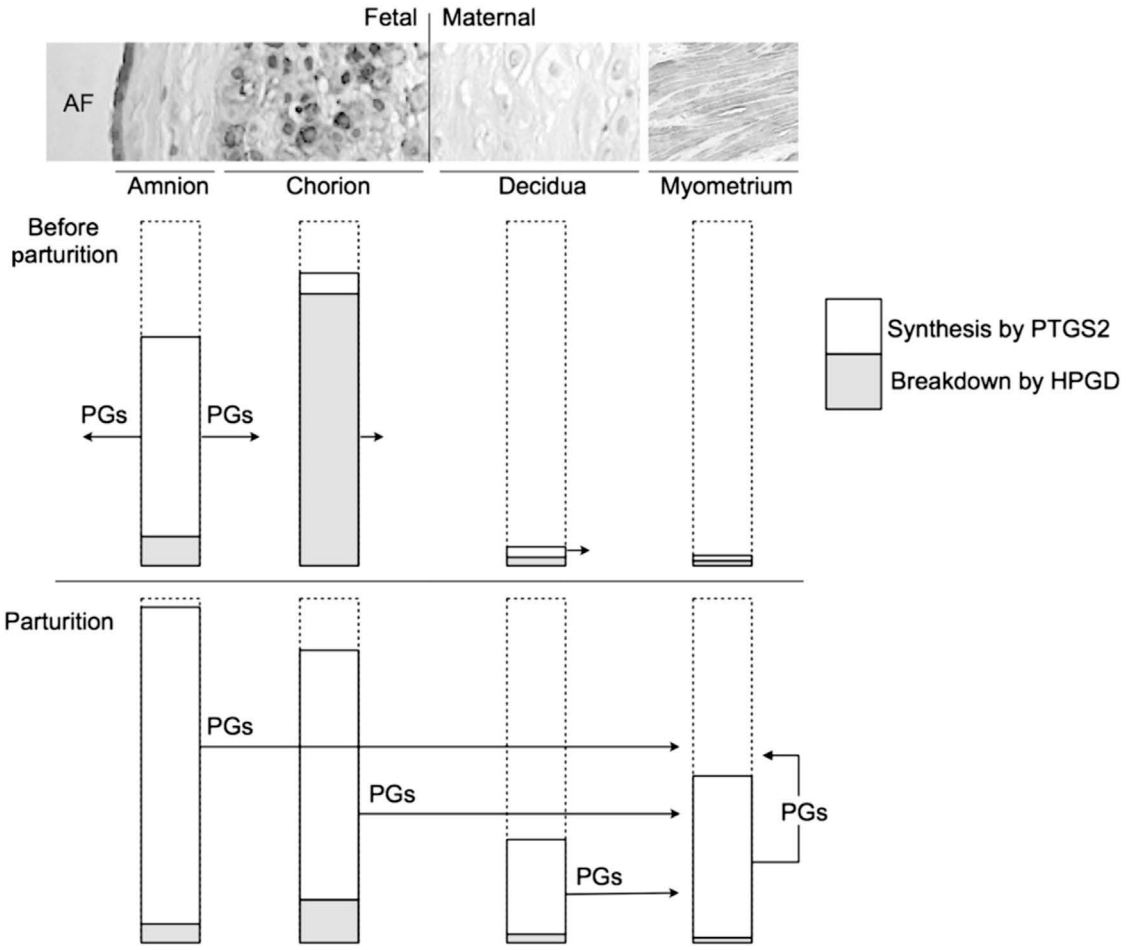

FIGURE 42.3 Changes in PG–endoperoxide synthase 2 (PTGS2) and hydroxyprostaglandin dehydrogenase (HPGD) activities in the gestational tissues (amnion, chorion, decidua, and myometrium) associated with the onset of human labor. Parturition is associated with increased PTGS2 activity in all tissues. HPGD is predominantly expressed by the chorion and effectively blocks amnion PGs from accessing the myometrium. Parturition is associated with decreased HPGD activity in the chorion that could allow more active PG to reach the myometrium. PGs are also produced by the myometrium at parturition and likely have autocrine and paracrine effects on contractility.

human fetal membranes are not vascularized. This lack of vascularity limits the ability of the fetal membranes to transfer nutrients between the mother and the fetus.

Paracrine signaling and biochemical functions of the fetal membranes: Through an extensive series of human, nonhuman primate, and other mammalian studies, the critical roles for the amnion and chorion in generating the biochemical signals that restrain or accelerate parturition, and promote fetal organ maturation, have emerged.[148] These critical biochemical pathways center on PG and glucocorticoid biosynthesis and degradation.

Prostaglandin metabolism: The amnion and chorion both contain the enzymatic machinery for PG biosynthesis.[153–155] In contrast, degradation of bioactive PGs to inactive metabolites is restricted to the cytotrophoblasts of the chorion.[156–158] This anatomical localization of the primary PG-degrading enzyme 15-hydroxyprostaglandin dehydrogenase (HPGD) provides an effective barrier to the passage of PGs (especially PGE_2 and $PGF_{2\alpha}$) that promote myometrial contraction and cervical ripening from the membranes to the uterus prior to term.[159]

PG biosynthesis in the fetal membranes occurs most robustly in the amnion and, to a lesser extent, in the chorion. The primary cell type within the amnion generating PGE_2 is the fibroblast.[160] Amnion-derived PGE_2 occurs largely through the initial step of type IV $cPLA_2$ releasing arachidonic acid from membrane phospholipids.[161] Arachidonic acid serves as the substrate for PG–endoperoxide synthases 1 (PTGS1, aka cyclooxygenase 1, or COX1) and PTGS2 (aka COX2) to generate PGH_2 (Figure 42.4), as described in the "Prostaglandins" section of this chapter. PGH_2 is an unstable intermediate that undergoes conversion to mature prostaglandin types (e.g., PGE_2, $PGF_{2\alpha}$, thromboxane, and prostacyclin) by specific synthases, and is capable of acting on their cognate G protein–coupled receptors.[162] With term and preterm labor in humans, the production of PGs by the

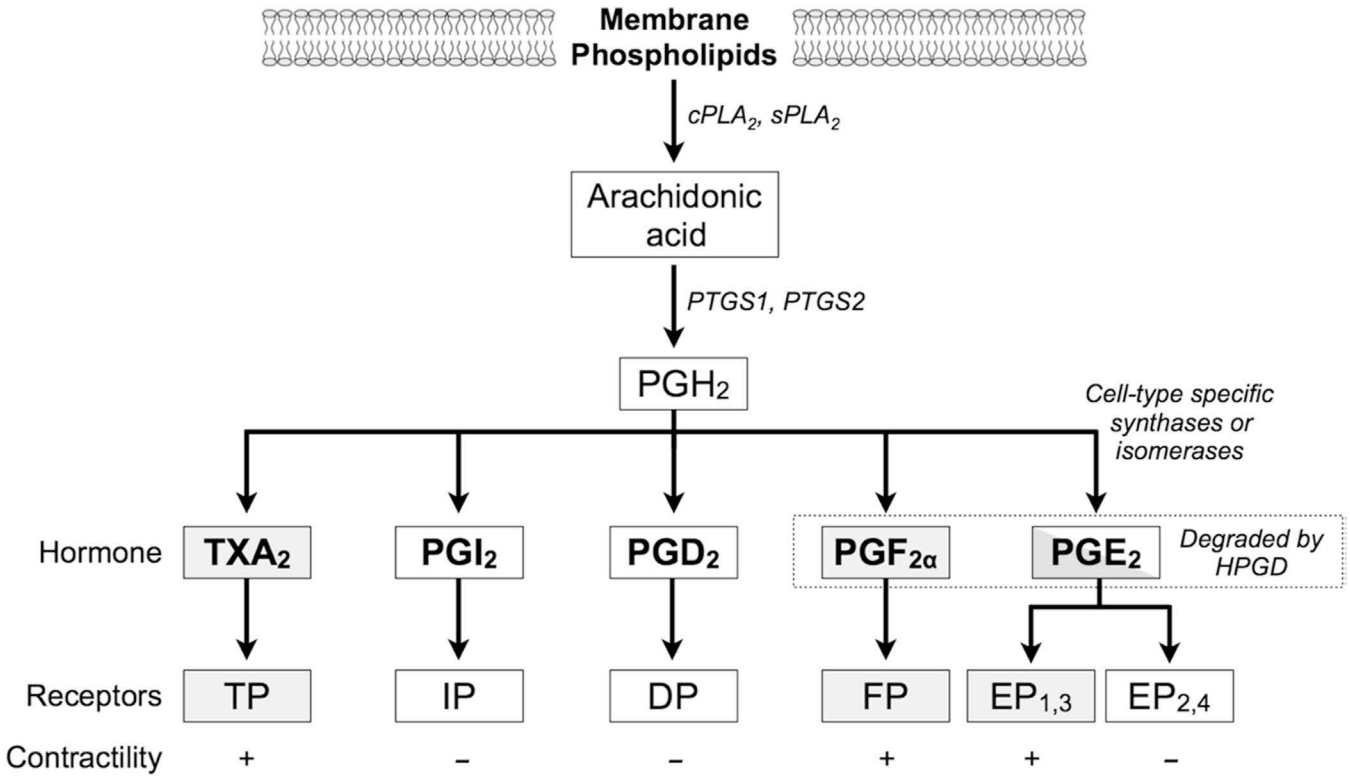

FIGURE 42.4 Synthesis of biologically active PGs from membrane phospholipids, the key enzymes involved, the receptors with which they interact, and their effects on myometrial contractility.

amnion is significantly increased.[163,164] The primary PG produced is PGE_2, which is capable of both stimulating uterine contractions, via EP1 and EP3 receptors (prostaglandin E receptor 1, subtypes EP1 and EP3) on myometrial cells, and cervical ripening.[165,166] This induction of PGE_2 is associated with enhanced expression of PTGS2 in the amnion.[160,167] PTGS2 co-localizes in expression with microsomal PGE synthase 1, which is inducible by cytokines or endotoxin,[168] and also couples its activity with microsomal PGE synthase 2, which is constitutively expressed in the Golgi apparatus.[169,170] Interestingly, glucocorticoids, which are increased in production in both maternal and fetal compartments at term or during stress throughout gestation, lead to the induction of PTGS2 and PGE_2 synthesis from primary amnion cells, in marked contrast to the usual antiinflammatory actions of glucocorticoids through the type II glucocorticoid receptor (NR3C1).[171,172] As the fetal membranes also have the ability to regenerate cortisol, a positive-feedback network accelerating contraction-promoting PGs has been proposed.[173,174]

PG degradation largely occurs through the action of HPGD for those types most highly implicated in the onset of labor, PGE_2 and $PGF_{2\alpha}$. Prostacyclin, thromboxane A_2, and prostaglandin D_2 (PGD_2), in contrast, undergo spontaneous degradation with a very short half-life.[175] Several stimuli modulate HPGD expression and activity in a manner consistent with its postulated role in restraining the onset of labor. Prior to term, progesterone promotes HPGD activity.[176] At term, HPGD activity normally decreases.[177] Cortisol, which increases at term, inhibits HPGD activity in vitro and may contribute to this decline.[178–180] In contrast, corticotropin-releasing hormone (CRH), which also increases as term approaches, stimulates HPGD activity in chorionic trophoblasts.[181] In women with chorioamnionitis and infection-associated preterm labor, the number of HPGD-expressing chorionic trophoblasts was found to be reduced, suggesting increased potential for passage of labor-augmenting PGE_2 to the myometrium.[157]

Glucocorticoid metabolism: Glucocorticoids, derived from the maternal and (later in gestation) fetal adrenals, play critical roles in accelerating fetal organ maturation (skin, gastrointestinal tract, and lung, among others) necessary for ex utero survival.[182–185] The primary glucocorticoids affecting development are cortisol in humans and other species with 17α-hydroxylase activity in the adrenal zona fasciculata, and corticosterone in those species lacking 17α-hydroxylase activity in the adrenal (e.g., rodents). In most species, maternal and fetal serum glucocorticoid concentrations increase as gestation progresses[186–188]; for sheep, this glucocorticoid rise is the trigger to initiate parturition by virtue of its actions in promoting estradiol synthesis from progesterone in the

placenta.[3,4] Conversely, glucocorticoids, when present in excess, exhibit teratogenic effects, including apoptosis in the fetal brain.[189–191] As a consequence, complex mechanisms have evolved to control glucocorticoid access to the fetal compartment.

