In young (≤ 6 months) and easily restrained animals (including kiwis and tinamous) induction may be accomplished using isoflurane alone; large subadult to adult birds require parenteral anesthetics. Inhalant induction is accomplished by starting at a high concentration (such as 5%), then decreasing to maintenance levels. This technique allows for rapid and smooth induction, and is the preferred method for ratites.

A variety of parenteral anesthetics alone or in combination (e.g., xylazine, ketamine, carfentanil, and tiletamine/zolazepam) (Table 26.2) have been investigated and used for induction. Selection is based on age, health status, and species. Known preexisting disease conditions are also considered.

Opioid Combinations Carfentanil has been used alone and in combination with xylazine for both immobilization and induction of anesthesia (Cornick & Jensen 1992; Honnas et al. 1991). Common complications include apnea, hypercapnia, excitability, agitation, and frenzied activity (Cornick & Jensen 1992). Naloxone, or preferably naltrexone, are used to reverse the effects of carfentanil, and tolazoline or atipamezole may be used to reverse the xylazine, making this a fully reversible combination. The addition of midazolam (0.1 mg/kg) to the C/X combination (0.025/1 mg/kg) allowed for smooth induction and recovery in an adult ostrich; midazolam was not reversed (S.B. Citino, pers. comm. 2006).

Other Combinations Tiletamine/zolazepam IV produced rapid and smooth induction with sternal recumbency in adult ostriches, and allowed for endotracheal intubation in juvenile ostriches (Ciboto et al. 2006; Gilsleider 1998; Honnas et al. 1991; Lin et al. 1997). Intravenous administration was facilitated by prior xylazine/butorphanol (X/B), xylazine, or acepromazine administration in adults; rheas required higher dosages of X/B than emus and ostriches to achieve the same level of sedation (Ciboto et al. 2006; Lin et al. 1997). Despite excellent induction, tiletamine/zolazepam IM is often associated with prolonged “rough” recoveries.

These effects are lessened by diazepam before or after tiletamine/zolazepam administration (Cornick & Jensen 1992; Tully et al. 1996b). Midazolam IM would be expected to produce similar effects as diazepam; benzodiazepine administration is encouraged when using tiletamine/zolazepam combinations. Finally, tiletamine/zolazepam IV may result in apnea, necessitating assisted ventilation (Cornick & Jensen 1992).

Immobilization with medetomidine/ketamine, followed by IV propofol, allowed for safe, smooth induction and recovery of anesthesia in juvenile ostriches (Langan et al. 2000). Transient apnea occurred but spontaneously resolved; all birds were bradycardic throughout the procedure. Light anesthesia was maintained with a constant rate infusion of propofol; higher doses are necessary for a surgical plane of anesthesia (Table 26.2). Successful sedation with IM acepromazine, followed by propofol IV has been reported in ostriches with minimal side effects, though volume to administer was reportedly large (Ciboto et al. 2006).

Ketamine alone is not recommended due to excitation during induction and recovery, and possible convulsions. Rather, it is combined with other drugs (e.g., diazepam, midazolam, medetomidine, or xylazine) (Al-Sobayil et al. 2009; Burba et al. 1996; Ciboto et al. 2006; Cornick & Jensen 1992; Langan et al. 2000; Tully et al. 1996a). High dosage diazepam/ketamine and other combinations result in “rough,” unpredictable inductions, but smooth recoveries (Cornick & Jensen 1992). Diazepam (0.3–0.5 mg/kg IM) premedication facilitates induction with ketamine/diazepam IV (Cornick-Seahorn 1996). Xylazine combined with carfentanil (X/C) or ketamine (X/K) has resulted in successful induction in healthy ratites. However, rough recoveries were noted in some birds with X/K along with bradycardia and apnea (Cornick & Jensen 1992; Fowler 1995; Gilsleider 1998; Matthews et al. 1991). Xylazine/ketamine is not recommended in debilitated birds because of cardiopulmonary depression.

Pharmacokinetics in ostrich chicks premedicated with romifidine and induced with IM ketamine revealed rapid absorption and elimination half-life of K, similar to that of mammals (De Lucas et al. 2007). However, there is considerable variation in effectiveness of anesthetic agents used for induction. This variability may be related to dosage, route of administration, species, age and metabolic rate, degree of excitation, or individual variation (De Lucas et al. 2007). In general, diazepam appears to improve induction and recovery regardless of the other drugs used.

Maintenance

Isoflurane is the inhalant anesthetic of choice for chicks and juveniles, and lengthy procedures in adult birds. However, halothane, methoxyflurane, and nitrous oxide have also been used successfully. Significant decreases in respiratory rate and blood pressure have

been recorded with isoflurane following X/K combinations in ostriches (Al-Sobayil et al. 2009).

Nonrebreathing systems are used in birds ≤ 7 kg, with an oxygen flow rate of 200 mL/kg/min. Circle rebreathing systems are used in larger birds (≥ 50 kg), with a flow rate of 20–30 mL/kg/min.

Injectable protocols have not provided adequate maintenance anesthesia for prolonged periods. Some success is possible using ketamine and xylazine for induction, followed by IV infusion of ketamine, xylazine, and guaifenesin (Cornick-Seahorn 1996) (Table 26.2). Repeated IV administration of ketamine (5 mg/kg) at 10–15 minute intervals can be used to prolong and/or maintain immobilization (Bruning & Dolensek 1986).

Intravenous pentobarbital is not recommended, as it has been associated with regurgitation and prolonged recoveries (Cornick-Seahorn 1996). Propofol may be a useful alternative for extended anesthetic procedures; clinical and research evaluation of its use in ratites is limited, but promising (Langan et al. 2000).

RECOVERY

Birds should be recovered in a dark, quiet, well-padded area to minimize stress and trauma. Use of diazepam (0.13–0.41 mg/kg IV) or midazolam (0.15 mg/kg IV) to produce a calming effect during the recovery period may help minimize self-trauma (Cornick & Jensen 1992; Cushing & McClean 2010). Alternatively, manual restraint of the bird in sternal recumbency until it is able to stand without assistance can be used. Some clinicians will restrain the bird in a towel or tarpaulin using tape or cargo straps until the bird is able to support itself. If this method of restraint is used, quick-release holding straps are recommended. Commercially available wraps are available for use in ratites (Raines 1998). An alternative method involves recovering the bird in sternal recumbency surrounded by hay bales, with a tent of bales over the top of the bird. The bird is not released from this enclosure until fully alert (D. Heard, pers. comm. 2006).

Reversal agents available include yohimbine, atipamezole, naloxone, naltrexone, diprenorphine, and flumazenil (Table 26.2). Reversal agents, such as yohimbine for antagonism of xylazine, are not commonly employed in ratite anesthesia protocols. Atipamezole is used for reversal of alpha-2 adrenergic agonists (xylazine, detomidine, and medetomidine), and flumazenil is used for reversal of the benzodiazepines. Flumazenil was not routinely used in the past because of associated costs and lack of necessity (Cornick-Seahorn 1996); recent reductions in flumazenil cost may allow for increased use for benzodiazepine reversal. Intramuscular injection of diprenorphine has been used to reverse the effects of etorphine. Intravenous naloxone administration followed by diprenorphine IM was noted to allow for smoother recovery following carfentanil

administration than naloxone alone (Cornick & Jensen 1992).

In some cases, clinicians may prefer intramuscular administration of reversal agents instead of intravascular administration to allow for a more gradual recovery. Extubation is not recommended until the bird is swallowing on its own, and able to maintain its head in a normal position. The oral cavity should be examined prior to extubation to ensure excess secretions, blood, or debris is removed to maintain a clear airway. Renarcotization has not been reported, but birds should be monitored closely following reversal administration.

FIELD ANESTHETIC TECHNIQUES

There is presently no ideal technique for immobilization or anesthesia of ratites. Field immobilization is complicated by large drug volumes, and “rough” induction and recovery periods. There are also only limited reported investigations of field techniques. Both blowpipes and carbon dioxide-powered guns have been used, in combination with plain or barbed darts, for remote drug injection (Chapter 12). Ideally, reversible anesthetic regimens are used.

Administration of medications using darts delivered by CO₂-powered pistol has had mixed success for immobilization of cassowaries and ostriches (Fig. 26.5). Pole syringe use is hampered by difficulty in gaining proximity and access to injection sites (Stoskopf et al. 1982). Blowpipes and nonbarbed darts have also been used to deliver drugs to the thigh or lumbosacral muscles (Samour et al. 1990) (Fig. 26.5). For successful dart injection, a perpendicular trajectory path into the muscle is required. Darts projected at an angle are likely to bounce out of the muscle prior to full delivery of medications (Samour et al. 1990; Stoskopf et al. 1982). Ratites accumulate fat over the pelvis and paralumbar musculature, and in obese captive birds, this area is avoided for IM injection.

Evaluation of medetomidate/azaperone in captive ostrich chicks resulted in successful immobilization; although recommended for field use, it was not evaluated in adult ostriches or non-captive settings (Van Heerden & Kefren 1991). Etorphine and Etorphine/medetomidine combinations have been used to capture adult ostriches (Fowler 1995; Ostrowski & Ancrenaz 1995). Based on investigations in captive ratites, high dosage ketamine/xylazine combinations may produce field capture and restraint; supplemental IV ketamine is necessary to prolong immobilization (Bruning & Dolensek 1986).

Carfentanil may cause induction excitement; this is lessened when combined with xylazine (Raath et al. 1992). This combination otherwise produced minimal to no adverse side effects, and was reversed with naltrexone and yohimbine without complication. Carfentanil/ketamine combinations have also been recommended (Fowler 1995).

Exertional rhabdomyolysis (capture myopathy) may occur in chemically immobilized ratites (Chapter 13); field procedures are conducted by experienced personnel and at appropriate ambient temperatures. If excessive stress, excitement, or activity occurs prior to darting, it is prudent to abort the procedure. Medications and supplies necessary for treatment of exertional myopathy should be available during immobilization procedures.

MONITORING

Depth of anesthesia is assessed using heart rate and rhythm, respiratory rate and character, arterial blood pressure, wing and/or neck tone, and assessment of pedal, palpebral, and corneal reflexes. Continuous cardiac monitoring is achieved using an electrocardiogram or manual auscultation. Esophageal stethoscopes are used in chicks or small ratites. The brachial, medial metatarsal, or digital arteries are used for pulse assessment. Heart rates of 45–80 beats per minute are considered normal in anesthetized adults. The respiratory rate in an anesthetized adult ratite ranges from 25 to 40 (Gilsleider 1998).

Direct arterial blood pressures are measured by inserting catheters at the arterial sites listed earlier (Cornick & Jensen 1992; Lin et al. 1997). Additional arterial sites include the cranial aspect of the tibiotarsal bone, and parallel to the mandibular beak within the oral cavity (Cornick-Seahorn 1996). Indirect blood pressure monitoring has met with mixed success (Al-Sobayil et al. 2009; Cushing & McClean 2010). Based on information from mammalian species, a mean arterial pressure ≥ 60 –70 mmHg is desirable. However, based on research it is proposed that ostriches normally have a higher arterial blood pressure than mammals (Cornick & Jensen 1992; Lin et al. 1997). Different drug combinations in different species and age animals are expected to affect the mean, systolic, and diastolic blood pressure; the limited ranges reported in the literature may serve as a rough guideline for acceptable values in ratites (Cornick & Jensen 1992; Lin et al. 1997; Matthews et al. 1991) (Table 26.3). Arterial blood gases and pH can also be monitored, although normal values are limited or nonexistent. Venous blood gas samples have been used to monitor acid-base status during anesthesia (Cushing & McClean 2010), and may be affected by age and sex of the bird (Bouda et al. 2009).

Additional monitoring includes capnography to assess ventilation, cloacal temperature, and pulse oximetry. The pulse oximetry probe can be applied at the wing web, tongue, intermandibular tissue, or tibiotarsal area. Juvenile birds in particular are susceptible to hypothermia, while adults may experience hyperthermia; frequent assessments of the cloacal temperature are recommended.

COMPLICATIONS

Complications associated with physical restraint either pre or post anesthesia include: wing fractures; tibiotarsal fractures; tarsometatarsal joint luxation; lacerations caused by hooks or other restraint devices; cervical vertebrae dislocation or fracture; compression injury of the trachea; hypoxemia; peroneal nerve damage; and capture myopathy.

Anesthetic complications noted in the literature include: hypothermia (especially very young and very thin birds); hyperthermia; regurgitation (especially in cases with preexisting gastrointestinal disease); hypoglycemia; neuropathy and myositis (due to insufficient padding during anesthesia); tracheal occlusion due to poor neck positioning; apnea; premature ventricular contractions (cause undetermined; Matthews et al. 1991); bradycardia; cardiac arrest; hypertension (Matthews et al. 1991); voluntary movement; self-trauma during recovery; excessive oral and respiratory secretions; hypocapnia (possibly related to excessive intermittent positive pressure ventilation); hypercapnia (Cornick & Jensen 1992; Cushing & McClean 2010); secondary fungal/yeast infections (Matthews et al. 1991) and rupture of great vessels (Cullen et al. 1995; Honnas et al. 1991).

Doxapram (5 mg/kg IV) can be used in cases of apnea, and hypotension can be treated using increased IV fluid administration, decreasing anesthetic depth, IV dobutamine (2–5 μ g/kg/minute), or IV dopamine (5 μ g/kg/minute). Epinephrine (0.02–0.2 mg/kg IV or intratracheal) can be used in cases of cardiac arrest, in conjunction with cardiac compression applied to the lateral aspect of the bird (Cornick-Seahorn 1996). Voluntary movement may be avoided by using butorphanol (0.02–0.05 mg/kg IV) to control pain, or by using ketamine intraoperatively (0.2 mg/kg IV). Bradycardia has been arbitrarily defined in the literature as heart rate < 30 beats/min. Anticholinergic agents, such as glycopyrrolate or atropine, have met with variable success in treatment of bradycardia in ratites (Cornick-Seahorn 1996). Xylazine administration is thought to be associated with bradycardia in ratites, but conclusive evidence is lacking at this time.

Myopathy is treated with supportive care (IV fluids with bicarbonate, dextrose, corticosteroids, vitamin E-selenium, calcium, antibiotics, and flunixin meglumine) and possibly dantrolene for muscle relaxation.

DISEASES OF CONCERN

Procedures requiring general anesthesia in the ratite include: laceration repair; evaluation of traumatic injuries; evaluation and treatment of exertional myopathy (Smith et al. 2005; Tully et al. 1996a); sequestra removal (Tully et al. 1996b); castration (Pye 2007); removal of retained or infected yolk sacs; esophagostomy tube

27 Raptors

Patrick T. Redig, Michelle Willette, and Julia Ponder

INTRODUCTION

The raptors or birds of prey are an assemblage of avian species representing convergent evolution from diverse lineages, as opposed to distinct taxonomic relationships among major orders. All are completely carnivorous birds, acquiring their food by active hunting and/or scavenging. The major orders of raptors are the Strigiformes (owls), Falconiformes (falcons), Accipitriformes (hawks and eagles), and the vultures. The taxonomic grouping of the vultures is not completely established. Two major groups exist, the so-called Old World vultures (order Falconiformes) and the New World vultures (order uncertain; possibly Falconiformes, or Accipitriformes, or Ciconiiformes [storks] or Cathartiformes [*Incertae sedis*]). There are approximately 280 species in various orders worldwide. Ravens (Passeriformes: Corvidae) are sometimes included among the raptors due to similarity in life history habits and a strong tendency to carnivory.

Average or representative weights for raptors range from the diminutive elf and Saw-whet owls (40–85 g) to the large eagles of the Amazon and Philippine rain forest (harpy eagle 5–9 kg M:F; Philippine eagle 4–6 kg M:F) and the condors (California and Andean 9–12 kg, respectively). In all species, except the New World vultures and ravens, reverse sexual dimorphism is expressed with females ranging from 10% to 30% larger than the males. With few exceptions, plumage characteristics are not dimorphic and there is substantial overlap in weights between males and females, hence sexual determination is not a definitive process except at the extremes of the size ranges.

ANATOMY AND PHYSIOLOGY

All raptors possess strong hooked beaks that are capable of inflicting mild to serious damage to handlers and can also damage anesthesia equipment, such as masks and hoses, if not properly restrained. Additionally, except for vultures, all have very strong grasping feet armed with sharp, curved talons, rendering the need for proper restraint to be of paramount concern. The mouth of nearly all is large and wide; the glottis is clearly visible at the base of the tongue.

Across species of raptors, the anatomy of the respiratory system does not vary appreciably except in size, and it exhibits the basic avian anatomy and physiology of lungs and air sacs as found in other avian groups (Heard 1997; Ludders 1998). As with other avian species, it is important to remember the tracheal rings are complete and cuffed intubation tubes should not be used.

Procedures involving anesthesia in raptors are regularly conducted in dorsal, lateral, and sternal recumbency without marked overt differences in ventilation or manner of managing the anesthetic episode. Studies involving air sac volumes by computed tomography (CT) of isoflurane-anesthetized red-tailed hawks demonstrated that subjects had the greatest lung and air sac volumes in sternal recumbency compared with lateral or dorsal positioning (Malka et al. 2009). There were no changes in ventilatory rate as a function of position, and other respiratory variables were not evaluated. Dorsal recumbency has long been regarded as reducing ventilatory function owing to increased effort to raise the sternum and pressure from viscera against the

abdominal air sacs. While this theoretical possibility is recognized, these differences appear to be minor in day-to-day use of anesthesia. For long orthopedic procedures, however, sternal recumbency is recommended by the authors and is usually concordant with the principal surgical approaches to avian long bones (Redig & Roush 1978).

The digestive tract of raptors is typical of carnivorous birds with some variations. Falcons, hawks, eagles, and vultures have a crop, a varying saccular or expandable portion of the esophagus that stores food. Owls do not possess a true crop; rather, the mid-cervical esophagus is freely expansible and functions as a site of temporary food storage. All have a proventriculus (glandular stomach) positioned as a bell-shaped structure on the anterior aspect of the ventriculus. The latter is the site of chemical digestion and pellet formation. Pellets are formed from nondigestible food residues that are egested at the completion of the digestion cycle. The intestinal tract is relatively short and has rapid transit times. Owls have ceca, while falconiformes do not. The functional significance of ceca is poorly understood. When the gastrointestinal tract is full of food or contains an as-yet unegested pellet, there can be considerable enteric expansion and concomitant reduction in airspace in the abdominal air sacs. A 12- to 24-hour fast is generally recommended prior to anesthesia in all but the smallest raptors, where a small amount of "clean meat" (devoid of bones, feathers, or fur) may be fed up to a couple of hours before anesthesia without complication.

CAPTURE AND RESTRAINT

Many raptors are maintained in captivity, some in very close association with humans, as in the sport of falconry or trained and bonded to handlers for use in educational programs; this bonding necessitates different approaches to handling for restraint than for their wild counterparts. Most raptors are armed "front and back," and even relatively, tame, docile birds will often strike with the beak or talons when being restrained; caution and protection are strongly advised in all situations. That said, puncture wounds from talons are much more serious injuries than bite wounds. An injury to the handler's face from either is also often serious. Proper restraint ultimately requires control of the legs and the head; covering the latter with a towel or a properly fitting hood after the bird is restrained will greatly reduce the tendency for the bird to struggle.

The overall goals of handling are to maintain safety of the patient, the handler, and the clinician, to provide proper positioning for medical procedures, to protect feathers from bending and breakage, and to minimize stress. The major hazards to clinician and handler safety include talon wounds, beak wounds, and wing

slapping, especially from eagles. The latter have been known to cause people black eyes and even to break their glasses. Personal protective gear, consisting of gloves of appropriate thickness and gauntlet length and safety glasses, are recommended. When handling eagles, the use of welder's leather cape, which protects the arms and shoulders from bites wounds, is further recommended.

To protect the bird and to avoid precipitating struggling and to prevent unintended injuries, it is important to cover the head of the patient with a hood or a towel to block out visual stimuli, to use slow, smooth continuous movements, and to establish good communication between the handler and the clinician so that who has control over the legs and head of the bird at any given time is never in doubt.

Capture of Untrained, Wild Birds

For wild birds being handled for rehabilitation or untrained display birds, "capture" is essentially the first component of the restraint procedure. On the one hand, the goal is capture with a minimum of risk to patient and the handler, with less concern about stress or psychological trauma to the bird; on the other hand, achieving firm control on a strong, struggling patient. Capture can be accomplished in any number of ways, depending on the demeanor of the bird and skill of the handler. Effective means include a dip net, or approaching the perched bird in the dark, using a light source that is quickly clicked off and on to provide the handler with a brief window of light to observe where the bird is and allow approach, or covering the bird with a large towel. Some species, great horned owls in particular, will sit on a perch giving a vivid threat display, but, in most cases, not make any attempt to escape or attack; these can be grabbed quite easily by the legs. Regardless of how the bird is approached, the objective is to bring one's hands in close proximity to the legs, one on either side. As the hands are moved closer slowly, there will come a point where the bird's personal space has been invaded (usually within about 3–5 in of the legs) and, instead of looking directly at the person approaching them, they will divert their gaze momentarily in the direction they intend to flee. In that moment, a quick grasping of each leg and lifting the bird off its perch will accomplish the capture portion. At that point, the wings are folded into the body and the bird is laid flat on a table or the floor, both legs are grasped in one hand with the index finger between the legs, and the other hand is used to grasp or cover the head (Fig. 27.1a,b).

These methods work "to a point" with most raptors up to about 5–6 Kg, which includes most species—the average handler can readily overcome their muscle strength. The very large eagles (harpy and Philippine) along with the large vultures demand greater skill and respect when being captured. The eagles have very large and powerful legs that require the handler to have

Figure 27.1. (a) Safely restrained raptor (red-tailed hawk) on the examination table. (b). Properly restrained large raptor (bald eagle). Notice protective gear worn by the handler, including leather welder's vest, gauntlet gloves, and safety glasses.

considerable strength and attention to detail in order to overcome their efforts to struggle free.

Vultures, both Old and New World, will defend themselves during capture by regurgitating. The material ejected is malodorous and difficult to remove from clothing.

Capture of Trained Raptors

For trained birds in which a bond of trust has been established, restraint is best accomplished without the drama of a capture episode. Though strictly manual methods are mostly used, chemical sedation can positively impact the process (see later). For manual restraint, if the subject is perched on a handler's gloved fist, it can be slowly approached (use of darkness is again helpful, but less necessary) from the front and the legs gently grasped by one hand with an index finger in between them. Control of the wings is gained as the bird is gently lifted off the fist and placed on a table and the head covered. Alternatively, the bird may be grasped over the wings from behind and firmly, but

gently lifted off the fist and laid on a table. Many falconry birds will have a hood on their head and this renders each of these methods that much easier. Another useful and relatively stress-free method for restraint of a hooded falcon is to place an oversized anesthesia face mask over the head of the bird and flow isoflurane for a few minutes until the bird is unstable, gently catching them when they fall backwards off the perch, and continue with induction.

Many of the issues of restraint of trained birds may be avoided by the use of small volumes of chemical restraint agents injected with a very small (27-gauge) needle into the pectoral muscle or given via the mouth or nares. An injected mixture of ketamine and dexmedetomidine (previously medetomidine) has been shown to be highly effective (Molero et al. 2007) and safe in large falcons and others (Table 27.1). This approach induced ataxia and general loss of response in 3–4 minutes that readily allowed further induction with low concentrations of isoflurane (2% induction and 1% maintenance). Upon cessation of isoflurane and intramuscular administration of the antagonist, atipamezole (0.15 mg/kg), smooth, uneventful recovery occurred within 10 minutes. The metabolism of ketamine while the bird was under isoflurane allowed recovery without the uncontrolled wing-flapping and other movements associated with recovery from ketamine anesthesia. Other injectable agents, especially midazolam, have been used in a similar manner (Table 27.1).

ANCILLARY ASPECTS OF ANESTHESIA IN RAPTORS

Intubation and Air Sac Cannulation

Intubation is not undertaken for short procedures, up to 20–30 minutes, and not at all in raptors weighing less than approximately 150g, especially sharp-shinned hawks. In these, the inside diameter of the tube that would fit inside the trachea becomes too small and too prone to blockage by mucous. Appropriately sized tubes should be available, however, in order to provide a means for rapid intubation and ventilation should the bird become apneic.

Intubation of raptors is a straightforward procedure and recommended to provide a means of ventilatory support for any procedures that exceed 20–30 minutes. Mask administration is generally adequate for procedures of shorter duration; however, it is recommended to have appropriate-sized intubation tubes readily available should apnea occur. An uncuffed tracheal tube that slides easily into the trachea is selected; it is inserted only sufficiently to prevent the tip from slipping easily out of the trachea. Pieces of white adhesive tape are used to affix the tube to the beak or the head to prevent its being dislodged (Fig. 27.2). Intubation should be conducted only in birds that have been previously taken to a plane of surgical anesthesia via mask

Table 27.1. Reported dosages of more commonly used injectable anesthetics in raptors

Agent	Red-Tailed Hawk	Bald Eagle	Golden Eagle	Great Horned Owl	Falcons	Others	Comment	Reference
Ketamine							Multiple species, dosed at 5–20 mg/kg, variable results, difficult recoveries	Samour et al. (1984)
Xylazine							Multiple species, 8–10 mg/kg IM and 2–8 mg/kg IV; generally inconsistent results and unfavorable levels of sedation; reversed with yohimbine (0.2 mg/kg)	Freed and Baker (1989)
Ketamine/ diazepam	x			x			10–30 mg/kg + 1.5 mg/kg K:D	Redig and Duke (1976)
Ketamine/xylazine							10–15 mg/kg + 2 mg/kg IM (K + X) For owls, response variable in <i>Bubo spp.</i> ^a	Carpenter (2013)
Ketamine/ xylazine/ yohimbine	x						Multiple species, dosage recommendations reflecting species variations in response using a 5:1 combination of ketamine and xylazine; largely superseded by ketamine/medetomidine procedures Yohimbine administered 20 minutes after induction with a 2:1 combination of ketamine and xylazine; yielded a dose-related reversal response and smooth recovery; xylazine superseded as earlier	Redig (1998)
Midazolam/ butorphanol (for sedation) Medetomidine ^c						x (Psittacines ^b)	0.5 mg/kg midazolam/1–3 mg/kg butorphanol—IM 2 mg/kg direct installation into nares	Degernes et al. (1988)
Dexmedetomidine					x	Common buzzard (<i>Buteo buteo</i>)	60–85 ug/kg as a preanesthetic agent for isoflurane 150–350 ug/kg IM Dosed at 25 ug/kg and 75 ug/kg for buzzards and kestrels, respectively. Reported better sedation than with medetomidine; smooth reversal with atipamezole	Lennox (2011) Mans et al. (2011)
Medetomidine/ butorphanol							Medetomidine: 5–20 ug/kg/butorphanol: 0.1–0.3 mg/kg	Lawton (2008) Carpenter (2013) Santangelo et al. (2009)
Ketamine/ medetomidine						x	Administered as pre-anesthetic to isoflurane in Saker falcons, reversed with atipamezole after Isoflurane anesthesia. Dosage schedule: 3 mg/kg-60 ug/kg-0.15 mg/kg ketamine-medetomidine-atipamezole 2–4 mg/kg + 25–75 ug/kg IV (K + M); 3–5 mg/kg + 50–100 ug/kg IM (K + M)	Carpenter (2013) BSAVA Small Animal Formulary Appendix Molero et al. (2007)
Ketamine/ medetomidine/ butorphanol						x (Psittacines ^b)	3 mg/kg + 40 ug/kg + 1 mg/kg IM (K + M + B) premed or supplement to isoflurane	Carpenter (2013)
Fentanyl	x						Fentanyl produced a dose-related reduction in isoflurane MAD	Pavez et al. (2010)
Fentanyl/lidocaine (brachial plexus blocks)						x	A combination of fentanyl:lidocaine (50 ug/kg:5 mg/kg) was effective for brachial plexus nerve block—required use of a nerve locator	d'Ovidio et al. (2011)
Propofol	x			x			Induction and CRI rates assessed in hawks and owls (4.48 mg/kg and 0.48 mg/kg/min for hawks and 3.36 mg/kg and 0.56 mg/kg/min for owls; hypoventilation, prolonged and variable recovery, moderate-to-severe excitation observed	Hawkins et al. (2003)

^aAuthor's experience.^bAuthor's opinion that this combination would be effective and safe in raptors.^cMedetomidine is no longer available at time of writing; has been replaced by dexmedetomidine; may be obtained by compounding.

Figure 27.2. Insertion of intubation tube in a falcon (a) and intubated raptor (gyrfalcon) (b) prepped for orthopedic surgery. Note capnography and Doppler unit included in monitoring equipment array. While the latter may have limited utility for monitoring blood pressure, it serves as a useful means of audible monitoring of heart rate.

induction—attempts to intubate an awake bird are extremely stressful and should not be attempted. In some birds, insertion of the endotracheal tube will induce a period of apnea. This can be preempted by topically applying a small volume of 2% lidocaine to the rim of the glottis a few minutes prior to tube insertion.

Raptors are also amenable to air sac cannulation and this is a very useful modality for relieving dyspnea associated with upper airway obstruction or for administering gas anesthesia in instances where the presence of an endotracheal tube would interfere with manipulations about the head and mouth. Caudal thoracic air sac cannulation takes advantage of the normal physiologic direction of airflow from caudal to cranial to enter the lungs for gas exchange. Depending on the reason for cannulation, two scenarios for tube size are

Figure 27.3. (a) Large-diameter air sac cannula in place for use as a breathing tube. (b) Small-diameter (8–12 Fr; 2.7–4.0 mm) air sac cannula made from red rubber tube (top) and commercially available dedicated air sac cannula tube (bottom) for use in administering gas anesthesia. Note added length to provide maneuverability without dislodging the tube from its insertion site (see Fig. 27.4c).

considered. Where relief of dyspnea from upper airway blockage is the goal, a tube should be selected that is similar in size or slightly larger than the trachea itself to provide a low resistance pathway for air movement during spontaneous breathing (Fig. 27.3b). Where the cannula is intended for anesthesia administration, a smaller diameter tube that is more flexible (8–12 French red rubber tube or silicon) and of sufficient length

(50–100 cm typ.) to allow attachment of the anesthetic machine tubing at some distance from the patient is desirable (Fig. 27.3b).

Insertion of the air sac cannula is relatively simple and can be accomplished following mask induction. The tube is inserted on either the right or left side. The site is prepared for surgical approach and a stab incision made in the last intercostal space midway between the attachment point of the ribs on the vertebral column and the intercostal joint (Fig. 27.4a–c) and extended slightly by blunt dissection with a hemostat. The tube is inserted between the ribs arriving in the posterior thoracic air sac. Successful placement of the tube can be assessed by holding a small feather over the open end of the tube, or by looking for condensation from expired air on the wall of a clear breathing tube. Once proper placement has been determined, adhesive tape “wings” are applied to the tube at the level of exit through the skin, and sutured to the body wall with

two small sutures (Fig. 27.4b). Breathing tubes may be left in place for several days to allow time for management and relief of the source of dyspnea.

Positive Pressure Ventilation

Intermittent positive pressure ventilation is essential for ventilator support during extended anesthetic periods (>30 minutes). Despite leakage from the loose fitting nature of the intubation tube, manual ventilation can be achieved by compression of a rebreathing bag attached to the open anesthesia circuit or by an ambu bag. Because of leakage as well as little risk of overinflation given the compliance of the air sacs and coelomic wall, pressures and volumes used for ventilation can be judged by watching the excursions of the sternum in the dorsally recumbent bird or elevations of the base of the tail in the ventrally recumbent bird. Rate of ventilation for the nonspontaneously breathing raptor is generally 6–12 respirations per

Figure 27.4. (a). Positioning of patient and preparation of insertion site in last intercostal space for air sac cannula: arrow indicates site. (b) Anchoring the air sac cannula in place by suturing tape wings to body wall. (c) Air sac cannula installed and attached to anesthesia administration tubing.

minute. Provision of intermittent positive pressure ventilation in the spontaneously breathing, anesthetized bird during a prolonged anesthetic episode is important; a rate of two cycles per minute is sufficient to maintain blood gases in a suitable range (Aguilar et al. 1995) for extended time periods. Though not commonly used, mechanical ventilators have been used to great effect by some clinicians (Hawkins & Pascoe 2007).

VASCULAR ACCESS

The sites for vascular access in general include the right jugular (in some cases, the left is sufficiently large to permit needle or catheter insertion), the basilic vein on the ventral aspect of the humerus, the cutaneous ulnar vein where it crosses the ventral aspect of the elbow, and the medial metatarsal vein, just proximal to the hock joint. The latter is somewhat variable. In addition, in raptors weighing less than 100g, the cutaneous ulnar vein may be too small to access, except in falcons, where even in the case of kestrels and merlins, it is sufficiently large to allow venipuncture.

INJECTABLE DRUGS FOR (SEDATION) AND ANESTHESIA

While inhalant anesthetic agents are the workhorse of avian anesthesia and presently are highly recommended over injectable agents, there is a historical (Cooper 1974; Cooper & Frank 1974; Redig & Duke 1976) as well as increasing contemporary interest in the role of injectable agents as stand-alone short-term, reversible anesthetic agents, as sparing agents for isoflurane and other inhalant agents, and for sedation and analgesia (Table 27.1).

Analgesia is an important component of surgical anesthesia, and gas anesthetics alone are generally insufficient. Pain management is best accomplished through a multimodal approach where combinations of injectable drugs to address various pain pathways are used, thereby allowing lower concentrations of gas anesthetic and more effective pain management.

The recognized disadvantages of injectable agents are the interspecies variation and the general lack of research on a species-by-species basis to establish optimal dosing schedules and knowledge about pharmacological effects, not only for raptors, but for most avian species (Chapter 25). Some injectable drugs commonly used for minor procedures or as a preanesthetic for gas agents are discussed later. Prior to use of any injectable agents, the patient should be weighed to the nearest 10g and the dose calculated accordingly.

Sedative Agents and Protocols

Benzodiazepines, such as diazepam (0.2–0.5 mg/kg IM) and midazolam (0.1–0.5 mg/kg IM), have been used

successfully for short nonpainful procedures or preanesthetic sedation. These drugs have sedative and antianxiety effects, as well as providing good muscle relaxation. However, they provide minimal analgesia. Recent reports in psittacines suggest use of midazolam directly instilled in the nares for sedation (2 mg/kg—Mans et al. 2011) or intramuscularly in combination with butorphanol (midazolam 0.25–0.5 mg/kg; butorphanol 1–3 mg/kg—Lennox 2011); limited experimentation in the clinic at The Raptor Center with bald eagles and a few other species suggests these protocols may have utility and should be researched further. Reversal of midazolam with flumazenil (0.05 mg/kg) is a further enhancement to its use.

Adrenergic agonists, such as xylazine (Freed & Baker 1989), medetomidine (Lawton 2008), and dexmedetomidine (Santangelo et al. 2009), may be used for general sedation or as a preanesthetic to inhalant anesthesia (Table 27.1). They have the advantages of requiring very small volumes and of being reversible with yohimbine or atipamezole. Lawton (2008) recommends the usage of medetomidine dosed at 60–85 µg/kg. Reported dosage ranges for the more potent dexmedetomidine ranged from 25 µg/kg in common buzzards (*Buteo buteo*) to 75 µg/kg in common kestrels (*Falco tinunculus*) (Santangelo et al. 2009). As adrenergic agonists, these agents may have some effect in countering hypotensive conditions associated with isoflurane anesthesia (Aguilar et al. 1995; Goelz et al. 1990; Schellbacher et al. 2011). Their use as immobilizing agents for anything other than minor surgical procedures is not recommended. These may have utility for conducting procedures in the field, such as a means of low stress restraint for transmitter attachment or blood collection (see later for use with opioids for analgesia).

These drugs are adequate for short procedures or can be utilized as a preanesthetic for inhalant anesthesia where they have a significant MAC-sparing and analgesic effects. Their use can cause notable bradycardia and respiratory depression. Xylazine has been used by some as a short-term sedative, but it is regarded as unreliable (though still useful with caution), owing to the cardiorespiratory effects and the possibility of hyperexcitability (Freed & Baker 1989; Lawton 2008).

Short-Term Anesthesia with Injectable Agents

Ketamine, a dissociative anesthetic, produces a dose-related unconsciousness and analgesia, but with highly variable species specific results and recoveries characterized by uncontrolled movements (Samour et al. 1984). Dosing varies between 10 and 200 mg/kg, according to the bird's size (the larger the bird, the smaller the per kilogram dose used; however, there is much species variability). We regard the upper end of this dosage range as excessively high and dangerous by a factor of 10. This drug should never be used alone. Despite indications of use in older literature (Redig &

Duke 1976), ketamine can be safely used only up to a dose of 20 mg/kg in raptors; lower doses are recommended, and these can be achieved by combining it with an adrenergic agonist.

Combinations of ketamine and α_2 adrenergic agonists (e.g., xylazine, medetomidine, and dexmedetomidine) or benzodiazepenes (diazepam and midazolam) have utility in anesthesia of raptors. A mixture of ketamine and diazepam was one of the original protocols utilized in raptors, but was found to be inferior to subsequent combinations of agents (Redig & Duke 1976). A combination of ketamine and xylazine (5:1 ratio) was extensively used at one time with varying degrees of success and marked species dependency as to results (Redig 1998). A combination of ketamine and xylazine in a 2:1 ratio was shown to be reversible with yohimbine and suggested to have utility for short procedures owing to the rapid metabolism of the ketamine (Degernes et al. 1988). Further study on xylazine alone as a sedative by Freed and Baker (1989) in a variety of raptors showed generally poor sedation, but good reversibility with yohimbine. For the most part, all uses of xylazine have been superseded by medetomidine or dexmedetomidine (Ramsey 2012).

Butorphanol (1–3 mg/kg IM q4–6h) is the most commonly used opioid for pain management in birds and is very effective for control of surgical pain at lower doses. Butorphanol, in combination with α_2 agonists (notably medetomidine), provides a useful protocol for short-term anesthesia (Ramsey 2012). Used as preoperative medication or a constant rate infusion (CRI) intraoperatively, butorphanol is inhalant-sparing. It is typically dosed at 1 mg/kg preanesthesia; however, doses as low as 0.3 mg/kg are effective as a preanesthetic agent; owing to its short half-life (1–q 2 hours), it may be repeated for long procedures (Hawkins & Pascoe 2007). Another opioid, fentanyl, has been demonstrated to reduce the minimum anesthetic dose (MAD) for isoflurane in red-tailed hawks (Pavez et al. 2010).

Propofol, a nonbarbiturate anesthetic, has been used as a bolus (1.33 mg/kg IV, titrate to effect) for induction and/or used as a CRI for maintenance of anesthesia. Propofol provides a rapid induction, but some species are reported to have extended recoveries and excessive excitement. A study in red-tailed hawks and great horned owls (Hawkins et al. 2003) utilizing propofol for induction by direct intravenous injection at 1 mg/kg/min followed by maintenance with CRI at predetermined doses (0.48 mg/kg/min for red-tailed hawks and 0.56 mg/kg/min for great horned owls) induced a light plane of anesthesia accompanied by transient CNS signs during recovery (Table 27.1). Respiratory depression and apnea were noted necessitating the recommendation that ventilatory support be provided in all phases of its use. The authors concluded this agent was of limited utility in these raptor species.

LOCAL AND REGIONAL ANESTHESIA (NERVE BLOCKS)

Regional anesthesia for perioperative anesthesia using nerve blocks have received scant attention and initial attempts involving blind injection of local anesthetics (lidocaine/bupivacaine) have yielded variable results in achieving brachial plexus nerve block (Brenner et al. 2010; Figueiredo et al. 2008). A significant improvement in efficacy has been reported by incorporating fentanyl with lidocaine (fentanyl 50 mcg/kg:lidocaine 15 mg/kg) and injecting it with the aid of a nerve locator. This approach was successful in providing analgesia and an isoflurane sparing effect in the repair of a humeral fracture in a peregrine falcon (d'Ovidio et al. 2011). While this appears to be a valuable approach to improving overall anesthesia for orthopedic procedures, clearly more work needs to be done to establish effective procedures across a variety of species and situations.

INHALANT ANESTHESIA

The halogenated hydrocarbons (isoflurane, sevoflurane, and desflurane) have been used successfully in wide variety of raptors (Table 27.2) and have replaced completely the use of halothane or methoxyfluorane. Each has its own characteristics of solubility in blood that affect the manner in which they are used. Isoflurane is the most utilitarian providing a suitably short induction time accompanied by little excitation, a sufficient downtime after mask removal to allow some short procedures, and a rapid recovery. It has been in use for raptors since the 1980s (Clutton 1986). Isoflurane has been shown to be arrhythmogenic in bald eagles (Aguilar et al. 1995). In addition, a Doppler echocardiography-based study showed that isoflurane, in addition to reducing heart rate, also reduced blood flow velocity; however, there was nonconcordant species variability in these measures (Straub et al. 2003). In contrast, sevoflurane and desflurane, while having shorter induction times and lesser cardiac and ventilatory impacts (Joyner et al. 2008), had very much more rapid recovery times, making it nearly impossible to conduct any examination or minor procedures with the mask removed before the bird began to recover (Granone et al. 2011). One study of sevoflurane in crested caracaras showed that while it caused mild reduction in various cardiopulmonary parameters, it was not arrhythmogenic (Escobar et al. 2009).

A study comparing isoflurane to sevoflurane was conducted in bald eagles (*Haliaeetus leucocephalus*) (Joyner et al. 2008). Sevoflurane produced more rapid induction and recovery than isoflurane, caused a lower increase in blood pressure, heart rate, and temperature over time, and had a slightly lesser occurrence of cardiac arrhythmias, though they were seen with both

Table 27.2. Inhalant anesthetics in raptors

Agent	Red-Tail	Bald Eagle	Golden Eagle	Great Horned Owl	Falcons	Other	Comment	Reference

			x					Clutton (1986)
								Granone et al. (2011)

agents. Sevoflurane had higher MAC values than isoflurane and was less likely to induce hypotension.

Preanesthetic Preparation

The goal of preanesthetic evaluation and preparation is to minimize the risk of anesthesia. While not always possible in emergency situations, taking the time to evaluate and prepare the patient can reduce the risk of an adverse event during anesthesia.

Fasting recommendations vary from none in small birds (use clean meat) with high metabolic rates to 12–24 hours in larger raptors (e.g., >500 g). If fasting is not an option, removing crop contents will reduce the risk of regurgitation and aspiration during recovery.

In addition to fasting, it is helpful to allow birds to acclimate in a quiet environment prior to anesthesia. This will allow for a decreased stress level and may reveal clinical symptoms previously hidden.

For raptors undergoing anesthesia for surgical procedures, fluids are routinely administered preoperatively during surgical preparation. Crystalloid (saline, lactated Ringers—up to 50 mL/kg) subcutaneously in the inguinal area or intravenous colloidal preparations (hetastarch—7 mg/kg) or combinations thereof may be used depending on circumstances. Crystalloids are generally sufficient to maintain vascular volume in the face of inhalant agent-induced vasodilatation (Steffey & Mama 2007). Colloids, however, may be indicated in providing prolonged vascular support if there is a need to enhance colloidal osmotic pressure and arterial blood pressure, for instance, in hypoproteinemic patients. Insensible loss of fluids associated with the administration of 100% oxygen can be counteracted by incorporating an in-line bubbler vessel (Fig. 27.5) in the system to provide humidification of the airstream.

Pain Management and Inhalation Agent Sparing

Inhalation agents are regarded as having generally inadequate analgesia properties and therefore additional pain control is desirable. Utilization of this also reduces the amount of isoflurane necessary for a procedure. Butorphanol is the drug of choice, although this is based on limited information derived from pigeons. While dosage recommendations range from 1 to 3 mg/kg, our experience is doses as low as 0.3 mg/kg are effective. Typical surgical candidates (e.g., fracture patients) will have been placed on meloxicam (0.5–1.0 mg/kg) prior to surgical preparation, and this effectively reduces the amount of butorphanol required.

Atropine is avoided as it does not effectively dry up oral and pharyngeal secretions, tending instead to make them more viscous (Fitzgerald & Blais 1993).

Dyspnea

Even when severe or arising from severe air sac disease (e.g., aspergillosis), dyspnea is not usually regarded as

Figure 27.5. In-line bubbler bottle for humidification of transport and anesthetic gases.

a contraindication to inhalant anesthesia. Between the state of unconsciousness, analgesia, and the 100% oxygen stream in which the gas is administered, dyspnea is almost always immediately lessened or relieved allowing relatively normal anesthesia to proceed. If possible, the cause of the dyspnea can be evaluated and sometimes alleviated (e.g., foreign body in the trachea).

Administration of Inhalant Agents

Induction While sedative and preanesthetic agents are recommended in situations where restraint is difficult or undesirable, most inductions are undertaken by direct mask administration of the gaseous agent. An advantage of the highly efficient avian respiratory system is that it is very easy to rapidly induce anesthesia through a face mask. Anesthesia is typically induced with 4–5% isoflurane (or sevoflurane at 5–8%) in oxygen (1–2 L/min, depending on size of the patient) using a face mask and a nonbreathing (Ayres T-piece or Bain) system. As soon as the bird begins to relax and the involuntary nictating membrane response slows, the vaporizer setting should be reduced to 2–3% and adjusted as necessary to maintain desired plane of anesthesia. For procedures lasting longer than 20–30 minutes, birds should be intubated as described earlier and in any case, intubation tubes should be available for emergencies. As many birds will keep their eyelids partially open during anesthesia, it is recommended to install ophthalmic ointment to prevent corneal drying.

Owls respond well to induction at lower concentrations of isoflurane, typically 1–2% with increasing concentrations as the animal begins to succumb to the agent. Use of higher levels results in a too rapid induction that increases the difficulty for equilibrating at a surgical plane without going into a dangerously deep level. Accipiters (especially sharp-shinned and sparrow hawks—goshawks and cooper's hawks to a lesser extent) and merlins also benefit from a similar low dose approach to induction.

Maintenance Most raptors can be maintained at 1.5–2.5% isoflurane or 2–4% sevoflurane (lower concentrations if premedicated with analgesics or sedatives) with an oxygen flow rate of 1–2L/min. Golden eagles and gyrfalcons require higher maintenance concentrations of isoflurane, usually at 3.5% or 4%. Anesthetic agents depress ventilation to a greater extent in birds than in mammals (Edling et al. 2001) and, therefore, hypoventilation should be presumed in all anesthetized birds. Intermittent positive pressure ventilation (2–4 times per minute) (Aguilar et al. 1995) manually administered is recommended to support the anesthetized patient. Since the avian patient can rapidly change condition during anesthesia, the patient should be constantly monitored by a person dedicated to this role. Key variables to monitor are respiratory rate and character (slow, even cycles being the desired condition), heart rate and rhythm, physical reflexes (especially corneal reflex), temperature, and blood pressure. Importantly, corneal and palpebral reflexes are slowed, but not eliminated during anesthetic episodes.

MONITORING

The following variables are routinely used for monitoring inhalation anesthesia: respiratory rate and character, nictating membrane response, toe pinch, heart rate, and muscle relaxation (neck or limb). In addition, monitoring body temperature through an esophageal or rectal thermometer is important to guard against both hyper- and hypothermia. In the intubated bird, end-tidal capnography using a side-stream sampling system (Fig. 27.6) is very effective for routine monitoring of ventilation (Desmarchelier et al. 2007; Edling et al. 2001). In such application, ventilation is managed so as to keep end-tidal CO₂ between 25 and 35 mmHg, effectively avoiding respiratory acidemia from inadequate ventilation, but not leading to respiratory alkalemia.

Respiratory Rate and Ventilation

As stated above, respiratory variables are the most important means of monitoring anesthesia. Respiratory patterns should be deep, even, and at a moderate rate—typically 12–20 cycles per minute. This rate, however, is highly variable depending on the size of the bird

Figure 27.6. Capnographic unit in use. Note that there are collocated esophageal stethoscope and pulse oximeter transducers (not visible in this image).

with larger patients having slower respiratory rates. The character and pattern over the duration of the episode is more important than the absolute rate. Since changes in respiratory rate typically precede cardiac changes, respiration is probably the single most important factor to monitor.

It has been held in the past that because of their lack of alveoli, birds do not have a functional residual volume of air in their lungs to buffer changes in PaO₂ and PaCO₂ (Edling et al. 2001; McLelland 1989), and gas exchange does not occur unless there is movement of air through the air capillaries; this would suggest apnea could be immediately serious. Experience, however, has shown this not to be the case, and it has been argued (Hawkins & Pascoe 2007) birds contain a large reservoir of air in the air sacs, and when maintained on a 100% O₂ supply, there is sufficient movement of gas across short diffusion distances to maintain O₂ levels for a short period of time. This observation is consistent with our experience in anesthesia of thousands of raptors, and while not dismissing the risks of apnea, nonetheless, it moderates the reaction to it. Conversely, if apnea occurs in a bird breathing room air (e.g., if anesthetized with an injectable agent), apnea would be a considerably more serious issue requiring aggressive response. Potential causes of apnea include placement of an endotracheal tube, poor ventilation, dive response in waterfowl (trigeminal nerve response), hypothermia, and respiratory depression secondary to anesthetic drugs. The most important monitoring system for avian anesthesia is an alert technician who recognizes changes in respiratory patterns, evaluates the underlying causes, and corrects them. Should apnea occur, anesthetic gases should be turned off, the delivery system purged, oxygen flow reestablished and the

patient manually ventilated. Oftentimes, manipulation or insertion (if not previously intubated) of the endotracheal tube or stimulation of the tongue, or the abdomen caudal to the sternum will reinitiate spontaneous breathing. If such stimulation is not effective, attach an ambu bag or other means of delivering air into the endotracheal tube (by mouth if necessary) and ventilate at 10–12 cycles per minute until respiration is restored. Gas delivery will need to be resumed at this point or the bird is likely to begin showing signs of recovery.

Heart Rate and Rhythm

In addition to a stethoscope (direct or esophageal), a Doppler monitor or EKG machine can be used to monitor heart rate and rhythm. Rates vary inversely with size of the bird. Small raptors will have rates >200bpm and generally too rapid to count. Mid-size birds (200–600 g) will maintain heart rates between 180 and 250, while eagles will have heart rates of 80–150. Maintenance of an even, steady rhythm in the range of an acceptable rate for a given species is more important than an absolute number. Cardiac complications can be minimized by proper fluid therapy, oxygenation, ventilation, and appropriate anesthetic depth. Decreased heart rate should prompt a reduction of anesthetic gas concentration, evaluation and treatment of hypotension, and review of the patient's surgical situation (pain, tissue trauma, and positioning). Atropine administered intratracheally or via vascular access will often eliminate pain-related bradycardia. Hypotension is countered by crystalloid or colloid fluid administration. Cardiac arrest is typically preceded by apnea; however, on rare occasions it can occur without warning and largely for unknown reasons—underlying pathology is seldom found. Unfortunately, cardiac arrest is typically not successfully reversed.

Arrhythmias, primarily A-V blocks, have been reported to occur in a high percentage of bald eagles anesthetized with isoflurane (Aguilar et al. 1995; Joyner et al. 2008). However, it is not accompanied by cardiac arrest or other complications. Their causes are not apparent. As a practical matter, in our application in thousands of anesthetic episodes of anesthesia in eagles, they do not appear to present undue risk of morbidity or mortality.

Reflexes

Anesthetic depth can be evaluated by standard reflexes, such as palpebral, corneal, and pedal withdrawal, with corneal reflex being the most useful. For nonpainful procedures, a light plane of anesthesia will correlate with loss of voluntary motion, but with presence of all three monitored reflexes. At a surgical plane of anesthesia, the palpebral and withdrawal reflexes will be absent and the corneal reflex will be present, but slow.

Complete absence of a corneal reflex indicates a very deep state of anesthesia and is avoided.

Temperature

Monitoring and maintaining body temperature is critical in anesthetized raptor. Small raptors may quickly lose body heat as a result of impaired thermoregulation due to their small body mass relative to surface area. Large species and northern owl species that have a very heavy insulating down feather coats may become hyperthermic. In addition to impaired thermoregulation, the use of room temperature fluids, alcohol during surgical preparation, cool anesthetic gases, and removal of feathers can contribute to hypothermia. Difficulty maintaining an even anesthetic plane can be seen with either hypothermia or hyperthermia as a result of changes in ventilation. Monitoring body temperature can be done with an esophageal thermometer or a cloacal probe. Heat loss can be mitigated by providing a heat source such as a forced-air warming system (Bair Hugger®) or a circulating warm water blanket, or a conventional heating pad maintained on a low setting and usually turned off after a procedure has begun. The use of clear plastic surgical drapes may be beneficial in small birds as they provide both insulation for the patient as well as visualization of the patient. However, they are good insulators and will result in hyperthermia in larger raptors. Hyperthermia can be prevented or reversed by placing ice packs alongside the body of the patient.

VASCULAR SUPPORT

Prior to anesthesia, patients should be given a subcutaneous bolus of fluids (5 mL/100g). For long surgical procedures or in critical patients, it is recommended to insert an indwelling catheter in an accessible vein shortly after induction, and provide a slow drip of an intravenous solution. This provides ready access to an injection port in the event antibradycardic (atropine) or emergency drugs need to be administered. Routinely, crystalloid fluids (saline or LRS) should be given at a rate of 10 mL/kg/h for the first 2 hours, and then reduced to 5 mL/kg/h for routine maintenance. Colloidal support may be added as deemed necessary, replacing a portion of the volume of crystalloids. Blood pressure assessment may be useful (Lloyd et al. 2007). When used with an appropriately sized blood pressure cuff, a Doppler unit may provide both heart rate and blood pressure information (Hawkins & Pascoe 2007); however, while useful for the former, high variability in blood pressure results diminish the usefulness of this method for routine monitoring (Zehnder et al. 2009). Alternatively, monitoring strength of pulse on a peripheral artery and the capillary refill time can be used as acceptable surrogates for actual blood pressure monitoring.

RECOVERY

Recovery is a critical phase of the anesthetic episode. Recovery is generally rapid once the gas anesthetic is removed, occurring gradually over several minutes (Joyner et al. 2008). The vaporizer should be turned off and the endotracheal tube briefly disconnected while the system is purged, then reattached so the bird can be maintained on oxygen during the recovery process and be prepared for assisted mechanical ventilation in the event of apnea. A brief excitatory phase will be experienced as the anesthetic plane lightens that may be accompanied by regurgitation. Extubation is done when the bird begins to make head movements. At the time of extubation and periodically during recovery, the oral cavity should be checked for signs of regurgitation or airway obstruction and any offending material removed with cotton-tipped applicators. It is critical not to impair the respiratory movements of the keel, as well as to be able to continue to monitor respiration. Gentle physical stimulation by moving the wings and legs can increase the rate/depth of respiration and help awaken the bird.

Once the bird is capable of upholding its head, it should be placed on a donut ring made from a towel and laid in a warm, dark, quiet environment to complete its recovery. Most birds are fully recovered in 30 minutes from inhalation anesthetic. Administration of butorphanol for intraoperative analgesia will typically cause the bird to sleep quietly for an extended time when left alone after recovery from the inhalant gases.

ANESTHETIC ADMINISTRATION THROUGH AN AIR SAC CANNULA

Gas flow rates need to be reduced relative to those that would be used for maintenance of a bird with either a face mask or an open system (0.5–1 L/min) (Fitzgerald & Blais 1993) or 2–3 times minute volume (Hawkins & Pascoe 2007) to prevent alkalemia from overventilation. Isoflurane and sevoflurane vaporizers have been shown to deliver anesthetics with acceptable precision and accuracy at flow rates as low as 0.05 L/min (50 mL/min), and some flow meters will allow accurate assessment of flow rate at levels as low as 0.05 L/min (Ambrisko & Klide 2006). Use of an in-line bubbler system not only humidifies the carrier gas, visualization of the stream of bubbles allows a further assessment of flow rate (Fig. 27.5). At this point, no guidelines exist for optimizing flow rates. As a practical matter, flow rates between 500 mL and 1 L/min are used; if there is a need to reduce ventilation, a smaller-diameter cannula size is used to reduce the rate of gas presentation into the air sac. Respiration movements cease entirely and monitoring is done by assessment of heart rate and corneal reflexes. Future refinements on this

methodology should include capnographic monitoring of exhaled gases and optimization of gas flows. A bird maintained with an air sac cannula will typically start to exhibit respiratory movements within less than a minute of the removal of the tube.

SPECIAL CONSIDERATIONS

Special attention needs to be applied when administering anesthetics to accipiter species of raptors (goshawks, Cooper's hawks, sparrowhawks, and sharp-shinned hawks). Injectable agents should be avoided entirely except as preanesthetic agents. It is advised that induction of these species start at low concentrations of isoflurane (1–2%) and be increased gradually over 2–3 minutes. A higher level of attention is paid to hydration status, pain reduction, and use of inhalant gas-sparing agents during anesthetic episodes. They are prone to sudden cardiac arrest, especially during recovery. The causes are not apparent (catecholamine-mediated?), but it appears to be associated with return of consciousness and visual awareness of their surroundings.

Additional use of pain management as an adjunct to isoflurane anesthesia is required for owls and golden eagles, and for most raptors when surgical procedures are being conducted on their feet (e.g., bumblefoot treatment). In general, this need can be met by dosing butorphanol at 1–3 mg/kg and repeating it every few hours during and after the surgical procedure, supplanting it with tramadol or meloxicam in the ensuing days.

28 Galliformes and Columbiformes

Darryl Heard

INTRODUCTION

The order Galliformes contains the megapodes, guans, chachalacas, currasows, pheasants, grouse, junglefowl, and peafowl. Most galliformes are robust ground-dwelling birds, but are able to fly. The order Columbiformes includes pigeons and doves. The typical columbiforme has a short bill, small head, compact body, and short legs (Baptista et al. 1997).

Several species from these two orders are important for food production. For example, the domestic chicken, derived from the jungle fowl, is used for both meat and egg production. Many are also displayed in zoos and kept as pets. Some are highly endangered (Baptista et al. 1997; del Hoyo et al. 1994). The chicken and the rock dove (*Columba livia*), or pigeon, are commonly used in avian research. The latter is also a ubiquitous urban inhabitant.

ANATOMY AND PHYSIOLOGY

Avian anatomy and physiology relevant to anesthesia is described in Chapter 24. Columbiforme species range in size from the 30-g common ground dove (*Columbina passerina*) to the 2-kg crowned pigeons of New Guinea (Baptista et al. 1997). One of the largest galliformes is the wild turkey (*Meleagris gallopavo*), weighing up to 8–10 kg. The currasows and guans have markedly elongated tracheas relative to body size (Fitch 1999). This is thought to be an evolutionary adaptation to exaggerate the apparent size of a vocalizing bird.

PHYSICAL RESTRAINT

Both columbiformes and galliformes are relatively easy to handle. The main threat to the human restrainer is

the large spurs present in some galliformes species. Galliformes will often sit still in the presence of a perceived threat. When given the opportunity, however, they use their powerful leg and flight muscles to explosively propel themselves into the air. In the process, many will shed feathers (fright molt) to prevent a predator or human grabbing hold. The feather loss can be extensive and aesthetically unpleasant, especially for zoo display animals and private pets. Rapid acceleration into the air can also propel the animal into a ceiling, cage top, or wire, causing severe trauma to the animal. Loss of skin on the skull can be extensive and potentially life-threatening. To reduce injury in aviaries, a false soft ceiling can be constructed to allow for absorption of the impact force. Similarly, when temporarily housing these birds, they should be kept in a quiet dark environment. Even short periods of struggling may lead to hyperthermia. This will be exacerbated in birds adapted to a cold environment (e.g., grouse and ptarmigan). Many galliformes are also excellent runners and readily escape a human pursuer. Camouflaged plumage sometimes makes detection in vegetation very difficult.

Pigeons can be gently held in the hand. One hold can incorporate the tail and legs in one grip. Similar to galliformes, however, they can launch themselves explosively into the air and escape.

Many food production species are obese and may have hepatic lipidosis. The author has seen spontaneous liver rupture and fatal hemorrhage in quail during handling related to the latter problem.

VASCULAR ACCESS

Vascular access is as in other birds (Chapter 25) and includes the external jugular, the basilic and the medial

tarsometatarsal or saphenous vein. The external jugular veins of pigeons are difficult to identify because they are usually made up of a plexus rather than a distinct vessel. Intraosseous catheters are placed in the humerus, tibiotarsus, or femur. Intraosseous catheters have been used for administration of propofol in pigeons (Guimarães et al. 2006; Lopez et al. 1994). In large galliformes, the medial saphenous vein is a useful site to administer parenteral anesthetics in physically restrained animals.

ENDOTRACHEAL INTUBATION

Endotracheal intubation is usually simple. Columbiformes and galliformes can sometimes produce copious amounts of tracheal mucous. This may obstruct the tube or produce a “flapper valve” effect that allows air into the respiratory system with positive pressure ventilation, but not out. In these species, the patient needs to be monitored carefully to prevent hyperinflation. Clear endotracheal tubes are preferred to visualize any respiratory discharge, and periodic extubation to assess for blockage may be necessary during prolonged procedures.

As discussed earlier, the convoluted tracheal anatomy of curassows and guans may cause problems if secretions increase in response to intubation or the bird aspirates gastric reflux under anesthesia. Some clinicians prefer not to intubate these species because of the potential for tracheal obstruction or stenosis post-operatively (Evans et al. 2009). This, unfortunately, precludes supportive ventilation. If fluid accumulation is suspected (i.e., increased respiratory noise), it must be removed with suction. A long suction tube is placed as far down the trachea through the endotracheal tube and aspiration performed as the tube is pulled out. If this fails to relieve the problem, then either endoscopy or radiographic evaluation must be performed. If the obstruction cannot be immediately corrected, an air sac cannula will need to be placed for recovery (Chapters 25 and 28).

PRE-ANESTHETIC CONSIDERATIONS

As with all patients, physical examination is indicated prior to anesthesia. This may, however, be difficult in some galliformes because of stress and struggling. Prolonged struggling may lead to hyperthermia and potential myopathy (Spraker et al. 1987). Species adapted to cold (e.g., grouse) or high montane (e.g., some species of pheasant and tragopan) environments are more likely to develop these problems.

Both galliformes and columbiformes possess large complex crops. Depending on the physiological status of the bird, fasting for 4 or more hours may reduce the amount of food in the crop. Fluids should also be removed in animals that are likely to drink excessively.

The body condition of the bird should be assessed. As mentioned previously, many domestic species bred for food production are obese and have substantial intracoleomic fat accumulation. This fat decreases air-sac volume and may contribute to lung compression in dorsally recumbent birds. Both effects may be additive to anesthetic-induced hypoventilation and explain the apparent increased anesthetic morbidity and mortality seen in these species. Similarly, birds bred for egg production are more likely to have egg-yolk coelomitis, which can lead to fibrosis, fluid accumulation, and debilitating systemic infection and illness. A high fat to total body ratio may also be associated with abnormal drug distribution and accumulation resulting in delayed induction and recovery.

LOCAL AND REGIONAL ANESTHESIA

Local anesthetics can be used as in other avian species (Chapter 25). Care must be taken to ensure accurate calculation and administration of local anesthetics to prevent intoxication.

Brachial plexus blockade has been used experimentally in chickens with variable success (Cardozo et al. 2009; Figueiredo et al. 2008). Figueiredo et al. (2008) dissected chicken cadavers to determine anatomical landmarks for correct catheter placement. They then sedated adult female chickens (midazolam 1 mg/kg, butorphanol 1 mg/kg IM) and after 15 minutes restrained the birds in lateral recumbency with their heads covered. The wing to be blocked was abducted at a 90° angle to the thorax, and the apex of the axilla (proximal condyle of the humerus, proximal region of the coracoid and scapula) was palpated. A 20-SWG 50-mm catheter electrode (Braun Melsungen AG, Melsungen, Germany), teflon-coated except at the tip, was attached to a peripheral nerve stimulator (2–5 Hz, 0.12 mA; S48 stimulator; Grass, Warwick, RI). The catheter extension was filled and connected to a 3-mL syringe containing either lidocaine (20 mg/mL, 1 mL/kg) with epinephrine or bupivacaine (5 mg/mL, 1 mL/kg). The catheter was inserted at a 45° angle to the skin just below the apex of the axilla. It was advanced through the pectoralis muscle and fascia toward the chest wall in to the region around the first rib. The appropriate muscle response was confirmed when there was muscle contraction and flexion of the wing. Proximity to the brachial plexus was assessed as when the strongest abduction of the humerus and flexion of the wing occurred. After localization of the brachial plexus by the nerve stimulator, the local anesthetic solution was injected in 0.5-mL aliquots into the plexus sheath over 60 seconds. Onset of sensory denervation was 3–5 minutes, and duration of blockade was 60–90 minutes. The researchers, however, observed a relatively high failure rate of 33% with this technique. Cardozo et al. (2009) had more success using ropiva-

caine (0.75%, 1 mL/kg of the). The onset and duration of effect was approximately 15 and 115 minutes, respectively.

ANALGESIA

Analgesia is covered in Chapter 7. NSAIDs, opioids, and tramadol have been used and studied in these and other birds. In birds, NSAID pharmacokinetics and therapeutic index is highly variable, making safe drug selection difficult (Baert & De Backer 2003). Of the presently available NSAIDs, this author prefers using meloxicam (0.2–0.5 mg/kg sid to bid, PO or IM). Regardless of the drug and species, each analgesic regimen should be tailored to the individual and the type and severity of pain (Chapter 7). A multi-modal approach may be necessary, especially for severe and chronic pain. Although birds appear to respond best to κ opioid agonists (i.e., butorphanol 0.3–2.0 mg/kg bid to tid), there are a few papers indicating μ opioid agonists (morphine and fentanyl) are appropriate in some species and situations (Chapter 7; Concannon et al. 1995; Evrard & Balthazart 2002). For example, in Japanese quail (*Coturnix japonica*), morphine at relatively high dosages (10 and 20 mg/kg IM) significantly altered response latency and threshold in the hot water and foot pressure quantitative nociception tests (Evrard & Balthazart 2002). These effects were blocked by naloxone.

Baert and De Backer (2003) studied the pharmacokinetics of a single intravenous dose of sodium salicylate (25 mg/kg), meloxicam (0.5 mg/kg), and flunixin (1.1 mg/kg) in five bird species, including chickens, turkeys, and pigeons. Chickens had a half-life (5.5 hours) approximately 10-fold as long as the other species for flunixin. The half-life of chickens (3.2 hours) and pigeons (2.4 hours) was threefold as long as the other bird species for meloxicam, and, for salicylic acid, the half-life in pigeons (14.9 hours) was at least three- to fivefold longer than in the other bird species. Once again, this study emphasizes the variability in response to NSAIDs in birds and the potential for toxicity.

Meloxicam (0.5 mg/kg IM) was ineffective in minimizing postoperative orthopedic pain in pigeons (Desmarchelier et al. 2012). A higher dosage (2.0 mg/kg IM), however, provided quantifiable analgesia that appeared safe in experimental conditions (Desmarchelier et al. 2012). In pigeons, carprofen (2–10 mg/kg IM once daily for seven days) was associated with increased aspartate aminotransferase and alanine aminotransferase enzyme concentrations, gross lesions in muscle injection sites and liver, and histologic lesions in liver and muscle (Zollinger et al. 2011). Meloxicam (5 mg/kg SC) and carprofen (25 mg/kg) improved gait function in a group of mildly lame broiler chickens (Caplen et al. 2013). The effects and safety of repetitive dosing were not evaluated.

Hussain et al. (2008) investigated the toxicopathological effects of diclofenac sodium (0, 0.25, 2.5, 10 and 20 mg/kg PO for 7 days) in broiler chicks (15 days old), pigeons (3 months old), and Japanese quail (4 weeks old). Dose-dependent clinical signs in all included depression, somnolence, decreased body weight, and mortality. Severity of clinical disease was most severe in broiler chicks, followed by pigeons and Japanese quail. Broiler chicks and pigeons developed visceral gout at the higher dosages (10 and 20 mg/kg), but not Japanese quail. The kidneys and liver were enlarged in all and the kidneys showed acute renal necrosis. The livers also showed fatty change and necrosis of hepatocytes.

Tramadol appears useful for managing postoperative as well as chronic pain associated with degenerative joint disease. This drug is metabolized to an active metabolite, O-desmethyltramadol (Black et al. 2010). Although relatively high dosages (≥ 5 –10 mg/kg once to twice a day PO) are being recommended in birds based on some pharmacokinetic studies (Black et al. 2010; Souza et al. 2009, 2011, 2012) and a pain response study in Hispaniolan parrots (Guzman et al. 2012), this author has seen good responses in some birds with degenerative joint disease at lower dosages (1–5 mg/kg once to twice a day PO). Further research is necessary to define blood levels associated with analgesia in birds, rather than using human levels. The main observed side effects are anorexia, ataxia and dysphoria, and vomiting. These effects may be seen at high dosages or after repetitive dosing. There also appears to be some individual variation in response, possibly due to variable metabolism to the active form.

INDUCTION AND MAINTENANCE PROTOCOLS

Sedative and parenteral anesthetic dosages are summarized in Table 28.1.

Sedation

All birds are relatively resistant to the effects of alpha-2-adrenergic agonists. In pigeons, xylazine (16 mg/kg IM) or detomidine (1.4 mg/kg IM) produced only minor to moderate sedation adequate for handling and sample collection (Durrani et al. 2008, 2009). Similarly, in pigeons, medetomidine (0.08–2.0 mg/kg IM) produced inadequate sedation for handling and minor diagnostic procedures accompanied by moderate bradypnea and bradycardia (Pollock et al. 2001; Sandmeier 2000). At the lower end of the dosage range, it only produced ataxia to sternal recumbency with retention of the righting reflex (Pollock et al. 2001). In chickens, and presumably other birds, xylazine inhibits ventricular activity (Park & Park 1988). The duration of this effect is dose dependent, and reversible with either yohimbine or 4-aminopyridine.

Table 28.1. Parenteral anesthetics used in domestic galliformes and columbiformes

Species	Ketamine (K)	Xylazine	Medetomidine (M)	Detomidine	Diazepam (D)	Midazolam	Butorphanol (B)	Comments	Reference
Chicken rooster	25 IM	3 IM			4 IM			Xylazine given 15 minutes before other drugs. Adequate anesthesia for typhyllectomy, but associated with hypothermia, cardiopulmonary depression, and prolonged recovery.	Mostachio et al. (2008)
Chicken white leghorn cockerel	10 IV	2 IV						Drugs combined in single injection. Induction and recovery approximately 2 and 70 minutes, respectively. Adequate anesthesia for typhyllectomy. Bradycardia and bradypnea.	Maiti et al. (2006)
Chicken white leghorn cockerel	75 IM				2.5 IV			Ketamine given 5 minutes after diazepam. Induction and recovery approximately 9 and 80 minutes, respectively. Adequate anesthesia for typhyllectomy. Hypothermia.	Maiti et al. (2006)
Chicken white leghorn cockerel	50 IV					2 IM		Ketamine given 5 minutes after midazolam. Induction and recovery approximately 18 and 100 minutes, respectively. Adequate anesthesia for typhyllectomy.	Maiti et al. (2006)
Chicken layer	15 IM							Approx. 30 minutes between loss of righting to sternal recumbency. Adequate anesthesia for typhyllectomy.	Eyarefe and Oguntoye (2012)
Chicken layer	15 IM							Combined with lidocaine 4 SC infiltrated along midline incision. Duration of recumbency approximately 100 minutes.	Eyarefe and Oguntoye (2012)
Guinea fowl	15 IM	2.5 IM						Mild bradycardia, bradypnea, and hypothermia relative to ketamine alone.	Ajadi et al. (2009)
Guinea fowl	15 IM	2.5 IM				0.3 IM		No apparent analgesia in response to clamping of skin and toes.	Ajadi et al. (2009)
Guinea fowl	25 IM	1.0 IM						Duration of analgesia 37 ± 24 minutes. Midazolam prolonged recumbency, but was associated with some regurgitation and bradypnea.	Teare (1987)
Pigeon	60 IM							Rapid onset and good surgical anesthesia. Yohimbine 1.0 IV 40 minutes after XK administration shortened recovery.	Durrani et al. (2008)
Pigeon				1.4 IM				Light sedation and anesthesia/analgesia. Hyperthermia and rough recovery. Not recommended for use alone.	Durrani et al. (2008)
Pigeon								Light sedation and anesthesia/analgesia. Bradypnea, bradycardia, and hypothermia. Safe for handling and least painful procedures.	Durrani et al. (2008)

Pigeon	60 IM	1.4 IM			Rapid onset of action (approximately 2 minutes). Prolonged deep anesthesia and recovery with bradypnea, bradycardia, and hypothermia. Can be used for major surgical procedures.	Durrani et al. (2008)
Pigeon	100 IM		0.2 IM		Ketamine given 15 minutes after MB. M reversed with atipamezole 60 minutes after K. Effective anesthesia for approx. 90% pigeons. Bradypnea, bradycardia, arrhythmias, and hypothermia.	Atalan et al. (2002)
Pigeon	120 IM		0.2 IM		K 10 minutes after M. Deep anesthesia 15–60 minutes associated with initial tachypnea then bradypnea, profound bradycardia and progressive hypothermia. Prolongation of P-R and R-R intervals on ECG.	Uzun et al. (2003)
Pigeon	30 IM		0.125 IM		M reversed with atipamezole 0.065 IM at first sign of recovery. Deeper anesthesia and analgesia than D-K. Recovery rapid and smooth. Clinically, level of anesthesia unreliable and associated with wing flapping.	Lumeij and Deenik (2003)
Pigeon	60 IM		2 IM		Prolonged recovery.	Lumeij and Deenik (2003)
Pigeon	10 IM		0.2 IM		Sedation and muscle relaxation without loss of consciousness.	Azizpour and Hassani (2012)
Pigeon	75–150 IM				Extensor rigidity, salivation, dose-dependent hypoxemia, respiratory acidemia, and hypercapnia.	Neal et al. (1981)
Pigeon				16 IM	Light sedation/anesthesia. Safe for handling and less painful procedures.	Durrani et al. (2009)
Pigeon	60 IM				Light sedation/anesthesia and rough recovery. Not recommended.	Durrani et al. (2009)
Pigeon	30 IM			8 IM	Rapid onset (2 minutes). Deep anesthesia/analgesia with prolonged recovery. Suitable for painful procedures \leq 90 minutes.	Durrani et al. (2009)
Pigeon				0.08–0.20 IM	Ataxia to sternal recumbency, but righting response retained.	Pollock et al. (2001)
Pigeon	5 IM			0.08 IM	Variable effects; mild to moderate sedation.	Pollock et al. (2001)
Pigeon				0.08 IM	Variable effects; mild to moderate sedation.	Pollock et al. (2001)

Note: Dosages are in mg/kg.