The primary glucocorticoid-metabolizing enzyme for most of gestation in the fetus and placenta is 11β-hydroxysteroid dehydrogenase type 2 (11βHSD2).[192,193] This NAD-dependent oxidase converts cortisol to the inactive metabolite cortisone, or corticosterone to its inactive metabolite, dehydrocorticosterone. The conversion to inactive metabolites limits the potential teratogenic actions of glucocorticoids on fetal tissues and other effects that accelerate labor, such as fetal membrane PG production. As a consequence of the high 11βHSD2 activity, human placenta and fetal blood display high concentrations of cortisone.[194,195] Even in the context of the robust 11βHSD2 activity, the cortisol–cortisone ratio in the amniotic fluid increases through gestation and is higher than that measured in cord blood.[196,197] This finding suggested that the fetal membranes could themselves be a site for cortisol synthesis. Indeed, studies have demonstrated that human amnion develops enhanced capacity to regenerate cortisol from cortisone as gestation progresses, potentially accounting for the elevated cortisol–cortisone ratio in amniotic fluid.[197,198] The regeneration of cortisol from cortisone is achieved through the activity of 11βHSD1, a nicotinamide adenine dinucleotide phosphate oxidase–dependent oxoreductase.[193,199] Expression of 11βHSD1 has been demonstrated in the amnion epithelium, fibroblasts, and chorionic trophoblasts, along with decidual stromal cells adherent to the chorion.[173,174] The expression of 11βHSD1 and its activity have been shown to increase through gestation. In contrast, little or no 11βHSD2 activity or mRNA expression has been detected in the amnion and chorion.[174]

Interactions of PG and glucocorticoid pathways to initiate labor: The predominant action of glucocorticoids on proinflammatory cytokines and PGs under nongravid conditions is to suppress their synthesis and downstream signaling through the inhibition of transcription factors such as NFκB (nuclear factor kappa light-chain enhancer of activated B cells), activating protein 1 (AP1), signal transducers and activators of transcription (STATs), and MAPKs.[200,201] Glucocorticoid action on the fetal membranes during gestation markedly diverges from this typical paradigm. In human fetal membrane primary cell cultures, glucocorticoids stimulate, rather than inhibit, PGE_2 synthesis.[160,202] This stimulatory effect is mediated by dose-dependent actions on amnion fibroblasts, which possess cytosolic phospholipases A2 ($cPLA_2$), PTGS2, and PGE synthases. As fetal membranes lack expression of PR-B but express PR-A, which is modulated by glucocorticoids, this paradoxical activity could occur either through the classical glucocorticoid receptor (GR) or through transdominant repression of glucocorticoid receptors by PR-A, as it is attenuated in the presence of the GR–PR antagonist RU486.[160,203] GR upregulates $cPLA_2$ by direct binding to its promoter region in amnion fibroblasts, providing one mechanism for the enhanced PGE_2 synthesis.[204]

The rise in glucocorticoids that occurs in virtually all species late in gestation serves to enhance preparation of the fetus for survival by promoting organ maturation and stimulating PG production, which augments myometrial contractile activity and cervical ripening. This process may be prematurely activated with infection of the amnion and chorion, chorioamnionitis. Cytokines such as IL1β and tumor necrosis factor alpha (TNFα), released after pathogen detection through Toll-like receptors (TLRs) on macrophages, directly stimulate PG synthesis in the fetal membranes and also induce 11βHSD1 in the membranes by activating its transcription.[173,205,206] This induction of 11βHSD1 would serve to regenerate more cortisol, activate membrane PTGS2 and $cPLA_2$, and further enhance production of the myometrial contractile agonist PGE_2, accelerating labor.

Decidual activation and membrane rupture: In humans, the initiation of forceful, synchronous uterine contractions together with rupture of the fetal membranes comprise the critical mechanical components of parturition. These two aspects of delivery of the fetus appear to be controlled separately.[207] For the majority of women who give birth at term, uterine contractions are the initial manifestation, followed by spontaneous rupture of the fetal membranes.[208,209] This sequence is not invariable, as for 10% or more of women, fetal membrane rupture without contractions is the initial symptom of parturition. In the context of preterm birth, approximately one-third of women will experience preterm premature rupture of membranes (PPROM) without uterine contractions as their presenting complaint.[208,209] As the mechanisms initiating human parturition at term or preterm remain unclear, whether PPROM and spontaneous labor with contractions reflect distinct pathophysiologies or variations of the same underlying pathophysiology continues to be controversial.[210]

Through many recent investigations in animal model systems and humans, evidence for both biomechanical and biochemical influences that promote membrane rupture have emerged. Early studies found that membrane deformation and thinning due to uterine contractions during labor lead to their weakening.[211,212] These contractions result in membrane deformation such that the original starting condition is not obtained. In addition, prelabor, Braxton-Hicks contractions increase intrauterine pressure approximately 10 mm Hg and enhance biochemical-mediated weakening by both direct biophysical actions and the capacity of stretch

forces in the membranes to activate the transcription of remodeling genes, which will be discussed further in the "The Hormonal Regulation of Parturition" section.[213–215]

The biochemical mechanisms that contribute to membrane rupture include both matrix remodeling and cellular apoptosis.[149] The chief source of tensile strength in the amnion is collagen I, found in the compact layer and mesoderm, and collagen IV, found in the basement membrane and the connections between the amnion epithelium and the mesenchyme.[216,217] Degradation of collagen is critical to the progression of membrane rupture, and it is controlled by the expression of matrix MMPs and their inhibitors, TIMPs.[216] A number of MMPs have been found in the amnion and chorion, each with different specificity for collagen degradation; these include MMP1, MMP2, MMP3, MMP8, and MMP9.[218–220] MMP1 is the major isoform prior to the onset of labor[219] and may be induced by IL1β.[221] MMP2 is not altered in expression in association with impending membrane rupture at term or preterm.[218,220] MMP9, however, increases in amniotic fluid with PPROM, and is responsive to PGE_2, $PGF_{2\alpha}$, and TNFα.[222,223] MMP9 activity may serve as a reliable marker for impending membrane rupture.[224,225] Conversely, the inhibitor TIMP1, a key regulator of MMP9 activity, decreases with PPROM and labor.[218] As a consequence of the enhanced MMP activity, collagen fibers have been shown to be decreased at term, along with general disruption of their architecture.[224–226]

Extracellular matrix degradation due to MMP activity not only directly disrupts biomechanical integrity of the membranes but also leads to cellular apoptosis.[216] One mechanism involves the release of membrane-bound cytokines such as TNFα and Fas ligand, which further serves to enhance the production of MMPs and provides a positive-feedback loop for membrane rupture.[227,228] In humans, several polymorphisms in TNFα, IL1β, MMP1, MMP8, MMP9, and SerpinH1 (heat shock protein 47) have been associated with patients with PPROM that likely contribute to individual risk for preterm birth through accelerating this positive-feedback pathway.[229–234] In animal models, increased apoptosis of the amnion epithelium, along with other compartments, follows the induction of MMP transcription and activity.[235–237] In the rat, this matrix reorganization and apoptosis occur in a widespread fashion throughout the fetal membranes. In humans, this general pattern throughout the membranes has not been observed, but rather a focal area of morphological change, both during active labor and in women undergoing Cesarean section delivery without labor, in the fetal membrane region adjacent to the cervix.[238–240]

With the advent of technologies to carefully and systematically measure membrane biophysical characteristics, the sequence of events leading to rupture has become clearer.[149] In vivo, the lower pole of the fetal membranes separates from the decidua of the lower uterine segment and is associated with the release of fetal fibronectin, normally present at the site of chorionic-decidual contact.[224,239–241] Fetal fibronectin serves as a robust biomarker for both term and preterm parturition.[242–244] Controlled observation of membrane rupture ex vivo, after distention of membranes, revealed that the amnion initially separates from the choriodecidua.[241] The amnion and choriodecidua then rupture separately, with the choriodecidua, being the weaker component, rupturing first. The amnion then ruptures after further nonelastic deformation. Even prior to the onset of contractions, the weak zone overlying the cervix, exhibiting increased expression of MMP-9 and apoptosis, can be demonstrated and may serve as the target for membrane disruption as it has been found adjacent to the tear line after spontaneous membrane rupture.[239,245,246]

THE HORMONAL REGULATION OF PARTURITION

The process of parturition is initiated and controlled by a complex set of hormonal interactions that impact the myometrium, cervix, decidua, and fetal membranes to induce and coordinate the events described here. A common characteristic of the hormonal axes that affect parturition is the development of positive-feedback loops locally within the gestational tissues that produce tissue-level inflammation, and a neuroendocrine interaction that augments OT secretion by the maternal pituitary. A general principal in biological control systems is that self-amplifying loops usually lead to a terminal event that breaks the positive-feedback interaction and restores homeostasis. In this case, the terminal event is emptying of the uterus.

Function of the gravid uterus is controlled by the net effect of hormones that promote relaxation and quiescence and those that promote labor. For most of pregnancy, the balance is in favor of hormones promoting relaxation and quiescence. Parturition is triggered by a switch in the balance toward pro-labor hormones. In this context, the hormonal control of parturition is dominated by the steroid hormones progesterone and estrogen; the potent stimulatory uterotonins $PGF_{2\alpha}$, PGE_2, and OT; peptide hormones that are produced by the placenta and modulate responsiveness to uterotropins and uterotonins; and cytokines and chemokines produced as part of tissue-level inflammation in the myometrium, cervix, and decidua. In addition, biomechanical signals in response to uterine distention may contribute to pro-labor signals. Each of these factors contributes to the development of positive-feedback hormonal interactions within the gestational tissues, between the fetus and the mother, and between the uterus and the maternal pituitary that ultimately lead to labor and delivery.