Intranasal pipette administration of either xylazine (30 mg/kg), diazepam (6 mg/kg), or midazolam (6 mg/kg) provided fast reliable sedation in pigeons (Moghadam et al. 2009). Unlike the benzodiazepines, however, xylazine failed to produce adequate sedation for dorsal recumbency, and sedation was prolonged. The onset of action of midazolam was more rapid than diazepam.

In rock partridges (*Alectoris graeca*), xylazine (10 mg/kg IM), medetomidine (0.15 mg/kg IM), detomidine (0.3 mg/kg IM), or diazepam (6 mg/kg IM) produced variable sedation adequate to allow handling and for radiography (Uzun et al. 2006). Duration of effect and time to recovery were prolonged, especially for diazepam and detomidine. The greatest sedation was observed with xylazine, but as would be expected, it produced profound respiratory depression. All drugs were associated with decreased cloacal temperatures over time.

Parenteral Anesthesia

Ketamine and ketamine combinations have either been evaluated or used clinically in both galliformes and columbiformes (Table 28.1). The adverse effects are the same as in other avian species. Ketamine alone is not recommended because of increased salivation, muscle rigidity, and rough, sometimes prolonged recoveries associated with wing flapping and struggling. The addition of a benzodiazepine (i.e., diazepam or midazolam) provides improved muscle relaxation and sedation, but not analgesia. The addition of an alpha-2-adrenergic agonist (i.e., xylazine, detomidine, medetomidine) is also associated with improved muscle relaxation, as well as surgical analgesia. They are, however, more likely to produce cardiopulmonary depression, hypothermia and prolonged recovery. Atipamezole, administered IM when birds first show signs of recovery, can be used to reverse medetomidine, detomidine and xylazine.

In guinea fowl, yohimbine (1.0 mg/kg IV) shortened recovery from a combination of xylazine (1.0 mg/kg IM) and ketamine (25 mg/kg IM) (Teare 1987). Butorphanol added to the ketamine combinations further enhances surgical analgesia, but will also further depress cardiopulmonary function (Atalan et al. 2002).

The short-acting anesthetic propofol has been evaluated in pigeons (Fitzgerald & Cooper 1990; Guimarães et al. 2006), wild turkeys (Schumacher et al. 1997), and chickens (Lukasik et al. 1997). Propofol administration using the medial saphenous vein facilitates induction of large birds. In turkeys, propofol (5 mg/kg IV) administered over 20 seconds produced a rapid induction, but was associated with a short period of apnea, then bradypnea, hypercarbia, hypoxemia, and hypotension (Schumacher et al. 1997). Anesthesia was successfully maintained with a constant rate infusion of 0.5 mg/kg/min. Recovery was rapid and smooth once the infusion was discontinued. Propofol does not produce analgesia,

and must be used with other drugs for painful surgical procedures.

In pigeons, propofol (14 mg/kg IV) produced smooth rapid induction and good muscle relaxation (Fitzgerald & Cooper 1990). The duration of effect was 2–7 minutes and associated with marked respiratory depression. A very narrow safety margin was observed when ventilation was not assisted.

In chickens, propofol (4.5–9.7 mg/kg IV), followed by a constant rate infusion (0.5–1.5 mg/kg/min) for 20 minutes produced rapid induction and general anesthesia (Lukasik et al. 1997). As in other species, sometimes, marked cardiopulmonary depression was observed. Single or multiple runs of premature ventricular complexes were also observed in many birds. One bird required lidocaine (0.5 mg/kg IV) for ventricular tachycardia. Propofol at three times the induction dosage was fatal in all birds, indicating it has a low therapeutic index (Lukasik et al. 1997).

Intubation and ventilation, preferably with oxygen, is recommended when parenteral anesthetics are used for surgery and prolonged anesthesia. Administration of balanced electrolyte solutions either IV or IO will also ameliorate some of their hypotensive effects.

Inhalation Anesthesia

Isoflurane and sevoflurane are the most commonly used inhalant anesthetics in clinical practice. Their physiological effects and potencies in galliformes and columbiformes are the same as in other avian orders (Korbel 1998; Naganobu & Hagio 2000; Naganobu et al. 2000). Sevoflurane is associated with a more rapid recovery (Korbel 1998). As described previously, many domestic species have large stores of intracoelomic fat that impair ventilation, potentially prolonging inhalant anesthetic equilibration and recovery.

In chickens, both the μ opioid receptor agonist morphine and the κ agonist U50488H decreased isoflurane MAC in a dose-dependent (1–3 mg/kg IV) manner without significant effects on heart rate and blood pressure (Concannon et al. 1995). Compared with halothane or pentobarbital, isoflurane anesthesia resulted in a significantly lower threshold for electrical fibrillation of the chicken heart (Greenlees et al. 1990). In isoflurane-anesthetized pigeons, controlled ventilation delivered by a pressure-limited device was not associated with clinically important adverse cardiopulmonary changes but may be associated with respiratory alkalemia and cardiovascular depression when air sac integrity has been disrupted (Touzot-Jourde et al. 2005).

Although not an anesthetic or analgesic, the non-depolarizing, short-acting muscle relaxant atracurium besylate (0.15–0.45 mg/kg IV) can be used as an adjunct to inhalation anesthesia (Nicholson & Ilkiw 1992). Muscle relaxation is monitored with a nerve stimulator, and reversed with edrophonium (0.5 mg/kg IV). In chickens, the effective dosage of atracurium to result in

95% twitch depression in 50% of birds was 0.25 mg/kg, whereas the dosage to result in 95% twitch depression in 95% of birds was 0.46 mg/kg (Nicholson & Ilkiw 1992). The duration of effect at 0.25 mg/kg was approximately 35 minutes; at the highest dosage (0.45 mg/kg), 50 minutes. The cardiopulmonary effects of atracurium and edrophonium were clinically insignificant.

MONITORING

Monitoring is the same as in other birds (Chapter 25), and similar to mammals (Chapter 3). The bispectral index has been successfully used and validated to monitor brain electrical activity and level of unconsciousness in chickens during isoflurane anesthesia (Martin-Jurado et al. 2008).

End-tidal carbon dioxide concentration (ETCO₂), an indirect measure of PaCO₂, is inaccurate in pigeons and probably other avian species (Touzot-Jourde et al. 2005). This is particularly so during celioscopy, when the air sacs are perforated (Touzot-Jourde et al. 2005). Similarly, in chickens, ETCO₂ was not accurate in predicting PaCO₂ values in birds ventilated using air sac cannulation (Paré et al. 2013).

FIELD IMMOBILIZATION (WILD CAPTURE)

Physical trapping and capture techniques are well described by Bub et al. (1996). As mentioned previously, the main problems associated with wild galliformes in particular, and columbiformes to a lesser degree, is self-trauma, "fright" molting, and hyperthermia with associated capture myopathy (Spraker et al. 1987). Inhalation anesthesia using a precision vaporizer, when available, is preferred for induction because it is rapid and likely to minimize struggling. Intranasal midazolam (1–2 mg/kg) may achieve rapid sedation and decrease struggling and stress-induced injury.

Alpha-chloralose has been used for sedation and capture of wild turkeys and doves (Bergman et al. 2007; Martin 1967). It is administered orally, has a prolonged effect, and can be associated with mortality. When used for capture of birds that may later be killed for food, local rules and regulations must first be reviewed.

Free-Living Waterfowl and Shorebirds

Daniel M. Mulcahy

INTRODUCTION

Waterfowl (ducks, geese, and swans) are aquatic birds within the family Anatidae, order Anseriformes. They vary greatly in body mass, from several 100 g to greater than 13 kg (Olsen 1994). Shorebirds belong to the order Charadriiformes, of which three species of the family Scolopacidae will be discussed.

The introduction of isoflurane to avian medicine in the 1980s made general anesthesia safe enough to permit long surgical procedures. Several articles pertinent to waterfowl and shorebird anesthesia and analgesia have been published recently (Abou-Madi 2001; Clyde & Paul-Murphy 1999; Gunkel & Lafortune 2005; Hawkins & Paul-Murphy 2011; Heard 1993, 1997; Ludders 2008; Machin 2004, 2005a, 2005b; Machin & Caulkett 1998a; Paul-Murphy & Ludders 2001).

Birds feel pain in much the same physiochemical ways as do mammals, which means the principles of anticipating and treating pain in mammals are applicable (see Chapter 7). Sufficient progress in avian anesthesia has been made so there is no excuse for not using appropriate regimens for surgery in birds (Mueller 1982). Compared with poultry, pigeons (*Columba livia*), quail (*Coturnix* sp.), and psittacines, waterfowl pain has received little attention (Machin et al. 2001). Almost no information is published for shorebird anesthesia and analgesia. Species and individual variation is to be expected; a routine “one dose fits all” approach should be avoided.

THE PATIENT

The influence of body condition on anesthetic morbidity has received little attention. Obesity, a very common

problem in domestic waterfowl, reduces tidal volume due to air sac compression. This can lead to hypercapnia, respiratory acidemia, and possibly death (Phalen et al. 1996). Free-living birds have increased intracoelemic fat at times during their life cycle and similar complications should be expected. Shorebirds (e.g., bar-tailed godwits, *Limosa lapponica*) may have a fat mass of 41% of their body weight at the beginning their very long migrations (Gill et al. 2005).

Birds at different stages of their life cycle have different anesthetic risks. Brooding hens trapped on the nest, and birds at the end of a long migration, are often dehydrated and in poor body condition. Overwintering birds and those caught after storms may be suffering nutritional stress. Harlequin ducks (*Histrionicus histrionicus*) caught during the winter had more anesthetic complications and deaths than those caught in the fall (Stoskopf et al. 2010). Harlequin ducks caught after a storm lasting 3 days or longer also exhibited more anesthetic complications and deaths than those caught during good weather or after storms lasting less than 2 days (Stoskopf et al. 2010). The ducks caught after the 3-day-long storm were hypoglycemic and hypokalemic, probably owing to higher exertion and reduced feeding opportunities during the storm, but the deficits were made up within a day. Ideally, avian blood glucose levels are ≥ 200 mg/dL before anesthesia. Inexpensive (about \$100), over-the-counter blood glucose monitors require little blood, give rapid results, and are relatively accurate (Lieske et al. 2002).

To reduce acute stresses capture and handling are done quickly and competently; the bird is handled gently and anesthetic induction is begun as soon as possible. All equipment and supplies are readied before removing the bird from the holding container. A highly

stressed bird is more likely to resist anesthetic induction than a less stressed bird.

FASTING

Fasting before anesthesia and surgery has been both recommended and discouraged. A fast of 3–12 hours is recommended to empty the crop to reduce regurgitation and aspiration (Curro 1998; Harrison 1991; Redig 1998). In wild-caught waterfowl, a preinduction fast of an hour is sufficient for ingested food to clear (D. Mulcahy, unpubl. data, 2000). As a precaution, the anesthetized bird is laid on a foam pad or other platform slightly elevated (3–5 cm) above the anesthetic table. The bird's head is positioned on the table lower than the rest of its body. This lessens aspiration of refluxing esophageal or gastric contents.

ANESTHETIC ENVIRONMENT

Patient stress and anesthetist distractions are minimized during the perianesthetic period. The awake or recovering birds are caged in an area that is quiet and protected from the elements. Wild-caught birds are housed outdoors in containers placed where human traffic is minimal and where they cannot be inadvertently kicked or shoved. Lightly anesthetized birds are roused by loud noises (e.g., laughter, motor noises, and raised voices), stimuli that should be avoided.

PHYSICAL RESTRAINT

Physical restraint is used in captive and wild birds if the procedure is of short duration, causes minimal pain or distress, and the holder is experienced. Of paramount importance is bird and handler safety. The main goal is completion of the desired procedure in the minimum time required, with the least stress on the bird. However, restraint may not always be minimal or even gentle; wild birds are especially alert for a relaxed grip. They will then make an explosive attempt to escape or inflict harm upon the restrainer and person performing the procedure. A firm grip and proper technique minimize the potential for injury to all species involved. Fortunately, restraint of waterfowl, shorebirds, and seabirds is much less riskier than some other avian groups (e.g., raptors, psittacines, and large ratites).

Covering the eyes with a hood or a stocking reduces stress during transportation and handling. However, these covers are sometimes dislodged by the bird shaking its head. Ducks and geese are picked up for short periods by grasping the base of both wings in one hand and supporting the feet and body with the other (Fig. 29.1). This places considerable stress on the wings and is used only with additional support and not for fractious birds that may fracture a wing bone. It is a useful technique for controlling birds as they are removed from a transport container.

Figure 29.1. Restraint technique used for ducks and small geese. The humeri are grasped with the fingers of one hand. For heavier birds, the other hand should be placed under the feet to support the weight of the bird. Using this technique, birds should not be held for more than a minute or two to avoid damage (photograph courtesy of Scott Larsen).

Figure 29.2. Temporary restraint of a male surf scoter (*Melanitta perspicillata*), here used to weigh the bird on a scale, by tucking the head under a wing and wrapping the bird snugly with “hook-and-loop” strapping. Care is taken to avoid interference with respiratory excursions of the keel and the duration of such restraint should be measured in seconds (photograph courtesy of Dan Esler).

Ducks and some geese are conveniently held by tucking their heads under a wing, which appears to cause mild sedation. For additional brief restraint, “hook-and-loop” strapping is wrapped snugly around the bird incorporating both folded wings. Care is taken not to restrict respiration. Restrained birds can then be weighed on a scale (Fig. 29.2).

For anesthetic induction, the bird is removed from the holding container and placed on a table. It is manually restrained by holding the folded wings and exerting slight downward pressure. Most birds will not struggle if the restraint does not vary. Handling during capture and processing can cause significant hyperthermia, which is exacerbated by environmental temperature (Davenport et al. 2004; Phalen et al. 1996). Plumage provides superb heat retention, especially in waterfowl and other species adapted for life in the cold water. Excess heat is lost by evaporation through panting, transdermally in featherless areas, and through the feet where blood circulation is under partial voluntary control.

RESPIRATORY CONTROL

Waterfowl have been used extensively in avian respiratory studies. A physiologic feature in waterfowl and other birds is the presence of intrapulmonary chemoreceptors that respond to $p\text{CO}_2$. They interface respiratory control and gas exchange by being more responsive to alterations in $p\text{CO}_2$ than $p\text{O}_2$ (Fedde et al. 1974; Hempleman & Burger 1984; Hempleman et al. 1986). These receptors provide feedback control to ventilation and match respiration with metabolism (Shoemaker & Hempleman 2001). Intrapulmonary chemoreceptors are afferent vagal neurons sensitive to $p\text{CO}_2$ tension variation in different parts of the avian lung (Hempleman & Bebout 1994; Hempleman et al. 2000, 2003). Receptor response is actually to H^+ from CO_2 hydration, and the receptors are inhibited rather than excited (Adamson & Burger 1986; Bebout & Hempleman 1999; Powell et al. 1978). Intrapulmonary receptors are located within the parabronchial gas exchange area (Nye & Burger 1978; Scheid et al. 1974). More than 95% of receptors are located in the caudal lung, an area that experiences marked CO_2 fluctuations during respiration (Scheid et al. 1974). Intrapulmonary chemoreceptors are part of a reflex arc that inhibits respiration when intrapulmonary $p\text{CO}_2$ decreases (Burger & Estavillo 1978).

MONITORING

Monitoring begins as soon as a bird is placed in front of the anesthetist, with observation of respiration and attitude. It ends when the bird is fully recovered and returned to its source. As is often stated, there is no better monitoring technique or device than a trained, experienced, and attentive anesthetist to assure the greatest patient stability and safety. Changes in anesthetic depth, body temperature, and cardiopulmonary status occur quickly in birds and must be identified and responded to just as quickly. In field work, a biologist is often drafted as anesthetist and given on the job training. To assure maximum efficacy, it is preferable

to concentrate acquisition of anesthesia experience in one person, rather than rotate the responsibility between multiple biologists. A trusted anesthetist allows the surgeon to concentrate on their job, contributing to quality work and reduced anesthesia time.

There are several schemes for staging anesthetic depth (Korbel 1998; Sandmeier 2000). In practice, most are too complicated, especially for relatively short procedures, and only serve to divert the attention of the anesthetist away from directly observing the patient. A simpler scheme for field work with a biologist anesthetist is given in Table 29.1 (Curro 1998; Rosskopf & Woerpel 1996). Successful induction has occurred when the legs and wings can be extended without being withdrawn and in most cases, this signals readiness for intubation.

Once intubated, the appropriate monitoring instrumentation is applied. Respiratory monitors, stethoscopes, electrocardiographs, capnographs, blood gas analyzers, blood pressure monitors, and cloacal and esophageal temperature probes have been used to assess anesthetic status of waterfowl (Fig. 29.3). Deciding the

Table 29.1. Simplified anesthesia levels of birds. The stages are continuous

Induction	Muscle relaxation, lowered head, drooping eyelids, wings and legs can be extended without being withdrawn.
Light	No response to positional change; corneal, palpebral and pedal withdrawal reflexes present; no volitional movement.
Medium	Respirations slow and deep; palpebral reflex absent; corneal and pedal reflexes sluggish or absent.
Deep	Respirations very slow and progressively shallow; reflexes absent.

The patient, prepared for surgery, is being electronically monitored with a digital thermometer, capnograph, and pulse oximeter, and a blood sample is being drawn from the jugular vein for blood gas determination.

instrumentation to use depends on practicality and procedure length. It is contrary to the best interests of the patient to significantly extend anesthetic duration in order to place additional monitoring sensors and instruments. The anesthetist must understand that no electronic or mechanical monitor is to be blindly trusted.

The essential physiologic variables to monitor include heart rate and rhythm, respiration rate and depth, and body temperature. Reference values for cardiopulmonary variables vary between species and conditions; representative values are given in Table 29.2.

Respiration is evaluated by observation. Depth is judged by the extent of sternal movement. Movement of the rebreathing bag does not reliably reflect occurrence and depth of respiration, as the cuffless endotracheal tube may not form a sufficient seal. Arterial blood gas analysis is the definitive means of evaluating ventilation, but is rarely done in the field.

Tracheal secretions tend to be very thick. Clicking or gurgling noises indicate partial tracheal or endotracheal blockage; the endotracheal tube is withdrawn and cleaned if necessary. Sometimes, the plug is located in the trachea instead of the tube. Complete tracheal obstruction (as from a plug) is suggested by marked inspiratory and expiratory efforts with little to no air movement. In many cases, the anesthetist can force air past the obstruction with positive pressure, but the material then reobstructs the tube. End-tidal CO₂ readings will be low, despite assisted ventilation. If this occurs, the tube is removed immediately and either replaced or cleaned and reinserted. Tracheal mucous plugs are sometimes removed by inserting a longer, smaller diameter endotracheal tube, rotating, then withdrawing with the mucus plug attached. Obstructions occur more often with dehydration, which thickens secretions. Wild birds held for hours prior to surgery are assumed to be dehydrated, as they will rarely drink water provided in a holding container.

Electronic monitors are available that connect to the endotracheal tube to monitor respiratory activity (see Chapter 6). These instruments also display a calculated respiratory rate, but this should not be uncritically accepted. Manipulations of the bird's body can cause excursions of air through the trachea that are not part of the respiratory cycle. Observation of the graphic wave form of a capnograph can confirm observed respiration rates that reflect a true respiratory cycle (Fig. 29.3). However, not every capnograph is accurate at small tidal volumes (see Chapter 3). Capnography is considered accurate only during positive pressure ventilation (Sap et al. 1993). The end-tidal partial pressure of CO₂ slightly underestimates the arterial partial pressure of CO₂ (Edling et al. 2001). When monitoring with a capnograph, manual or positive pressure ventilation is adjusted to keep end-tidal CO₂ partial pressures at 30–45 mmHg (Edling et al. 2001).

The purpose of cardiovascular monitoring includes assuring that the heart is beating and the blood is circulating. Pulses are palpable at the tibiotarsal or elbow (cubital) joints, if the hands of the anesthetist and extension of a leg or wing will not disturb the procedure. A stethoscope, esophageal stethoscope, electrocardiograph, or Doppler flow detector is used for cardiovascular monitoring. In practice, only a single electronic monitor is used.

Pulse oximetry can be undependable due to motion artifact, inaccuracy, lack of calibration to avian hemoglobin, and discontinuity of values during surgical emergencies (Schmitt et al. 1998). Pulse oximeters are calibrated for human blood, and will give a lower saturation value for avian blood (Schmitt et al. 1998). For routine monitoring, the relative inaccuracy of oxygen saturation is not critical, and the pulse oximeter can be used to monitor trends in heart rate and oxygen saturation. Relying solely on pulse oximetry to monitor birds anesthetized with isoflurane in 100% oxygen is inadequate as they may be poorly ventilated despite adequate oxygenation (Edling et al. 2001).

Some commercial pulse oximeters measure very rapid heart rates, but it is advisable to query oximetry manufacturers about the possibility of modifying a unit to assure that function. Having a display of heart rate and oxygen saturation levels is valuable for monitoring avian anesthesia. It is often difficult to find a suitable site for placing the pulse oximeter probe. The interdigital webbing of the feet is used, but the presence of pigment may make the site unsuitable for a transmittance probe. Similarly, clamp probes are placed on the tip of the upper bill of ducks with lightly pigmented bills (Fig. 29.4). Reflectance probes are placed into either the esophagus or cloaca. Maintaining a constant, proper position with reflectance probes is a problem; the anesthetist may have to make frequent adjustments to assure adequate tissue surface contact.

Auscultation of the heart is a simple and direct means for monitoring heart rate and rhythm. The large pectoral muscle mass of waterfowl reduces transmission of cardiac sounds; the stethoscope diaphragm is placed on the dorsal thorax, lateral thorax, or thoracic inlet. However, placing a stethoscope under the surgical drape may be disruptive to the surgeon. The easiest cardiac monitor to use is an electronically amplified, battery powered, esophageal stethoscope (Audio Patient Monitor[®], A.M. Bickford, Inc., Wales Center, NY). The sensor is a hollow plastic tube with multiple openings at the distal end, covered with a plastic cuff. Sensor tubes are available in a variety of diameters; the largest tube compatible with the esophagus is used for the best signal. The tube is inserted to the level of the heart (Fig. 29.3). Positioning is evaluated by listening to the volume and clarity of the signal. The long necks of waterfowl and shorebirds facilitate intraoperative adjustments without disturbing the surgeon. An audible

signal of the heartbeat allows everyone involved in the surgery to monitor the patient. The sensor tube is placed immediately after intubation. Sometimes, respiratory sounds are also heard. Diminished or no heart sounds are usually due to inadvertent displacement of the sensor. However, the anesthetist must not spend too much time adjusting the sensor before raising the alarm about potential cardiac abnormalities.

An ultrasonic Doppler flow detector (Parks Medical®, Parks Medical Electronics Inc., Aloha, OR; Minidop®, Jorgensen Laboratories, Inc., Burlington, WI) is most commonly used for cardiac monitoring. The ultrasound probe is commonly taped over the cranial tibial artery, but the superficial ulnar artery at the distal humerus, and the carotid artery, are also used (Lichtenberger 2005; Zantop & Bowles 2000). The Doppler flow detector allows indirect monitoring of systolic blood pressures, using the appropriate pressure cuff size (40% of appendage circumference) around the leg proximal to the probe. Reference blood pressure values have been determined for a few species of waterfowl (Table 29.1). Diastolic, and therefore mean, blood pressure cannot be obtained with this method. Birds with systolic blood pressures ≤ 90 or ≥ 145 mmHg are evaluated for causes of hypotension and hypertension, respectively (Lichtenberger 2005). Hypovolemia is treated with bolus administration of crystalloids (10–20 mL/kg) or colloids (5 mL/kg) until systolic pressures are restored (Lichtenberger 2004). For immediate effect, fluids are given IV or intraosseously (Valverde et al. 1993).

Digital thermometers are more useful than traditional thermometers because their displays are easier to read. Digital thermometers are placed in either the cloaca or deep in the esophagus (Fig. 29.3). Cloacal sensors are taped in place, but the tape is easily dislodged by fecal fluid and the thermometer is difficult

to read if covered by a surgical drape. Digital thermometers with long, flexible extension sensors (e.g., Electrotherm Model 99A, Cooper Instrument Corporation, Middlefield, CT) are preferred for esophageal placement. To read core temperature, the sensor is inserted until it is past the thoracic inlet. Normal body temperature in waterfowl is 40–42°C, but tends to decline during anesthesia.

MAINTENANCE OF BODY TEMPERATURE

Body temperature maintenance within a normal range begins with a patient that is dry, clean, and minimally stressed. Hypothermia is more likely to occur in a patient with feathers wetted during capture and handling or fouled by feces and urine during transportation. Conversely, a bird severely stressed during capture, transported in a poorly ventilated container, and held for hours before a procedure at high environmental temperatures is very likely to be hyperthermic. In the author's experience with Arctic waterfowl and shorebirds, hyperthermia occurs more commonly than hypothermia, which is fortunate as it is more easily treated.

During normal respiration, the turbinates warm and humidify inspired air (Schmidt-Nielsen et al. 1970). The efficiency of evaporative heat exchange by the turbinates is such that the nasal surface temperature may be less than that of the ambient air (Jackson & Schmidt-Nielsen 1964). During exhalation, water and heat losses are minimized by the air being cooled and supersaturated as it passes over the turbinates. The reduction in evaporative water loss ranges from 55% to 71% in birds (Geist 2000). Exhaled air temperature at the external nares averaged 19.6°C lower than core temperature, while oropharyngeal temperature measured only 3.5°C lower, indicating the trachea is minimally involved in heat exchange (Geist 2000). The condensed moisture and heat recovered at the turbinates are returned to the body. In the intubated bird during anesthesia, breathing is shifted from nasopharyngeal to oropharyngeal, bypassing the countercurrent heat exchange and moisture recovery mechanisms in the nasal cavity. This accelerates heat and moisture loss. The type of breathing system used for avian anesthesia has little effect on body temperature loss. Pigeons anesthetized with three different systems had lost about 1.7°C by 45 minutes and 2.7°C at 90 minutes (Boedeker et al. 2005).

Correction of abnormal body temperatures is begun as soon as it is recognized. Hyperthermia is treated by wetting the unfeathered legs and feet with isopropyl alcohol. The feet of waterfowl efficiently control body temperature due to the presence of the *rete tibiotarsale*, a vascular network (Midtgård 1980). In severe hyperthermia, rapid correction requires other concerns be ignored. It may be helpful to also wet the axilla with

alcohol, despite the risk of removing waterproofing of the feathers.

Correction of hypothermia is more difficult, and is best avoided. If body temperature decreases suddenly, dislodgment of the temperature sensor from within the thorax is suspected first. To treat a hypothermic bird, external heat is applied to the exposed skin of the feet and lower legs. Bags of water or saline heated up to 43°C, or chemical heat packs wrapped in a layer of cloth are placed on the feet. Leaks in the bags are avoided to prevent feather wetting that will exacerbate hypothermia. Waterfowl reduce heat loss by decreasing blood flow to their hind limbs, making external heat application to the feet less efficient. Hypothermic birds recover very slowly from anesthesia. They are held wrapped in a towel to conserve body heat during recovery. It is best to correct the body temperature abnormality during anesthesia rather than to expect the postanesthetic patient to recover on its own. Hypothermic birds are recovered and rewarmed with caution and with constant observation. Rewarming reverses peripheral vasoconstriction and increases metabolic demand for glucose (Heard 2000). Deaths of hypothermic birds that occur within several hours of the end of anesthesia may be due to the effects of induced hypothermia (Heard 2000).

Efforts to reduce thermal loss under anesthesia usually involve placing the bird on an insulated pad, a heated circulating water mattress, or wrapping in bubble wrap (Harrison 1994). These methods have little effect because of the high insulative value of feathers. A radiant energy source placed just above anesthetized birds was the only effective technique for maintaining a constant body temperature (Phalen et al. 1996; Rembert et al. 2001). The effectiveness of radiant heat was demonstrated in a sun conure (*Aratinga solstitialis*) that died of heat stroke (body temperature of 48.1°C) during surgery under an unusually hot surgical lamp (Hofmeister & Hernandez-Divers 2005).

RECOVERY

For recovery, the anesthetized bird is positioned in lateral to slightly ventral recumbency. The bird remains intubated and respiration is assisted until it shows controlled, voluntary motion and objects to the presence of the endotracheal tube. The tube and esophageally placed monitoring sensors are removed at that time. Newly extubated birds remain sedated by the anesthetic and may become quiescent.

Many recovering birds go through a period of disorientation, wing flapping, and struggling (emergence delirium) that may result in self-inflicted trauma (Curro 1998). To avoid this, recovering birds are wrapped in a towel (unless hyperthermic) and observed closely for continued respirations. Only when the bird holds its head erect and steady is it replaced in the recovery

container. It is then regularly observed for flexion of its head and neck that may obstruct the airway. If this occurs, the bird is repositioned or removed from the recovery container and held until fully recovered. Recovery time depends on the choice of anesthetic, anesthetic duration, and extent of physiologic alteration that has occurred. A bird that is hypothermic, hypoglycemic, or that has impaired drug elimination mechanisms will take longer to recover (Heard 2000).

ANTICHOLINERGICS

Anticholinergic drugs (atropine or glycopyrrolate IM) reduce pharyngeal and tracheal secretions, but may also increase their viscosity. Consequently, they are recommended only for treatment of severe bradycardia.

INHALATION ANESTHESIA

Inhalation anesthetics offer the advantages of familiarity and ready availability of equipment for veterinarians. With an inhalation anesthetic in birds, an agent-specific vaporizer and a nonrebreathing circuit (e.g., Bain) are usually used. Anesthetic breathing systems are disinfected between uses, but must be thoroughly rinsed to remove residual toxic substances that may damage the respiratory system (Greenacre 1993).

Isoflurane has been the primary inhalant anesthetic for birds since the mid-1980s (Bednarski et al. 1985; Ludders et al. 1988b, 1989a). Others (i.e., methoxyflurane and halothane) are rarely used now because their manufacture has been discontinued (Goelz et al. 1990; Greenlees et al. 1990; Ludders et al. 1988a). The recently introduced sevoflurane is increasingly used in clinical settings. Due to its lower blood gas partition coefficient, induction and recovery of birds occur more rapidly than with isoflurane (Korbel 1998; Quandt & Greenacre 1999). Sevoflurane is less pungent than isoflurane for human beings (TerRiet et al. 2000). The pungency of volatile anesthetics may contribute to the breath holding seen in birds when an anesthetic mask is placed over their faces.

In mallard ducks, isoflurane has a minimum anesthetic concentration of 1.3% (Ludders et al. 1990). In birds generally, it causes dose-dependent reduction in spontaneous ventilation that extends to apnea at high concentrations (Ludders et al. 1990). The calculated Anesthetic Index (anesthetic concentration causing apnea/minimal anesthetic concentration) for ducks (1.65) is lower than for dogs (2.51), cats (2.40), and horses (2.33) (Ludders et al. 1990, 1995; Steffey & Howland 1977; Steffey et al. 1977). The lower Anesthetic Index for ducks indicates hypoventilation occurs at lower isoflurane concentrations in this species than in others. In Pekin ducks, isoflurane caused tachycardia and hypotension (Goelz et al. 1990). Although

arrhythmias were uncommon, one duck died when ventricular bigeminy and multifocal ventricular rhythms progressed to ventricular fibrillation (Goelz et al. 1990). In other avian species, arrhythmias, cardiac irritability, and premature ventricular contractions have also been observed (Aguilar 1996; Greenlees et al. 1990; Jaensch et al. 1999; Langlois et al. 2003; Ludders et al. 1988a, 1989a; Matthews et al. 1991; Naganobu & Hagio 2000; Straub et al. 2003). Once waterfowl have stabilized under isoflurane anesthesia, cardiopulmonary variables should be carefully monitored (Table 29.3).

Induction

Inhalant anesthetics are often administered through a mask for induction. Commercially available cat or dog masks are used for small ducks and geese. Shorebirds may require custom masks fashioned from tubing or syringe cases to accommodate their long bills. The mask must include the nares at the base of the upper bill. The mask aperture can be altered with a piece of surgical glove stretched over the opening, taped around the edges and with a slit cut into the center. The apnea and bradycardia that occur when an induction mask is placed over a bird's beak and face are commonly attributed to a "dive response," but more likely are owing to a stress response caused by stimulation of trigeminal nerve receptors (Butler 1988; Jones et al. 1988; Woakes 1988). Preoxygenating ducks with 100% oxygen for several minutes reduced this response in dabbling ducks, but not in diving ducks (Furilla & Jones 1986).

The isoflurane vaporizer is set to 3–4% for induction. Although it is recommended the concentration be slowly increased to prevent breath holding, this author has not found this to be effective. In ducks and geese, the oxygen flow rate is 1–2 L/min to allow relatively rapid changes in anesthetic concentration as vaporizer setting is altered. A system for scavenging or venting waste anesthetic gases is used for safety (Altman 1992; Mason et al. 1998). Alternatively, for portable anesthetic machines, a canister filled with activated charcoal is used. However, not all cartridge brands work equally well (Smith & Bolon 2004). The charcoal canister is always laid on its side to avoid blocking the bottom vents, causing unwanted back-pressure on the nonbreathing circuit. If apnea is prolonged during induction, respiration is encouraged by lifting the bird at the base of the wings, then gently pressing its body down on the table. Inflation and deflation of the reservoir bag is used to monitor breathing and ventilation, assuming the mask is snugly fitted against the face of the bird. Anesthetic depth is judged by pulling out a wing or a foot and releasing it. A conscious bird will withdraw either into the folded position. When the bird is assessed as unconscious, oxygen flow is turned to zero. It is preferable to turn the oxygen flow on and off (stopping flow of anesthetic through the vaporizer) rather than turning the vaporizer down and then back

up again (during which time isoflurane vapor continues to flow through the dead space and into the room).

Intubation

Except for very brief procedures, all birds are intubated and ventilated. Waterfowl and shorebirds generally have long necks, allowing for a long endotracheal tube. Since the syrinx is inside the thoracic inlet, the length of the neck is used to measure the maximum endotracheal tube length.