Progesterone

In all viviparous species studied so far, progesterone is essential for the establishment and maintenance of pregnancy, and its withdrawal is a key trigger for parturition. The "progesterone block" hypothesis, proposed by Arpad Csapo in the 1950s,[2] posits that progesterone maintains pregnancy by blocking labor (i.e., it promotes myometrial relaxation, cervical closure, and decidual quiescence), and that parturition initiates when the block is withdrawn. Studies in multiple species, including humans, support this hypothesis and show that progesterone withdrawal is the central trigger event in the hormonal control of parturition.[247,248]

Progesterone needed to establish and maintain human pregnancy is initially provided by the maternal corpus luteum (CL), whose life span is prolonged by chorionic gonadotropin secreted by trophoblast cells of the blastocyst (luteolysis usually occurs at the end of the luteal phase of a nonfertile cycle). Progesterone also is produced by the developing villous syncytiotrophoblast, which by the 10th to 12th week of gestation increases in mass and produces enough progesterone to obviate the need for the CL. After this stage of pregnancy, referred to as the luteal–placental shift, the maternal ovaries can be removed without affecting the pregnancy. In contrast, removal of the ovaries prior to the luteal–placental shift causes miscarriage, which can be avoided by progesterone replacement therapy.[249,250] Production of progesterone by the villous syncytiotrophoblast of the placenta continues for the remainder of human pregnancy.

In most species (e.g., sheep, goat, rat, and mouse), parturition is triggered by a fall in maternal progesterone levels, referred to as systemic progesterone withdrawal, due to luteolysis in species that rely on the CL for progesterone, or modulation of placenta steroidogenesis in species in which the placenta is the source of progesterone. In humans and other species (including higher primates, guinea pig, and armadillo), placental progesterone production persists during parturition and decreases only when the placenta is delivered. In these species, the uterus transitions to the laboring state, even though it is exposed to high levels of progesterone.[251] Nonetheless, treatment with antiprogestins induces labor at all stages of pregnancy, consistent with the concept that withdrawal of the progesterone block triggers parturition.[252] To resolve this apparent paradox, it is proposed that parturition in humans and other species that lack a systemic progesterone withdrawal is triggered by a functional progesterone withdrawal whereby target cells in the myometrium, cervix, and decidua desensitize to the pro-gestational (i.e., labor-blocking) actions of progesterone. Thus, diversity in parturition control between species is due mainly to differences in (1) the source of progesterone (placenta or maternal CL) to maintain pregnancy, (2) the mechanism for progesterone withdrawal (systemic or functional), and (3) the upstream hormonal interactions that induce progesterone withdrawal.

The extent to which fetal and maternal hormones affect the parturition trigger mechanism differs markedly among viviparous species. In mice, luteolysis at parturition is induced by increased PG production by the maternal decidua. In this species, maternal signals, likely operated by a clock mechanism, determine the timing of birth. In contrast, parturition in sheep is triggered by the fetus (Figure 42.5). In this species, parturition is induced by a surge in cortisol production by the fetal hypothalamus–pituitary–adrenal (HPA) axis 1–2 weeks before term,[253] which alters placental steroidogenesis and leads to a dramatic decrease in placental progesterone secretion[254] and a concomitant increase in placental estrogen production by inducing activity of P450c17 (CYP17A1). The fall in circulating progesterone levels (i.e., systemic progesterone withdrawal), coupled with a rise in circulating estrogens, transforms the uterus and cervix to the laboring state. As cortisol is the principal stimulator of fetal organ system maturation, the prepartum fetal cortisol surge ensures that parturition is coordinated with fetal maturation. Although cortisol also stimulates the maturation of organ systems in the human fetus, it does not affect the parturition process. Administration of glucocorticoid to women in threatened preterm birth situations does not advance the parturition process, and parturition occurs normally at term in pregnancies where the fetus cannot produce cortisol.[255,256]

Progesterone promotes human pregnancy via its interaction with nuclear PRs in myometrial, cervical, and decidual cells. The importance of PR-mediated signaling for the maintenance of human pregnancy is reflected by the fact that administration of PR antagonists at any stage of pregnancy induces labor and rapid remodeling of the cervical ECM and loss of tensile strength.[257–261] This suggests that the progesterone block to parturition operates, at least in part, through progesterone- and PR-mediated mechanisms, and that inhibition or disruption of PR activity is sufficient to induce the full parturition cascade.

The human PRs exist as two major isoforms, PR-A (83 kD) and PR-B (99 kD). PR-A is a truncated (by 165 N-terminal amino acids) form of PR-B (Figure 42.6). Other PR transcripts generated by alternate translational start sites, exon splicing, intronic insertions, and exon deletions have also been described, but their levels of expression in most tissues, including the gestational tissues, are low, and their physiological significance is uncertain.[262]

PR-A and PR-B function primarily as ligand-activated nuclear transcription factors and affect target cell phenotypes primarily by modulating gene expression.[263] This genomic mode of action suggests that in

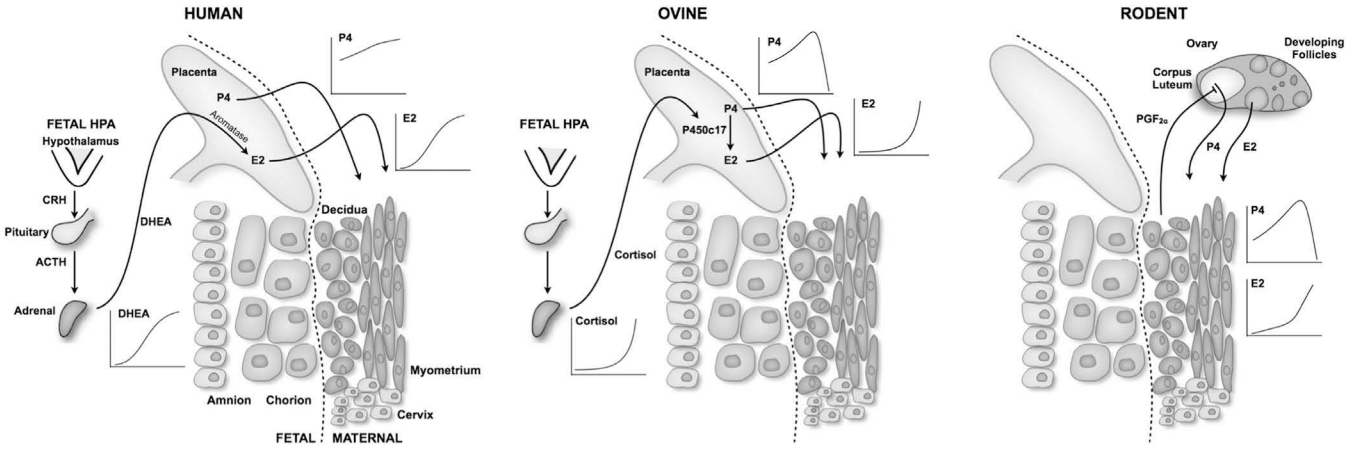

FIGURE 42.5 Comparison of tissue synthesis and changes in circulating progesterone (P4) and estradiol (E2) in human, ovine, and rodent pregnancy. In the human, the placenta produces progesterone throughout pregnancy, and there is no systemic decrease in P4 at parturition. In addition, the placenta produces estrogens (E2 (shown), estriol, estrone, and estetrol) from dehydroepiandrosterone (DHEA) supplied by the fetal adrenal cortex. In ovine pregnancy, the placenta is the principal source of P4. Late in gestation, activation of the fetal hypothalamic–pituitary–adrenal axis leads to a surge in cortisol that induces expression of P450c17 in the placenta, which converts P4 to androstenedione that can be used for estrogen synthesis. This causes a decrease in circulating P4 levels and a coordinated increase in circulating E2 levels. In rodent pregnancy, the maternal ovaries are the exclusive source of P4 (secreted by CLs) and E2 (secreted by developing follicles). At parturition, $PGF_{2\alpha}$ produced by the decidua induces luteolysis, leading to systemic P4 withdrawal, and E2 levels increase in response to further ovarian follicle development, which is in response to increased gonadotropin exposure due to removal of P4 negative feedback to the maternal hypothalamus and pituitary.

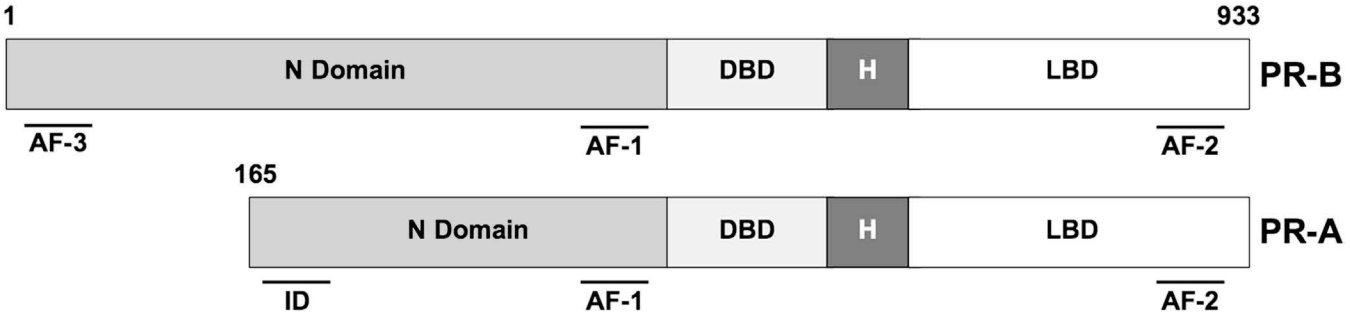

FIGURE 42.6 Organization of human PR-B and PR-A. The molecules can be divided into four functional domains: (1) the N domain at the N terminus, (2) the DNA-binding domain (DBD), (3) the hinge (H) domain, and (4) the ligand-binding domain (LBD). AF-1, AF-2, and AF-3 refer to transcription activation regions, and ID is the inhibitory domain that confers PR-A-mediated inhibition of PR-B.

myometrial, cervical, and decidual cells, the PRs promote the expression of genes encoding pro-gestational factors and inhibit the expression of pro-labor genes. However, the exact transcriptional mechanism is not clearly understood as the promoter regions of most parturition-related genes lack distinct progesterone response elements. In this case, progesterone may affect parturition-related gene expression indirectly via effects on other genes. It is also possible that the PRs modulate the abundance of specific micro-RNAs (miRNAs) that target pro-labor mRNAs and inhibit translation.[264–266]

Progesterone responsiveness in reproductive tissues involves the combined actions of PR-A and PR-B, each mediating distinct effects on specific gene targets (Figure 42.2). At some promoters, PR-A represses the activity of PR-B, and as such it is generally considered that the net transcriptional activity of PR-B is inversely related to the relative amount of PR-A and PR-B.[267,268] This concept led to the PR-A–PR-B hypothesis for functional progesterone withdrawal,[269] which posits that pro-gestational actions of progesterone are mediated by PR-B and that functional progesterone withdrawal at parturition is caused by an increase in the myometrial cell PR-A:PR-B ratio due to increased expression of PR-A.[269] Consistent with this hypothesis, PR-A represses the transcriptional activity of PR-B in human myometrial cells,[269–273] and the onset of labor is associated with increased PR-A expression in myometrial cells leading to a rise in the PR-A:PR-B ratio.[269,270,273,274]

Functional progesterone withdrawal also may be mediated by other mechanisms that decrease PR-induced

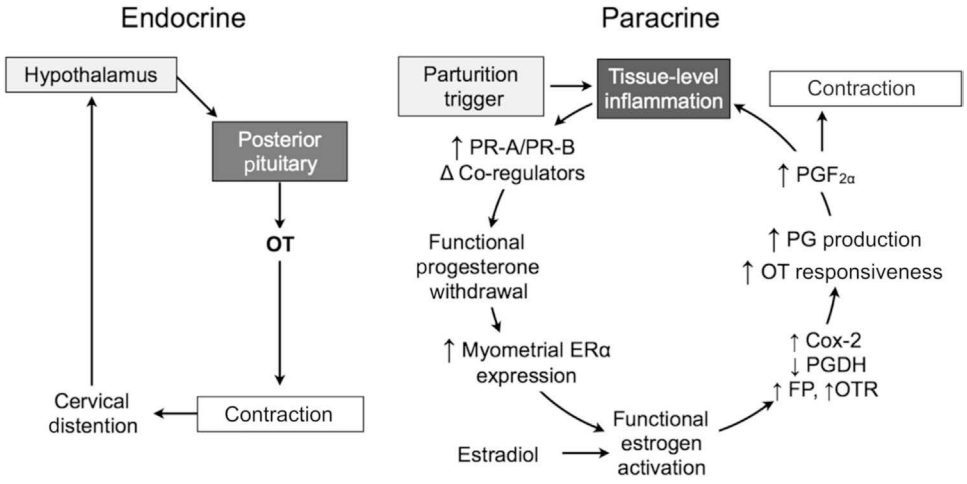

FIGURE 42.7 Positive-feedback hormonal loops in the physiology of parturition. Left: Endocrine feedback loop involving OT secreted from the hypothalamus–posterior pituitary in response to cervical distention induces contractions that further distend the cervix to increase pituitary OT release. Right: Paracrine feedback loop within the gestational tissues. Tissue-level inflammation induces functional progesterone withdrawal, which induces functional estrogen activation, which increases responsiveness to estrogens that augment PG synthesis and responsiveness to OT. PGs induce contractions and cervical ripening and augment tissue-level inflammation.

transcriptional activity. For example, critical PR co-activators are decreased in the myometrium in association with the onset of labor, and as such the capacity for ligand-activated PR-B to control gene expression could be compromised.[275] The transcriptional activity of PR-B also may be blocked by the NFκB transcription factor complex.[276,277] This mechanism may be active in infection-associated preterm labor since NFκB is a major mediator of the inflammatory response.[278–281] Progesterone withdrawal also may be mediated by the conversion of progesterone to a less active form with diminished progestin activity. Studies in transgenic mice and human tissue show that at the time of labor, conversion of progesterone to the inactive 20α dihydroprogesterone increases in endocervical fibroblasts.[282,283] Thus, current data indicate that in human parturition, the progesterone block to the onset of labor is removed by a combination of biochemical events that abrogate the capacity for PR-B to mediate pro-gestational actions of progesterone.

Multiple studies have shown that parturition is an inflammatory process.[284,285] During the prelude to labor, the myometrium, cervix, and decidua exhibit edema, neutrophil infiltration, and expression of chemical mediators of inflammation, especially proinflammatory cytokines, chemokines, and PGs.[133,134,286] It is now generally accepted that inflammatory mediators and intrauterine inflammation are key stimulators of parturition. In fact, stimuli such as mechanical distention and infection, which commonly induce proinflammatory cytokine expression and inflammation, are associated with premature delivery and are often effective as abortifacients. Implicit in the hypothesis that labor is induced by intrauterine inflammation is the concept that uterine quiescence ensues if proinflammatory pathways in myometrial, cervical, and decidual cells are repressed. In the 1970s, Siiteri and colleagues proposed that progesterone promotes pregnancy maintenance by suppressing proinflammatory responses in the gestational tissues.[287] Recent studies have shown that progesterone indeed represses inflammation in the gestational tissues via its interaction with specific PR isoforms[271,277] and with the glucocorticoid receptor.[288] Importantly, antiinflammatory actions of progesterone in myometrial cells were mediated by PR-B, and this effect was inhibited by PR-A (Figure 42.2).[271] Based on those observations, it is proposed that withdrawal of PR-B-mediated transcriptional and antiinflammatory activity by increased expression of PR-A allows for the activation of proinflammatory pathways, which induces tissue-level inflammation that transforms the myometrium, cervix, and decidua to the laboring state (Figure 42.7).

Understanding the hormonal control of parturition requires elucidation of the hormonal interactions that induce progesterone withdrawal. In sheep (Figure 42.5), this pathway is well characterized.[253,289,290] In human parturition, the pathway is less clear. Based on the PR-A–PR-B hypothesis for functional progesterone withdrawal, it is possible that parturition is induced by factors that augment PR-A expression and/or activity in the gestational tissues. Studies examining the control of PR-A expression in human myometrial cells suggest that it is upregulated by $PGF_{2\alpha}$,[291] a key uterotonic hormone whose production by the gestational tissues increases before labor.[292,293] Clinical studies show that administration of $PGF_{2\alpha}$ induces labor at all stages of human pregnancy.[294,295] Thus, it is possible that $PGF_{2\alpha}$ induces labor by first increasing myometrial cell PR-A expression to cause functional progesterone withdrawal. This paradigm suggests that any process that increases exposure of the gestational tissues to $PGF_{2\alpha}$ (e.g., uterine distention, intrauterine infection, or fetal membrane PG production) could induce functional progesterone withdrawal. A threshold level of PR-A likely exists, above which it represses the antiinflammatory activity of PR-B. At this point, a positive-feedback proinflammatory loop develops within the gestational tissues that further increases the inflammatory state, leading to

a further increase in $PGF_{2\alpha}$. Eventually, the $PGF_{2\alpha}$ levels increase to a point whereby the hormone exerts potent uterotonic actions to induce labor. This positive-feedback proinflammatory interaction may explain why labor is difficult to stop once it initiates. Further studies are needed to fully elucidate the molecular links between PR-mediated progesterone signaling and inflammation in the physiology of human parturition.

Evidence from in vivo and in vitro studies supports the hypothesis that progesterone nongenomically influences myometrial contractility via its interaction with specific membrane PRs (mPRs) (Figure 42.2) linked with intracellular signaling cascades.[296] In contrast to nuclear PRs that affect target cell function by modulating gene expression, the mPRs mediate a rapid direct response to progesterone. In one of the first clinical trials of progestin tocolysis, Hendricks et al.[297] found that administration of a large bolus of progesterone into the amniotic fluid of women in active labor at term almost immediately decreased contraction frequency and responsiveness to OT. In the mid-1960s, Pinto et al.[298] reported that large amounts of progesterone (100–200 mg bolus IV; this is close to the amount that the placenta produces in a day) administered to women in active labor at term inhibited the frequency and intensity of uterine contractions within minutes. Importantly, Pinto and colleagues later found that progesterone exerted the same relaxatory effects on isolated myometrial strips.[299] However, subsequent studies on myometrial strips produced conflicting outcomes, with some reporting a rapid relaxatory effect of progesterone,[299–303] while others reported augmented contraction frequency but decreased contraction duration and amplitude.[304–306] The reason for this variability could be due to differences in the contractile state of the tissue at the time of collection (i.e., relaxed or in active labor), and differences in the methods used to prepare the progestin solutions and perform the contraction measurements. Nonetheless, the studies clearly demonstrated that progesterone exerts rapid effects on myometrial contractility, typical of a direct nongenomic mode of action.

In recent years, specific mPRs have been identified. The mPRα, mPRβ, and mPRγ family are derived from separate genes, and are structurally related to seven-transmembrane G-protein coupled receptors.[307,308] mPRα is expressed in the myometrium from the lower uterine section, its expression increases with the onset of active labor,[309] and studies in primary cultures of term myometrial cells showed that mPRα and mPRβ are coupled with inhibitory G-proteins and increase contractility by decreasing cAMP and augmenting the transcriptional activity of PR-B.[310] However, controversy exists regarding the roles of mPRα, mPRβ, and mPRγ in the human pregnancy myometrium because some studies in a variety of cell types have found that these mPRs do not localize to the plasma membrane and are not activated by progesterone.[311]

Another family of mPRs are progesterone receptor membrane component 1 and 2 (PGRMC1 and PGRMC2), which have a single transmembrane domain and a steroid-binding extracellular domain.[312–314] PGRMC1 is expressed in the lower uterine section of the human myometrium and may mediate the relaxatory actions of progesterone.[315] Levels of PGRMC1 decrease in the myometrium in association with the onset of labor, and inhibition of PGRMC1 signaling in term myometrial strips suppresses progesterone-induced relaxation.[315] In granulosa cells, binding of progesterone to PGRMC1 activates PKG and decreases intracellular free Ca^{2+} levels.[316] Similar outcomes were observed in sensory neurons in which PGRMC1 appeared to mediate progesterone-induced inhibition of Ca^{2+} accumulation.[317] Interestingly, studies in primary cultures of term myometrial cells showed that progesterone rapidly decreases intracellular free Ca^{2+} levels[300,318] and increases cAMP,[319,320] nongenomic actions that would be expected to promote relaxation.

In addition to the direct regulation of gene transcription, ligand-activated steroid hormone receptors can also activate cytosolic signaling cascades. This "extranuclear" activity of steroids is characterized by rapid activation (within seconds to minutes) that does not require de novo gene transcription and occurs without the translocation of the steroid receptor to the nucleus. Nongenomic actions of progesterone may be mediated by extranuclear actions of PR-A and PR-B. Studies to determine the mechanism by which progesterone exerts tropic actions in breast cancer cells revealed that ligand activation of PR-B rapidly activated the extracellular signal-regulated kinase (ERK)-signaling pathway (the MAPK pathway) by interacting directly with c-Src.[321,322] c-Src is a key intermediate that couples hormone (mainly growth factor) signaling through plasma membrane receptors with intracellular transduction pathways involved in regulating cellular processes such as proliferation, differentiation, adhesion, migration, and apoptosis.[321] Studies in breast cancer cells show that only PR-B activates c-Src; PR-A has no effect, and PR-B interacts directly with ERα to form a complex that also initiates the Src–Ras–ERK cascade.[323] Thus, it is possible that progesterone and estrogen promote uterine growth via a mutual extranuclear interaction that activates the Src–Ras–ERK cascade. In contrast, effects on contractile phenotype may be limited to genomic pathways and mPR-mediated nongenomic mechanisms.