Some male waterfowl have a bulbous expansion of the trachea, and some geese and swans have tracheal loops that lie in the caudal cervical area or within the thorax (McLelland 1989b). The avian trachea is 2.7 times as long and 1.29 times as wide as the trachea of a similarly sized mammal (McLelland 1989a). Consequently, the anatomical dead space is about 4.5 times that of a mammal (McLelland 1989a). The increased dead space is compensated for by a low respiratory frequency, about one-third that of mammals. This results in minute tracheal ventilation of about 1.5–1.9 times that of mammals (McLelland 1989a). However, respiration is depressed under general anesthesia, causing a larger percentage of minute ventilation to be devoted to dead space.

Birds have complete endotracheal rings and cuffless endotracheal tubes are preferred to prevent trauma. However, careful use of cuffed endotracheal tubes has been suggested to obtain a good seal (Curro 1998). Overinflation of a cuffed endotracheal tube may cause a longitudinal rupture of the tracheal rings that is not obvious for 5–7 days after intubation, until healing of the lesion and fibrotic narrowing of the tracheal lumen occur (Ludders 1998). A Cole endotracheal tube is appropriate for very small birds or chicks and ducklings, to prevent passing the tube too far into the trachea. The appropriate diameter of endotracheal tube must be chosen for the species of bird and its gender and age. An estimate of the external tracheal diameter is made by palpating the throat. In waterfowl, females may require one-half to one full size-larger endotracheal tube than males of the same species. In this author's experience, all ducks and geese can be intubated and ventilated with 2- to 4-mm (internal diameter) cuffless tubes. Because of the comparatively long necks found in most waterfowl and shorebird species, overintubation is a problem only with small species or immature birds. However, care is always taken to avoid striking the syrinx with the end of the endotracheal tube.

Except for birds with very long bills and small oral openings, intubation of waterfowl and shorebirds is relatively easy. The glottis is positioned at the base of the tongue and easily seen in most species. In some, a dorso-ventral septum (*crista ventralis*) is present just inside the glottal opening. If a tube cannot be readily passed through the glottis into the trachea, a tube with a smaller outside diameter is used.

Table 29.3. Mean cardiopulmonary values given as mean with SD (\pm) or range (–) for waterfowl after at least 15 minutes under injectable anesthesia

A. Mean Cardiopulmonary Values Given as Mean with SD (\pm) or Range (–) for Waterfowl after at Least 15 Minutes under Isoflurane Anesthesia												
Species	Heart Rate (beats/min)	Respiration Rate (breaths/min)	Body Temperature ($^{\circ}$ C)	Systolic Blood Pressure (mmHg)	Diastolic Blood Pressure (mmHg)	Mean Blood Pressure (mmHg)	pHa	PaO ₂ (mmHg)	PaCO ₂ (mmHg)	HCO ₃	Reference

Figure 29.5. Bristle-thighed curlew (*Numenius tahitiensis*) being intubated. The left hand is used to hold the upper and lower bills apart while the right hand inserts the endotracheal tube. It is sometimes easier to intubate long-billed birds by holding the head dorsal side down, which permits the slight curve of the endotracheal tube to follow the curve of the beak (photograph courtesy of Dan Ruthrauff).

For intubation, the upper and lower bills are held agape with the fingers of one hand while inserting the endotracheal tube into the glottis with the other (Fig. 29.5). Alternatively, in large or long-billed birds, an assistant holds both bills, so the person intubating can use one hand to pull the tongue forward while passing the endotracheal tube with the other. Endotracheal tubes are usually inserted without lubrication.

Correct tube position is confirmed by direct visualization of the tube in the glottis, condensation on the inside of the tube, and chest excursions during mechanical ventilation or by the use of capnography. It is a good habit to immediately confirm proper placement by palpating the throat of the bird. If the tube is within the trachea, only one hard tubular structure, the trachea, will be felt ventral to the cervical vertebral column. If the tube was inadvertently passed into the esophagus, two hard tubular bodies will be felt, and corrective action can be immediately taken. The endotracheal tube is secured in place by tying or taping to the lower bill. Since the glottis is located on the ventral oral cavity, taping the tube to the upper bill would allow for movement of the glottis independent of the tube, which may cause inadvertent extubation.

After intubation the anesthetic system is reconnected and oxygen flow restarted to restore isoflurane flow. The vaporizer setting is reduced to maintenance. Anesthetists must ensure the bird's head and neck are

in extension to prevent kinking of the endotracheal tube. They must also be alert for gurgling sounds and exaggerated respiratory movements indicative of a blocked endotracheal tube. The use of a mechanical ventilator may reduce the likelihood of endotracheal tube blockage (Kramer 2002).

The minimal anesthetic concentration (MAC) is relatively constant (about 1.5% for isoflurane) for most species of birds. Many birds will be apneic following induction. It is prudent to use a lower vaporizer setting initially to slightly reduce anesthetic depth and to restore spontaneous ventilation. A decision to lighten anesthetic depth following induction is accompanied by attention to the anesthetic status of the patient to prevent sudden motion.

Ventilation

Most surgical procedures are performed in dorsal recumbency. This position can cause profound respiratory alteration. In conscious chickens placed in dorsal recumbency, tidal volume decreased 40–50%, although breathing frequency increased by 20–50% (King & Payne 1964). King penguins (*Aptenodynes patagonicus*) injected with tiletamine-zolazepam were immobilized about 50% longer if held in dorsal compared with ventral recumbency, and body temperatures were also significantly higher (Thil & Groscolas 2002). Respiratory compromise may be worsened in waterfowl by the inertial resistance of the relatively large pectoral muscle mass to respiratory excursions of the keel. The pressure of viscera on the abdominal air sacs also reduces their effective volume.

Inhalant anesthetics cause a dose-dependent depression of spontaneous ventilation (Ludders 1992; Ludders et al. 1988b, 1989a, 1990). Intermittent positive pressure ventilation is used in anesthetized birds, even if some spontaneous breathing is continuing, to assure adequate oxygenation of the blood (Edling et al. 2001). In geese, an average PaCO₂ of 53 mmHg was necessary for spontaneous respiration to occur; no respiration occurred with a PaCO₂ ≤40 mmHg (Pizarro et al. 1990). Ventilation is assisted manually using the reservoir bag on the breathing system or a mechanical ventilator (Carpenter & Mason 2001; Hernandez-Divers 2001; Pettifer et al. 2002). Analysis of blood gases has showed that effective gas exchange is achieved using mechanical ventilation (Edling et al. 2001; Ludders et al. 1989a; Mitchell et al. 2001; Pettifer et al. 2002; Piiper et al. 1970).

Although a decrease in mean arterial blood pressure is observed in mammals during positive pressure ventilation, in sandhill cranes (*Grus canadensis*), pigeons (*Columba livia*), and Amazon parrots (*Amazona ventralis*), blood pressures increased or were maintained during ventilation (Ludders et al. 1989a; Pettifer et al. 2002; Wilson & Pettifer 2004). However, blood pressure decreased in positive pressure-ventilated chickens anes-

thetized with sevoflurane (Naganobu et al. 2003). The cardiovascular effects of positive pressure ventilation in birds are still uncertain, and have not been examined in waterfowl and shorebirds.

A spontaneously breathing bird is given at least 2 assisted breaths/min. If an anesthetized bird is apneic, the assisted ventilation rate is 8–15 breaths/min depending on size (large birds require fewer breaths than small). If pulse oximetry and capnography are used to monitor respiration, the rate is guided by the end-tidal CO₂ level and the relative hemoglobin saturation (Fig. 29.3).

OXYGEN AND ANESTHESIA

Inhalant anesthetics depress spontaneous ventilation (Ludders et al. 1988a, 1989a, 1990; Goelz et al. 1990). It is essential to avoid hypoventilation during anesthesia because birds lack the respiratory reserve capacity to compensate. Oxygen within air sacs does not diffuse into the blood to any great extent (Magnussen et al. 1976).

Using oxygen to deliver inhalant anesthetics to birds can alter respiratory variables. Respiratory rate decreased (but not significantly) as the fraction inspired oxygen increased to more than 90% (Seaman et al. 1994). Increasing oxygen concentration above 40% decreased tidal volume, a decrease that was significantly correlated with arterial CO₂ (Seaman et al. 1994). High oxygen concentrations may depress ventilation by acting on O₂-responsive chemoreceptors (Ludders et al. 1995). The use of air instead of oxygen during avian anesthesia would not depress the O₂-sensitive chemoreceptors and should have a less depressive effect on ventilation.

Air Sac Cannulation

Air flow through the lung is continuous and unidirectional. It is, therefore, possible to ventilate and to provide anesthesia through an air sac cannula (Brown & Pilny 2006; Jaensch et al. 2001; Rode et al. 2003; Whittow & Ossario 1970). A common application of this technique is in patients with tracheal obstructions (Clippinger & Bennett 1998; Graham 2004; Mama et al. 1996; Rode et al. 2003). The abdominal air sacs are generally used (Good et al. 2001). The clavicular air sac has been used, but it appears to participate less in ventilation than the thoracic and abdominal air sacs (Jaensch et al. 2002; Rode et al. 2003). Cannulation of the caudal thoracic air sac has been used to anesthetize zebra finches (*Taeneopygia guttata*) as small as 10g (Nilson et al. 2004). The technique could easily be adapted for anesthesia of very small ducklings and shorebird chicks.

Placing an air sac cannula requires the selected site (on the lateral abdominal wall well ventral to the spine

so as to avoid damage to the kidney) be prepared as with any surgical site. Feathers are taped aside and the skin is prepped. While general anesthesia makes placement easier, in conscious birds, the surgical site is infiltrated with lidocaine (≤ 2 mg/kg). The skin is incised with a scalpel blade. The muscle layer is penetrated with either sharp dissection by making a puncture with a blade or by blunt dissection using hemostats to work through the muscles and air sac membrane. The cannula, often an endotracheal tube, is pushed into the air sac. The tube is secured by suturing tape butterfly wings to the skin. The breathing system is then connected and the animal ventilated. Waste anesthetic gases exit through the trachea and are an exposure risk to personnel. The cannula is removed when spontaneous ventilation is reliable. Sutures or surgical glue are used to close the incision.

Ducks anesthetized with phenobarbital and breathing room air through clavicular air sac cannulas had no significant differences in arterial blood gas values compared to ducks that were tracheally intubated (Rode et al. 2003). Caudal thoracic air sac cannulation in sulfur-crested cockatoos (*Cacatua galerita*), anesthetized with isoflurane in 100% oxygen, provided adequate blood oxygenation and maintained tidal and minute volumes (Jaensch et al. 2001). However, clavicular air sac cannulation did not provide adequate ventilation or anesthetic maintenance (Jaensch et al. 2001).

PARENTERAL ANESTHESIA

Parenteral anesthesia has several advantages over inhalant anesthesia, including ease of use, rapid onset, minimal equipment, reasonable cost, and minimal contamination of the work space with toxic chemicals. Like inhalants, parenteral anesthetics produce dose-dependent cardiopulmonary depression. Few parenteral anesthetics are reversible; once injected, they cannot be adjusted, and most require renal or hepatic biotransformation to be cleared. Other potential disadvantages include species and individual differences, the need to determine body weight for accurate administration, and a relatively narrow margin of safety. In waterfowl, most parenteral anesthetics are delivered into the pectoral muscles, although the large leg muscles can be used.

Empirically derived dosages for parenteral drugs are only available for a few avian species. Alternatively, allometric scaling is used to approximate effective dosages. However, allometrically derived drug dosages in new species should be used with caution (Dorrestein 1991; Dorrestein & Van Miert 1988). Allometric scaling can be used to estimate respiratory variables in birds (Frappell et al. 2001). Monitoring of cardiopulmonary variables is essential when using parenteral anesthetics (Table 29.4).

Table 29.4. Injectable drugs used in waterfowl anesthesia

Common Name	Purpose	Primary Drug	Dosage (mg/kg)/Route	Second Drug	Dosage (mg/kg)/Route	Additional Drug	Dosage (mg/kg)/Route	Reference
Pekin duck (<i>Anas platyrhynchos</i>)	Liver biopsy	Tiletamine-zolazepam	13 IM ^a	Lidocaine	100mg infiltrated			Carp et al. (1991)

							Machin and Livingston (2002)

^aAdditional doses of 3 mg/kg were used to extend anesthesia.

Tiletamine/Zolazepam

Tiletamine/zolazepam has been used both as an injectable and as an oral immobilizing drug in birds, especially larger animals (e.g., ratites, raptors, cranes, and penguins) (Howard et al. 1993; Janovsky et al. 2002; Kreeger et al. 1993; Lin & Ko 1997; Lin et al. 1997; Thil & Groscolas 2002; Van Heerden & Keefen 1991). This combination is rarely used in waterfowl because it does not provide adequate analgesia for painful procedures. In Pekin ducks (*Anas platyrhynchos*) tiletamine/zolazepam (13 mg/kg IM), with lidocaine (100 mg) infiltrated into the skin and musculature at the incision site, was used for anesthesia to surgically collect liver biopsies (Carp et al. 1991).

Ketamine

Ketamine alone is not used in waterfowl and shorebirds because of poor muscle relaxation and spontaneous movement, even at high dosages. It is often combined with other drugs to minimize these unwanted side effects. In Pekin ducks, xylazine alone (1 mg/kg IV) or combined with ketamine (20 mg/kg IV) induced hypoventilation and hypoxemia (Ludders et al. 1989b). In Pekin, mallard, and tufted ducks (*Aythya fuligula*), a combination of ketamine (10 mg/kg IV), midazolam (2 mg/kg IV), and medetomidine (0.05 mg/kg IV) was effective for anesthesia and surgery (Blogg et al. 1998; Machin & Caulkett 1998b).

Alpha 2-Adrenergic Agonists

Xylazine/ketamine combinations were commonly used for avian field anesthesia. Xylazine has largely been replaced by medetomidine. In mallards IV, but not IM, medetomidine/midazolam/ketamine produced adequate analgesia and anesthesia for a 30-minute period (Machin & Caulkett 1998a). In the same study, various combinations of medetomidine, ketamine, fentanyl, midazolam, butorphanol, methohexital, or alphaxalone-alphadolone delivered IM or intranasally were either ineffective or lethal. Medetomidine and xylazine, alone or in combination with other drugs, are used with caution. Sometimes, they fail to immobilize birds or else they produce significant cardiopulmonary side effects (Atalan et al. 2002; Pollock et al. 2001; Sandmeier 2000; Uzun et al. 2003; Varner et al. 2004). An advantage to the use of α -2 agonists alone or in combination with other drugs is their reversibility with the α -2 antagonists, atipamezole and yohimbine.

Local Anesthetics

Lidocaine and bupivacaine, both lipophilic aminoamides, are most commonly used. Their duration of effect has not been determined in birds, but in mammals, lidocaine lasts 1–2 hours and bupivacaine 4–6 hours (Lemke & Dawson 2000; Skarda 1996). Use of local anesthetics in birds has been limited by fear of toxicity. To avoid adverse side effects (i.e., depression,

drowsiness, seizures, and cardiovascular collapse), the maximum dose is calculated prior to the start of the procedure (4 mg/kg lidocaine, 2 mg/kg bupivacaine) (Hocking et al. 1997; Machin 2005a). Vasoconstrictors (i.e., epinephrine) have been added to lidocaine solutions to slow systemic absorption and extend the duration of action. However, when a longer duration of action is desired, a longer-acting drug (e.g., bupivacaine) should be chosen instead. A recent pilot study reported the use of lidocaine and bupivacaine in the development of a brachial plexus nerve blockade in mallard ducks (Brenner et al. 2010).

Propofol

Propofol has found increasing popularity in waterfowl anesthesia. It can be used for induction followed by an inhalant for maintenance (Goulden 1995). Although not a widely used technique in birds, propofol can be administered by a constant rate infusion. Canvasback ducks (*Aythya valisneria*) were maintained with a constant rate infusion (0.8 mg/kg/min) following a bolus induction (15 mg/kg) (Machin & Caulkett 1999). More commonly, it is given by bolus, both to induce and to maintain anesthesia, and the frequency and size of the boluses are titrated to maintain the desired anesthetic depth. Propofol has a narrow therapeutic index. Artificial ventilation may mask overdose because the initial sign of toxicity is hypoventilation (Machin & Caulkett 1999). With waterfowl and shorebirds, apnea should be expected in all individuals given propofol.

Alphaxalone/Alphadolone

A mixture of alphadolone acetate (3 mg/mL) and alphaxalone (9 mg/mL) has found limited use in waterfowl. This combination has been used for induction and as a sedative for handling (Cooke 1995; Machin & Caulkett 1998b; Samour et al. 1984).

VASCULAR ACCESS

The veins most commonly used for vascular access are the jugular, medial metatarsal, and basilic. For both waterfowl and shorebirds, the jugular vein is used to obtain blood samples of greater than 1 mL and can be used for placement of relatively large catheters. The jugular is the largest peripheral vein, has a fairly thick wall, and hematoma formation is uncommon. The right jugular vein is often stated to be larger than the left, but either is used.

The basilic vein crosses the medial distal humerus and, because it is visible under the skin, is a favorite phlebotomy site for the inexperienced. However, its narrow lumen, thin walls, and curving course make it difficult to obtain more than a small blood sample. In small birds, it can be pierced with a needle tip and a few blood drops collected on the skin using capillary tubes. Hematomas occur very commonly, because of its

thin wall and poor technique. Their formation is prevented in several ways. First, place pressure over the needle and vein prior to withdrawing the needle, preventing blood leakage. Second, place just enough pressure to reduce blood flow, but not to empty the vessel. If the latter occurs, a hematoma forms when the pressure is lifted and blood rushes back into the vein and out the puncture. Finally, place gentle pressure over the puncture site for at least 2 minutes to allow adequate clotting.

The medial metatarsal vein courses along the medial aspect of the tarsometatarsal bone and crosses the tibiotarsal joint. The presence of scaly skin may increase the level of discomfort for the bird when this site is used. However, the vein is usually visible, the featherless skin permits good disinfection, and the tightness of the skin discourages hematoma formation. Blood is obtained using the needle-nick technique, a needle and syringe, or a butterfly catheter. The relatively small diameter of the vein minimizes the amount of blood that can be obtained, especially in small birds. However, it is useful for administration of drugs, including propofol. Although clotting at this site is usually not a problem, clotting enhancers can be used.

ANALGESIA

In waterfowl and shorebirds, any procedure that would cause pain in humans or result in tissue damage should be performed under anesthesia with consideration for analgesia (see Chapter 3). However, species differences in response to analgesics, and the relative paucity of published research in waterfowl, makes selection and dosing difficult. As with mammals, preemptive administration of analgesics is more effective in easing the pain caused by tissue damage during surgery than is postoperative analgesic administration.

Nonsteroidal Anti-Inflammatory Drugs (NSAIDs)

Flunixin meglumine, ketoprofen, meloxicam, and carprofen have all been used in waterfowl. Flunixin meglumine is not recommended because of a greater risk of adverse effects than in mammals (Clyde & Paul-Murphy 1999). These effects, noted in other bird species, include renal toxicity, regurgitation, tenesmus, and injection site necrosis (Clyde & Paul-Murphy 1999; Machin 2005a; Machin et al. 2001; Mansour et al. 1988). Nonsteroidal drugs that are not selective for cyclooxygenase-2 are used with caution. In male eiders, the nonselective NSAID ketoprofen was implicated in renal toxicosis and death when given perioperatively (Mulcahy et al. 2003). Female eiders were not adversely affected. This sex-related difference was thought to be due to physiologic changes associated with male behavior on the nesting grounds. Ketoprofen (5 mg/kg IM) takes about

30 minutes from injection to the onset of analgesia (Machin & Livingston 2002).

Birds eliminate NSAIDs rapidly, but differences in elimination rates occur between species (Baert & De Backer 2003). Compared with chickens, ostriches (*Struthio camelus*), turkeys (*Meleagris gallopavo*), and pigeons (*Columba livia*), ducks (*Anas platyrhynchos*) are intermediate in elimination half-life for meloxicam (0.72 hour), a NSAID selective for cyclooxygenase-2 (Baert & De Backer 2003). Allometric scaling can be used to predict clearance of drugs, including NSAIDs, but caution should be used using this technique (Hunter et al. 2008).

Opioids

Opioids have generally been avoided in waterfowl because of fear of respiratory depression. Birds differ from mammals in their response to μ agonist opioids. This appears to be due to a preponderance of κ opioid receptors over μ (Mansour et al. 1988). Butorphanol (1 mg/kg) combined with midazolam (2 mg/kg) was used as premedication for isoflurane anesthesia in a mallard duck (Wilson & Pettifer 2004). Buprenorphine (0.05 mg/kg, IM) given to domestic ducks 1 hour before induction with isoflurane effectively reduced reaction to painful stimuli, but had strong respiratory depressant effects (Wilberg 2005). In tufted ducks buprenorphine (0.06 mg/kg IM) was given at the time of anesthetic induction to provide postsurgical analgesia (Blogg et al. 1998). Premedication with butorphanol (1 mg/kg IM) or morphine (0.1–3.0 mg/kg IV) allows a dose-dependent reduction in inhalant anesthetics in chickens (Concannon et al. 1995) and in a psittacine (Curro et al. 1994), but not turkeys (Reim & Middleton 1995). In harlequin ducks (*Histrionicus histrionicus*), pre-anesthetic administration of butorphanol (0.5–2.0 mg/kg IM) did not reduce isoflurane requirement for surgery (D. Mulcahy, unpubl data, 1997).

FIELD TECHNIQUES

Free-living waterfowl and shorebirds are anesthetized for a variety of reasons, including restraint. Laparoscopic sexing was a common indication (Fiala 1979; Garcelon et al. 1985; Greenwood 1983; Ketterson & Nolan 1986; Richner 1989; Risser 1971). However, unless immediate results are needed, surgical sexing has largely been supplanted by molecular techniques (Boutette et al. 2002; Griffiths 2000). An increasing number of field anesthesia and surgeries are done to collect liver biopsies for determination of cytochrome P450 1A, a hepatic enzyme induced by exposure to hydrocarbons from spilled oil (Esler et al. 2002; Golet et al. 2002; Jewett et al. 2002; Mulcahy & Esler 2010; Peterson et al. 2003; Trust et al. 2000;). Isoflurane is the anesthetic of choice for taking surgical liver biopsies from birds (Degernes et al. 2002). The cytochrome

P450 isoenzyme responsible for the limited isoflurane metabolism that occurs is different from that assayed for oil spill exposure (Kharasch & Thummel 1993).

There is a growing need for avian field anesthesia to surgically implant transmitters and data loggers (Butler & Woakes 1979; Olsen et al. 1992). Many waterfowl species, especially diving birds, do not tolerate external attachment of transmitters. Implanted transmitters are better tolerated, but signal strength is greatly attenuated. An important advance in the technique has been the addition of percutaneous antennas that solved the signal attenuation problem (Korschgen et al. 1996). Percutaneous antennas also allowed recently miniaturized satellite transmitters (PTT-100, Microwave Telemetry, Columbia, MD) to be implanted in waterfowl, especially sea ducks (Petersen et al. 1995, 1999, 2003, 2006). Coelomically implanted transmitters are placed in an abdominal air sac, but no studies have evaluated the respiratory effects of a large foreign body in this air sac.

Complicating the anesthesia required to implant transmitters into the air sacs is that the surgeries are often done in remote locations in tents, on boats, or even inside helicopters (Brown & Luebbert 2002). The opening of part of the respiratory system to the atmosphere carries its own complications. In spontaneously breathing pigeons anesthetized with isoflurane, the opening of an air sac for endoscopic splenic biopsy worsened hypoventilation, despite an increased respiratory rate (Touzot-Jourde et al. 2005). This response was possibly due to high PaCO₂ or to a lighter anesthetic plane following dilution with room air entering the incision. If the birds were ventilated mechanically, the ventilator did not achieve the selected inspiratory pressure due to leakage through the open air sac. In those birds, a respiratory alkalemia developed, and PaCO₂, HCO₃⁻, base excess, heart rate, and mean arterial blood pressure were all significantly decreased, although PaO₂ was maintained (Touzot-Jourde et al. 2005). The incision required to implant a transmitter creates a much larger opening in the abdominal air sac than does that for an endoscopic biopsy. This suggests the cardiovascular effects during implantation are the same or worse.

When free-living birds require general anesthesia, it is rarely practical to do more than a quick physical examination prior to induction. The ability to do hematology and serum chemistries is rarely available. However, the emergence of point-of-care blood analyzers has begun to permit at least some screening of patients in the field (Stoskopf et al. 2010). Consumer-grade blood glucose analyzers have begun to be used in seabird rehabilitation (Lieske et al. 2002). The prandial status of wild avian anesthetic candidates is usually unknown, and it is advisable to hold wild birds for as short a time as possible, to limit stress. It is recommended to hold birds for about an hour before anes-

thesia, to prevent intra-operative draining of crop contents with subsequent aspiration.

Holding, Transportation, and Handling

Surgical facilities for field research are usually centralized and the birds are transported by truck, boat, aircraft, or by being hand-carried from the capture site. Birds are transported in soft bags, boxes, or animal carriers. Cardboard boxes are rarely suitable because of the lack of air circulation, even if holes are punched through the sides. Techniques for carrying birds are directed at protecting them from trauma, minimizing stress, and preserving the protective function of the feathers. It is preferable to transport birds individually, to prevent fighting. If more than one bird must be placed in a transport container, mixing birds of the same sex is avoided.

The size of the container should be sufficient to allow the bird to stand and turn around. Shorebirds especially prefer standing, and it may be detrimental to place them in a container that prevents them from doing so. Placing a number of birds into a larger container is not recommended; the birds generally huddle in the back of the container and will not use the extra space. If too many birds are placed into a single container, trauma or death from suffocation may result from birds piling up in a corner.

The insulation of feathers and aquatic lifestyle of waterfowl contribute to hyperthermia during dry transportation. This author has seen body temperatures as high as 43.9°C at induction in birds that survived anesthesia and surgery. A transport container must have adequate ventilation to prevent hyperthermia. Commercial cat and dog crates have grated windows, which let air circulate (Fig. 29.6). However, the grid may permit bird bills to pass through and suffer damage. This is especially important when holding long-billed shorebirds. The existing grid is covered with finer mesh netting that prevents trauma, but still allows air circulation and observation of the bird.

Prevention of feather soiling during transportation and holding is very important. Soiled feathers are a source of infection during surgery, and are less capable of maintaining a constant body temperature during anesthesia and recovery. Following release, a soiled bird has to devote more time to preening. This leads to increased energy expended, reduced feed consumption, and increased risk of predation. A towel or other absorbent material is placed on the bottom of the transport container. If the bird is permitted to rest directly on the bottom of the container, the towels are changed frequently to assure a clean and dry substrate. It is preferable to have waterfowl and shorebirds rest on netting suspended from a frame on the bottom of the container (Fig. 29.2). The mesh size should be small enough to prevent toe entanglement, but allow excreta

Figure 29.6. Examples of holding and recovering cages made by modifying an animal carrier by the addition of artificial turf (top) or mesh surrounding a PVC-pipe frame (bottom) to reduce fecal soiling of feathers. A turf bottom (top) is safer for a bird like the bar-tailed godwit (*Limosa lapponica*), that has a long bill and toes, to reduce the chance of entanglement. A finer mesh net should be attached to the inside of the wire-grid door and air holes to prevent damage to bills of shorebirds and ducks such as the common eider (*Somateria mollissima*), shown in the bottom picture.

to pass through. Alternatively, artificial turf is used for the substrate (Fig. 29.2).

When captured, wild birds rarely eat or drink in transport or temporary holding facilities, especially with humans nearby. Pretreatment holding times are, therefore, usually limited to 1–2 hours to reduce stress and dehydration. For most procedures, birds are returned to their holding containers for about an hour after they have recovered, then released.

The feathers are often disarranged or damaged during capture and initial handling to free the bird from nets or traps. Handling must be gently done to maintain feather integrity and waterproofing, especially for waterfowl that will be released into cold waters. If surgery is done on wild-caught water birds intended for immediate release, feathers are not be plucked because it will increase the amount of heat lost when the bird is released into cold water. It also imposes an increase in energy demand during feather replacement. Instead of plucking, the feathers are swept clear of a surgical site and held to the side with a water-soluble “liquid bandage” (e.g., Facilitator, IDEXX Pharmaceuticals, Greensboro, NC). The covering feathers are held apart to expose the down and a line of liquid bandage is

placed on them and massaged in. The liquid bandage collapses the structure of the down feathers, allowing them to be swept to the side, exposing the skin. The liquid bandage quickly becomes tacky, holding the collapsed down to the sides. The cleared surgical field is relatively small, but is sufficient to allow an incision. Since it is water soluble, the liquid bandage is quickly preened free of the feathers within hours of the bird’s release. Honey has been used in lieu of liquid bandage in field work (Cheryl Scott, personal communication). Tape (Micropore Surgical Tape®, 3M Health Care, St. Paul, Minnesota, USA) can be applied to the feathers wetted with liquid bandage to further prevent contamination of the surgical site. A transparent sterile barrier drape (Veterinary Specialty Products, Mission, Kansas, USA) with an adhesive backing will stick to the tape, and following the procedure, both tape and drape can be peeled off with minimal feather loss.

Lingering sedative effects are undesirable in field anesthesia of wild birds. Birds are released relatively quickly after recovery from anesthesia, placing them at risk of injury or predation or unable to maintain social status in a flock or a pair bond commitment. Due to these risks, analgesics that might compromise reactivity (e.g., opioids) are not used.

Field Anesthesia

Oral Drug Administration Waterfowl and other birds have been captured using bait treated with alpha-chloralose, a centrally active chloral derivative of glucose (Bailey et al. 1999; Belant & Seamans 1997, 1999; Belant et al. 1999). Other oral drugs used to capture waterfowl have not had the same level of use and experimentation (Cline & Greenwood 1972). Alpha-chloralose is a soporific and narcotic; it does not produce general anesthesia. It has been most used as an avicide to control nuisance birds. Although usually added to corn, it has also been combined (30 mg/kg) with margarine and used in tablet form to capture Canada geese (*Branta canadensis*) (Belant & Seamans 1997; Crider 1967). This approach is used for birds that habitually use a certain area. When applied to a substrate like bread, individual birds can be targeted if they can be approached and thrown the bait. However, induction is very long and recovery may take many hours. As a result, this drug is not suitable for birds that are to be quickly released after a procedure. Multiple exposures may be complicated by drug accumulation in the tissues.

Alpha-chloralose is hazardous to use, and a current Material Safety Data Sheet must be obtained from the manufacturer and consulted for the proper personal protective equipment. Legal use of alpha-chloralose in the United States requires an Investigational New Animal Drug Application (#6602) issued by the Food and Drug Administration to the Animal and Plant Health Inspection Service, U.S. Department of Agriculture. In mallard

ducks, the effective dose (ED_{50}) is 15 mg/kg, and the lethal dose (LD_{50}) is 34 mg/kg, resulting in a therapeutic index ($TI = LD_{50}/ED_{50}$) of 2.2 (Cline & Greenwood 1972). Alpha-chloralose is much less safe in mallard ducks than chickens where $ED_{50} = 45$ mg/kg, $LD_{50} = 300$ mg/kg, and $TI = 6.7$ (Loibl et al. 1988). This difference indicates that interspecies variability in susceptibility must be carefully considered. Overdosing is a potential problem; birds that have ingested alpha-chloralose are at risk of drowning if they enter the water. Drugged birds that escape and die in wetlands are a slight risk for starting an outbreak of avian botulism in waterfowl (Goldberg et al. 2004). Care is taken to prevent secondary poisoning of nontarget species, including domestic animals (Segev et al. 2006).

Other drugs have been added to bait, but none are registered for use as veterinary drugs. Although tiletamine-zolazepam (80 mg/kg PO) caused deep sedation of common buzzards (*Buteo buteo*), this combination has not been evaluated in wild waterfowl (Janovsky et al. 2002).

Inhalation Anesthesia

Inhalation anesthesia in free-living birds is usually performed with isoflurane. The minimum equipment for administration includes a tank of oxygen, regulator and pressure tubing, flow meter, vaporizer, and breathing system (see also Chapter 6). Most people prefer the vaporizer and flow meter mounted on a stand for convenience. Concepts of portability vary, and a "mobile" anesthesia apparatus to anesthetize 150-g doves might be one that fits snugly into the back of a truck (Small et al. 2004).

Use of compressed oxygen in the field at low ambient temperatures may contribute to loss of body heat. If safely possible, oxygen cylinders are kept in a warmed environment. Exposure to very cold temperatures can shrink metal parts and seals causing gas leakage. This author has had oxygen cylinders fresh from refilling plants prove to be empty after transportation to very cold field sites. Cylinder valves transported to cold environments should be tightened more than usual and checked upon arrival at the field location. It is prudent to always have a plan for an alternative anesthetic technique (e.g., injectable drugs).

Induction of wild-caught waterfowl is done using isoflurane and a mask. The vaporizer is set at 4% with a minimum oxygen flow of 1 L/min for most ducks and small geese. Occasionally, a wild bird is sufficiently stressed to resist induction, and the vaporizer is turned to 5%. If induction resistance occurs regularly, consideration should be given to preanesthetic sedation of the birds.

Intranasal Drug Administration

Intranasal administration of sedative drugs has seldom been used in avian anesthesia. In mallard ducks, intra-

nasal alphaxalone-alphadolone had no effect (Machin & Caulkett 1998a). Intranasal ketamine, midazolam, methohexital, and butorphanol alone or in combination produced light sedation at best, as did intranasal ketamine and midazolam when combined with IV propofol (Machin & Caulkett 1998a). However, intranasal delivery was not combined with isoflurane administration. Intranasal midazolam or diazepam sedated canaries (*Serinus canarius*) and ring-necked parakeets (*Psittacula krameri*) sufficiently that they tolerated dorsal recumbency, while xylazine and detomidine caused sedation (Vesal & Eskandari 2006; Vesal & Zare 2006). The effects took only 1–2 minutes to occur. Diazepam and midazolam administered intranasally to domestic pigeons (*Columba livia*) caused sedation sufficient to maintain dorsal decumbency for mean times of 47 and 23 minutes for the two drugs, respectively (Moghadam et al. 2009). Diazepam and midazolam administered intranasally to finches (*Taeneopygia guttata*) permitted dorsal recumbency to be maintained for mean times of 68 and 32 minutes, respectively (Bigham & Moghaddam 2013). Intranasal xylazine caused sedation, but it was not sufficient to permit dorsal recumbency of pigeons or finches (Bigham & Moghaddam 2013; Moghadam et al. 2009). Flumazenil and yohimbine are also successfully used via the intranasal route to reverse the alpha-agonist sedatives. The same agonists can be given IM as preanesthetic sedatives, but onset of action will not be as fast. Flumazenil should not be given IM due to the pain caused by its acidity. The rapid onset and duration of action of sedatives given intranasally to birds warrants further attention for use in reducing stress in captured wild birds intended for anesthesia and surgery.

Injectable Anesthesia

Given the difficulties of transporting inhalant anesthetics and compressed oxygen cylinders, it is not surprising that injectable anesthetics have been assessed for their usefulness in field surgeries. For the intracoelemic implantation of radio transmitters, propofol has been used as a general anesthetic, combined with bupivacaine or a 2:1 mixture of bupivacaine/lidocaine infused at the incision site (Machin & Caulkett 1999, 2000; Mulcahy et al. 2011). The propofol/bupivacaine anesthetic system eliminates shipping hazardous materials. In addition, the equipment required for propofol/bupivacaine is much less expensive, and the mass of materials required is a fraction of that required using isoflurane as an anesthetic (Fig. 29.7).

For several years, the author has used propofol and bupivacaine/lidocaine in field surgeries to implant transmitters into hundreds of birds. The medial aspect of the tibiotarsus is prepared for catheter placement by cleaning and disinfecting with nondetergent iodophor solution. A 0.508-mm (25-g), 1-cm butterfly catheter (No. 4573, Abbott Laboratories, North Chicago, IL), or

Figure 29.7. Comparison of equipment and supplies required to perform an identical number of surgeries using isoflurane (left) or propofol (right). The latter system totals about 10% of the weight of the former. The cartons containing the oxygen cylinders bear Hazardous Materials labels.