Estrogens

Estrogens exert uterotropic effects on the gravid uterus. They promote protein synthesis, tissue growth, and blood flow in the myometrium, decidua, and cervix,

and, in conjunction with progesterone, modulate maternal physiology to favor the pregnant state.[324–328] Thus, for most of pregnancy, estrogens function as pro-gestational agents. This activity ceases, however, at parturition when estrogens oppose the pro-gestational actions of progesterone by promoting the expression of genes in the myometrium, decidua, and cervix whose products increase contractility and promote cervical ripening and membrane rupture.[324] At parturition, estrogens increase the responsiveness of myometrial cells to uterotonic agents such as OT and PGs,[329–331] increase the production and release of PGs by the gestational tissues and fetal membranes,[332] and increase the formation of gap junctions between myometrial cells[333–337] (Figure 42.2). Estrogens also promote cervical ripening and dilation and membrane rupture by stimulating the expression of proteolytic enzymes (e.g., collagenase) by endocervical fibroblasts and decidual cells, respectively.[121,122]

In most species, maternal estrogen levels are low during most of pregnancy and rise prior to, and in some cases in conjunction with, progesterone withdrawal at parturition.[338] In humans and higher primates, however, levels of estrogens (estrone, estradiol, estriol, and 15α-hydroxyestriol (estetrol)) are high for most of pregnancy and increase further over the final weeks of gestation.[251,338] The principal source of estrogens in human pregnancy is the placenta, which expresses high levels of the aromatase enzyme and, as such, efficiently converts C19 androgens (mainly dehydroepiandrosterone sulfate (DHEA-S)) to estrogens.[339–341] The human placenta, however, cannot synthesize C19 steroids and therefore is dependent on other steroidogenic organs, primarily the fetal adrenal, to supply precursor androgens for estrogen synthesis. This steroidogenic axis is referred to as the feto-placental unit. Estrone and estradiol are produced from DHEA-S, supplied in roughly equally amounts by the maternal and fetal adrenals,[342] and estriol (produced from 16-hydroxy-DHEA-S) and estetrol (produced from 15-hydroxy-DHEA-S) are produced from fetal adrenal DHEA-S that is hydroxylated at the 16 and 15 positions, respectively, by the fetal liver.[340,343] Thus, maternal levels of estriol and estetrol—and, to a lesser extent, estradiol and estrone—reflect activity of the fetal HPA axis.

Congenital abnormalities affecting the feto-placental unit provide insight into the role of placental estrogens in the regulation of human parturition. Increased placental estrogen synthesis occurs in pregnancies in which the fetal adrenals cannot synthesize cortisol due to 21-hydroxylase deficiency. In these pregnancies, fetal adrenocorticotropic hormone (ACTH) levels are elevated due to a lack of cortisol negative feedback on the fetal hypothalamus and pituitary, leading to increased production of DHEA-S that is converted by the placenta to estrogens. Despite the elevated estrogens throughout most of pregnancy, these pregnancies deliver normally at term.[255] Thus, increased estrogen synthesis by the feto-placental unit beyond the already high level does not induce parturition. Likewise, the timing of parturition is not markedly affected by abnormalities that decrease placental estrogen production (i.e., anencephaly,[344,345] congenital adrenal lipoid hyperplasia,[346,347] placental aromatase deficiency,[348–352] and placenta sulfatase deficiency[353–355]). Those experiments of nature, however, do not exclude a role for estrogens in the parturition process, as in most cases of decreased placental estrogen synthesis, the levels of maternal estrogens, although low compared with those of normal pregnancies, are still in a physiologically significant range (1–1.6 nmol/l) and comparable to levels reached in the midcycle and luteal phases (0.6–2.0 nmol/l). In this regard, it is noteworthy that no natural conditions have been identified in which parturition occurs in the complete absence of estrogens. Thus, under normal conditions, estrogen levels in human pregnancy far exceed the amounts needed to effect parturition. In this highly estrogenic milieu, the uterine tissues are refractory to estrogen-induced pro-labor gene expression for most of pregnancy. A key question therefore is: how are pro-labor estrogenic actions on the gestational tissues activated at parturition? A likely scenario is that in human pregnancy, estrogen action is regulated by target tissue responsiveness rather than absolute circulating levels. If this is the case, then the source of estrogen may be of lesser importance provided that estrogenic drive is appropriate when target cell responsiveness to the pro-labor mode of estrogen action is increased (i.e., functional estrogen activation).

The regulation of estrogen responsiveness in the gestational tissue likely involves modulation of ER abundance or transcriptional activity and may be affected by progesterone. In most estrogen- and progesterone-responsive tissues, progesterone decreases estrogen responsiveness by inhibiting expression of ERα.[269,356–360] In the rhesus monkey, treatment with RU486 at midgestation increases myometrial expression of ERα,[357] and in human pregnancy myometrial ERα expression increases during the prepartum period and in association with PR-A-mediated functional progesterone withdrawal.[269] These data suggest that one mechanism by which progesterone maintains pregnancy is by blocking estrogen-induced expression of pro-labor genes through inhibition of ERα expression in the gestational tissues. According to this paradigm, progesterone withdrawal at parturition leads to an increase in ERα expression, which increases the responsiveness of the gestational tissues to pro-labor actions of circulating estrogens. This reciprocal interaction would effectively synchronize progesterone withdrawal and estrogen activation (i.e., functional progesterone withdrawal induces functional estrogen

activation), provided that the myometrium is exposed to estrogenic hormones.

This model does not explain how estrogens exert uterotonic actions on the gravid uterus, especially as ERα is barely detectable in the human pregnancy myometrium.[87] One possible explanation for this conundrum is that estrogens interact with splice variants of ERα that signal via extranuclear nongenomic mechanisms.[361] Estrogens have been shown to directly regulate the activity of multiple intracellular signaling pathways, including the ERK pathway, the phosphatidylinositol 3-kinase (PI3K)–protein kinase B (PKB) pathways, and Gα subunit signaling.[321] Activation of the ERK signaling pathway by estrogens has been extensively studied in breast cancer cells, where this cascade is thought to mediate the proliferative response to estrogens.[362] Further studies are needed to determine the role of this signaling pathway and the specific ERs involved in mediating estrogenic actions on the gestational tissues of the gravid uterus in the context of pregnancy maintenance and parturition.

Oxytocin

OT is a nine-amino-acid peptide with potent uterotonic activity; it markedly increases the frequency and force of myometrial contractions. OT is primarily a neuropeptide, synthesized by magnocellular neurosecretory cells in the supraoptic and paraventricular nuclei of the hypothalamus and stored in axon terminals that project to the posterior pituitary. In the gravid uterus, OT is also produced by the decidua and, to a lesser extent, the amnion and chorion.

During pregnancy, OT is inactivated by a cystine aminopeptidase, known as oxytocinase, produced by the decidua, chorion, and placenta.[363–368] The extent to which OT affects the myometrium is therefore dependent on the balance between peptide production in the brain and decidua and catabolism by oxytocinase. The rapid and efficient breakdown of OT is thought to limit the amount of intact OT that accesses the myometrium. Combined with the pulsatile release of OT from the maternal posterior pituitary during labor,[369] this metabolic barrier may ensure intermittent stimulation of the myometrium, especially during the phasic contractions of labor.

OT is secreted from the posterior pituitary in response to cervical and vaginal distention during labor.[370,371] It is also secreted as part of the milk letdown reflex during lactation. During labor, OT secreted by the posterior pituitary is part of a positive-feedback neuroendocrine loop whereby distention of the cervix due to the contractions of labor induces the release of OT, which stimulates the myometrium to contract to further distend the cervix (Figure 42.7). Secretion of OT by the maternal posterior pituitary also represents a mechanism for maternal control of certain aspects of parturition, including circadian timing and response to environmental stressors.[372]

The role of intrauterine OT is less clear. OT released from the decidua may gain access to adjacent targets, including the myometrium, via a paracrine route.[373,374] Intrauterine OT production, however, is low compared with the amount released by the posterior pituitary during active labor and in response to cervical distention.[375] Moreover, the amount of local OT that reaches the myometrium is uncertain as the decidua and chorion express high levels of oxytocinase. Nonetheless, it is clear from studies of animals hypophysectomized during pregnancy that OT from other sources contributes to the parturition cascade. OT production by the decidua is upregulated by estrogen.[376] This suggests that local OT contributes to estrogen-induced transformation and activation of the uterus. Interestingly, the OTR also is expressed in the human decidua,[367] and OT stimulates the production of PGs by decidual cells.[377] Taken together, the data suggest that OT produced by decidual cells in response to estrogens acts in an autocrine manner to increase the production of PGs that could in turn affect the myometrium. Thus, locally produced OT may serve to mediate pro-labor actions of estrogens during the prelude to active labor and amplify a positive-feedback loop within the gestational tissues involving PG production by the decidua.

The direct uterotonic actions of OT on the myometrium occur predominantly during the expulsive phase of active labor. In this regard, the positive-feedback loop between OT release from the posterior pituitary and cervical–vaginal distention plays a central role during labor. OT is commonly administered to women in whom augmentation of labor is needed. The potency of OT is reflected in the increased risk of abruption and hemorrhagic detachment of the placenta from the uterine wall, if excessive amounts of OT are administered.[378] In contrast to its effects during active labor, OT treatment is far less effective at inducing labor. For induction of labor, OT is usually used as a supplement to procedures such as amniotomy that trigger the parturition cascade by provoking tissue-level inflammation.

Although maternal pituitary OT is a potent stimulatory uterotonin during active labor, it is not essential for the successful completion of labor and delivery. Birth occurs normally in women with posterior pituitary dysfunction,[379] reflecting redundancy in the parturition process. In animal models, pharmacologic inhibition of OT delays but does not abolish parturition,[380,381] and transgenic mice lacking OT have a normal parturition,[382,383] although pups from OT-null mice die because the mother cannot produce milk.[383] Thus, OT is essential for lactation, but redundant mechanisms, possibly mediated by

vasopressin, operate to allow successful parturition in its complete absence.

Actions of OT in the uterus are mediated by the OTR, a Gq-coupled receptor, expressed by myometrial and decidual cells mainly at the end of pregnancy.[384] In myometrial cells, activation of the OTR leads to an increase in intracellular Ca^{2+} that stimulates contractions (as discussed in this chapter). In decidual cells, activation of the OTR by OT leads to increased expression of PTGS2 and production of PG.[377] OTR expression in the gravid uterus, and especially in the myometrium, is increased at term and in response to estrogens and progesterone withdrawal.[370,385–387] Uterine stretch also increases OTR expression in myometrial cells.[388]

Before active labor, levels of OT in the maternal circulation do not increase substantially,[389,390] and the extent of OTR expression in the myometrium and decidua is relatively low.[391] As part of the parturition cascade, OTR expression in the myometrium and decidua increases in response to progesterone withdrawal, increased estrogenic stimulation, and stretch, and as a consequence, the responsiveness of tissues to OT increases.[392] In rats, OTR is induced by locally produced PGs,[393] and activation of the OTR in endometrial cells increased PG production.[394] These data suggest a complex positive-feedback loop between estrogens, locally produced PGs, the uterine OT system, and OT responsiveness in the gestational tissues. Animal studies show that disruption of OTR signaling represses labor and delays parturition,[370] and clinical trials of OTR antagonists show that inhibition of OTR can be used to repress preterm labor.[395–400]

Thus, the role of OT in parturition is complex. It is a potent uterotonin that contributes to the contractions of labor during the expulsive phase. It is part of a maternal positive-feedback neuroendocrine loop that augments labor and possibly synchronizes labor with circadian rhythms. It is also produced within the gravid uterus and appears to be involved in the regulation of PG production within the gestational tissue. One of the major functions of estrogens in preparing the uterus for labor is the stimulation of myometrial and decidual OTR expression and the stimulation of OT production by decidual cells. Despite its key actions during labor, OT is not essential for the successful completion of labor. This likely reflects redundancy in the parturition control process.