Figure 29.8. A 0.508-mm (25-gauge), 1-cm butterfly catheter placed in the tibiotarsal vein of a yellow-billed loon (*Gavia adamsii*) and connected to a syringe holding propofol. The wings of the “butterfly” have been cut off to reduce the chance of dislodging the needle.

an alternative catheter of suitable size and length for the bird, is placed in the medial metatarsal vein (Fig. 29.8). Stability of the catheter is improved by snipping the plastic butterfly wings from the needle. Other butterfly catheters and over-the-needle catheters can also be used, depending on the length of the bird’s leg. Birds are induced by slow administration of propofol (20 mg/kg or to effect, depending on the temperament and level of excitement of the bird). Following induction, which occurs within seconds, the catheter and its tubing are taped in place. Following preparation of the surgical site, bupivacaine or bupivacaine/lidocaine

mixture (2:1 v/v) is infused at and around the incision site to a maximum of 2 mg/kg. Additional propofol is given by bolus (1–4 mg/kg) to maintain a plane of anesthesia suitable for the procedure being done. Clues to indicate the need for additional propofol are movement or tone in the legs and wings, or opening of the eye with the presence of a reflex movement of the nictitating membrane. Following induction, bar-tailed godwits and bristle-thighed curlews *Numenius tahitiensis*) were given the first additional bolus of propofol at 1–11 minutes (median 2 minutes) for godwits and at 1–10 minutes (median 3 minutes) for curlews (Mulcahy et al. 2011).

Following induction with 8 mg/kg of propofol, a continuous rate infusion (0.85 mg/kg/min) was compared to bolus administration (2.9 mg/kg) in mute swans (*Cygnus olor*) (Müller et al. 2011). In that study, bolus administration of propofol was considered to be unsatisfactory due to sudden awakening of the swans. However, that result suggests a difficulty by the researchers to detect signs of anesthetic lightening in time to administer additional propofol. The present author has used propofol administered by bolus to anesthetize tundra swans (*Cygnus columbianus*) without problems with unexpected awakenings.

Hazardous Material Shipping

Inhalant anesthetics and compressed oxygen cylinders are classified as hazardous materials for air transportation and can only be shipped as cargo, never as checked baggage (Anonymous 2006). Failure to follow regulations governing shipment of hazardous materials may result in significant legal sanctions. They must be shipped in specific packaging, with appropriate hazard labels and forms. Hazardous materials shipping agents should be consulted to assure proper packaging and labeling. Adequate time and planning must be allowed to assure the anesthetic and oxygen will arrive when needed. Additional regulations apply to moving hazardous materials on other forms of public transportation (e.g., buses, trains, and ferries) and via transportation corridors, such as tunnels and bridges. Empty oxygen cylinders are not classified as hazardous materials and may be transported on passenger aircraft. To avoid confusion and delay, empty oxygen tanks and their packaging should have all hazardous materials labels removed or covered. It is prudent to leave the valves of empty cylinders open during shipping to avoid partial repressurization due to temperature or air pressure changes, and to attach a large label stating “Empty” to the container.

Properly packaged and labeled isoflurane and other inhalant anesthetics can be shipped (as cargo) on an aircraft bearing passengers, but compressed oxygen cylinders can only be carried on purely cargo flights. In some cases, it may be possible to transport isoflurane, but not compressed oxygen, to a field site because of

Figure 29.9. Assembly of an air-driven inhalant anesthetic system that drives a vaporizer with compressed air from a low pressure, small-volume air tank filled by an electrical air compressor.

the types of aircraft services available to the nearest staging area. If medical-grade oxygen cannot be shipped to a location, a large tank regulator can be fitted to a tank of welder's oxygen, which can often be found in remote villages and on commercial fishing boats. Alternatively, it is possible to drive an anesthetic vaporizer using compressed air. A small electric air compressor and a low pressure, 22-L portable air tank such as those used by house painters to power paint sprayers can be shipped to the field as baggage without concern for Hazardous Material shipping regulations. Most field camps have small electrical generators for recharging batteries. The air tank is filled using the air compressor and then is connected to a flow-meter and thence to the vaporizer (Fig. 29.9). The air pressure in the tank should not fall below 0.34 Mpa (50 psi), limiting this technique to short-duration procedures unless the compressor is run continuously. It is theoretically possible to fill the air tank using a hand-driven bicycle tire air pump, assuming sufficient enthusiasm for prolonged physical exertion. Specialized draw-over vaporizers, developed for military use, use ambient air, and have been adapted for use in wild animals (Lewis 2004). With any inhalant anesthetic system that uses air, it is critical to provide adequate ventilation to assure oxygenation.

Anesthesia to Prevent Nest Abandonment

Waterfowl are commonly captured while sitting on nests during laying or incubating eggs. These captures may be of short duration for the purposes of marking, measuring, or sampling. The stress of removing a sitting bird and the presence of humans when the bird is replaced on the nest causes a high rate of nest abandonment. Briefly anesthetizing gray partridges (*Perdix perdix*) and mallards being returned to the nests on which they had been captured almost eliminated nest abandonment (Rotella & Ratti 1990; Smith et al. 1980).

Despite widespread use, it is considered inappropriate and hazardous to use any inhalant anesthetic by pouring it onto cotton balls (Heard 1997). In that technique, methoxyflurane is placed on cotton in a container at the nest site; the head of the bird is then placed into the container until muscle relaxation occurs. The bird is then placed on the nest with its head tucked under its wing and the researcher quickly withdraws. The bird is closely monitored to prevent anesthesia becoming too deep because no vaporizer is used. A light anesthetic depth is sufficient because the bird only needs to be obtunded for the length of time it takes to place it on the nest and withdraw. When methoxyflurane manufacture was discontinued in the 1990s, some biologists switched to isoflurane delivered via cotton ball to birds being replaced on nests. However, the properties of isoflurane make it more hazardous than methoxyflurane to use for this purpose.

Propofol has recently been used to render birds unconscious to prevent nest abandonment (Hepp & Manlove 2001; Machin & Caulkett 2000). Propofol (10 mg/kg over 1 minute followed by additional 1–2 mg/kg boluses until induction) is delivered via a catheter in the medial metatarsal vein (Machin & Caulkett 2000).

Induction of wood ducks (*Aix sponsa*) with methoxyflurane averaged 5 minutes; although not stated, it is presumed that wood ducks given propofol IV were immediately induced (Hepp & Manlove 2001). There was no significant difference in mean time to recovery for wood ducks anesthetized with methoxyflurane (11.8 ± 1.6 minutes) compared with propofol (9.2 ± 0.8 minutes) (Hepp & Manlove 2001). The disadvantage of using propofol is that the biologist must be able to deliver it into a vein at the nest site. An advantage of propofol is that it is not classified as a hazardous material for the purpose of shipping.

Mention of trade names does not imply government endorsement.

Birds: Miscellaneous

Darryl Heard

INTRODUCTION

The orders of birds are summarized in Table 30.1. This chapter covers the anesthesia of bird groups not specifically covered elsewhere. The anesthetic principles, regimens, and drug dosages described in the other avian chapters can, for the most part, be extrapolated to the birds of a similar size in this chapter.

ANATOMY AND PHYSIOLOGY

For those readers interested in a more detailed discussion of avian anatomy and physiology, I recommend King and McLelland (1984) and Whittow (2000). The anatomy and physiology of birds is similar across all orders and is summarized in Chapter 23. This similarity is probably due to the evolutionary constraints of flight. These include the needs to minimize weight (lightweight bone structure, rapid digestion, and assimilation of nutrients) while at the same time maximize cardiopulmonary and muscular function. The main differences between species are related to capture and prehension of food (e.g., beak shape and size), and lifestyle (aquatic, terrestrial, and arboreal). For example, in one study (Mortola & Seguin 2009), the respiration rate in aquatic birds was lower (allometric equation $14.5 W[\text{kg}]^{-0.56}$) compared with terrestrial species ($13.4 W^{-0.26}$).

All birds, except kiwis, have their nares at the base of the upper beak. The nares of toucans and related birds (Piciformes) are also in this position, but covered by feathers and the edge of the beak. Gannets, pelicans (Pelecaniformes), and some other diving birds have partially or fully occluded nares, and breathe through a gap in the commissure of the beak (Fig. 30.1a) (King & McLelland 1984). Many species of marine, as well as

terrestrial birds from arid environments secrete salt through their nares from glands located within the head (Gerstberger & Gray 1993). The operculum in procellariiformes (albatrosses and petrels) is converted into a tube on the dorsal aspect of the bill (King & McLelland 1984).

The large beaks of hornbills (Coraciiformes), toucans (Piciformes), storks (Ciconiiformes), and cranes (Gruiformes) are lightweight, yet able to deliver powerful blows to kill small vertebrates, excavate tree cavities for nests and defend themselves (Seki et al. 2010). Unfortunately, the beaks of these animals are easily damaged if too much side to side pressure is applied. The toucan (*Ramphastos toco*), possesses the largest beak relative to body size of all birds. It is able to regulate heat distribution by modifying blood flow, using the bill as a transient thermal radiator (Tattersall et al. 2009) (Fig. 30.2a).

Cranes, similar to curassows and guans discussed in Chapter 29, possess long convoluted tracheas that may extend back into their sternum. This anatomy makes these species very susceptible to the adverse effects of fluid accumulation in the trachea. Pelicans possess subcutaneous air cells not connected to the respiratory system. These cells can expand during administration of nitrous oxide (Reynolds 1983).

CAPTURE AND PHYSICAL RESTRAINT

The main defensive weapon of birds is the beak, although the sharp talons of some species can also cause pain and injury (Fig. 30.1b). When restrained, birds will often orient on the handler's eyes as a place to strike. This is because the eyes are constantly moving and attract the attention of the bird. Long-necked birds, such as egrets, herons, cranes, loons, and pelicans,

Table 30.1. Classification of the class Aves

Order	Common Names	Chapter
Struthioniformes	Ostrich, rheas, cassowaries, emu, and kiwis	26
Tinamiformes	Tinamous	26
Sphenisciformes	Penguins	25
Gaviiformes	Divers (loons)	30
Podicipediformes	Grebes	30
Procellariiformes	Albatrosses, petrels, shearwaters, storm petrels, and diving petrels	30
Pelecaniformes	Tropicbirds, pelicans, gannets, boobies, cormorants, darters, and frigatebirds	30
Ciconiiformes	Herons, hammerkop, storks, shoebill, ibises, and spoonbills	30
Phoenicopteriformes	Flamingos	30
Anseriformes	Screamers, ducks, geese, and swans	29
Falconiformes	Vultures, osprey, hawks, eagles, secretary bird, caracaras, and falcons	27
Galliformes	Megapodes, guans, chachalacas, currasows, pheasants, grouse, and hoatzin	28
Gruiformes	Mesites, buttonquails, plains-wanderer, cranes, limpkin, trumpeters, rails, coots, finfoots, kagu, sunbittern, seriemas, and bustards	30
Charadriiformes	Shorebirds	29
Columbiformes	Doves and pigeons	28
Psittaciformes	Parrots	24
Cuculiformes	Turacos and cuckoos	30
Strigiformes	Owls	27
Caprimulgiformes	Oilbird, frogmouths, potoos, and owl-nightjars	30
Apodiformes	Swifts and hummingbirds	30
Coliiformes	Mousebirds	30
Trogoniformes	Trogons	30
Coraciiformes	Kingfishers, todies, motmots, bee-eaters, rollers, hoopoes, and hornbills	30
Piciformes	Jacamars, puffbirds, barbets, honeyguides, toucans, and woodpeckers	30
Passeriformes	Small perching birds, including crows and ravens.	30

Source: de Juana (1992).

are particularly dangerous. Consequently, protective glasses are recommended when working with these species.

Restraint is similar for most bird species. For large species, protective gloves may be worn. They, however, reduce the dexterity of the handler, and also may act as a fomite for pathogens if not properly cleaned. Towels are a useful alternative because they are more easily cleaned or discarded after use. They are perceived as a barrier by the birds and facilitate holding the wings and the legs at the same time. Covering the head and eyes will also calm many species (Fig. 30.3).

When holding any bird, regardless of size, care must be taken to prevent inhibiting respiration. The breathing pattern is similar, yet different from mammals. For a bird to inhale, the sternum must be able to move rostral and outward, along with the ribs.

Hyperthermia is common during restraint. This is exacerbated in birds adapted to cold environments. Prolonged muscle contraction including isometric, will produce heat, lactic acidemia, and hyperkalemia. Death may occur due to cardiac arrhythmia and muscle injury (capture myopathy or exertional rhabdomyolysis) (Burgdorf-Moisuk et al. 2012; Businga et al. 2007; Hanley et al. 2005; Marco et al. 2006; Ruder et al. 2012; Windingstad et al. 1983; Chapter 13). Physical restraint, whether it be using a towel or gloves, or tying the legs, will also potentially inhibit a bird's ability to dissipate

heat. Dehydration and malnutrition exacerbate hyperthermia and muscle damage.

Conversely, care must be taken with cold-adapted species to not interfere with their adaptive thermoregulatory anatomy and physiology. For example, anesthetic drugs may alter blood flow affecting countercurrent heat exchange. Disruption of their protective feather covering with alcohol or plucking to facilitate jugular blood collection and surgery can impair their ability to return immediately to a cold or aquatic environment. Restraint devices have been designed to facilitate handling many avian species. These include body wraps and hoods with Velcro attachments (Fig. 30.3). As mentioned previously, care must be taken using these devices to ensure adequacy of breathing and thermoregulation. Many, but not all species are quieter when their eyes and ears are covered, or they are maintained in a quiet darkened environment (Fig. 30.3).

Good quality nets are essential regardless of a bird's ability to fly. Many can outrun humans and a long-handled net can be invaluable for capture. It is important to have a variety of small to large nets available.

Diurnal birds will often stay still in a dark environment and are unable to perceive red light. If a handler approaches slowly, deliberately, and directly at a bird, they may stay still long enough to allow a close approach and then a grab by hand or with a towel.

Figure 30.1. (a) The nares of brown (*Pelecanus occidentalis*) and other pelicans are partially occluded making them predominantly mouth breathers. As in most birds the nares are located at the base of the upper bill. (b) An aggressive American white pelican (*Pelecanus erythrorhynchos*) demonstrating the potential danger of the beak to handlers. Birds will orient on the human eyes to attack because they are constantly moving. The glottis is located deep within the caudal portion of the oropharynx and very mobile. (c) The closed glottis of a brown pelican (*Pelecanus occidentalis*) deep in the caudal portion of the oropharynx. (d) The open glottis of a brown pelican (*Pelecanus occidentalis*). The cartilaginous septum in the larynx can be gently displaced by the tube for endotracheal intubation. Stabilization of the glottis from outside the pouch and a good light source will facilitate intubation. (e) An intubated pelican connected to a nonrebreathing system. A circle breathing system would also be appropriate for this-size bird. The cuff of the endotracheal tube is not inflated to prevent damage to the tracheal mucosa. This bird was induced with propofol administered to effect into a catheter placed in the medial metatarsal vein.

Figure 30.2. (a) Inhalant anesthetic induction of a toucan (*Ramphastos toco*) using a small human pediatric mask placed over the nares at the base of the bill and connected to a nonbreathing system. (b) An aracari being induced using a mask made from a plastic bottle to accommodate the long beak.

VASCULAR ACCESS

The main sites for blood collection in all avian species are the external jugular vein, the basilic vein, and the medial saphenous vein. As the species gets smaller, the main site is the jugular vein. The right jugular vein is usually the most developed. In some individuals, however, the left is most prominent. Even when the right is prominent, the left will often be identifiable, but smaller. The basilic vein on the medial surface of the elbow can be used in large birds. It is problematic, however, because hemostasis is difficult and keeping the wing still to prevent accidental movement of the needle is hard. The medial saphenous vein is useful for collecting blood from birds restrained by a handler in the upright position. In hornbills, the jugular veins are often covered by extension of the air sacs, making accurate venipuncture difficult. This author consequently uses the medial saphenous vein for these birds.

Not all birds, especially aquatic and cold-adapted birds, have feather spaces (apterylae) over the jugular.

Figure 30.3. A hospitalized sandhill crane (*Grus canadensis*) demonstrating the use of purpose-made hood to keep the animal quiet. This can also be used during physical restraint and examination, or for transportation.

In birds without apterylae, the author wets the feathers over the vein with alcohol and treats the feathers as the outer skin. Wetting the feathers down will often allow the occluded jugular vein to be identified. Alternatively, it can be palpated through the feathers.

In healthy birds, 10% of the blood volume can be collected safely without any adverse effects. Since the blood volume is approximately 10% of the bodyweight (1 g = 1 mL), then 1% of the bodyweight can be collected. More athletic birds are able to tolerate greater blood loss than ground-dwelling species. Obese animals have proportionately smaller blood volumes, since fat has a relatively small blood supply.

Although not recommended in the living bird, blood can also be collected terminally or after death from the vertebral vessels, as well as the heart. To collect blood from the vertebral vessels, the needle is placed as for a CSF tap in a mammal. That is, the head is flexed ventrally and a 22- to 25-gauge needle is inserted into the space between the back of the skull and the atlas. A 1- or 3-mL syringe is then used to collect the blood. Cardiac puncture in most birds is made difficult by the complete sternum. A long needle must either be introduced in the midline from the caudal or rostral aspect of the sternum.

Depending on the size of the bird, catheters for fluid administration can be placed in either the jugular or medial saphenous veins. Keeping a catheter in the jugular vein of an awake bird is not recommended

Figure 30.4. (a) The oral cavity of an aracari demonstrating the position of the glottis at the base of the thin tongue. (b) The oral cavity of a kookaburra (*Dacelo novaeguineae*) also showing the closed glottis at the base of the tongue.

because of the potential for hemorrhage if the bird struggles. Intraosseous catheters in either the proximal and distal ulna, or the proximal tibiotarsal bones are alternatives to intravenous catheterization. In very small birds, regular hypodermic needles can be used, but spinal needles are recommended in larger birds. In pelicans, the ulna is pneumatic and, therefore, intraosseous catheterization is contraindicated.

ENDOTRACHEAL INTUBATION

Despite the extreme variation in tongues of some birds, the glottal opening is always at its base (Fig. 30.1c,d and Fig. 30.4a,b). The jaws of flamingos do not open very far, inhibiting visualization of the glottis and placement of the endotracheal tube. The tube is either placed blindly by palpation or with the use of an endoscope. Some birds have septa at the glottal opening; these can be gently displaced to the side with the endotracheal tube (Fig. 30.1d). The glottis of pelecaniformes is located deep in the pouch and very mobile (Fig. 30.1b–d). Outside manipulation may be necessary to keep it still to allow intubation. A good light source is necessary for the intubation of some species. A head lamp makes glottal visualization easier in some species.

PREANESTHETIC CONSIDERATIONS

Regurgitation or vomiting in the perianesthetic period must be prepared for in many avian species. Some birds will regurgitate as a defensive mechanism when

handled (e.g., both New and Old World vultures). Fish-eating and fruit-eating birds seem particularly prone to regurgitation or reflux of stomach contents under anesthesia. Fasting is usually not an option in birds either because of the situation or the size of the bird. The smaller the bird the higher the metabolic rate and the more likely it will develop hypoglycemia. It is virtually impossible and not recommended to fast a bird to the point of no gastrointestinal contents. Water may be removed a couple hours before a procedure. When reflux is a concern, use a gauze roll placed past the glottis to prevent the liquid from entering the glottal area. The gauze is attached to tape that extends outside the bird's head so it is not forgotten at the end of the procedure.

The tracheal rings of birds are complete. Consequently, it is recommended cuffed endotracheal tubes not be used or the cuff inflated. This is because of the greater potential for tracheal mucosal damage. Trauma also occurs from the tip of endotracheal tube. The trachea of most birds narrows from the glottis. If a large tube is jammed into the trachea, mucosal damage will occur. This is exacerbated by head and neck movement during anesthesia.

ANALGESIA

Analgesia is described in detail in Chapters 6 and 24. Nonsteroidal anti-inflammatory drugs (NSAIDs) are highly variable in their effects and ability to cause injury across avian species. Great care must, therefore,

be taken in drug and dosage selection. Birds appear to respond predominantly to kappa opioid agonists, but there are some studies indicating mu opioids may produce analgesia in some species (Chapter 24). Tramadol is an alternative for use postoperatively in avian species. The judicious use of local anesthetics and blocks can also be a valuable part of a multi-modal analgesia plan.

INDUCTION/MAINTENANCE PROTOCOLS

Parenteral anesthetic regimens and response to drugs are similar across all birds and described in the other chapters. Ketamine alone is not recommended because of poor muscle relaxation. Consequently, parenteral anesthetic regimens based around this drug usually include either a benzodiazepine (diazepam and midazolam) or an alpha-2 adrenergic agonist (xylazine, detomidine, medetomidine, and dexmedetomidine). Unfortunately, birds seem to be very resistant to the effects of the latter drugs, requiring dosages much higher than in mammals of a similar size.

Propofol and alfaxalone can be used in all species of birds when vascular access is available, but they do produce dose and administration rate dependent cardiopulmonary depression. Although alfaxalone can be given intramuscularly, the large injection volume of drug required in anything, but the smallest of birds is inhumane.

All birds can be induced and maintained with an inhalant anesthetic. For some species, however, mask induction is problematic. In birds with long or large beaks, commercially available masks do not extend to cover the nares at the base of the beak. In these species, masks can be made from water bottles or a plastic bag (Fig. 30.2b). Alternatively, a small mask can be placed over the nares (Fig. 30.2a). Some species of birds do not have patent nares, but rather breathe around the side of the mouth (Fig. 30.1a). It is important to ensure the nares are patent in obligate nasal breathers when using a mask that closes the beak.

MONITORING

Mortality during anesthesia appears higher for birds than mammals. Monitoring is, therefore, very important in preventing injury and death. One person should always be dedicated to monitoring during the peri-anesthetic period. Clear surgical drapes facilitate visualization of respiration and auscultation of small patients during surgery. Redundancy in monitoring when possible is also important. For example, the use of both a Doppler flow detection device and an esophageal stethoscope to monitor heart rate.

Anesthetic depth is determined using basic reflexes and responses; muscle and cloacal tone, pupil size, palpebral and corneal response, toe pinch, response to

surgical incision, feather plucking, heart rate, and so on. Interestingly, birds appear more likely to respond to feather plucking than a skin incision. This may be related to the clustering of nociceptors and mechanoreceptors around the feather follicles. Palpebral response is usually absent at light surgical planes of anesthesia. Sudden pilo-erection under anesthesia can be indication of cardiac arrest rather than decreased anesthetic depth.

Hypothermia is common in anesthetized birds, and temperature monitoring is essential. Unfortunately, cloacal may not accurately reflect core body temperature. Forced air warmers are preferred for maintaining normothermia in anesthetized birds.

Heart rate is monitored by palpation or placement of a Doppler flow probe on a peripheral artery (metatarsal and ulna), auscultation of the heart (stethoscope, including esophageal), pulse oximeter, or by electrocardiography. Positional maintenance of the Doppler flow probe is sometimes difficult. A soft clamp can be constructed from two tongue depressors and used to keep the probe in place over the ulna artery. Alternatively, in large birds, the flow probe can be placed in the oropharynx or esophagus and directed at the major arteries ventral to the neck vertebra. Pulse oximetry is inaccurate and unreliable in birds. Capnography can be used to monitor respiration, but is also inaccurate for reasons discussed in previous chapters.

RECOVERY CONSIDERATIONS

The recovery period is a critical period for anesthetized avian patients and a common time for mortality. This may be related to the physiologic instability associated with transitioning from anesthetized to an awake animal. For example, as a hypothermic bird becomes warmer peripheral vessels dilate and metabolic rate increases. The former may unmask hypovolemia and hypotension, leading to decreased cardiac output. Increased metabolic rate increases glucose and oxygen use exacerbating or precipitating hypoglycemia and hypoxemia, respectively.

FIELD IMMOBILIZATION (WILD CAPTURE)

Physical capture of most birds is well described by Bub et al. (1991). The main issues when working with free-living birds is injury due to struggling, hyperthermia, and exertional rhabdomyolysis (capture myopathy) (Burgdorf-Moisuk et al. 2012; Businga et al. 2007; Hanley et al. 2005; Marco et al. 2006; Ruder et al. 2012; Windingstad et al. 1983; Chapter 13). Restraint and anesthesia time should be minimized by planning and preparation, and rapid processing. When birds are to be kept for periods of time, care must be taken to use appropriately designed crates or holding structures appropriate to the species (e.g., see Chapter 29).

Figure 30.5. (a) Intravenous administration of propofol into the medial metatarsal vein of a purple swamp hen (*Porphyrio porphyrio*). (b) A purple swamp hen (*Porphyrio porphyrio*) anesthetized with propofol for surgical implantation of a radiotransmitter. The mid-line surgical site was infiltrated with a combination of lidocaine and bupivacaine. Meloxicam was also administered for additional analgesia. Note the use of a flexible esophageal thermometer (white line) and esophageal stethoscope for monitoring. The bird is intubated and ventilated four to six times a minute using an Ambu bag.

Intranasal midazolam (0.5–2.0 mg/kg) administration may be a rapid way to provide sedation in wild birds (Ward et al. 2011). Propofol or alfaxalone can be used for short-term immobilization, as well as maintenance of anesthesia (Chapter 29) (Fig. 30.5a,b). Neither drug provides good analgesia, and other drugs must be added to the anesthetic regimen when painful procedures are planned. As with all avian anesthetics, respiratory support must be provided. Inhalation anesthesia can also be used for induction and maintenance. Administration of the inhalant anesthetic is preferably done using a precision vaporizer. The use of isoflurane without a vaporizer is not recommended because of the potential for anesthetic over dosage.

Section IV

Mammal Anesthesia

31 Monotremes (Echidnas and Platypus)

Peter Holz

INTRODUCTION

The monotremes are unique among mammals as they lay shell-covered eggs but nurse their young. There are five species: the short-beaked echidna (*Tachyglossus aculeatus*) found throughout Australia and New Guinea, three species of long-beaked echidna (*Zaglossus attenboroughi*, *Zaglossus bartoni*, and *Zaglossus bruijnii*) found in New Guinea only, and the platypus (*Ornithorhynchus anatinus*) found in Tasmania and along the east coast of mainland Australia (Van Dyke & Strahan 2008).

ECHIDNAS

Short-beaked echidnas weigh between 2 and 7 kg, while long-beaked echidnas can weigh up to 10 kg. Their dorsal surface is completely covered in spines, which are firmly attached to the skin and do not pull out the way porcupine spines do.

Capture and Physical Restraint

Echidnas have strong front feet and large pectoral muscles adapted for digging. When approached, the echidna will attempt to bury itself into the ground, rolling into a partial ball with its head tucked under its body, leaving only its spine covered dorsum exposed. Although they do not contain venom, the spines are sharp and can injure the unwary handler.

Male echidnas have spurs on their hindlegs which, until recently, were not believed to contain venom. However, new research has found that these spurs connect to a crural gland that contains proteins similar to those found in platypus venom (Koh et al. 2010). At this stage, it is unknown if the echidna “venom” is toxic to humans, and echidnas do not strike out with their spurs the way platypus do.

To dislodge the semi-buried echidna, a spade is required to dig under its body and lift it up. Alternatively, a hindfoot can sometimes be grasped. The entire echidna can then be lifted up by the foot and placed in a suitable receptacle, such as a plastic garbage can. Bags are not suitable for holding or transporting echidnas because of their spines.

If the echidna is placed on a solid surface, it will attempt to curl into a ball if approached. Again, a hand should be slid under the rear of the body and attempts made to grasp a foot. Alternatively, the entire echidna can be picked up either with a towel to protect the hands or while wearing sturdy leather gloves. If picking the echidna up by the leg, it is important to be wary of the cloaca, as stressed echidnas frequently spray urine and feces.

Anesthesia

General anesthesia is required for examination because of the echidna's tendency to roll into a ball. As the echidna usually tucks its beak quite tightly into its body it is often not possible to access the beak for mask induction. Consequently, the echidna should be placed in an induction chamber connected to an anesthetic machine and flooded with a mixture of isoflurane and oxygen. Once sufficiently sedated, the animal is removed, a mask is placed over its beak, and it is maintained with the inhalant anesthetic. Intubation is not possible because of the narrow oral cavity, inability to visualize the larynx, and presence of a keratinous pad on the dorsal surface of the base of the tongue.

Occasionally, echidnas are presented wedged into the luggage compartment of automobiles or other areas where they cannot be physically removed. Injectable agents will be required to anesthetize the echidna and extract it. A combination of xylazine (2 mg/kg IM)

and ketamine (10 mg/kg IM) works well. This can be reversed with yohimbine (0.1 mg/kg IV). Alternatively, tiletamine/zolazepam (3–10 mg/kg IM), or a combination of medetomidine (0.5 mg/kg IM) and ketamine (5 mg/kg) have also been reported to be effective (Vogelnest & Woods 2008). The latter combination can be reversed with atipamezole given IM at five times the medetomidine dose. Intramuscular injections can be administered into the hindleg, proximal to the stifle.

Analgesics that have been used in echidnas include butorphanol (0.1 mg/kg IM, IV BID), buprenorphine (1 mg/kg IM, IV SID), flunixin meglumine (0.5 mg/kg SC, IM, IV SID), ketoprofen (1 mg/kg SC, IM, IV SID), and meloxicam (0.5 mg/kg SC, IV SID or 0.2 mL PO SID).

Vascular Access

On the dorsal surface of the beak, just caudal to the nostrils, lies a soft swelling that represents a venous sinus. This sinus is suitable for blood collection using a 25-gauge needle and 2- to 3-mL syringe. A heparinized winged infusion set (butterfly catheter) will reduce the likelihood of the needle coming out of the sinus if the echidna moves. Do not exert too much pressure on the syringe, as this will collapse the sinus (Johnston et al. 2006). The jugular vein can also be used, but is more difficult to access because of the echidna's short neck (Fig. 31.1).

Physiology

Normal body temperature is 28–33°C, heart rate is 80–110 beats per minute, and respiratory rate is 8–14 breaths per minute (Jackson 2003).

PLATYPUS

Capture and Physical Restraint

Platypuses weigh from 0.6 to 3.0 kg. Males possess a sharp spur on each hindleg that is connected to a

Figure 31.1. A dorsally recumbent, anesthetized echidna demonstrating the technique for blood collection from the jugular vein.

venom gland located in the upper thigh region. Spurring and envenomation, although not fatal, is extremely painful (Jackson 2003). Platypuses are more aggressive and their venom more potent during the breeding season (August–October). Consequently, extra care is required when handling them during this time.

Platypuses are restrained by holding them by the tail base (Fig. 31.2). This keeps the spurs out of reach. Docile or hand-raised platypuses can be cradled in the hands. Platypuses are easily transported in bags such as pillow cases.

Anesthesia

Platypuses are anesthetized using a mask placed over the bill and induced with isoflurane and oxygen (Fig. 31.3). They are impossible to intubate because of their small gape, inability to visualize the larynx, and bulbous structure (torus linguae) at the base of the tongue (Vogelnest & Woods 2008).

Vascular Access

A vascular sinus suitable for blood collection is located running transversely along the rostral border of the bill (Fig. 31.4). A 25-gauge needle, attached to a 2- to 3-mL syringe, is inserted either side of the midline. Alternatively, a heparinized winged infusion set can be used as the needle is less likely to come out of the sinus if the platypus moves. Gentle pressure on the syringe is required to avoid collapsing the sinus. Blood can also be collected with greater difficulty from the ventral coccygeal vessels.

Figure 31.2. A manually restrained adult platypus demonstrating the correct position of the hand at the base of the tail to avoid the spurs in adult males.

Figure 31.3. An anesthetized platypus induced and maintained with isoflurane in oxygen administered through a mask.

Figure 31.4. Venipuncture can be achieved in platypuses by introducing a small-gauge needle into the sinus at the edge of the bill.

Physiology

Normal body temperature is 32.5–34.5°C, heart rate is 60–150 beats per minute and respiratory rate is approximately 25 breaths per minute (Jackson 2003).

32 Marsupials

Peter Holz

INTRODUCTION

Marsupials are a diverse group of mammals comprising approximately 330 species located predominantly in Australasia, with representatives in North and South America (Tyndale-Biscoe 2005; Van Dyke & Strahan 2008). The subclass Marsupialia is divided into seven orders: Dasyuromorphia (carnivorous marsupials), Peramelemorphia (bandicoots and bilbies), Diprotodontia (koala [*Phascolarctos cinereus*], wombats, possums, and macropods), Notoryctemorphia (marsupial moles), Didelphimorphia (opossums), Paucituberculata (shrew opossums), and Microbiotheria (monito del monte [*Dromiciops gleroides*]).

ANATOMY AND PHYSIOLOGY

The physiology of marsupials is well described by Tyndale-Biscoe (2005). Marsupials have a lower metabolic rate and a lower body temperature than eutherians. Instead of a separate anus and urogenital opening they combine the two into a single cloaca. To effectively measure a marsupial's temperature, the thermometer needs to be inserted into the dorsal part of the cloaca, leading to the rectum. Thermoregulatory ability is slow to develop, for example, kowaris (*Dasyuroides byrnii*) cannot thermoregulate until about 100 days after birth. Consequently, it is important to provide supplemental heat if young animals, particularly unfurred, are anesthetized. Marsupials combat cold by shivering. They do not have brown adipose tissue, which is used by some eutherians to generate heat. They cope with excessive heat by panting and licking. Kangaroos, in particular, will lick their forelegs to keep cool.

The majority of marsupials weigh less than 10 kg (Table 32.1) and can be manually restrained with

minimal risk to the handler. Consequently, where possible, mask induction with isoflurane is the anesthetic technique of choice. Standard analgesics and anti-inflammatory agents have been used at small animal dosages with no adverse effects (Table 32.2). Venipuncture sites are listed in Table 32.3 (Fig. 32.1a–d). Reference ranges for heart rate, respiratory rate and body temperature for a variety of marsupials are given in Table 32.4.

DASYUROMORPHIA

Physical Restraint

Physical restraint is only used for minor procedures or to induce general anesthesia, as restrained animals will struggle and attempt to bite. Antechinus or dunnart bites are only mildly painful, but larger members of the group, such as the Tasmanian devil (*Sarcophilus harrisii*), can inflict severe injuries (Fig. 32.2).

Small dasyurids are gripped by the scruff of the neck or held around the body and placed in a bag (Fig. 32.3). Do not clasp them too firmly, as suffocation is possible. Larger dasyurids, such as quolls and devils, can be caught in a net or restrained by the tail and then lowered into a bag. They should not be carried long distances held only by the tail. Devils must be closely monitored while in the bag as they can chew their way out.

Smaller dasyurids, such as antechinus, dunnarts, and phascogales, should not be restrained by the tail as severe degloving injuries and tail fractures can occur. If quolls are held by the tail, care is required as some are agile enough to turn and potentially bite the handler.

Bags are a convenient way of transporting dasyurids short distances. They can range in size from a pillow case for smaller animals up to a large hessian (burlap) sack for Tasmanian devils. Animals in bags tend to relax

Table 32.1. Body weights of selected marsupial species (Van Dyke & Strahan, 2008)

Species	Body Weight	Species	Body Weight
Tasmanian devil	7–10 kg	Ring-tail possum	700–900 g
Eastern quoll	0.7–2.0 kg	Feathertail glider	10–15 g
Tiger quoll	1–5 kg	Sugar glider	95–160 g
Brown antechinus	20–70 g	Eastern gray kangaroo	17–85 kg
Fat-tailed dunnart	10–20 g	Western gray kangaroo	17–72 kg
Kowari	70–170 g	Red kangaroo	17–92 kg
Brush-tailed phascogale	100–300 g	Red-necked wallaby	12–24 kg
Southern brown bandicoot	0.4–1.8 kg	Swamp wallaby	10–20 kg
Bilby	0.8–2.5 kg	Tasmanian pademelon	2–12 kg
Koala	4–15 kg	Parma wallaby	3–6 kg
Common wombat	22–39 kg	Tammar wallaby	4–10 kg
Southern hairy-nosed wombat	18–36 kg	Marsupial mole	40–70 g
Brush-tail possum	1.2–4.5 kg	Virginia opossum	2.0–5.5 kg

Table 32.2. Dosages (mg/kg) of analgesics and anti-inflammatory drugs used in marsupials (Vogelnest & Woods 2008)

Drug	Dose	Species
Butorphanol	0.4 SC/IM	Macropods
	0.2 IM	Koalas
	0.4 SC/IM	Possums and gliders
Buprenorphine	0.01–0.05 SC/IM TID	Macropods
	0.01 SC/IM BID	Koalas, bandicoots and bilbies
	0.005–0.01 SC/IV BID	Possums and gliders
Fentanyl	5 µg/kg IV bolus, then 3 µg/kg/h IV infusion	Koalas
Pethidine	1 SC/IM/IV q 4–8 h	Koalas
Methadone	0.25–0.50 SC/IM q 4–6 h	Koalas
Paracetamol +/- codeine	15 PO BID-TID	Koalas
Flunixin meglumine	1 IM/IV SID 3 days	Macropods
	1 SC/IM/IV SID 1–3 days	Koalas
Carprofen	2–4 SC SID	Macropods
	4 PO SID-BID 24 h, then 2 PO SID	Koalas
	4 SC once	Possums and gliders
Meloxicam	2 SC BID	Bandicoots and bilbies
	0.2 PO/SC SID	Macropods
	0.1–0.2 PO SID	Koalas
Tolfenamic acid	0.2 PO/SC followed by 0.1 PO SID for 5 days	Possums and gliders
	0.3 PO followed by 0.1 PO SID for 5 days	Bandicoots and bilbies
Tolfenamic acid	4 SC q 48 h	Macropods
	4 SC SID for 5 days	Possums and gliders

Table 32.3. Accessible veins in marsupials**Ventral coccygeal vein (artery):**

Insert the needle perpendicular to the tail in the ventral midline, and advance it until the vertebrae are reached. Withdraw the needle slightly and blood should enter the hub. This vein is useful for smaller dasyurids, possums, and gliders.

Lateral coccygeal vein:

A large vein is present on both lateral aspects of the tail. Applying pressure or a tourniquet to the tail base will raise the vein. This vein is useful for macropods and opossums.

Femoral vein and artery:

Direct the needle at the pulse felt in the inguinal region. Arterial blood is often obtained and digital pressure is required to prevent hematoma formation. This vein is useful for dasyurids, bandicoots, bilbies, koalas, wombats, possums, gliders, and opossums.

Medial metatarsal (saphenous) vein:

This is a small vein running along the medial aspect of the hindleg. It is useful for small dasyurids, wombats, possums, gliders, and macropods.

Cephalic vein:

This vein is present on the dorsal surface of either foreleg. It is useful for Tasmanian devils, quolls, bandicoots, bilbies, koalas, wombats, larger possums, gliders, macropods, and opossums.

Jugular vein:

This vein is useful for dasyurids, bandicoots, bilbies, koalas, wombats, possums, gliders, and macropods, but can be difficult to access in wombats and possums due to their short necks.

Figure 32.1. (a) Blood collection from the jugular vein of a Tasmanian devil (*Sarcophilus harrisi*). (b) Blood collection from the saphenous vein of a ringtail possum (*Pseudocheirus peregrinus*). (c) Blood collection from the jugular vein of a ringtail possum (*Pseudocheirus peregrinus*). (d) Blood collection from the cephalic vein of a juvenile common wombat (*Vombatus ursinus*).

Table 32.4. Heart rate, respiratory rate, and body temperature of selected marsupials

Species	Heart Rate/Minute	Respiratory Rate/Minute	Temperature (°C)
Tasmanian devil	85–120	20	31–38
Bandicoot		31–37	33–34
Sugar glider	200–300	16–40	35–36
Koala	65–90	10–15	35.5–36.5
Wombat	60–120	12–30	32.0–36.5
Macropod ^a	60–150	10–30	35–36
Virginia opossum	90–160	12–24	35–36

^aHeart rate and respiratory rate varies with the species, the rate decreases with increasing body size.

Figure 32.2. A Tasmanian devil (*Sarcophilus harrisi*) demonstrating its large gape and powerful jaws.

Figure 32.3. Physical restraint of an eastern quoll (*Dasyurus viverrinus*), a small carnivorous marsupial.

as outside stimuli and visual threats are removed. The chance of injury is also decreased, as they cannot lash out against solid objects. Most wild dasyurids are small enough to be caught in pit fall traps or Elliott traps baited with meat.

Anesthesia

Dasyurids are not prone to regurgitation under anesthesia, but preanesthetic fasting for 6–8 hours is recommended (Vogelnest & Woods 2008).

Inhalation anesthesia via mask induction is the method of choice. For animals in bags, anesthesia can be induced by extracting the head and placing it in the mask. It is important to grasp quolls and devils very firmly behind the head, as they will attempt to pull back out of the mask to bite the handler. Tasmanian devils and quolls have a wide gape and are easily intubated for more prolonged procedures (Fig. 32.2).

If the animal cannot be mask induced, an injectable induction is required (Table 32.5). While tiletamine/zolazepam (TZ) is a useful drug combination because of its low volume and rapid effect relaxation is variable and constant limb movement can occur in Tasmanian devils. Recoveries can also be prolonged, in excess of 6 hours in one Tasmanian devil (Holz 1992).

PERAMELEMORPHIA

Physical Restraint

Bandicoots and bilbies are nervous animals. Care is required with physical restraint as they will attempt to kick and can struggle so vigorously that spinal damage results. They have sharp teeth and will bite if provoked.

Table 32.5. Dosages (mg/kg) of tiletamine/zolazepam (TZ), xylazine/ketamine (X/K), medetomidine/ketamine (M/K), and alfaxalone for immobilization of marsupials (Vogelnest 1999; Vogelnest & Woods 2008)

	TZ	X/K	M/K	Alfaxalone
Dasyurids	7–10	4/20		2–3
Bandicoots and bilbies		10/30		
Koalas	4–10	5/15		1.5 IV 3.0 IM
Wombats	3–8	4/20	0.125/2	3–5
Possums and gliders	4–10	6/30	0.02–0.1/1–3	5–8
Macropods	4–10	2–5/10–25	0.1/5 ^a	1.5–3.0 IV 5–8 IM
Opossums	15	5/10	0.05–0.1/2–3	

Note: Administration is by IM injection unless otherwise indicated.

^aSee Macropod section.

To restrain a bandicoot, grasp it firmly behind the neck between the first two fingers of one hand and support the rump with the palm of the other. This form of restraint should only be used for minor procedures or to transfer the bandicoot into a bag. Bilbies can be grasped by the base of the tail and then transferred to a bag.

Anesthesia

Preanesthetic fasting is not necessary. Both bandicoots and bilbies can be mask induced and maintained on isoflurane and oxygen. Because of their wide gape, visualization of the glottis and intubation is not difficult. A 2-mm uncuffed endotracheal tube can be used for bandicoots and a 3.0- or 3.5-mm tube is suitable for bilbies (Vogelnest & Woods 2008).

KOALAS (DIPROTODONTIA)

Physical Restraint

Depending on the temperament of the koala manual restraint may be sufficient for blood sampling, examination or minor treatments (Fig. 32.4). However, care is required as agitated koalas can deliver serious bites and painful scratches.

If the koala is in a tree, and within reach, it can be coaxed down using a pole with a hessian (burlap) sack or piece of material tied to the end. Waving the sack just above the koala's head will encourage it to descend. When it is close enough, a bag is placed over the koala's head, back, and rump. With the koala's body contained within the sack, the claws are disengaged from the tree and the koala should tumble into the bag. It is important to keep the bag over the koala's head and detach the animal from the top down. Otherwise it will attempt to climb back up the tree (Jackson 2003). One person can catch docile koalas. However, agitated animals need at least two people, one to cover the koala with the sack and one to detach its claws.

Figure 32.4. Physical restraint of a juvenile koala (*Phascolarctos cinereus*) adapted to human contact. These animals are still capable of injuring with their claws an unwary handler.

Figure 32.5. Blood collection from the cephalic vein of an awake koala restrained in a large bag.

Once in the bag, a foreleg can be extended for blood sampling (Fig. 32.5). Detailed examination and treatment should be performed under general anesthesia. When transporting the koala in the bag, it is important to hold the bag away from the body and not sling it over the shoulder, as the koala can bite and scratch through the bag.

Young hand-raised koalas can be carried on the handler's body, like a human child, with one hand supporting the rump. Make sure there is enough padding between the koala and the handler's skin, as claws will

readily penetrate a shirt. Quiet adult koalas can be held with one hand on the scruff and the other supporting the rump.

Anesthesia

Preanesthetic fasting is not necessary. For inhalant induction, the koala's head is extracted from the bag and placed into the anesthetic mask. Koalas are very strong and the head must be firmly grasped as it is placed into the mask.

For prolonged procedures, koalas should be intubated. Intubation is difficult as they have a narrow oral cavity and small gape. However, if the neck is extended and a long straight-bladed laryngoscope is used, it is possible to visualize the larynx. An endotracheal tube of approximately 3- to 5-mm internal diameter can then be passed.

If the koala cannot be restrained to induce inhalation anesthesia, it will require an injectable induction (Table 32.5). Koalas high up in trees have been successfully darted with a combination of TZ (3.5 mg/kg) and medetomidine (55 µg/kg), reversed with atipamezole (2 mg IV) (Lynch & Martin 2003). Relaxation with TZ (7 mg/kg IM) alone is variable and moderate salivation can occur. Koalas take 3–4 hours to recover (Bush et al. 1990). Alfaxalone can be administered either IV or IM and provides approximately 10 minutes of anesthesia, if given by the former route. Propofol (6–8 mg/kg IV) can be used for very short procedures (Vogelnest & Woods 2008).

WOMBATS (DIPROTODONTIA)

Physical Restraint

Wild wombats are extremely strong and can be aggressive, potentially inflicting painful bites on unwary handlers. Manual restraint should not be attempted. Hand-raised wombats may permit themselves to be carried. One or both arms should be placed under the axilla, behind the forelegs, and the wombat picked up. A hand may be used to support the rump (Jackson 2003).

Anesthesia

Preanesthetic fasting is not necessary for adult wombats. Milk dependent juveniles should be fasted for at least one hour. Juvenile and hand-raised wombats can be mask induced and maintained on isoflurane. Diazepam (0.5–1.0 mg/kg IM) provides sedation for several hours. Wild adult wombats are unlikely to allow mask induction and an injectable agent will be required (Table 32.5). Despite their bulk and short legs, wombats can run as fast as a human and, given the opportunity, will rapidly dive down their burrow. As they are nocturnal, chasing wombats can be extremely hazardous due to the danger of tumbling down an unseen burrow. To catch a wild wombat, blind it by shining a powerful

light at it. The handler should then approach the wombat in the dark, trap it with a net and inject it. TZ is the combination of choice as it results in rapid induction and a good level of relaxation. Recoveries can take several hours. Alfaxalone can also be used but more than 10 mL may be required to anesthetise an adult wombat.

For prolonged procedures wombats should be intubated. Intubation is difficult as they have a narrow oral cavity and small gape. However, if the neck is extended and a long straight-bladed laryngoscope is used, it is possible to visualize the larynx. Adult wombats require a 5- to 7-mm diameter endotracheal tube.

The use of long-acting neuroleptics cannot be recommended at this time. Fluphenazine decanoate (2 mg/kg IM) caused prolonged (4 weeks) sedation and inappetence in both southern (*Lasiorhinus latifrons*) and northern hairy-nosed wombats (*Lasiorhinus krefftii*) (Vogelnest & Woods 2008). The author has seen similar effects in common wombats (*Vombatus ursinus*).

POSSUMS AND GLIDERS (DIPROTODONTIA)

Physical Restraint

Many possums scratch and the larger ones will deliver painful bites. They are often presented in boxes or other containers, such as wire traps, that make restraint difficult. Bags or pillow cases are preferable. If presented in a trap, a towel should be used to cover the possum. Thick gloves can be worn, but large possums are able to bite through these and they markedly decrease sensitivity. Once under the towel, the possum is grasped firmly behind the head. Brush-tail possums (*Trichosurus spp.*), in particular, are stronger than they appear and will pull back out of a grasp that is too lax. The handler is more likely to be bitten than strangle the possum, so be firm. It is also necessary to grasp the base of the tail with the other hand. Otherwise, the possum will swing its hindlegs forward in an attempt to scratch. It can then be examined or anesthetized.

Anesthesia

Regurgitation is unlikely but 1–2 hours preanesthetic fasting has been recommended (Vogelnest & Woods 2008). If the possum is presented in a bag, the material is rolled back and the face placed in an anesthetic mask for induction.

If the animal cannot be restrained to induce inhalant anesthesia, it will require an injectable induction (see Table 32.5). Relaxation with TZ is variable and deaths occurred when it was used in squirrel gliders (*Petaurus norfolcensis*) (Holz 1992).

MACROPODS (DIPROTODONTIA)

Physical Restraint

Manual restraint is only used for minor procedures or prior to the induction of general anesthesia as macro-

pods will attempt to kick the individual restraining them. Because of the size of the claw on digit four and the powerful hindlimb muscles, this can cause serious injury to the handler. Macropods will also bite and can inflict painful injuries with their teeth. Large kangaroos should never be manually restrained, as their hindlegs cannot be adequately controlled. Chemical restraint is strongly recommended.

Smaller macropods can be caught in a net. Care is required with exhibit design (Jackson 2003), since macropods will tend to run close to the fence when pursued. All poles and supporting structures must be outside the pen. The inside wall of the pen must be smooth with no protuberances. Patience and quiet are required. Many species panic easily and may collide with the fence, resulting in soft tissue trauma and cervical fractures.

Once caught in a net, the macropod can be grasped by the base of the tail and lowered into a hessian (burlap) sack or pillowcase, depending on the size of the animal. It is important not to hold the bag against the handler's body while the animal is being transported. They can still kick or bite through the bag injuring the handler.

If restraint and examination of the conscious macropod is required, small wallabies can be grasped by the tail base and held firmly behind the head. A second handler is required to restrain the hindlegs, which should be held above the hock. Otherwise, if the animal kicks out, it may break a leg. The animal can then be examined.

It is important to emphasize that animals restrained in this way, unless they are tame or hand-raised, will be extremely stressed and struggle vigorously against the restraint. It should only be used for short term procedures or as a prelude to chemical restraint.

Anesthesia

Sedation suitable for transport will occur 5–20 minutes after diazepam injection (1–2 mg/kg IM). Duration of effect is approximately 1–2 hours. Midazolam (0.3–0.4 mg/kg IM or IV) is a shorter acting alternative. If necessary, the benzodiazepines can be antagonized with flumazenil (1 mg flumazenil per 25 mg benzodiazepine). Azaperone (1–2 mg/kg IM) may also be used. Effects appear after 15–20 minutes and last for 6–8 hours (Vogelnest & Woods 2008).

For animals in bags, anesthesia is induced by extracting the macropod's head and placing the face in the mask. In this way, the handler is protected to some extent from the powerful hindlimbs, as they are contained within the bag.

If the animal cannot be restrained to induce inhalation anesthesia, it will require an injectable induction (Table 32.5). TZ inductions are swift and the low volume required makes it an ideal combination for immobilization by dart. However, recoveries can be

prolonged (1–5 hours). Ketamine combined with medetomidine provides superior relaxation to TZ and, if concentrated medetomidine (10 or 20 mg/mL) is used, is also suitable for remote immobilizations. It is, however, extremely expensive. Induction times are longer than with TZ (up to 20 minutes). It is important not to stimulate the animal during induction, as this will extend the time to recumbency or result in inadequate immobilization.

The author has successfully used a combination of ketamine (5 mg/kg) and medetomidine (100 µg/kg) for immobilization of docile red (*Macropus rufus*) and western gray kangaroos (*Macropus fuliginosus*). A recent study also used this combination to immobilize Bennett's wallabies (*Macropus rufogriseus*) (Bouts et al. 2011). However, in the author's experience, this combination at this dose failed to effectively immobilize the more nervous species, such as eastern gray kangaroos (*Macropus giganteus*), or smaller macropods, such as pademelons (*Thylogale* spp.) and parma wallabies (*Macropus parma*). There are several published dosages for ketamine/medetomidine combinations in macropods (2–3 mg/kg/50–100 µg/kg, Shima 1999; 2–3 mg/kg/40–80 µg/kg, Vogelnest 1999; and 4 mg/kg/40 µg/kg, Pye & Booth 1998). However, in the author's experience, these dosages are too low to induce effective immobilization.

Recent studies have also described immobilization of Bennett's wallabies using combinations of ketamine (15 mg/kg) and xylazine (2 mg/kg), ketamine (5 mg/kg) and dexmedetomidine (0.05 mg/kg) (Bouts et al. 2010), and alfaxalone (4 mg/kg) and medetomidine (0.1 mg/kg) (Bouts et al. 2011).

Ketamine/medetomidine and ketamine/dexmedetomidine anesthesia is reversed using atipamezole (IM or SC) at five times the dose of medetomidine or dexmedetomidine. The author has successfully used this dosage IV with no adverse effects. Animals are standing, but still ataxic, approximately 10–20 minutes after reversal.

TZ (0.5–1.0 mg/kg) can be combined with either medetomidine (30–40 µg/kg) or dexmedetomidine (30–40 µg/kg) for remote injection of captive red kangaroos (Heard pers. communication). This combination allows a small injection volume (when using a concentrated solution of medetomidine), relatively rapid induction and relatively shorter recovery period after reversal (60 minutes+).

For wild macropods, the TZ combination is preferred. A recent study recommended 4.7–4.9 mg/kg for wild eastern gray kangaroos, which resulted in a mean induction time of 7–10 minutes with a recovery time of 116–130 minutes (Roberts et al. 2010).

For prolonged procedures, macropods should be intubated as they may regurgitate. Intubation is difficult as they have a narrow oral cavity and small gape. However, if the neck is extended and a long straight-

bladed laryngoscope is used it is possible to visualize the larynx. An endotracheal tube can then be passed. Alternatively, the animal can be placed in dorsal recumbency and a guide catheter used to facilitate passage of the tube. Lidocaine sprayed on the glottis may assist passage of the tube.

Long-Acting Tranquilizers

Many macropod species are naturally nervous and may benefit from the use of long-acting tranquilizers when settling into new exhibits. The author has successfully used a combination of zuclopenthixol decanoate (10 mg/kg IM) and pipothiazine palmitate (10 mg/kg IM) administered to red-necked wallabies (*Macropus rufogriseus*). This dosage is much higher than that recommended for hoofstock but lower dosages proved ineffective. Duration of effect was approximately 10 days (Holz & Barnett 1996). Others have recommended using fluphenazine decanoate (2.5 mg/kg IM), the effect of which peaks by 72 hours and lasts up to 10 days, zuclopenthixol acetate (5–10 mg/kg) which has an effective duration of 72 hours, or haloperidol decanoate (4–6 mg/kg) (Vogelnest & Woods 2008). There are anecdotal reports of mortalities in bridled nail-tailed wallabies (*Onychogalea fraenata*) and agile wallabies (*Macropus agilis*) following the use of zuclopenthixol (Portas pers. comm.).

NOTORYCTEMORPHIA

Marsupial moles are rarely found in captivity. They can be held in the hand and do not attempt to bite, but resent being restrained (Jackson 2003). They can be mask induced and maintained with isoflurane.

DIDELPHIMORPHIA, PAUCITUBERCULATA AND MICROBIOTERIA

Physical Restraint

Opossums will defend themselves by biting, but they may also feign death. It is important to remain vigilant if this happens as the opossum may suddenly become active and either bite or attempt to escape. To restrain the opossum, a towel should be placed over the animal, which can then be firmly grasped behind the head. They can also be lifted by grasping the base of the tail. However, some animals may be able to lift themselves to bite and require additional restraint around the nape of the neck.

Anesthesia

The opossum is placed in a bag for transport or mask induction with isoflurane. A plastic induction chamber, connected to an isoflurane machine, can also be used. If inhalation anesthesia is not possible, an injectable induction is required. Dosages are given in Table 32.5.

High doses of TZ or xylazine/ketamine were used in the past (Stoskopf et al. 1999), but more recent literature recommends using a combination of medetomidine (50–100 µg/kg IM) and ketamine (2–3 mg/kg IM) (Johnson-Delaney 2006), or medetomidine (70 µg/kg IM) and ketamine (10 mg/kg IM), combined with butorphanol (0.5 mg/kg SC) (Capello 2007).

Insectivores (Hedgehogs, Moles, and Tenrecs)

Darryl Heard

TAXONOMY AND BIOLOGY

The order Insectivora has traditionally been used to unite several disparate mammalian groups (i.e., hedgehogs, moles, tenrecs, shrews, and solenodons) based on size and “primitive characters” (Nowak 1999). Recent revisions based on molecular evidence has redistributed insectivores into several orders: Afrosoricida (tenrecs and golden moles, 51 species), Erinaceomorpha (hedgehogs, 24), and Soricomorpha (moles, shrews, and solenodons, 428) (Wilson & Reeder 2005). For this discussion, however, these animals are grouped together. The tree shrews appear more closely related to primates and are classified within their own order Scandentia (Wilson & Reeder 2005).

The most commonly encountered insectivores in clinical practice in Europe and North America are the West European (*Erinaceus europaeus*) and four-toed or white-bellied (*Atelerix albiventris*) hedgehogs, respectively. The biology, anatomy, and physiology of hedgehogs are well described by Reeve (1994). Their major anatomical characteristic is their spines. Each is erected by a muscle originating in the deeper layers (Reeve 1994). When threatened and unable to flee, hedgehogs usually roll into a ball using several specialized muscles. All spiny hedgehogs appear able to hibernate during adverse conditions. Hibernation is associated with polycythemia and relative hypoglycemia (Reeve 1994). The “normal” body temperature of nonhibernating European hedgehogs is $35 \pm 2^\circ\text{C}$ (Reeve 1994). Heart rate is approximately 200–280bpm, declining to ≤ 25 bpm during hibernation.

Moles and shrews are occasionally encountered as injured wildlife. Torpor occurs in shrews, some golden moles, and tenrecs (Reeve 1994). Shrews have some of

the highest metabolic rates, oxygen consumption rates, water turnover, and heart and respiration rates of any mammal (Ishii et al. 2002; Ochocinska & Taylor 2005). Although moles are adapted to low oxygen environments and can tolerate prolonged hypoxemia, it is no reason to allow this to occur during the perianesthetic period.

PHYSICAL RESTRAINT

All insectivores can bite. In addition to the trauma that may be inflicted, shrews have venom, blarina toxin, within their saliva (Kita et al. 2004).

Reeve (1994) describes several techniques for unrolling a hedgehog. Leather gloves are worn to protect from the spines, as well as bites. If you are right-handed, gently lift the hedgehog’s hind end in your right palm. Use your left hand under its front, head turned away from you. Gently bounce it up and down in your hands. The hedgehog will extend its feet and unroll its snout. Without hurrying, keep bouncing it gently and allow the snout to poke between the thumb and index finger of the left hand. Place the thumb on the back of its neck using gentle, firm pressure. This prevents it from tucking its head back down. Gently gripping the rear underside of the animal with your right fingers put your right thumb in the small of its back and gently open out the animal by flexing it backwards. Alternatively, the rolled-up animal is held head down over a table. It then usually unrolls cautiously and tries to reach the surface. The back legs can then be grasped gently and the animal held by them. Alternatively, the animals are transferred directly to an inhalant anesthetic induction chamber.

PREANESTHETIC PREPARATION

Fasting is not recommended since most insectivores are very small, have high metabolic rates and small glucose reserves, and are prone to develop hypoglycemia. Cardiomyopathy is a relatively common postmortem finding in captive white-bellied hedgehogs (Black et al. 2011; Raymond & Garner 2000). Orbits in hedgehogs are shallow and the palpebral fissures are large. This may predispose them to proptosis during the perianesthetic period, especially if the periocular area is damaged and inflamed (Wheler et al. 2001).

House musk shrews (*Suncus murinus*), and perhaps other shrew species, are very sensitive to inhalant- and parenteral anesthetic-induced emesis (Gardner & Perren 1998; Horn et al. 2012). Conversely, morphine alone appears not to produce emesis in musk shrews (Selve et al. 1994). The NK1 antagonist GR205171 (1–3 mg/kg SC) and the 5-HT3 antagonist ondansetron (3 mg/kg SC) each inhibited inhalant anesthetic induced emesis in house shrews (Gardner & Perren 1998).

PARENTERAL ANESTHESIA

Description of parenteral anesthesia in insectivores is scant—drugs and dosages are extrapolated from those used in rodents (Chapter 66). Although inhalation (isoflurane and sevoflurane) is preferred, parenteral anesthesia may be indicated for remote field work. Xylazine (3 mg/kg SC), and ketamine alone (20–30 mg/kg IM) or in combination with midazolam (1–2 mg/kg IM) will cause a hedgehog to unroll and to allow examination (Reeve 1994). Buprenorphine (0.01–0.03 mg/kg SC q 12 h) has been used by this author for analgesia (Table 33.1).

Injection Sites

For SC injections in hedgehogs, forceps are used to grasp a small fold of the spiny skin over the rump. Injection is made into the connective tissue at the base of the pleat formed with the needle parallel to the animal's body (Reeve 1994). A skin fold can also be raised by pulling upward on a spine. Alternatively, an injection is made in the flank while a gloved helper pins the animal on a table. Intramuscular injections are made in the large muscles of the thigh, not the back. This route is avoided in most other insectivores because of the potential to cause irritation and self-trauma. Intraperitoneal injection is as described for rodents. Intravenous injection is difficult or impossible in most. Potential sites include cephalic (over the forearm) and intraosseous injection into the femur, tibia, and possibly the humerus.

INHALATION ANESTHESIA

Inhalation anesthesia provides rapid induction and recovery. An induction chamber can be constructed from a plastic container with an attachment for administration of the inhalant and another for removal of waste gases. Alternatively, a mask is held over the nose or used to completely enclose a small insectivore (Fig. 33.1). Animals caught in traps are either dropped into the induction chamber, or the trap enclosed in a plastic bag for anesthetic administration.

Most insectivores are too small for endotracheal intubation. A large adult white-bellied hedgehog may be intubated with a 2 mm uncuffed endotracheal tube. Alternatively, an endotracheal tube made from an over-the-needle catheter can be used.

Table 33.1. Anesthetic and analgesic drugs used in insectivores

	Drug		Hedgehogs	Moles	Shrews	Tenrecs	Comments
Inhalant anesthetics	Isoflurane	Induction	5%	5%	5%	5%	
		Maintenance	2–5%	2–5%	2–5%	2–5%	
	Sevoflurane	Induction	7–8%	7–8%	7–8%	7–8%	
		Maintenance	3–4%	3–4%	3–4%	3–4%	
	Halothane	Induction	5%	5%	5%	5%	
		Maintenance	1–2%	1–2%	1–2%	1–2%	
Parenteral anesthetics	Ketamine		20 mg/kg IM				
	Ketamine/ midazolam						
	Ketamine/ xylazine		20–40/3–5 IP IV	50–70/2–3 IP	50–200/5–10 IP	20–40/3–5 IP IV	
	Ketamine/ medetomidine		5/0.06 IM				
Opioid analgesics	Propofol		6–8 mg/kg IV				
	Morphine						
	Meperidine						
	Buprenorphine						
NSAIDs	Butorphanol						
	Ketoprofen						
	Carprofen						
	Meloxicam		0.2–0.5 mg/kg IM PO				
	Tramadol		1–5 mg/kg PO				

Figure 33.1. Inhalation anesthesia is preferred for anesthesia in all insectivores. This white-bellied hedgehog (*Atelerix albiventris*) is being induced with isoflurane in oxygen administered into a commercial dog mask connected to a nonrebreathing system.

MONITORING AND SUPPORTIVE CARE

Monitoring and supportive care are as for rodents (Chapter 68). The high metabolic rate, oxygen requirement and water turnover of many insectivores (especially shrews) make them very susceptible to hypothermia, hypoglycemia, hypoxemia, and dehydration. All effort should be made to minimize the duration of anesthesia. As described earlier, vascular access is very difficult or impossible to attain. Intraosseous catheterization of

the humerus, tibia or femur is a possible alternative. Monitoring should include pulse oximeter, Doppler flow detection, or ECG.

Edentata (Xenartha)

Gary West, Tracy Carter, and Jim Shaw

INTRODUCTION

Edentata are immobilized to facilitate diagnostic procedures and treatment of medical conditions in zoological institutions (Ferrigno et al. 2003). These species have also been immobilized for a variety of captive and field research projects (Carter 1983; Deem & Fiorello 2002; Herrick et al. 2002; Shaw et al. 1987). Although several studies have been done describing immobilization of these species, very little scientific data exists on anesthesia and monitoring of this order (Table 34.1).

PREANESTHETIC PREPARATIONS

The Edentata encompass animals with a wide range of body sizes and unique anatomical features (Divers 1986; Gillespie 2003; Wallach & Boever 1983). Body weights of edentates are often underestimated prior to immobilization (Deem & Fiorello 2002). Edentates are often characterized as heterothermic or incompletely homeothermic with wide ranges in normal body temperatures. For instance, sloths have a normal body temperature range of 24–40°C. Body temperatures in edentates may be influenced by ambient temperatures. Captures should be avoided during cold or inclement weather conditions (Deem & Fiorello 2002). The capture of free-ranging edentates during cold weather may prolong their recovery and contribute to postimmobilization mortality. Fasting smaller species of edentates for 4–6 hours is appropriate, and large species (giant anteater, giant armadillo, and sloths) should be fasted for 12–24 hours.

Preparation for the capture of free-ranging giant armadillos is labor intensive. The location of an active giant armadillo burrow must be made before capture can be attempted (Carter 1983). Giant armadillos will

create new burrows nightly, unless they are rearing young (Carter & Encarnacao 1983). Occupied burrows are located using domestic dogs, or by observation of recent digging activity at a burrow entrance. Large traps constructed of reinforced metal are set at the entrance of occupied giant armadillo burrows. As the armadillos exit their burrows, they enter the trap. The armadillo is confined in the trap by closing a metal door. The metal door is often propped open with a small wooden stick and the armadillo bumps the stick and the door closes. Capture teams must wait near the trap site and immediately immobilize the animals after they are caught, since giant armadillos often destroy the traps and injure themselves if they are left in the traps for prolonged periods of time (see Fig. 34.1).

PHYSICAL RESTRAINT

Most armadillos can be manually restrained by grabbing the animal by the sides (Fig. 34.2 and Fig. 34.3, restraint). Gloves are often used to avoid claw or biting injuries. *Euphractus*, the six-banded armadillo, will readily bite handlers. Wild giant armadillos are typically captured in traps as previously mentioned, and caution should be used with this species, as they are powerful and can inflict serious trauma to handlers before being fully immobilized. Sloths can be manually restrained with gloves or nets. Two-toed sloths can move very quickly when harassed, and will bite. Restrained sloths are capable of using their powerful forelimbs for pulling themselves closer to a restrainer's hand and inflict serious bite injuries using their large, sharp, caniform incisors. Individual sloths can be restrained for exams, blood collections, or induction of anesthesia by holding in dorsal recumbency with forelimbs extended laterally over a flat surface at a distance

Table 34.1. Normal adult body weights of select Edentate species

Giant armadillo, <i>Priodontes maximus</i>	40–60 kg
Six-banded armadillo, <i>Euphractus sexcinctus</i>	3–6.5 kg
Three-banded armadillo, <i>Tolypeutes</i> spp.	1–2.0 kg
Long-nosed armadillo, <i>Dasypus</i> spp.	3–10 kg
Fairy armadillo, <i>Chlamyphorus</i> spp.	100 g
Giant anteater, <i>Myrmecophaga tridactyla</i>	18–50 kg
Lesser anteater, <i>Tamandua</i> spp.	2–8 kg
Silky anteater, <i>Cyclopes didactylus</i>	0.4–0.8 kg
Two-toed sloth, <i>Choloepus</i> spp.	4–9 kg
Three-toed sloth, <i>Bradypus</i> spp.	3–5 kg

**Figure 34.1.** Reinforced metal trap placed at the entry to a giant armadillo (*Priodontes maximus*) burrow.**Figure 34.2.** Manual capture of a six-banded armadillo (*Euphractus sexcinctus*).

where the sloth cannot reach and bite. A second handler can help restrict hindlimb movements.

Lesser anteaters can be restrained with gloved hands, or held by the tail for injections. In one study, animals were restrained with their head and forelimbs in a bag while held by the tail for hand injections of immobilizing agents (Fournier-Chambrillion et al. 1997). Lesser

**Figure 34.3.** Manual restraint of captive giant armadillo (photo by Bob Klemm at Complejo Ecológico Municipal at Saenz Peña, Argentina).**Figure 34.4.** Free-ranging giant anteater (*Myrmecophaga tridactyla*) being restrained with wooden forked stick and hand injected with immobilization drugs.

anteaters have powerful claws that must be avoided. Giant anteaters have very powerful front limbs, with prominent claws, and are difficult to restrain manually. Wild giant anteaters can be pinned to the ground with forked wooden sticks, and immobilizing drugs are then administered by hand (Shaw et al. 1987); see Figure 34.4. Nets should not be used for anteater capture as their lips and mouths may be easily abraded (Wallach & Boever 1983).

INDUCTION

All edentates can be effectively immobilized with cyclohexamine (ketamine or tiletamine) drugs in combination with benzodiazepines or alpha-2 agonists. Such combinations include ketamine-midazolam, tiletamine-zolazepam, ketamine-xylazine, or ketamine-

medetomidine. In smaller species of edentates, manual restraint and induction with inhalants is preferred. All armadillo species, except the giant armadillo, can be manually restrained for mask or chamber induction with inhalants. Isoflurane or sevoflurane are very effective induction agents in these species. But anesthetic induction with inhalants can be prolonged due to breath holding of most edentates. Wild armadillos have been induced with isoflurane-soaked cotton balls (Deem & Fiorello 2002). Caution must be used with this method of administration, as isoflurane can be vaporized to very high concentrations at normal atmospheric pressures (up to 33%), and inhalant overdose could easily occur.

A variety of injectable immobilizing agents has been used effectively in armadillo species, and may be used in field conditions. These include: tiletamine-zolazepam, ketamine-midazolam, ketamine, ketamine-xylazine, or ketamine-medetomidine. Ketamine-medetomidine appeared to be a superior option in field conditions, due to the ability to reverse the medetomidine component (Fournier-Chambrillion et al. 2000). Tiletamine-zolazepam will cause good muscle relaxation, but prolonged recoveries are a problem in free-ranging species. Intraperitoneal or intravenous pentobarbital has also been used experimentally in armadillos, but does not have the margin of safety of other immobilizing combinations. Droperidol and fentanyl (Innovarvet®) in combination have also been used effectively in armadillos, but this combination is no longer commercially available in the United States (Thurmon et al. 1996). Giant armadillos are most easily caught in burrow traps, and are successfully immobilized with ketamine and xylazine given intramuscularly (see Fig. 34.5). Drugs should be administered with 16- or

Figure 34.5. Immobilized giant armadillo (*Priodontes maximus*) having ear tag applied (photo by Bob Klemm, Complejo Ecológico Municipal, Saenz Peña, Argentina).

18-gauge, 1.5-in needles. Giant armadillos immobilized with ketamine-xylazine are not routinely given alpha antagonists, but the use of the alpha-2 antagonist, atipamezole at 0.1 mg/kg IM, may help shorten recoveries (Table 34.2).

Sloth species can often be approached and hand injected for immobilization while they are perching or resting. As the drugs take effect, the sloth can be supported with gloved hands to avoid biting injuries. A sedated sloth that is incapable of holding onto a support branch but capable of biting can be manipulated into a restraint box or container until maximum effect of induction drugs is reached. Sloths may also be manually restrained and induced by facemask using an anesthetic inhalant, such as sevoflurane. But sloths may hold their breath for prolonged periods, making mask inductions difficult. A variety of injectable immobilizing drug combinations has been used in sloths (Gilmore et al. 2000; Hanley, et al. 2008; Vogel et al. 1998). Ketamine-medetomidine IM was found to be the best for field conditions due to its reversibility (Vogel et al. 1998). Tiletamine-zolazepam IM is a safe and effective immobilizing drug in captive situations, but recoveries are prolonged. A combination of ketamine-midazolam is also a good choice for induction. Animals may need to be confined during recovery before allowing them to climb again.