Prostaglandins

PGs exert important labor-promoting actions in all mammals.[165,166,401] In addition to augmenting uterine contractions, PGE_2 and $PGF_{2\alpha}$ may serve as components of the timing mechanism that initiates labor.[166,402,403] In humans and rodents, amniotic fluid and uterine tissue PGE_2 and PGF_{2a} concentrations rise shortly before the onset of labor.[167,404–407] Moreover, PG synthesis inhibitors or receptor blockers delay the timing for onset of parturition in both human and animal studies, including spontaneous preterm labor in humans.[166,167,408,409] Understanding the biology for regulation of PG production and degradation provides an important avenue for elucidating the clock that meters the timing for birth and identifying potential therapeutic strategies to prevent preterm birth.

As summarized in the "The Decidua and Fetal Membranes" section of this chapter, the synthesis of PGs is a complex, multistep process that is tightly regulated to compartmentalize their actions both spatially and temporally. The initial release of the requisite substrate for PG biosynthesis, arachidonic acid, from membrane-anchored phosphatidylethanolamine and phosphatidylinositol occurs through the action of either phospholipase A_2 or phospholipase C[410,411] (Figure 42.4). Of these two phospholipases, PLA_2 exerts the more robust role in parturition. The PLA_2 enzymes constitute an approximately 30-member family of related enzymes that display different cellular and subcellular localizations and actions.[410,411] The chief groupings among these isoforms are into cytosolic calcium-dependent (c)PLA_2s, calcium-independent (i)PLA_2s, platelet-activating factor acetylhydrolases, lysosomal PLA_2s, adipose-specific PLA_2s, and secretory (s)PLA_2s. Of the PLA_2s, group IV cPLA_2 appears to be the primary mediator of parturition-associated PGs, as is it selective for phospholipids containing arachidonic acid at the sn-2 position of membrane glycerophospholipids,[155,161,412] although some sPLA2 isoforms are also present in amnion and other gestationally relevant tissues.[155] While it has been found that sPLA_2 is secreted from fetal membranes, the myometrium, and the placenta, the contributions of sPLA_2 to the progression of labor remain unclear. Type II sPLA_2 is the primary isoform, and it has been found to increase with labor in some studies in the placenta, amnion, and choriodecidua.[413,414] Once released from membrane phospholipids, arachidonic acid can be metabolized through either the PG synthetic pathway (by the action of PTGS1 or PTGS2) or the lipoxygenase pathway to generate leukotrienes and related compounds.[9,162,415] The PG pathway is critical for the onset and progression of labor. PTGS1 and PTGS2 convert arachidonic acid to PGH_2, the first committed precursor for bioactive prostaglandin synthesis. These enzymes are highly homologous, sharing 60–65% amino acid identity within a species and similar capacity to convert arachidonic acid to PGH_2.[415,416] A splice variant in human PTGS1, designated cyclooxygenase-3, has also been described.[417] Cyclooxygenase-3 may play an important role in fever generation and attenuation by acetaminophen and related compounds,[417] but its specific role in the genesis of parturition-associated PGs has not been evaluated. PTGS1 and PTGS2 demonstrate significant differences in their patterns of expression. PTGS1 is expressed

by most tissues, and in most circumstances it exhibits little change in level of expression; hence, it has largely been considered a "housekeeping" gene. In contrast, PTGS2 is often undetectable at baseline but is highly induced by inflammatory signals, such as TLR engagement, cytokines, growth factors, and tumor promoters.[415]

In the mouse, PTGS1 in the uterine epithelium is the primary source of term parturition-promoting $PGF_{2\alpha}$ during late gestation.[405] In contrast to its typical "housekeeping gene" regulatory profile, PTGS1 mRNA is induced 40-fold during gestation, and 10-fold precisely between days 14.5 and 15.5 of mouse gestation (term at day 19.5).[418] In contrast, with infection- or inflammation-induced preterm labor in mice, uterine PTGS2 generates $PGF_{2\alpha}$, which mediates luteolysis and uterine contractions.[419] During human gestation, PTGS1 expression does not vary considerably in the uterus, placenta, and fetal membranes.[167,420–422] PTGS2 expression is highly induced in the amnion and appears to be the driver for labor-promoting PGE_2 during human term and preterm labor.[167,420–422] PGH_2 undergoes conversion to PGI_2, PGD_2, thromboxane A_2, PGE_2, and $PGF_{2\alpha}$ by specific isomerases that constitute several multiisoform families of diverse structure and regulation.[423–426] PGI_2, prostacyclin, is a major product of cyclooxygenase activity in the myometrium during pregnancy, and serves to relax uterine smooth muscle.[427,428] Changes in PGI_2 with parturition have not been delineated, although PGI_2 synthase decreases with advancing gestational age.[429] The enzymes generating PGE_2 and $PGF_{2\alpha}$ have garnered the greatest attention for parturition effects.[401] Prostaglandin E synthases (PGES) comprise a group of at least three different enzymes. Two of these isoforms are membrane bound (mPGES1 and mPGES2). mPGES1 can be induced by proinflammatory stimuli and has been shown to be functionally coupled with PTGS2.[430] mPGES2 is initially synthesized as a Golgi-associated protein and is further processed to a mature cytosolic enzyme after the cleavage from its N-terminal hydrophobic domain.[431] mPGES2 is functionally coupled with both PTGS1 and PTGS2. Cytosolic PGES (cPGES) is constitutively expressed in a wide variety of cells and is functionally linked to PTGS1.[430] $PGF_{2\alpha}$ can be synthesized from three different pathways starting at PGE_2, PGD_2, or PGH_2. The PGF synthases utilizing PGH2 as substrate are part of the aldo-ketoreductase superfamily and undergo upregulation during late gestation in the mouse.[418,424]

PG receptors have contrasting roles on the myometrium[165] and, in those species undergoing luteolysis, on the CL of the ovary.[432] Each PG acts on a specific group of receptors—PGE_2 on $EP_{1–4}$ (prostaglandin E receptors 1 through 4), $PGF_{2\alpha}$ on FP, prostacyclin on IP, thromboxanes on the thromboxane receptor (TP), and PGD on the prostaglandin D receptor (DP) (Figure 42.4). For myometrial function, PG receptors can either relax (IP, DP, EP_2, and EP_4 receptors) or contract (EP_1, EP_3, and FP receptors) uterine smooth muscle.[165,166] Similarly, on the CL, PGE_2 promotes luteal function through actions on EP_2 and perhaps other receptors,[432,433] while $PGF_{2\alpha}$ causes luteolysis through FP.[403] All PG receptors are G-protein coupled receptors that stimulate the production of IP3 and intracellular Ca^{2+} release when signaling through Gq (e.g., FP and EP_1), or they stimulate (e.g., IP, DP, EP_2, and EP_4) or inhibit production (e.g., EP_3) of cAMP when signaling through $G\alpha_s$ or Ga_i, respectively.[434,435] The consequences of exposure to PGE_2 or $PGF_{2\alpha}$ for myometrial or CL function depend upon timing during gestation, as receptor subtypes differ in their patterns of temporal expression. Studies applying PG receptor agonists and antagonists to human term myometrium demonstrated the presence of the contractile receptor subtypes EP_3, FP, and TP and relaxation-promoting subtypes EP_2, DP, and IP.[436,437] More detailed temporal expression of FP and EP2 receptor mRNAs has been performed in both rat and human myometrium.[438,439] In rat myometrium, EP_2 was highest in expression at day 16 of gestation and declined as delivery approached at day 22.[439] In contrast, FP mRNA expression was low at day 16 and increased significantly until the day of delivery, consistent with its inclusion as a CAP.[439] The induction of FP is inhibited by progesterone but not altered by uterine stretch.[440] Immunohistochemical localization of FP has demonstrated a redistribution of FP protein from both nuclear and cytosolic to primarily cytosolic as term approaches.[441] Redistribution of EP_2 in the rat myometrium has also been observed, with notable cell membrane localization near term.[165] In human myometrium, EP_3 and FP receptors decrease during Phase 0 of pregnancy compared to the nongravid state, consistent with a period of uterine quiescence.[442] From mid- to late gestation, EP_2 expression decreased, as did FP in the lower uterine segment of the human myometrium.[438] The decline in FP in the lower uterine segment is consistent with the need for relaxation of this component of the uterus, in contrast to the needed increase in contractile activity of the fundus to expel the fetus. Indeed, PGE_2 and $PGF_{2\alpha}$ stimulate contractions on the myometrium derived from the upper uterine segment, while PGE_2 inhibited and $PGF_{2\alpha}$ had no effect on contractility in the human myometrial lower segment.[443,444] These findings, together with an increase in EP_4 in the lower segment,[165] suggest a regionalization of PG receptor expression in the human myometrium to enhance net contractile direction toward emptying the uterus toward the cervix. Regionalization of PG receptors has also been found in the baboon uterus.[445,446] While regulation of specific isoforms differed, the net consequence was enhanced contractile function in the fundus as compared to the lower uterine segment.

To limit the action of PGs during pregnancy, they undergo metabolism by the nicotinamide adenine dinucleotide-dependent enzyme HPGD.[175,447] The activity of this enzyme produces 15-keto and 13,14-dihydro-15-keto molecules that have substantially diminished signaling capacity through the PG receptors. The abundant expression of HPGD in the chorion may act to specifically restrict the amnion effects of PGE_2, such that the myometrium and decidua are not activated.[157,448] Analysis of the regulation of HPGD in the chorion during human gestation reveals decreased expression during active term labor compared to women at term but not in labor, and decreased expression in spontaneous idiopathic or infection-associated preterm labor compared to gestation-matched controls.[157,158] Expression in the baboon is quite similar to that in humans, with HPGD found in the chorion, decidua, uterine lower segment, fundus, and cervix.[449,450] HPGD mRNA expression decreases in the decidua, fundus, and cervix through late pregnancy and labor.

Cytokines and Chemokines

Multiple studies have shown that human parturition is an inflammatory process characterized by increased proinflammatory cytokine production[133,286]; increased infiltration of neutrophils and macrophages into the myometrium, cervix, and decidua[134,135]; and activation of the NFκB[279] within the myometrium, decidua, and cervix.[284,451] Proinflammatory cytokines and chemokines, especially IL1, IL6, IL8, and tumor necrosis factor alpha (TNFα), appear to play key roles in the parturition process, although they do not exert uterotonic effects directly.[452,453]

The most likely mode of action for local cytokines in the parturition cascade is that they promote tissue-level inflammation and local production of PGs that then induce myometrial contraction, cervical ripening, and membrane rupture.[454,455] In the rhesus monkey, activation of the inflammatory system in the gestational tissues, including the myometrium, precedes the onset of labor,[456,457] and studies in rhesus monkeys and mice have shown that administration of pro-inflammatory cytokines or factors that induce a proinflammatory response initiates preterm labor.[455,458–460] Moreover, stimuli such as mechanical or chemical trauma and infection that commonly induces the expression of proinflammatory cytokines and chemokines leading to tissue-level inflammation, are associated with premature delivery and are often effective as abortifacients. A significant proportion of preterm births are associated with intrauterine infection,[461,462] clinically silent upper genital tract infection, and bacterial vaginosis.[285,463,464]

A key player that may be pivotal in this process is the NFκB transcription factor complex, which, in response to inflammatory cytokines, increases the expression of key CAP genes, including PTGS2, GJA1, FP, and OTR in myometrial cells.[279] As described here, progesterone may prevent labor indirectly by inhibiting tissue-level inflammation through repression of NFκB activity. According to this model, progesterone withdrawal releases inhibition of NFκB, making it susceptible to activation by local proinflammatory cytokines.