Anteater species have been immobilized with a ketamine-xylazine (Shaw et al. 1987) combination. Xylazine does not seem to cause regurgitation as reported in other species (Fournier-Chambrillion et al. 1997). In one study of lesser anteaters, increased ketamine doses seemed to increase relaxation, but also caused severe bradycardia. (Fournier-Chambrillion et al. 1997). Giant anteaters can be induced with ketamine and alpha-2 agonist combinations with good recovery after reversal of the alpha agonist. Ketamine-medetomidine will adequately immobilize captive

Table 34.2. Doses for anesthetic induction agents in Edentata

Armadillos	
Tiletamine/zolazepam	2–8 m/kg IM
Ketamine + midazolam	5 mg/kg (K) + 0.2 mg/kg (Mi) IM
Ketamine	10–15 mg/kg IM
Ketamine + xylazine	5 mg/kg (K) + 1 mg/kg (X) IM
Ketamine + medetomidine	5 m/kg (K) + 0.02–0.07 mg/kg (M) IM
Sloths	
Ketamine + medetomidine	3 mg/kg (k) + 0.04 mg/kg (M)
Tiletamine/zolazepam	2–6 mg/kg IM
Ketamine + midazolam	5–10 mg/kg + 0.2 mg/kg IM
Anteaters	
Ketamine + midazolam	5–10 mg/kg (k) + 0.2 mg/kg (Mi)
Ketamine + xylazine	5–10 mg/kg (K) + 0.5–1.5 mg/kg (x) IM
Ketamine + medetomidine	2–4 mg/kg (k) + 0.02–0.04 (M)

anteaters. In captive situations, blow darts can be used to administer immobilizing drugs. Giant anteaters can be darted in leg musculature. However, in free-ranging giant anteaters, darting episodes caused severe agitation, longer induction, and incomplete immobilization. The preferred field capture method is to approach the animal from a downwind location, restrain them with a forked stick, and quickly administer the immobilizing agent by hand injection in a hind limb, which resulted in more reliable immobilization (see Fig. 34.4). Etorphine, in combination with diazepam and atropine, may be an effective immobilizing combination for giant anteaters (Gillespie 2003; Gillespie & Adams 1985). No cardiac or respiratory depression was noted, but details were not given on how these parameters were monitored (Gillespie 2003; Gillespie & Adams 1985). The advantage of the combination would be rapid recovery after opioid antagonist administration. Salivation may be controlled by anticholinergics, but blood pressure monitoring is essential if anticholinergics are given in conjunction with alpha agonists (Sinclair 2003; Wallach & Boever 1983).

MAINTENANCE

After immobilization, edentates are typically maintained in lateral recumbency. In a captive situation, anesthesia is maintained with inhalants, and the alpha agonist drugs can be antagonized. Alpha agonists are antagonized because they cause severe bradycardia, bradyarrhythmias, decreased myocardial contractility, and likely cause decreased cardiac output (Sinclair 2003). Armadillo and sloth species are easily intubated with the aid of a laryngoscope, whereas anteater species are not routinely intubated. Anteaters have very small mouths, and appropriate-sized endotracheal tubes cannot be advanced orally (Gillespie 2003; Gillespie & Adams 1985). Giant anteaters may accommodate a 10- to 14-mm endotracheal tube, and tracheotomy supplies should be available for emergency situations. Armadillos can hold their breath and seem to tolerate hypoxemia better than other mammalian species (Thurmon et al. 1996).

Often the front claws of giant anteaters are banded during anesthesia to prevent claw injuries to handlers. However, if the animal is adequately immobilized and monitored, this should not be necessary. In the field, immobilized edentates will have their eyes covered with a blindfold to protect them from direct sunlight.

SUPPORT

Blood pressure can be monitored in edentates with indirect methods, since intravenous and intra-arterial access sites are challenging to locate in edentates. Catheterization may require a venous cut down procedure

(Gillespie 2003; Gillespie & Adams 1985). Intravenous access sites include the femoral and cephalic veins in all edentates. Sloths also have cubital veins and vertebral veins that can be used for blood collection (Divers 1986; Wallace & Oppenheim 1996). Anteaters and armadillos also have jugular or ventral tail veins. Jugular cut down procedures have been used to administer intravenous fluids in giant anteaters, although thick skin and large salivary glands make this a challenging task (Gillespie 2003; Gillespie & Adams 1985). Cardiocentesis has been advocated for armadillos or sloths, but could have severe complications and cannot be recommended (Divers 1986). Intraosseous or intraperitoneal fluid administration may also be appropriate in emergency situations.

It has been reported that armadillos will spontaneously recover from ventricular fibrillation with no treatment (Thurmon et al. 1996). Armadillos can also tolerate longer periods of apnea and hypoxemia than most mammals (Thurmon et al. 1996). Heart rates (HRs) for immobilized armadillos range from 120 to 220 beats per minute and respiratory rates (RRs) from 60 to 80 breaths per minute. Body temperatures in armadillos may range from 30 to 35°C. Cardiac output studies have been done in three-toed sloths using a dye solution technique, and these data were similar to domestic species (Gilmore et al. 2000). EKG evaluation in the three-toed sloth has been completed (Silva et al. 2005). Sloths have extreme lability in their blood pressure, and stress can have a great influence on these values. (Gilmore et al. 2000). Pulse oximetry has been used in the sloth and may be influenced by hypothermia, hypotension, and pigmentation of tissues. Sloths immobilized with ketamine/alpha-2 agonists or tiletamine/zolazepam exhibited hypoxemia based on pulse oximetry readings (Vogel et al. 1998). But blood gas values were not collected in these sloths to confirm these readings (Vogel et al. 1998). The normal HR for sloths is 45–60 bpm, and RR 10–80. Anteaters may have HR of 110–160 bpm and RR of 10–30 bpm normally.

Capnography can be used in edentates and the readings are more accurate in intubated animals. The difficulty in locating arteries can make blood gas analysis challenging, but blood gases should be monitored when possible.

RECOVERY AND COMPLICATIONS

Severe cardiovascular abnormalities can occur when alpha-adrenergic agonist agents are used for immobilization (Sinclair 2003). Alpha-adrenergic drugs can be antagonized with atipamezole, both as a treatment for negative cardiovascular effects and to hasten recoveries. Antagonism of benzodiazepines with the use of flumazenil may reduce recovery times. However, the short duration of flumazenil antagonism (60 minutes) makes its use impractical, since the duration of ben-

zodiazepine effects can be up to 4 hours. Captured, free-ranging animals may require treatment of dart or injection sites to prevent screwworm infestation (Deem & Fiorello 2002). Postrecovery excitement and self-trauma can occur if the animals are confined after recovery. Animals may pace excessively and injure claws and feet by pawing at shift doors.

Isoflurane administered by cotton balls was associated with postcapture mortality in armadillos (Deem & Fiorello 2002). The authors suggest that liver failure may have been caused by isoflurane, although when properly administered, isoflurane is the least likely inhalant to cause liver damage (Steffey 1996). In addition, anesthetic-induced hepatic damage would not cause liver failure for several days after anesthetic administration. The administration of isoflurane by cotton ball may have caused severe anesthetic overdose and cardiovascular failure, with resulting liver congestion. Vaporization of isoflurane in room air could reach 33% concentrations and cause inhalant gas overdose.

Hypothermia in field situations is possible and difficult to treat in remote locations. Trauma from capture in traps can occur as animals may rub their face or head on the traps. Claw trauma can occur from animals trying to escape enclosures after being darted.

Intubation of anteaters would require tracheotomy and close monitoring as they heal. Tracheostomy was described in a cadaver specimen of the giant anteater (*Myrmecophaga tridactyla*). The authors stated that the procedure was possible but difficult due to the large submaxillary salivary glands and deep location of the larynx beneath neck musculature (Brainard et al. 2008). Additionally, the position of the larynx can enter the thoracic cavity, and full extension of the neck must be performed to access the larynx. Handling wild nine-banded armadillos in the Southeastern United States could expose human handlers to *Mycobacterium leprae* or *Sporothrix schenkeii* (Kaplan et al. 1982; Truman 2005; Wenker et al. 1998).

Respiratory arrest was suspected in a giant anteater immobilized with ketamine and xylazine (Strom 2003). The animal began to breathe after the administration of doxapram hydrochloride. Ketamine will cause apnea in certain individuals. Doxapram will stimulate respiratory centers in the central nervous system and increase ventilation, but will not be effective during respiratory arrest.

Tubulidentata and Pholidota

Jennifer N. Langan

INTRODUCTION

Data on captive husbandry, medicine, and anesthesia of both armadillos and pangolins in captivity are very limited. They are infrequently kept in zoos and are not favored as exhibit specimens because of their inactivity and nocturnal propensities. Some specimens of armadillos have lived up to 20 years in zoological institutions, but the life span of captive pangolins has been significantly less.

TUBULIDENTATA

The armadillo (*Orycteropus afer*) is the only living representative of the order Tubulidentata. Their natural habitat is confined to Africa, south of the Sahara Desert. They have solid bodies, a long snout, and powerful legs. They have long spadelike toenails that are used to dig burrows, find food, and defend themselves. Armadillos range in weight from 50 to 70 kg. The animal's thick skin is covered with bristly hair. Armadillos have a long extensible tongue used to collect termites and ants in the wild. Their teeth lack enamel and are continuously growing; this predisposes them to malocclusion and dental disease. Their cheek teeth are composed of numerous hexagonal prisms of dentin surrounding a tubular pulp cavity. This pattern of growth gives the order its name, Tubulidentata (tubule-toothed). The dental formula for armadillos is I 0/0, C 0/0, P 2/2, M 3/3 (Fig. 35.1). They are primarily nocturnal and sleep most of the day in underground burrows (Nowak 1991).

Armadillos can be conditioned to allow physical examination and minor clinical procedures (skin scrapes and conjunctival swabs) without chemical restraint, but sedation is usually required for noxious or invasive procedures, such as venipuncture. Armadillos

are extremely strong animals with an incredibly powerful kick. Manual restraint of adult armadillos is not recommended. Neonates and juveniles can be physically restrained for procedures, but should be sedated once they are greater than 10 kg to prevent injury to the animal and the handler.

Chemical restraint for armadillos is generally required for most medical procedures. A variety of anesthetic agents have been used successfully in armadillos. A combination of ketamine and medetomidine intramuscularly is currently one of the most widely used anesthetic protocols (Table 35.1) (Langan 2003; Stetter 2003). This combination provides rapid, smooth inductions, and at least 30 minutes of anesthesia. In the author's experience, hand injection has not yielded consistent drug delivery because of the explosive reaction of the armadillo upon needle insertion. Contrastingly, remote drug delivery using CO₂-propelled darts has provided excellent results. However, owing to the armadillo's extremely tough skin, several modifications to dart removal have been needed. Pliers are used to pull out intramuscular darts, and pressure is applied around the area of needle insertion to prevent subcutaneous air accumulation during dart withdrawal. When invasive or painful procedures are necessary, supplementation with gas anesthesia is recommended. At the completion of the procedure, atipamezole is given intramuscularly to antagonize the effects of medetomidine and speed recovery. Recoveries are substantially smoother if the reversal is given at least 30 minutes after induction when medetomidine and ketamine are used in combination. Other successful drug combinations have included the following: tiletamine and zolazepam, ketamine, and detomidine (Vodicka 2004), ketamine and xylazine (Nel et al. 2000), ketamine and midazolam (Nel et al. 2000), ketamine and droperidol in combination

with fentanyl (Dieterich 1986), and etorphine with acepromazine (Stetter 2003) (Table 35.1).

Inhalant anesthetics reported in aardvarks include both halothane and isoflurane (Langan 2003; Nel et al. 2000; Stetter 2003). Animals can be maintained with gas anesthesia using either a mask or endotracheal intubation. Precautions should be taken to prevent nasal edema caused by tightly fitting face masks or gauze used to secure the endotracheal tube. Medical problems seen in aardvarks in captivity, such as conjunctivitis, postoperative wound dehiscence, and decubital ulcers can be treated by maintaining animals on a face mask using isoflurane.

Dental disease is by far the most common medical problem reported in captive aardvarks. Tooth root abscesses typically present as painful firm swellings. Buccostomies are often required to access teeth that need to be extracted because of the small size of the oral opening (Fig. 35.2 and Fig. 35.3). Curettage to remove surrounding infected bone can lead to significant hemorrhage associated with dental infections. Endotracheal intubation in these cases is especially important to protect the animal's airway. The long and narrow oral cavity of the aardvark can make intubation challenging. Blind intubation with a size 10-mm endotracheal tube for adult aardvarks has been very reliable for the author. Following induction, the animal is placed in sternal or lateral recumbency, and the animal's head and neck are maximally extended. Gentle traction is used to pull the

tongue cranially out of the oral cavity (Fig. 35.4), at which point the endotracheal tube is advanced over the base of the tongue. While holding one's ear to the proximal open end of the tube, the tip of the endotracheal tube is slowly moved into the larynx to the position at which maximal audible respiratory sounds and expiration are noted. Frequently, the tube is inadvertently advanced past this point and introduced into the cranial esophagus instead of the trachea. This happens most frequently when the animal is still swallowing. Supple-

Immobilization Drug	Dose	Antagonist	Dose	Reference
Tiletamine/zolazepam	4–5 mg/kg	Flumazenil	0.01 mg/kg	Langan (2003)
Ketamine/medetomidine	3 and 0.03–0.07 mg/kg	Atipamezole	0.15–0.4 mg/kg	Langan (2003)
Ketamine/detomidine	4–8 and 0.09–0.18 mg/kg	Atipamezole	0.05–0.09 mg/kg	Vodicka (2004)
Ketamine/midazolam	15–20 and 0.28–0.68 mg/kg			Nel et al. (2000)
Ketamine/xylazine	14 and 0.94 mg/kg	Atipamezole	0.3 mg/kg	Nel et al. (2000)
Ketamine/diazepam	11 and 0.26 mg/kg			Goldman (1986)

Figure 35.4. Withdrawing the aardvark's long tongue out of the mouth provides the needed space within the oral cavity and larynx to intubate the animal with an endotracheal tube.

menting with isoflurane via a mask until the animal no longer swallows makes intubation much simpler. While auscultating and watching the chest cavity, the tube is gently advanced into the trachea during inspiration. Rotation of the tube during advancement facilitates placement of the endotracheal tube. Alternatively, a long slender-bladed laryngoscope or flexible endoscope may be helpful to facilitate intubation; but these typically are not necessary in the author's experience. The tongue should be manually returned to the oral cavity after the animal is intubated to prevent lingual edema. In one instance, an animal was unable to retract its edematous tongue and subsequently stepped on it, causing a severe laceration during recovery. The animal later required amputation of the distal third of its tongue. Because of the very small oral opening and depth of the cavity, dental examination with a laryngoscope blade prior to intubation is essential. Once the endotracheal tube is in place, there is insufficient space to do a thorough dental and oral examination.

It is the author's experience that many aardvarks pace excessively once they recover from anesthesia, causing excessive wear and bleeding of the toenails during the first 24–72 hours following immobilization. Oral diazepam given once a day at 10 mg/aardvark in the late afternoon has prevented excessive pacing behavior during their nocturnal activity.

Occasionally, females are extremely restless and do not allow their infants to nurse sufficiently or injure them inadvertently because of excessive activity in the nest box. In these cases, low doses of oral diazepam (0.25–0.45 mg/kg SID-BID) have alleviated this behavior and allowed successful rearing of the calf by the dam. The female is weaned off diazepam after 3–4 weeks, once the infant is sufficiently ambulatory and is more efficient at nursing.

Data from aardvarks that have been anesthetized between 1999 and 2006 at Brookfield Zoo have included

Figure 35.5. Venipuncture from the medial saphenous vein in an aardvark.

heart rates ranging from 60 to 95 beats per minute, respiratory rates between 12 and 18 breaths per minute, and temperatures of 95 to 100°F.

Anesthetic monitoring using auscultation, pulse oximetry, ECG, and temperature is as in other mammals. Blood collection and intravenous catheterization can be best accomplished from the medial saphenous vein (Fig. 35.5), but is also possible using the cephalic, ventral tail, or facial vein. Frequently, peripheral vessels appear to contract during venipuncture attempts, yielding very little blood despite large vessel diameter and good blood pressure. Large-bore (18-gauge) needles and slow manual syringe collection appear to yield the best results. The aardvark's skin is extremely thick and tough, often necessitating a modified cut-down procedure for catheter placement. The location of catheter placement is selected and appropriately prepared by clipping the fur and disinfecting the skin. The skin over the vessel is pulled lateral to the vein, and a scalpel blade is used to make a small stab incision through the skin. The skin is then allowed to return to its normal position over the vessel, at which point the intravenous catheter can be routinely placed.

Infrequent monitoring of blood pressure has been attempted using a cuff distal hind limb and proximal tail with varying results. Arterial blood samples for blood gas analysis are easily obtained from the femoral or auricular artery. Arterial catheterization for continuous direct blood pressure monitoring would also likely be possible from the auricular artery. Field techniques

used to capture free-ranging aardvarks include the use of nets and funnel traps set at burrow entrances. All animals require immobilization to be handled and examined (Nel et al. 2000).

PHOLIDOTA

Animals belonging to the order pholidota include one genus (*Manus*) and seven species, and are often referred to as scaly anteaters. The white-bellied tree pangolin (*Manus tricuspis*), long-tailed tree pangolin (*Manus tetradactyla*), giant pangolin (*Manus gigantean*), and Cape pangolin (*Manus teminckii*) are African, whereas Asia is inhabited by the Indian (*Manus crassicaudata*), Chinese (*Manus pentadactyla*), and Malayan pangolins (*Manus javanica*). Some are arboreal and have strong prehensile tails, whereas others live in burrows. Pangolins attain a weight of 4–27 kg, with males being larger than females. They feed primarily on ants and termites at night, which they mechanically digest in a crop-like stomach modified for the grinding process (Wilson 1994). Pangolins have stout powerful clawed limbs used for digging and long, ribbon-like tongues. The musculature of the tongue is remarkable and has attachments reaching along the xiphoid all the way to the pelvis. It retracts into a sheath in the chest cavity when at rest. Pangolins have very well-adapted salivary glands that extend posteriorly, nearly to the shoulder. The glands produce sticky secretions that facilitate the collection of their insect prey. Pangolins completely lack teeth, and the lower jaw is a small blade-like bone. The most obvious feature of pangolins is their scaly epidermal armor. The dorsal surface of their elongate body is covered in continuously growing, overlapping scales. Confronted with a threat, pangolins curl into a tight ball to protect their soft underparts and spray urine and noxious anal gland secretions (Nowak 1991).

Large pangolins must be handled with caution because their surprising strength and sharp body coverings can injure personnel. Smaller specimens may be safely restrained with leather gloves. The normal pangolin behavior upon handling is to curl into a protective ball. Forced manual attempts to uncoil a pangolin can result in injury to the animals, and chemical restraint is typically advised to permit examination and specimen collection. Captive animals can be accustomed to handling and may become quite tractable, which facilitates routine veterinary procedures (Heath & Vanderlip 1988; L. Greer, pers. comm.).

Historically, ketamine has been used for sedating *M. pentadactyla* (Heath 1986) and *M. tetradactyla* (Robinson 1983), with doses of approximately 16–25 mg/kg, administered IM in the hind limbs. Uncoiling is possible at the higher dose; however, some muscle tone persists and salivation occurs. The duration of effective restraint is relatively short (10–20 minutes) (Robinson 1983). More recently, chamber or mask induction and maintenance with isoflurane has replaced injectable

anesthesia with excellent results (L. Greer, pers. comm., 2006).

Resting heart rates have been reported to range from 80 to 86 beats per minute, and respiratory rates varied from 14 to 53 breaths per minute (Heath & Vanderlip 1988).

Literature on clinical medicine of pangolins is sparse. The most common reported disease concerns are related to gastrointestinal ailments. Captive pangolins have the propensity to ingest bedding materials (wood shavings and saw dust), which have resulted in gastric impactions and death (Griner 1983; Heath & Vanderlip 1988). Inappropriate diet, parasitism, and malnutrition are commonly reported problems in the literature (Heath & Vanderlip 1988; Kuehn 1986; Robinson 2003). One source reports that pangolins appear to be highly susceptible to *Cryptococcus* spp. when they were housed in mixed-species exhibits (Wilson 1994).

Conventional peripheral vessels are difficult to access. Blood sampling can be accomplished under chemical restraint from a ventral surface of the tail by clipping a portion of a scale to gain access to the skin (Heath 1986; Heath & Vanderlip 1988).

36 Chiropterans (Bats)

Darryl Heard

INTRODUCTION

After rodents, bats are the most diverse and widely distributed mammal group (Wilson & Reeder 2005). They are also the most abundant and form the biggest mammalian aggregations known (Nowak 1999). The order Chiroptera contains 18 recent families and ≥ 1116 bat species (Wilson & Reeder 2005). It is divided into suborders Microchiroptera and Megachiroptera. The latter comprises just one family, the Pteropodidae, with 42 genera and ≥ 186 species.

Bats inhabit most of the temperate and tropical areas of the world, except for some remote oceanic islands and beyond the tree growth line in the colder parts of either hemisphere. The Megachiroptera are confined to the tropical and subtropical regions of the Old World, east to Australia, and the Caroline and Cook Islands.

PHYSIOLOGY AND ANATOMY

“Chiroptera” is derived from the Greek *cheir* (hand) and *pteron* (wing). Skeletal adaptations for flight include a keeled sternum and elongated second to fifth metacarpals that form long rigid spokes for wing membrane. The thumb (digit one) is an agile grasping tool, and the only digit with a functional claw. The thoracic vertebrae are interconnected to form a rigid column that supports the flight muscles.

Compared with other mammals, the acetabular opening is rotated and shifted dorsally, and the legs are rotated 180° around their long axis so the knees face the rear. Since they usually perch inverted, their legs are adapted for pulling rather than pushing. At rest, the entire bodyweight is suspended from the toes. Most have a locking mechanism that keeps the claws in a

flexed position without muscular contraction (Fig. 36.1). Consequently, bats must be “unhooked” from a perch rather than pulled; excessive force will injure toes and in juveniles may cause epiphyseal fractures. The hind limb claws are compressed into hooked blades that will lacerate skin during restraint of larger bats.

The maximal aerobic capacities are the same as similar-sized birds. The minimal metabolic requirement in level flight is 1.5 greater than the maximal aerobic capacity of a similar-sized nonflying mammal. Consequently, bats at rest are not likely to manifest overt clinical signs until respiratory dysfunction is well advanced.

Active bats are homeotherms, maintaining their body temperature between 35 and 39°C. They utilize a large amount of energy to compensate for heat loss due to a high body surface area to metabolically active tissue ratio. Additionally, large lungs and naked flight membranes result in heat loss from a surface area six times larger, and a thermal conductance 1.5–4 times greater, than wingless animals. Some bats compensate for this with heterothermy; temperate bats and tropical Vespertilionids and Molossids have a variable ability to lower body temperature and go into torpor (diurnal lethargy) or hibernation. This is based not only on temperature, but also food availability and reproductive condition. Lowered body temperature and metabolic rate in hibernating or torpid animals is assumed to reduce anesthetic requirement, and alter drug uptake and elimination.

Bats consume large quantities of food relative to their body size. Gastrointestinal transit is also very rapid, possibly to minimize bodyweight for flight. Vomiting is, therefore, unlikely unless animals are anesthetized immediately after feeding. Bats usually feed at night when they are most active. Consequently,

blood glucose and tissue glycogen levels are lowest at dusk before the animals begin feeding (Widmaier & Kunz 1993).

ZOONOTIC DISEASES

Bats populations are known reservoirs for several infectious agents of significance to humans and other

Figure 36.1. Most bats possess a locking mechanism in the toes that allows them to hang without effort. Pulling downward causes the claws to turn inward. To remove bats from a perch the claws must be unhooked to prevent injury. Golden-mantled flying fox (*Pteropus pumilus*).

animals (e.g., Lyssaviruses, Henipaviruses, and *Leptospira* spp) (Calisher et al. 2006; Constantine 1970; Rupprecht et al. 2001). It is recommended that all personnel working with bats should be vaccinated against rabies and other lyssaviruses (Rupprecht et al. 2001). Care is taken to minimize contact with blood, saliva, and other secretions or emissions that may contain infectious organisms. Although the teeth of many Microchiropterans are very small, they can still penetrate human skin. Furthermore, saliva contact with skin is also a possible source of infection. It is recommended bats be anesthetized for procedures requiring close contact to reduce biting and transmission of secretions.

PHYSICAL RESTRAINT

Techniques used for capturing free-living bats are described by Kunz and Kurta (1988). All restrained bats are capable of delivering a defensive bite. Most have jaws that are shortened giving them a powerful bite. Neonatal bats possess needle-like, caudally directed milk teeth for gripping the nipple. The thumbs and associated claws of large bats will scratch an unprotected handler and are used to pull fingers in for a bite.

Bats are restrained with leather gloves (Fig. 36.2a,b). Alternatively, a towel is used to cover the head and confine the limbs. In small bats, nets can be used for initial capture, but are cumbersome in larger animals. However, they should always be available in case of an escape. The duration of manual restraint is minimized to reduce stress and prevent hyperthermia. Prolonged restraint induces marked elevations in cortisol and glucose (Widmaier & Kunz 1993). Carrying cages must be sufficiently tall to prevent the head of the bat from touching the floor.

Figure 36.2. (a) Leather gloves are recommended for handling even small bats, such as this evening bat, from bites. (b) Physical restraint of a large flying fox (*Pteropus vampyrus*) for sample collection. Note the use of long-sleeved gloves to protect the holder from scratches, and the hold around the neck and feet.

Figure 36.3. Venepuncture of the right median vein in an anesthetized large flying fox (*Pteropus vampyrus*). Note the positioning of the elbow in a right angle to facilitate access to the vessels on the ventral aspect of the distal humerus.

Wimsatt et al. (2005) describes the use of a restraint device made of polyvinyl chloride tubing in big brown bats (*Eptesicus fuscus*). An attachment at one end is used to administer inhalant anesthesia.

BLOOD COLLECTION AND HANDLING

The blood volume of active bats is approximately 9.0–11.0 mL/100 g. Blood is collected in bats ≥ 100 g from the median artery or vein on the medial aspect of the distal humerus with a 25-gauge needle and 1- or 3-mL syringe (Fig. 36.3). If the collector is right handed, the right wing of the supine bat is extended until the elbow joint forms a 90° angle. The left hand of the collector is then used to rotate the biceps muscle laterally while compressing the median veins to cause their distension. The right hand is supported on the table surface and the needle and syringe rest across the proximal radius as the needle enters the vessel. Once blood is identified in the needle hub, continued flow must be “finessed” with gentle alteration in suction, rotation of the needle, and patience. There are usually two or more veins and an artery in close contact at the insertion site. Although arterial blood can be used for sampling, care must be taken to ensure adequate hemostasis. Large hematomas are common, even with venous puncture, and in small bats may result in death. Since collection time may be prolonged, heparinization of the syringe is recommended when a plasma sample is appropriate (Heard et al. 2006a). However, if collection lasts >2 minutes and is traumatic, the anticoagulant effect of the heparin will be overcome by thromboplastin released from tissue. Further excessive pressures will result in hemolysis.

In small bats, blood samples are collected from the cephalic vein along the leading edge of the patagium

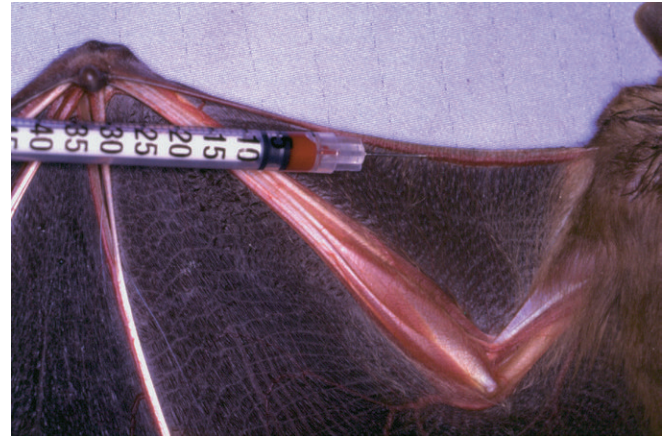

Figure 36.4. Venepuncture of the cephalic vein in an anesthetized Egyptian fruit bat (*Rousettus aegyptiacus*).

(Fig. 36.4). A 25-gauge needle is used to make a hole in the vessel and blood is collected into a microhematocrit tube from the incision site. Alternatively, a 1/2-mL insulin syringe with attached 27-gauge needle is used. This technique is also used to collect blood from the interfemoral (Fig. 36.5a,b) and saphenous vessels. In very small bats, the uropatagial vessels can be dilated with the application of a warm pack (Wimsatt et al. 2005).

The external jugular veins are large in Microchiropterans and may in some species be used for collection. Cranial vena caval collection has also been successful in some large bat species. The internal and external jugular veins of Megachiropterans are small and of similar size.

Bat blood is easily altered by inappropriate collection, handling, and storage. Even moderate hemolysis during sample collection will cause pseudo-hyperkalemia, hyponatremia, hypochloremia, and elevated aspartate transaminases (Day et al. 2001). Hyperkalemia in otherwise healthy animals is usually an indication of sample collection error. If the plasma remains in contact with the red cells for ≥ 6 hours, there will be an elevation in phosphorus and decreases in chloride and glucose concentrations (Day et al. 2001). Heparinized blood samples allow centrifugation immediately after collection and the plasma to be removed from the blood cells and frozen until analysis (Day et al. 2001; Heard et al. 2006).

PARENTERAL ANESTHESIA

Inhalation anesthesia is preferred in bats. There are circumstances, however, where it is either not available or appropriate to the situation (i.e., anesthesia of free-living animals in remote locations). Parenteral anesthetic regimens are summarized in Table 36.1.

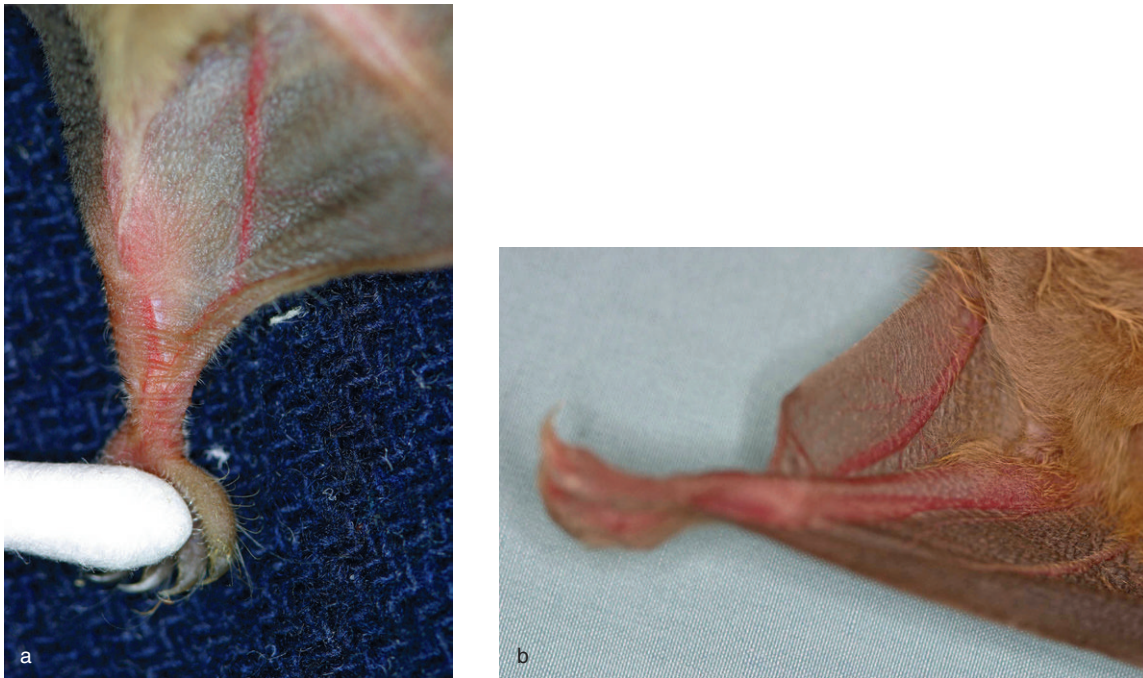

Figure 36.5. (a) The interfemoral vein in the uropatagium of a microchiropterans, a Mexican free-tail bat (*Tadarida brasiliensis*). This vessel can be used for small volume blood collection. (b) The interfemoral vein in the uropatagium of an Egyptian fruit bat (*Rousettus aegyptiacus*).

Injection Sites

When possible, intramuscular injection in the flight muscles is avoided. However, in large aggressive bats, it is easier to press them into sternal recumbency and administer drugs in the large triceps or thigh muscles. The sternum is relatively narrow, and pectoral muscle injection may result in the needle passing between the ribs if the bat moves.

Intravenous injection sites are the same as those used for blood collection: cephalic (Fig. 36.4), median, and femoral or saphenous. Small-gauge catheters are placed temporarily in the cephalic and median veins. Awake bats usually do not tolerate catheters. Intraosseous catheterization of the radius is an alternative route for administration of fluids. This route can be used in even the smallest bats.

Microchiropterans

Although there are several examples of “big” little bats, most Microchiropterans are <50g. Small body size is usually associated with a higher anesthetic dosage required for a given level of analgesia or anesthesia. Most reported studies of parenteral anesthetics in Microchiropterans investigate their effects on wing membrane capillary function; no mention is made of anesthetic effect (Harris et al. 1971; Longnecker & Harris 1972; Longnecker et al. 1974).

Megachiropterans

In variable flying foxes (*Pteropus hypomelanus*), ketamine alone (30–37.5 mg/kg IM) produced short-term

chemical restraint, but poor muscle relaxation and struggling during recovery (Heard et al. 1996). In the same species, xylazine (2 mg/kg IM)/ketamine (10 mg/kg IM) and medetomidine: ketamine (50 µg/kg: 5 mg/kg IM) combinations produce short-term immobilization (30 minutes), with good muscle relaxation and quiet recovery (Heard et al. 1996, 2006b). Similar dosages have been used in free-living variable flying foxes, both IM and IV (Epstein et al. 2011; Sohayati et al. 2008).

During induction with medetomidine/ketamine, the palpebral response was lost first, followed by clench and bite response (Heard et al. 2006b). These responses returned in the reverse order during recovery. It is recommended xylazine or medetomidine not be reversed, except in an emergency, because the adverse effects of ketamine (wing flapping and struggling with associated hyperthermia) will be unmasked during recovery. In other bat species, the dosages/kg are increased as the size of the animal decreases.

Tiletamine/zolazepam (20–40 mg/kg) produces immobilization, but prolonged recovery. However, it has been used to immobilize free-living animals suspected of being rabid or trapped in barbed wire (Vogelnest 1999). The drug combination is sprayed into the open mouth, preventing contact with people until anesthetized.

Propofol (8–10 mg/kg IV) provides 5–15 minutes of anesthesia in animals in which a vessel can be accessed for injection. Propofol may be diluted 1 : 4 with saline to facilitate administration (A. Olsson, pers. comm.).

Table 36.1. Anesthetic and analgesic drugs used in megachiropteran and microchiropteran bats

Drug	Dosage			Comments
	Route	Megachiroptera	Microchiroptera	
Parenteral				
Ketamine	IM	40–50 mg/kg	≥100 mg/kg	Not recommended because of poor muscle relaxation, and prolonged recovery with wing flapping.
Xylazine/ketamine	IM	Combine equal volumes xylazine (20 mg/mL) and ketamine (100 mg/mL); 0.4 mL/kg		Variable flying fox (<i>Pteropus hypomelanus</i>) (Heard et al. 1996). Australian flying foxes (<i>Pteropus</i> spp.) (A. Olsson, pers. comm.)
Xylazine/ketamine	IV	Xylazine 1 mg + ketamine 5 mg in 0.1 mL		Free-living variable flying foxes. Provided safe short-term immobilization for collection of biological samples (Sohayati et al. 2008).
Medetomidine	IV	0.03 mg/kg		Free-living variable flying foxes (Epstein et al. 2011).
Medetomidine/ketamine	IM	Combine equal volumes medetomidine (1 mg/mL) with ketamine (100 mL/kg); 0.5 mL/kg		Captive variable flying foxes (Heard et al. 2006a).
Medetomidine/ketamine	IV	0.05/5.0 and 0.025/2.5 mg/kg		Free-living variable flying foxes (Epstein et al. 2011).
Tiletamine/zolazepam	PO	40 mg/kg		For immobilization of large bats when physical restraint is dangerous (i.e., suspect rabid bats or animals caught in barbwire). Drug combination is squirted into mouth of animal (Vogelneust 1999). Recovery is prolonged—not recommended for routine anesthesia/immobilization.
Propofol	IV	6–8 mg/kg	8–10 mg/kg	Dilute 1 : 4 with saline to obtain injection volume in small bats. (A. Olsson, pers. comm.)
Inhalation				
Halothane	Inhalation	Induction 4–5%, maintenance 1–1.5%		
Isoflurane	Inhalation	Induction 5%, maintenance 2.5%		
Sevoflurane	Inhalation	Induction 6–7%, maintenance 3–4%		
Analgesics				Expensive
Butorphanol	SC, IM	0.4 mg/kg q 4 h	2 mg/kg q 4 h	
Buprenorphine	SC, IM	0.03 mg/kg q 6–12 h	0.05–0.1 mg/kg q 6–12 h	
Morphine	SC, IM	0.5–1.0 mg/kg q 4–6 h	2–5 mg/kg q 4 h	
Carprofen	SC, IM, PO	1–4 mg/kg q 24 h (q 12 h PO)	3–5 mg/kg q 12 h	
Meloxicam	SC, IM, PO	0.1–0.3 mg/kg q 12 h	1–2 mg/kg q 12 h	
Tramadol	PO	0.5–2.0 mg/kg q 24 h		

Figure 36.6. Medium to large bats, as in this Wahlberg's epauletted fruit bat (*Epomorphorus wahlbergi*) can be intubated with commercially available endotracheal tubes (≥ 2 mm ID). The trachea is relatively short and the endotracheal tube should be premeasured before placement.