Studies in human myometrial cell lines show that $PGF_{2\alpha}$ stimulates PR-A expression and increases the PR-A:PR-B expression ratio.[291] The functional link between tissue-level inflammation and PR-A-induced functional progesterone withdrawal may be a mechanism through which inflammation in response to danger signals (e.g., intrauterine infection, fetal stress or maturation, and uterine wall overdistention) induces labor (Figure 42.7).

Placental Peptide Hormones

The general structure and function of the placenta are the subjects of Chapters 39 and 40. As detailed therein, the placenta produces a plethora of protein (including cytokines and growth factors) and steroid hormones, which it secretes, usually in large quantities, into the maternal circulation.[465] In general, most hormones produced by the placenta are pro-gestational and serve to adjust maternal physiology, usually in favor of pregnancy maintenance (e.g., progesterone) and to support the resource needs of the fetus (e.g., placental lactogen). With regard to the control of parturition, certain placental hormones may play a critical role. One of those is CRH.

CRH is a 41-amino-acid peptide that stimulates the expression and processing of proopiomelanocortin (POMC) by pituitary corticotropes and the secretion of ACTH. The human placenta, fetal membranes, and decidua also express CRH that is identical to that produced by the hypothalamus.[466] CRH expression by syncytiotrophoblasts can be detected from the seventh week of pregnancy and increases progressively until term.[467] Several actions have been ascribed to placental CRH in the control of human pregnancy.[468] CRH may serve an autocrine–paracrine function within the placenta by regulating expression and processing of POMC.[469] In this context, placental CRH may be part of the fetal–placental stress response. Neurotransmitters and neuropeptides activated in response to stress stimulate placental CRH release in vitro.[470,471] The physiologic implication of this is that the fetus may be able to mount a stress response via placental CRH. This may be critical in conditions such as preeclampsia, placental vascular insufficiency, and intrauterine infection.

Placental CRH is released mainly into the maternal compartment. Levels of CRH in the maternal circulation

can be detected as early as 15 weeks of gestation and then increase through gestation, reaching maximum levels of 1–10 ng/ml at term[472] (Figure 42.8). A binding protein (BP) for CRH also exists, and for most of pregnancy it is present in excess of CRH in the maternal circulation.[473–475] As the CRH-BP binds CRH with greater affinity than the CRH receptor, it effectively suppresses CRH bioactivity. Thus, for most of pregnancy, the bulk of the placental CRH is thought to be sequestered by the CRH-BP, limiting its bioavailability. However, during the last 4 weeks of pregnancy, CRH-BP levels decrease markedly.[476–478] This coincides with the exponential increase in placental CRH production, which could result in a dramatic increase in CRH biological activity.[476]

Studies of maternal CRH levels during human pregnancy suggest that CRH produced by the placenta plays a role in the physiology of parturition. The level of CRH in the maternal circulation increases exponentially as gestation progresses, and the pattern of change in maternal CRH levels at midgestation is predictive of the gestation length[476] (Figure 42.8). The rate of CRH increase is inversely related to the length of gestation, such that the incidence of preterm birth is greater in women with a rapid rate of increase in maternal CRH at midgestation, whereas postterm birth is more common in those with a slow rate of increase at midgestation.[476] This effect may be related to the bioavailability of CRH as the CRH-BP levels fall during late pregnancy. Thus, the ratio of CRH to its binding protein may have a threshold level that is achieved at specific times depending on the trajectory of placental CRH expression established early in gestation.

CRH may affect myometrial contractility. Receptors for CRH have been identified in the human myometrium and fetal membranes,[479–481] and in vitro studies have shown that CRH stimulates the release of PGs from human decidua and amnion,[482,483] and augments the action of OT and $PGF_{2\alpha}$ on myometrial contractility.[484–486] During most of pregnancy, CRH increases adenylate cyclase activity in the myometrium, leading to an increase in intracellular cAMP, which promotes relaxation. At the time of parturition, and especially during active labor, the capacity for CRH to increase cAMP decreases.[487] Thus, for most of pregnancy, CRH may contribute to the maintenance of myometrial relaxation, and this effect appears to decrease at parturition.

One important characteristic of placental CRH expression is that it is increased by glucocorticoids,[488–490] an effect that is opposite to hypothalamic CRH expression, which is decreased by glucocorticoids. Stimulation of placental CRH production by glucocorticoids may result in a positive-feedback loop whereby placental CRH stimulates ACTH production by the fetal pituitary, which would increase cortisol and DHEA-S secretion by the fetal adrenals. Fetal adrenal cortisol could then further stimulate placental CRH production, and the DHEA-S would serve as substrate for placental estrogen synthesis. The marked rise in placental CRH during the last 10 weeks of pregnancy could be due to such a positive-feedback interaction, especially as the capacity for the fetal adrenal cortex to synthesize cortisol develops.[325] Interestingly, CRH also may influence fetal adrenal steroidogenesis directly by increasing DHEA-S production[491–493] and ACTH

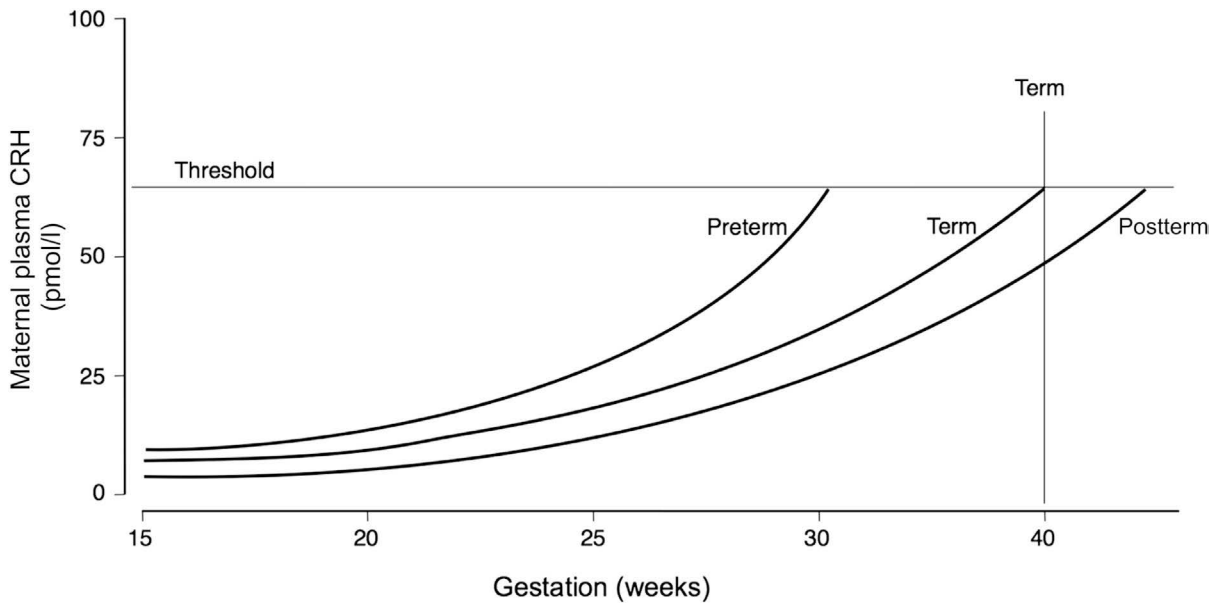

FIGURE 42.8 Schematic representation of maternal plasma CRH levels between 15 and 30 weeks of gestation in pregnancies destined to deliver preterm, at term, and postterm. A theoretical threshold for CRH-induced parturition is shown. The trajectory of CRH increase established early in gestation will influence when the threshold is reached. *Source: From Ref. 476.*

receptor expression in fetal adrenal cortical cells.[494] Thus, a positive-feedback endocrine loop may develop between placental CRH and the fetal adrenal cortex as a consequence of the direct action of CRH on the fetal adrenal cortex and the stimulation of placental CRH expression by cortisol. The effect of this endocrine axis on the physiology of human parturition is not clearly defined; however, it may represent a link between the fetal-placental stress response and parturition. Some investigators have suggested that the complex functional interaction between placental CRH and the fetal HPA axis represents a potential link between the putative placental clock, reflected by placental CRH, and the production of glucocorticoids needed for fetal organ maturation and estrogens needed for the process of parturition.[476]

Biomechanical Influences

Uterine distention has been proposed as a signal for the induction of parturition to ensure that the fetus does not grow larger than the pelvic opening. The human uterus is subjected to a significant amount of distention, especially late in the third trimester and in pregnancies with multiple fetuses. A likely scenario is that a threshold of uterine wall distention exists above which the induction of pro-labor and proinflammatory gene expression contributes to the parturition cascade.

Clinical evidence that uterine wall distention contributes to the parturition process is that gestation is generally shorter in pregnancies with multiple fetuses.[495,496] Studies in rats have shown that distention of a nonpregnant uterine horn induces changes in the expression of genes associated with contraction and parturition similar to those in the pregnant horn, and that the parturition-related changes in gene expression are inhibited by progesterone.[39,40,497–500] The stimulatory effect of distention was also observed in cultured human myometrial cells.[388,501–504] Stretch of cultured uterine myocytes also increased the expression and release of IL8, a potent proinflammatory chemokine that promotes the infiltration of activated macrophage and neutrophil infiltration.[502] Thus, myometrial cell distention could contribute to the positive-feedback proinflammatory loop that leads to tissue-level inflammation and the onset of labor. Similar mechanotransduction signaling pathways could be operating in the cervix, especially as it ripens and becomes more distensible.

Signals from the Fetus

At birth, the fetus is abruptly required to establish and maintain physiologic homeostasis independent of the placenta and in a markedly altered environment. Survival of the neonate is therefore dependent upon the functional maturation of organ systems during fetal life that will be essential for extrauterine life. Critical among these are organs that interface with the environment (e.g., the lungs, gut, and immune system) and those that maintain homeostasis (e.g., the HPA axis, kidneys, liver, and pancreas). The coordination of organ maturation and the timing of parturition such that birth occurs when the fetus is sufficiently mature to survive as a newborn is therefore critical for the success of pregnancy.

In most species, glucocorticoid produced by the fetal HPA axis promotes the functional maturation of fetal organ systems and coordinates fetal maturation with birth timing.[248,505] In sheep, fetal organ maturation is induced by a prepartum surge in cortisol secretion by the fetal adrenals.[505] The cortisol surge also triggers the onset of labor. Thus, in sheep, the fetal HPA axis, via cortisol, mediates a physiologic link between the timing of birth and fetal organ maturation. A prepartum fetal cortisol surge does not occur in human parturition, and the fetal HPA axis plays a minor role (if any) in the control of human parturition. Nonetheless, glucocorticoid is a key stimulator of fetal organ maturation in humans. Critical processes induced by glucocorticoid include surfactant production by the fetal lungs; activity of enzyme systems in the fetal gut, retina, pancreas, thyroid gland, and brain; and deposition of glycogen in the fetal liver. Synthetic glucocorticoids that readily cross the placenta are a standard form of therapy administered to women in preterm labor.[506] This treatment significantly increases survival rates among preterm infants, mainly by promoting lung maturation and decreasing the severity of respiratory distress syndrome.

The extent to which cortisol from the fetal adrenals regulates fetal organ maturation in human pregnancy is uncertain. Experiments of nature suggest that maturation of the human fetus during late gestation is independent of fetal adrenal cortisol production. Fetuses with congenital adrenal hyperplasia (CAH) due to an inability to synthesize cortisol are usually born at term without any apparent signs of organ immaturity.[255] This observation suggests that cortisol produced by the fetal adrenal gland is not essential for fetal organ maturation; another source of glucocorticoid, possibly from the maternal adrenals, could contribute to fetal organ maturation at the end of human gestation; or maturation of the human fetus is not dependent upon glucocorticoids alone and other factors may be involved.

Although cortisol stimulates maturation of fetal organ systems, it also can have adverse effects on fetal development. To protect the fetus from these negative effects, the human placenta prevents maternal cortisol from entering the fetal compartment throughout most of human pregnancy by converting cortisol to the inactive cortisone.[507] Late in human pregnancy (around 34–35 weeks), however, the placental barrier to maternal

cortisol weakens. The evidence for this is that estriol levels in the maternal circulation during late pregnancy are inversely related to the circadian changes in circulating maternal cortisol levels.[508] Thus, when maternal cortisol goes up, estriol goes down. This implies that, late in gestation, some maternal cortisol crosses the placenta to the fetal compartment and suppresses ACTH production by the fetal pituitary gland that leads to decreased DHEA-S production by the fetal adrenals and, in turn, decreased estriol production by the placenta. Increased transfer of maternal cortisol to the fetus may represent a backup mechanism to ensure fetal organ maturation. This transfer of maternal cortisol, rather than lack of dependence on cortisol, may explain why fetuses with glucocorticoid deficiency are born without overt signs of organ system immaturity.

The fetus may trigger parturition as an adaptation to escape intrauterine stress caused by pathophysiologic conditions such as preeclampsia, intrauterine growth retardation, nutritional stress and increased uterine wall distention due to multiple fetuses, and intrauterine infection, all of which are associated with preterm birth.[509,510] The physiologic link between fetal stress and parturition may be via placental CRH. Placental CRH production is increased in cases of intrauterine infection and hypoxia.[511] Whatever the mechanism, it is clear that fetal stress is somehow linked to the parturition trigger mechanism. This is an important clinical issue because, in some cases of preterm birth, the fetus may be escaping a hostile intrauterine environment, and therefore prevention of preterm birth in those cases may be detrimental to the fetus if the cause of the stress is not treated.

PATHOPHYSIOLOGY OF HUMAN PARTURITION

Preterm Birth

Understanding the mechanisms coupling the rate of fetal maturation with the timing for birth provides a fundamental area for biological investigation that is as important for mammalian survival as the sequence of events producing a differentiated multicellular organism from a single-cell embryo. Beyond this intrinsic scientific interest, elucidation of the determinants of the onset of human parturition will advance interventions for perhaps the most challenging, and refractory, syndrome in women's and children's health, preterm birth.[512] Human preterm birth, defined as birth at less than 37 completed weeks of gestation, results in 75% of perinatal mortality and the majority of long-term perinatal morbidity.[513] While the World Health Organization definition of preterm birth at less than 37 weeks is somewhat arbitrary, it is clear that birth at every gestational age before term, including in the 37th and 38th weeks of gestation, is associated with increased perinatal morbidity and neonatal mortality.[514,515] Approximately 75% of preterm births occur between 34 and 36 weeks of gestation, which are designated "late-preterm" births. The increase in frequency of delivery rises exponentially as term approaches, such that approximately 5% of preterm births, or less than 1% of total births, occur at less than 28 weeks of completed gestation, when fetal mortality and morbidity are highest.[208] The impact of late-preterm births should not be underestimated, however, as a three- to sixfold increase in neonatal mortality has been found for infants born at these gestational ages.[516]

Several recent comprehensive review articles exist regarding the epidemiology of human preterm birth.[208,512,517,518] The conceptual framework for parsing the etiology of preterm birth first begins with dichotomizing the pattern of delivery as "spontaneous" or "medically indicated". Medically indicated deliveries account for approximately 30% of preterm births. The vast majority of medically indicated deliveries occur in the late-preterm gestational age window and are initiated because of the appearance of maternal or fetal abnormalities that could ultimately compromise healthy pregnancy outcomes, including maternal or fetal death. One frequent antecedent of medically indicated deliveries is preeclampsia.[519,520] The diagnosis of preeclampsia encompasses increased maternal blood pressure (systolic > 140 mm Hg or diastolic > 90 mm Hg) with proteinuria (>300 mg protein per 24 h urine collection). A spectrum of severity for preeclampsia exists, with additional manifestations including maternal cerebral or visual disturbances, pulmonary edema, liver function abnormalities, and thrombocytopenia, and fetal growth restriction. Importantly, this disorder, which manifests structural vascular changes in the maternal kidney and other organs, with compromised tissue perfusion due to vasospasm, resolves with delivery of the placenta.[521–523] A complete discussion of the pathophysiology and etiology of preeclampsia is beyond the scope of this chapter, but can be found in several excellent reviews.[519,524] The remainder of the discussion on preterm birth will focus on causes of spontaneous preterm birth that could arise from either dysregulation of typical parturition control mechanisms or distinct pathological pathways.

Among the 70% of preterm births ascribed as being spontaneous, approximately two-thirds are due to spontaneous preterm labor and one-third arise from PPROM.[208] In the United States, 11.7% of births are preterm based upon 2011 data.[525] This rate is 15% higher than the preterm birth rate in 1990, although it reflects a consistent decline from its peak in 2006 at 12.8%.[526] The etiology of the decline in preterm births in the United States stems largely from changes in obstetric practice for labor induction or Cesarean section in the late-preterm

category.[208,517,525,527,528] Births at less than 34 weeks of completed gestation, in contrast, have not changed substantially in frequency over the last 20 years. The direct causal pathways for spontaneous preterm birth are unknown in any given pregnancy in more than half of the cases.[208,518] Multiple gestations, arising either naturally or as a consequence of assisted reproductive technology, complicate 2–3% of pregnancies but result in 15% of all preterm births. While the traditional mechanism for early births in twin or higher multiplicity pregnancies has been attributed to uterine overdistention, recent evidence measuring uterine wall strain calls this model into question.[529]

For singleton gestation pregnancies, several maternal demographic characteristics have been associated with increased preterm birth risk. These include low maternal body mass index (BMI), extremes of maternal age, African-American race, low socioeconomic status, smoking, lack of prenatal care, short interpregnancy interval, and previous preterm birth.[208,530–532] How these characteristics disrupt the normal timing for birth remains uncertain. In addition to these maternal demographic factors, strong evidence provides causal links of genetics, infection, and stress to preterm birth risk.[518,533–539]

Genetics and preterm birth risk: Several lines of evidence converge to implicate the importance of genetic factors in the mother or fetus as influencing the duration of gestation and preterm birth risk. Studies exploring familial patterns for birth timing have been particularly informative. Large-scale epidemiological analyses from European populations demonstrate a significantly increased risk of preterm birth in sisters of women who have experienced a preterm delivery, but little or no increase in risk to women who are sisters of fathers who have had a preterm child.[540,541] Analysis of birth timing in children born to monozygotic twins, in comparison with dizygotic twins or nontwin siblings, supports an important role for maternal genetics in the determination of gestational age at birth, with heritability estimates ranging from 14% to 40%.[542–545] The role of paternal genes has not been as extensively investigated, but studies suggest a much smaller role based on mixed-race pregnancies[546] or no role based on children of twin-type analysis.[543] The role of fetal genes in parturition has recently received considerable attention. Elegant family-based and twin-modeling investigations have demonstrated an important role for fetal genetics, contributing approximately 11% of the variability in birth timing,[545,547] which is supported by segregation analysis in family pedigrees.[548]

Armed with this evidence for genetic contributors to human birth timing, the hunt for human genomic variations that contribute to preterm birth risk has gained considerable attention. Initial interrogation of the role of gene polymorphisms exploited candidate gene approaches, exploring pathways that have been implicated in parturition such as inflammation and immunity, connective tissue remodeling, hemostasis, and control of myometrial contractility and quiescence. While individual studies have found small to moderate associations with variants in cytokines, their receptors, MMPs, coagulation factors, and adrenergic receptors, for example, these have in general not been replicated or generalized. Several excellent summaries of candidate gene studies in preterm birth have recently been published.[537,549,550] Nonbiased, genome-wide association studies and whole-exome sequencing are currently underway, but to date, novel common or rare genetic variants lending new insight into parturition pathways have not been reported.

Infection and preterm birth risk: Clinical, histological, and microbiological evidence suggests that infection may contribute to 25–40% of preterm births.[208,462,539] Bacterial colonization of the placenta or amniotic fluid, particularly with *Ureaplasma urealyticum*, as detected by culture or polymerase chain reaction, is found in 79% of pregnancies with birth at 23 weeks of gestation and declines to 11% in pregnancies with birth at 31–34 weeks of gestation.[551] Intriguingly, in women found to be colonized in amniotic fluid with *Ureaplasma* at midgestation, only 30% go on to deliver preterm.[552,553] Histologic evidence of both maternal and fetal inflammatory responses similarly increases in frequency in what have otherwise been deemed idiopathic spontaneous preterm births as gestational age at birth diminishes.[554] Together, these findings suggest that infection may contribute most prominently to very early gestation preterm birth. Unfortunately, pregnant women with vaginal colonization with *Ureaplasma* or *Mycoplasma* receiving prophylactic treatment with antibiotics do not experience a reduction in the preterm birth rate.[555]

More recent concepts regarding the role of bacterial pathogens as contributors to preterm birth risk consider, rather than a primary microorganism, a shift in the microbial community as the driver of adverse pregnancy outcomes.[556–559] One such example is bacterial vaginosis. Analogous to results from attempts to eradicate *Ureaplasma*, treatment for bacterial vaginosis,[560] or other chronic, low-grade infections such as trichomoniasis[561] and periodontal disease,[562] has not reduced preterm birth risk. Ongoing attempts to more fully characterize the full microbial community—encompassing bacteria, fungi, and viruses—defining the metagenome of pregnancy may reveal new, previously cryptic pathogens that would not have been eradicated by previous antibiotic interventions.

Stress and preterm birth risk: Many maternal demographic factors that increase risk for preterm birth directly or indirectly associate with the frequency and severity of physiological or psychosocial stress that mothers experience.[208,518,536,563,564] Examples of these demographic factors include living in poverty, low