Figure 36.7. The oral cavity of a dorsally recumbent Wahlberg's epauletted fruit bat (*Epomorphorus wahlbergi*) before endotracheal intubation. The tongue is pulled dorsally. The epiglottis lies just beyond the opening in the soft palate.

Rapid injection is associated with marked cardiopulmonary depression and possibly apnea; endotracheal tubes, laryngoscope, and a mechanism for providing assisted ventilation must be available.

INHALATION ANESTHESIA

Inhalation anesthesia is very safe and effective in both captive and free-living bats (Wimsatt et al. 2005). An efficient respiratory system (Canals et al. 2005) makes induction and recovery times comparable with those of birds. Isoflurane (5% by mask, then maintenance 2–2.5%) provides rapid (1–2 minutes) induction and recovery, as well as rapid response to changes in vaporizer setting. For prolonged anesthesia, bats are attached to a nonbreathing system with either an endotracheal tube or a mask (Fig. 36.6). Portable, lightweight inhalant anesthetic systems developed for avian anesthesia (Chapter 25) are ideal for field immobilization.

Endotracheal Intubation

Bats ≥ 150 g are intubated with a ≥ 2 -mm internal diameter endotracheal tube. For intubation, the author prefers to place the bat in dorsal recumbency to visualize the glottis (Fig. 36.7). The mouth is opened using gauze placed around the upper and lower jaws and the tongue pulled forward and to the side. A laryngoscope with a small straight pediatric blade is used for illumination. Topical anesthetic applied to the glottal opening decreases reflex coughing.

Monitoring

Cardiovascular Heart rates range from 100 beats/min (bpm) in large Megachiropterans at rest to 1000 in the smallest. Heart rates are influenced by restraint, anesthesia, environmental temperature, and size. The rate of the 5- to 10-g *Myotis lucifugus* ranges from around 350 bpm at thermoneutrality (33–38°C) to as low as 6 bpm during hibernation (rectal 6°C) (Kallen 1977). Although the electrocardiogram is typically mammalian, its configuration in Microchiropterans varies with rate, and there are species differences. In some Vespertilionids, at high rates, the T and R waves fuse, and the P wave is difficult to identify. Active and dormant bats may develop a functional bradycardia interrupted by transitory compensatory tachycardias. At low body temperatures, supraventricular arrhythmias and second-degree heart block are common, but reverse with warming. However, bats appear resistant to hypothermia-associated ventricular fibrillation (Kallen 1977). Heart rate and rhythm and peripheral blood flow are assessed with a Doppler flow probe secured over the tibial artery behind the knee or the pedal artery on the palmar surface of the feet.

Respiratory Hemoglobin saturation and heart rate are monitored with a pulse oximeter probe placed on the tongue, foot, or median artery, or with a rectal reflectance probe. Arterial blood samples can be collected from the ulnar artery on the medial surface of the humerus.

Body Temperature The thermoneutral zone is for setting environmental temperatures for captive bats. This is the ambient temperature range in which a resting, fasting animal consumes the least amount of oxygen. Within this range, an animal can maintain a constant body temperature without additional energy cost. For large flying foxes (500–1000 g), the thermoneutral zone lies between 24 and 35°C, whereas for a lightweight bat, such as *Saccopteryx bilineata* (7 gm), it is restricted to 30–35°C.

Bats die quickly if the ambient temperature is above body temperature, particularly if the humidity is high. Their only means of lowering body temperature are evaporative cooling and the creation of convection currents by air movement. Flying foxes roost in large trees, often in full sun. As the ambient temperature rises, they initially start fanning the air with bent wings. If the ambient temperature approaches body temperature, they wet their fur with saliva and urine and pant, but they cannot sweat. Microchiropterans and smaller Megachiropterans avoid intense heat through their choice of diurnal roosts. Caves, crevices, and hollow trees are ideal, thermally stable environments with temperatures in or near the thermoneutral zone. Because the bats only fly out at night, they never run the risk of overheating. Since most bats roost in sites with localized climates, preferred roost humidity is likely to be greater than 30%, and may approach 100%. Humidity is an important influence on the elasticity of the patagium, and very dry conditions will be associated with dry membranes.

A temperature probe is placed in either the rectum or esophagus; the latter is preferred because it reflects core body temperature. Rectal temperatures in healthy animals may be as low as 35°C.

Metabolic Hypoglycemia is very likely to occur in the perianesthetic period, particularly in very small, anorectic animals (Widmaier & Kunz 1993). Blood glucose levels should be maintained above 80 mg/dL.

Supportive Care

To prevent hypothermia, the wings are folded to the body, and the animal is placed on a circulating water blanket. When possible, the bat is wrapped in either a blanket or bubble-wrap. Alternatively, a commercial forced air warmer developed for human surgery is used. Electric and chemical heating pads, as well as heated water bottles, are avoided because they will cause severe burns to the wing membranes. The wing membrane is also very susceptible to ischemic damage from bandaging and taping.

Intravenous over-the-needle catheters can be placed in anesthetized bats in the cephalic (Fig. 36.8), ulnar, and saphenous veins. The catheter needs to be removed before recovery or the animal will chew it out. Catheters are secured with glue or tape.

Figure 36.8. Cephalic vein catheterization in an anesthetized large flying fox (*Pteropus vampyrus*). Most bats are intolerant of catheters when awake. Care is taken to not compress the patagium (wing membrane) within constrictive bandages.

Recovery

For recovery, bats are wrapped in a towel and left in a quiet cage to prevent struggling and wing flapping; the animals are usually sufficiently recovered when they are able to crawl out. Alternatively, once gripping returns the bat is suspended from its perch.

37 Prosimians

Cathy V. Williams and Randall E. Junge

INTRODUCTION

The group of primates referred to as prosimians or strepsirhine primates include lemurs, lorises, pottos, and bush babies. All lemurs are endemic to the island of Madagascar. Under current classification, there are five families and over 90 separate species of lemurs recognized (Mittermeier et al. 2010), although taxonomic groupings continue to change as more information on their genetics becomes available. Lorises, pottos, and bush babies are small bodied, nocturnal primates. Lorises are native to Southeast Asia and India while pottos and galagos are endemic to Africa (Nowak 1999; Rowe 1996).

When using anesthetic agents in prosimians, it is important to remember that there is very little controlled data on the pharmacokinetics of any drug class in these species. The information contained in this chapter is predominately derived from the authors' personal experiences and the few published reports that mention use of a particular drug without apparent side effects. Thus, the doses provided here may not be the most pharmacologically appropriate, and there is no guarantee the drugs are entirely safe even though problems have not been documented. It is important to use all drugs conservatively in this group and to monitor animals' physiologic and behavioral responses carefully to minimize complications.

Prosimians are a very diverse group of primates and physiological responses to a particular drug may vary by species. It is unknown if prosimians respond to anesthetic agents similar to other primates but, in most instances, studies performed in anthropoid primates are the best resource from which to derive information when extrapolating drug doses. The reader is referred to chapters in this book discussing anesthesia in monkeys,

gibbons, and great apes, and to other selected references for more extensive information on the pharmacologic action of anesthetic agents particular to higher primates (Horne 2001; Popilskis & Kohn 1997).

SPECIAL PHYSIOLOGY

Prosimian primates exhibit considerable anatomical and physiological variation (Mittermeier et al. 2010; Rowe 1996; Sussman 1999). Size ranges from 30g for the smallest mouse lemur (*Microcebus myoxinus*) to more than 8kg for some members of the Indridae family: diademed sifakas (*Propithecus diadema*) and indri (*Indri indri*). Table 37.1 gives approximate adult weight ranges for a variety of prosimian species. Prosimians have a low basal metabolic rate compared to other primates (Ross 1992). Several behaviors exhibited by lemurs, such as basking and huddling, are related to energy conservation and thermal regulation. Dwarf lemurs (*Cheirogaleus sp.*) and mouse lemur (*Microcebus sp.*) are unique among primates in that they hibernate or undergo periods of torpor, an adaptation which allows them to conserve energy during periods of reduced food and water availability (Hladik et al. 1980; Schmid et al. 2000; Schülke & Ostner 2007).

The body temperature of lemurs and bush babies generally ranges between 97 and 99°F, however dwarf and mouse lemurs undergoing torpor may have temperatures significantly below 90°F (Dausmann et al. 2005; Schmid et al. 2000). Core body temperatures of fat-tailed dwarf lemurs track ambient temperatures for hours or days a time during deep torpor (Dausmann et al. 2005). The rectal temperature of lorises is slightly lower than that of lemurs and bush babies and ranges between 95 and 97°F at normal room temperatures (Müller et al. 1985; Whittow et al. 1977).

Table 37.1. Body weight ranges for various prosimian species

Scientific Name	Common Name	Adult Weight (kg)
<i>Avahi</i>	Woolly lemur	1.0–1.5
<i>Cheirogaleus medius</i>	Fat-tailed dwarf lemur	0.16–0.25
<i>Daubentonia</i>	Aye-aye	2.5–3.0
<i>Eulemur coronatus</i>	Crowned lemur	1.5–2.0
<i>Eulemur fulvus</i>	Brown lemur	2.0–2.7
<i>Eulemur macaco</i>	Black lemur	2.0–2.5
<i>Eulemur mongoz</i>	Mongoose lemur	1.4–1.6
<i>Galago moholi</i>	Southern lesser bush baby	0.15–0.25
<i>Hapalemur griseus</i>	Eastern lesser bamboo lemur	0.75–2.50
<i>Indri indri</i>	Indri	6.00–7.25
<i>Lemur catta</i>	Ring-tailed lemur	2.0–3.0
<i>Lepilemur</i>	Sportive lemur	0.5–1.0
<i>Loris tardigradis</i>	Slender loris	0.15–0.25
<i>Microcebus murinus</i>	Mouse lemur	0.06–0.09
<i>Mirza</i> spp.	Giant mouse lemur	0.028–0.320
<i>Nycticebus pygmaeus</i>	Pygmy loris	0.35–0.45
<i>Nycticebus coucang</i>	Slow loris	0.80–1.30
<i>Otolemur crassicaudatus</i>	Thick-tailed greater bush baby	0.70–0.85
<i>Perodicticus potto</i>	Potto	0.85–1.60
<i>Propithecus coquereli</i>	Coquerel's sifaka	3.3–4.5
<i>Varecia</i> sp.	Ruffed lemur	3.0–3.8

Prosimians have no active mechanism for cooling, such as sweating or panting, and temperature regulation is accomplished primarily by limiting activity, seeking cool locations during hot weather, and licking hands to generate evaporative cooling. Therefore, capture and handling during warm weather should be done either early in the morning while outdoor ambient temperatures are cool or indoors in temperature-controlled environments.

The amount of time necessary to withhold food prior to anesthesia varies by species due to differing rates of gastric emptying. While all prosimians have simple stomachs, the size and conformation of the cecum and large bowel varies depending on the dietary profile of the species. Campbell et al. (2004) measured gastric emptying times in four species of lemurs. Gastric emptying times ranged from 3 to 4 hours in the ruffed lemur (*Varecia variegata*), a frugivorous species, and up to 24 hours in eastern lesser bamboo lemurs (*Hapalemur griseus*) and Coquerel's sifaka (*Propithecus coquereli*), both species that are highly folivorous. The brown lemur (*Eulemur* sp.), a generalist feeder, had gastric emptying times of 8 hours. Thus, while withholding food for 8 hours is sufficient for the majority of lemur species, longer periods of fasting are likely necessary for highly folivorous species.

RESTRAINT

Physical restraint of small prosimians weighing < 1 kg is relatively simple. Animals are restrained by grasping initially over the back of the neck and around the mandible with a gloved hand to control the head while using a second hand to control the lower abdomen and back legs.

Figure 37.1. Single handler technique for manual restraint of lemurs weighing 1–4 kg.

For animals weighing between 1 and 4 kg, the animal is first netted in its enclosure or out of a transport kennel. The head is initially controlled by placing one hand around the back of the neck with fingers extending under the jaw to secure the animal. The second hand is then placed under the neck and mandible to prevent serious bites. The animal is allowed to grasp the handler's arm with front and back limbs. Limited exams and minor treatments, such as the administration of subcutaneous fluids or SC or IM injections, can be performed with animals in this position (Fig. 37.1). When manually restraining lemurs, it is recommended that the handler wear arm guards to protect against scratches when animals grasp the handler's forearm. If more control is needed, a second handler is employed to restrain the hind limbs and

Figure 37.2. Two-handler technique for manual restraint of lemurs for physical examination or collection of blood and urine.

extend the hind legs while the animal is positioned on its back (Fig. 37.2). It is important that the person restraining the hind legs grasp the thighs above the stifles to prevent injury to the knee joint. Although it is possible for experienced handlers to physically restrain lemurs weighing more than 5 kg, the larger species are usually anesthetized for procedures.

Squeeze cages can also be used to restrain medium- to large-size lemurs for the administration of IM injections. Animals should be squeezed slowly to avoid undue stress.

VASCULAR ACCESS SITES

Several standard sites are accessible in prosimians; however, the preferred site depends on the species, the size of the animal, and whether it is under manual or chemical restraint. Blood can be collected from the cephalic, external saphenous, and jugular veins, and from the femoral artery or vein. Peripheral veins, such as the cephalic and external saphenous, tend to collapse easily, making withdrawal of more than minimal amounts of blood difficult from these sites. The authors prefer the region of the femoral triangle site in the inguinal region for blood collection requiring more than 1 mL of blood. With the animal in dorsal recumbency, the pulse of the femoral artery is palpable in the femoral triangle. The femoral vein lies immediately adjacent and medial to the femoral artery. In most cases, the close approximation of the vessels means that the artery is sampled nearly as often as the vein. The main disadvantage with using this site for blood collection is the increased risk of hematoma formation if the artery is sampled and inadequate attention paid to ensuring proper hemostasis after needle withdrawal. This is particularly true in animals that are manually restrained as blood pressure can be substantially higher

Figure 37.3. Route of the external saphenous vein on the caudal aspect of the tibia and positioning for occlusion of the proximal venous return in a ring-tailed lemur.

than in animals under chemical restraint. In extreme cases, lemurs have died from exsanguination secondary to inadequate hemostasis following blood collection from the femoral artery.

For indwelling catheter placement in lemurs, the external saphenous vein is most accessible; however, the cephalic and jugular veins can be used in larger species. When placing a catheter in the external saphenous vein, position the animal in ventral recumbency with the hind legs extended behind the animal. After shaving and preparing the skin of the caudal aspect of the tibia, an assistant grasps the caudal thigh of the hind leg and places his/her thumb horizontally across the mid- to lower thigh, thus closing off the proximal return of the external saphenous vein. The route of the external saphenous vein is visible along the posterior aspect of the tibia (Fig. 37.3).

ENDOTRACHEAL INTUBATION

Endotracheal intubation is relatively straightforward in most prosimians but can be challenging in select species. In lemurs, the epiglottis is long and points dorsally, completely obscuring visualization of the glottis. With the animal in sternal recumbency, the tongue is grasped and pulled forward to visualize the epiglottis. A small blade laryngoscope is useful to aid visualization and move the epiglottis ventrally to expose the glottis. When inserting the endotracheal tube, direct the tube toward the ventral aspect of the glottis.

Some lemurs, in particular aye-aye (*Daubentonia madagascariensis*) and ring-tailed lemurs (*Lemur catta*), are more challenging to intubate. The heavy musculature of the jaws in aye-aye prevents the mouth from opening widely and the long upper and lower incisors obscure visualization of the caudal oral and pharyngeal cavities. In ring-tailed lemurs, the opening of the vocal

folds is narrow compared with other species. Intubation is most easily performed in both aye-eyes and ring-tailed lemurs by first inserting an 8-Fr plastic urinary catheter into the trachea as a guide, then passing the endotracheal tube over the catheter into the trachea. Once the endotracheal tube is in place, the guide catheter is removed.

Prosimians, like other primates, have a short trachea. Care must be taken to avoid inserting the endotracheal tube too far and thus intubating a mainstem bronchus. Measuring the length of the endotracheal tube relative to the animal prior to intubation is advised. Once the tube is in place, auscult both sides of the chest for air sounds and monitor end-tidal CO₂ by capnography whenever possible. Cuffed endotracheal tubes ranging in size from 3.0 to 4.5 mm are suitable for animals weighing between 1.5 and 5 kg, while 2.5-mm uncuffed Murphy tubes can be used for individuals ranging in size between 750 g and 1.5 kg. For animals weighing less than 1 kg, infant feeding catheters or urinary catheters can be used as endotracheal tubes (Morris et al. 1997).

PRE-ANESTHETIC CONSIDERATIONS

As with any animal, disease or abnormalities that alter metabolic pathways or gas exchange affect the safety of anesthesia in prosimian primates. It is important to do a thorough preanesthetic evaluation when possible

prior to using anesthetic agents. The ease of manual restraint in prosimians makes it possible to perform limited exams and even draw blood without chemical immobilization in many cases. However, if preanesthetic evaluations are not possible, careful selection of agents, using the minimum dosage necessary to accomplish the procedure, improves safety.

When developing a preoperative regime, it is important to consider the analgesic potential of drugs under consideration. Analgesia is most effective when provided preemptively and the administration of analgesics preoperatively decreases the amount of drugs needed to manage pain postoperatively and may lessen the amount of anesthetic needed by blunting pain perception during the procedure.

It is not always possible to give preanesthetic medications, but when possible, their administration provides a smoother induction, a more stable plane of anesthesia, and decreases the amount of other drugs needed to produce general anesthesia. Non-steroidal anti-inflammatory drugs (NSAIDs), benzodiazepines, alpha-2 agonists, and opioids, have all been used in prosimians successfully. Each can be combined with other drugs to take advantage of the synergistic effects of using drugs that have differing mechanisms of action. Dosages of anesthetic agents commonly used in prosimians are given in Table 37.2, and doses of analgesic drugs are given in Table 37.3.

Table 37.2. Drugs commonly used for sedation and anesthesia in prosimian primates

Agent	Dosage (mg/kg)	Route	Duration	Reversal ^d
Diazepam	0.5–2.5	IV	30 minutes	Flumazenil
Midazolam	0.1–0.3	IM, IV	30 minutes	Flumazenil
Butorphanol	0.1–0.4	IM, IV, SC	3–4 hours	Naloxone
Dexmedetomidine	0.02	IM	30–60 minutes	Atipamazole
Ketamine	5–15	IM, IV	30 minutes	None
Tiletamine/zolazepam	3–5	IM		None/flumazenil
Propofol	3–6	IV	10–15 minutes	None
Fentanyl	0.001–0.03/h	IV CRI ^b		Naloxone

^aDoses for reversal agents: atipamazole (0.2 mg/kg IM); naloxone (0.02 mg/kg IM); flumazenil (0.02 mg/kg IV).

^bConstant rate infusion.

Table 37.3. Doses of analgesic drugs used in prosimian primates

Agent	Dosage (mg/kg)	Frequency	Route
NSAIDS			
Acetaminophen	10–15	q 8–12 h	PO
Aspirin (Acetylsalicylic acid)	10–20	q 8–12 h	PO
Ibuprofen	10	q 8–12 h	PO
Ketoprofen	2 first dose then 1	Once	PO, SC, IM, IV
		q 24 h	
Flunixin meglumine	0.25–0.50	q 24 h	SC, IM, IV
Meloxicam	≤0.2 first dose then ≤0.1	Once	PO, SC, IV
		q 24 h	
OPIOIDS			
Butorphanol	0.1–0.4	q 3–4 h	SC, IM, IV
Buprenorphine	0.01–0.02	q 8–12 h	SC, IM, IV
Tramadol	1–4	q 12 h	PO

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS)

NSAIDs have no inherent sedative qualities; however, their analgesic effects make their use beneficial perioperatively as well as for the management of acute and chronic pain not associated with surgery. NSAIDs used in prosimians without obvious side effects include acetaminophen, aspirin, ibuprofen, ketoprofen, meloxicam, and flunixin meglumine (Table 37.3). As a class cyclooxygenase, inhibitory NSAIDs may be associated with adverse gastrointestinal side effects and renal toxicity. All animals receiving NSAIDs should be closely monitored for signs of gastric ulceration or bleeding and remain well hydrated during treatment. Because of potential side effects on renal and platelet function, the use of NSAID's preoperatively is controversial. (Crandell et al. 2004; Lemke et al. 2002; Lobetti & Joubert 2000). Careful patient and drug selection is important if this class of drugs is used preemptively.

BENZODIAZEPINES

Benzodiazepines are beneficial premedication agents due to their antianxiety, sedative, and muscle relaxant effects, and for antiseizure activity. Diazepam and midazolam have similar pharmacological actions; however, midazolam has advantages over diazepam in that it can be given IM whereas diazepam is incompletely absorbed when given IM. When used alone in lemurs, midazolam provides minimal or no detectable sedation, but when used in conjunction with other medications has a synergistic effect. When midazolam is combined with ketamine for induction, muscle relaxation is improved and the likelihood of seizures is reduced. The authors frequently use midazolam in combination with dexmedetomidine prior to induction with gas anesthesia. The combination produces a moderate level of sedation, increasing the ease of handling during mask induction.

OPIOIDS

Information on the physiologic response of prosimians to opioids is limited. Butorphanol has been shown to cause profound respiratory depression in primates. This is largely due to the fact that in primates, butorphanol's effect on the mu receptor is one of a strong agonist rather than the weak agonist or antagonistic effect seen in domestic species (Butelman et al. 1995). Whether butorphanol has the same respiratory depressant effects in lemurs or other prosimians is unclear. Studies in ring-tailed lemurs (*Lemur catta*) using butorphanol at 0.3 mg/kg IM in combination with medetomidine and ketamine, or medetomidine and midazolam to provide complete anesthesia resulted in only mild decreases in

respiratory rates relative to animals receiving no butorphanol. Oxygen-hemoglobin saturation, end-tidal CO₂, and PaCO₂ values were not affected suggesting oxygenation was not compromised. Butorphanol is used by the authors both for short-term analgesia and as a premedication prior to inhalation anesthesia in lemurs; however, until more data is available on receptor activity in this group of primates, it is recommended that respiratory parameters be monitored.

The authors routinely use buprenorphine and tramadol for relief of moderate pain postoperatively with good results. Buprenorphine is often combined with an NSAID to provide stronger analgesia for moderate to severe pain. Although there are no references for the use of morphine in prosimians, it is reasonable to expect that it can be employed safely if used judiciously and animals are appropriately monitored.

ALPHA-2 AGONISTS

Alpha-2 agonists are very useful in prosimians both for their sedative and analgesic qualities and as a means of decreasing the amount of other anesthetic agents needed. The alpha-2 agonist, medetomidine, is one of the few agents studied in lemurs. Medetomidine administered IM to ring-tailed lemurs under isoflurane had no effect on heart rate, blood pressure, or oxygen-hemoglobin saturation (Williams et al. 2003). In contrast, bradycardia occurs in many domestic animals as a compensatory response to rapid and intense vasoconstriction resulting in significant hypertension (Cullen 1996; Paddleford & Harvey 1999). Dexmedetomidine combined with midazolam is used at the Duke Lemur Center for premedication prior to inhalation anesthesia. The use of dexmedetomidine preoperatively decreases the amount of inhalant anesthesia needed and reduces the degree of hypotension seen when isoflurane or sevoflurane are used alone.

INDUCTION AGENTS

Ketamine is a widely used anesthetic agent in primates for chemical restraint. The effect of ketamine on prosimians, however, is variable. There are both species and individual differences in the degree and duration of immobilization, the character of recovery, and the frequency of side effects. When used alone, ketamine provides unpredictable levels of immobilization, poor muscle relaxation, and frequently, vomiting on recovery. In the authors' experience, seizures may occur in ruffed and black lemurs at doses of 5–10 mg/kg IM. Side effects of ketamine are diminished and the quality of anesthesia improved when it is combined with either midazolam and/or dexmedetomidine; however, the duration of effective immobilization remains short at only 10–15 minutes.

Telazol®, a combination of tiletamine and zolazepam, is frequently used in lemurs, particularly for field immobilizations. Benefits of using Telazol include a wide margin of safety, good muscle relaxation, and smooth recoveries. The main disadvantages include prolonged recovery times in the range of 2–6 hours and a short shelf life of the reconstituted drug. In a clinical setting, reversible injectable combinations allow better control over recovery time and depth of anesthesia.

In a study in ring-tailed lemurs, combining medetomidine with either ketamine and butorphanol, or midazolam and butorphanol produced heavy sedation to complete immobilization lasting from 20 to 60 minutes (Williams et al. 2003). Both combinations can be used for induction prior to gas anesthesia or as complete injectable regimes. The combinations produce minimal cardiorespiratory effects, and the level of analgesia is sufficient to perform minor surgical procedures. Members of the *Eulemur* genus (brown and black lemurs) tend to require higher doses of the drug combinations than ring-tailed lemurs, ruffed lemurs, and Coquerel's sifaka (*Propithecus coquereli*) to produce equal effects. When mild to moderate sedation is desired for premedication or to increase the ease of handling during manual restraint, administering dexmedetomidine in combination with midazolam is effective. Table 37.4 lists several useful combinations.

Propofol is an injectable alkylphenol that acts similarly to the ultra-short acting barbiturate, thiopental. Propofol can be used for induction to provide short duration immobilization for diagnostic procedures or as a constant rate infusion to achieve a light plane of anesthesia for longer periods (Short & Bufalari 1999). Because the compound must be administered intravenously its use in prosimians, it is most feasible in animals receiving premedication in advance of induction. Propofol decreases cardiac contractility and is a potent vasodilator, which can result in hypotension. It is also a respiratory depressant. Administering propofol slowly and to effect minimizes the occurrence of cardiopulmonary effects. The quality of induction and the rapid rate of metabolism, and hence recovery, make the use of propofol advantageous in some circumstances.

INHALATION ANESTHESIA

Both isoflurane and sevoflurane work well in prosimians and are safe in most species; however, respiratory arrest has been reported in giant mouse lemurs (*Mirza* spp.) induced with isoflurane and inhalation agents should be used with extreme caution in this species until more information is available. Both isoflurane and sevoflurane are potent vasodilators, and hypotension is frequently observed in prosimians anesthetized with these agents. It is important to monitor blood pressure in animals under inhalant anesthesia and be prepared to administer IV fluids or other supportive measures as necessary to maintain adequate blood pressure. Information is not available regarding the mean alveolar concentration (MAC) of either agent in prosimians; however, it is the authors' impression that MAC may vary by species. Aye-ayes, in particular, seem acutely sensitive to inhalant anesthetics and require lower concentrations relative to other lemur species to achieve a surgical plane of anesthesia. Hypotension unresponsive to fluid administration alone is a frequent complication of inhalant anesthetic use in lemurs. Until more information is available, it is advisable to intensively monitor cardiopulmonary function and be prepared to support blood pressure if needed.

Prosimians can be induced with gas anesthetics via facemask or in an induction chamber. Administering premedication markedly improves the quality of mask induction. Sevoflurane offers advantages over isoflurane for mask or chamber induction as it is nonirritating to airways. Animals induced by mask with sevoflurane are more compliant than those induced with isoflurane and appear less stressed during the initial phases of induction. Induction rates are faster with sevoflurane compared with isoflurane due to very low blood and tissue solubility of sevoflurane. The cardiopulmonary effects of sevoflurane are similar to isoflurane (Clark 1999).

MONITORING

All anesthetic agents have the potential to adversely affect the major organ systems of the body. Body tem-

Table 37.4. Useful combination regimes for prosimian primates^a

Drug Combination	Dosage ^a (mg/kg)	Duration of Effect (minute)	Level of Sedation
Dexmedetomidine/ Midazolam	0.02 0.2	30–40	Light to moderate sedation
Dexmedetomidine/Ketamine	0.02 3–5	10–20	Heavy sedation to complete immobilization
Butorphanol/ Dexmedetomidine/ Ketamine	0.3–0.4 0.02 3–5	15–30	Complete immobilization
Butorphanol/ Dexmedetomidine/ Midazolam	0.3–0.4 0.02 0.2–0.3	20–50	Complete immobilization

^aAll drugs are given IM.

perature, heart rate and rhythm, respiratory rate, and capillary refill time can be monitored in even the smallest lemur or loris. With experience and the proper equipment, monitoring cardiac electrical activity (ECG) and obtaining reliable readings for oxygen-hemoglobin saturation (pulse oximetry), end-tidal CO₂ (capnography), and blood pressure (oscillometry) can be accomplished in patients weighing more than 1.0 kg. Monitoring should start in the preoperative phase and continue until the animal is in sternal recumbency or until safety precludes further measurements.

Lemurs are highly prone to developing hypothermia under anesthesia due to their lean body confirmation and high surface area to body mass ratio. Heat loss is further compounded by shaving and using skin cleansing solutions during aseptic preparation of the surgical site. Opening a body cavity during surgery further enhances the loss of body heat. Hypothermia decreases liver and renal blood flow and slows the elimination of anesthetic agents, prolonging recovery (Sessler 2000). It is important to monitor temperature regularly during anesthetic procedures. Heat loss can be minimized by insulating animals from cold surfaces using warm water-circulating blankets, warm air blankets, placing hot-water bottles under the drapes; and minimizing exposure by covering body areas outside of the surgical field. Additional precautions include pre-warming surgical skin preparation solutions and fluids used for intravenous support or lavage. (Haskins 2007)

Blood pressure can be measured directly by arterial catheterization or indirectly using either Doppler sphygmomanometry or automated oscillometry. In the majority of instances, the authors find that automated oscillometry units made for small companion animals are easy to use and provide reliable readings in animals over 1.5 kg. The cuff is placed on the hind leg just above the tarsal joint. Additional sites for cuff placement in lemurs include the base of the tail and the upper forearm close to the axilla. It is important to maintain the mean arterial pressure (MAP) above 60 mmHg to ensure adequate tissue blood flow.

Pulse oximetry can be challenging in prosimian primates. Their tongues are short and thin and probes tend to slip off easily. Several lemur species have heavy pigmentation of the tongue, mucous membranes of the oral cavity, and skin of the hands and feet, making readings inconsistent and difficult to obtain. In lightly pigmented animals, reliable readings can generally be obtained by placing a fingertip probe on the cheek wall, tongue, or first digit of the fore or hind limbs. In heavily pigmented lemurs, rectal readings using a rectal probe provide reliable readings. To ensure proper placement of the rectal probe, place the animal in dorsal recumbency and direct the probe signal toward the dorsal wall of the rectum. Manual evacuation of feces in the rectum avoids trapping feces between the probe and rectal mucosa, which interferes with signal transduction.

The use of capnography in prosimians is similar to that in other small animals. Capnography provides important information on cardiac function and pulmonary perfusion. For more information on the use of capnography and interpretation of end-tidal CO₂ measurements, the reader is referred to articles describing their use in veterinary patients (Grosenbaugh 1998; Marshall 2004).

Arterial blood gas analysis is the most reliable method of assessing pulmonary function. The development of relatively inexpensive hand-held analyzers makes measuring blood gases possible and practical, even in field settings. In prosimians, arterial blood samples are easiest to obtain from the femoral artery.

RECOVERY

The quality and speed of recovery depends on the agent used, the general health of the animal, and the success of maintaining physiological processes within optimal ranges through the use of monitoring and appropriate supportive care. Reversible agents allow smooth and controlled recovery from anesthesia. Providing supplemental heat during recovery is beneficial for animals in which body temperatures drop during anesthetic procedures. Animals should be recovered in a quiet, confined space and prevented from attempting to climb or jump until well coordinated.

REMOTE IMMOBILIZATION AND FIELD TECHNIQUES

Remote immobilization of lemurs is routinely performed in the field; however, the safety of the procedure is related to the skill of the darter, the type of darting equipment used, and the extent to which animals are monitored during immobilization. Lemurs present a difficult target, particularly when high up in a tree. Lemurs are small animals with lean body confirmation and safe sites for dart placement are limited. The caudal thigh muscles provide the safest location to dart lemurs. Because of lemurs' small size and minimal muscle mass, low impact delivery devices such as blow guns are the least traumatic and provide the greatest margin of safety when darting. The lower impact pressure of darts delivered by blow gun may result in incomplete delivery of anesthetic in some instances, however, resulting in the need to use more than one dart for successful immobilization. While complete drug delivery is more likely to occur when using CO₂-powered remote injection devices, it is important that the discharge power be adjusted downward as much as possible to minimize tissue injury associated with high pressure dart impact. Dissociative anesthetics are the most frequently used class of drugs for field immobilizations in lemurs. Telazol is widely used and provides rapid induction and a wide margin of safety though

muscle relaxation may not be adequate for some procedures, such as taking dental impressions. A main disadvantage of Telazol is a long recovery time, in the range of 4–6 hours. Published doses for Telazol used in lemurs in the field vary from 10 to 20 mg/kg (Dutton et al. 2003; Glander et al. 1992; Junge & Louis 2005, Larsen et al. 2011). Larsen et al. (2011) reported that young ring-tailed lemurs (2–4.9 years of age) required both higher initial doses and higher total doses of Telazol for successful immobilization than mature lemurs (≥ 5 years of age) in the field. The authors commented that young animals in the study were smaller and leaner than mature animals, making dart placement more challenging and resulting in incomplete injections.

Initial doses of Telazol provide ~30–40 minutes of immobilization. If longer periods of immobilization are needed, supplemental doses of either Telazol or alpha-2 agonists, with or without the addition of butorphanol, can be given via hand syringe. In one study, depth of anesthesia and muscle relaxation improved following the administration of medetomidine (0.04 mg/kg) IM or medetomidine (0.04 mg/kg) + butorphanol (0.2 mg/kg) IM 20 minutes after initial induction with Telazol (Larsen et al. 2011). The authors noted that the time to recovery in mature lemurs was correlated with total Telazol dose. The ability to reverse both medetomidine and butorphanol may result in quicker recoveries for animals needing supplementation than if additional doses of Telazol are given.

Ketamine at doses of 17–50 mg/kg (Garell & Meyers 1995; Glander et al. 1992; Richard et al. 1991) has been used for field immobilizations in lemurs, but the results are generally inferior to those produced with Telazol. Ketamine immobilizations are typically plagued by poor muscle relaxation, unpredictable levels of restraint, and rocky recoveries. Vomiting on recovery is common.

Monkeys and Gibbons

Rolf-Arne Ølberg and Melissa Sinclair

INTRODUCTION

Primates are found in the wild, research facilities, zoos, and kept as pets. Anesthesia is an integral part of veterinary work with nonhuman primates. It is used to relieve stress, pain, or discomfort, as well as to ensure safe handling when performing medical examinations, treatments, and research.

TAXONOMY AND BIOLOGY

Monkeys belong to the suborder Haplorhini (higher primates) which, excluding great apes and humans, contains five families and over 200 species (Table 38.1). The Tarsiidae, Cercopithecidae, and Hylobatidae families are Old World primates from Africa or Asia, while the Callitrichidae and Cebidae are New World primates from the neotropics.

Tarsiers are small nocturnal insectivorous species; they can turn their head 360° and some can leap as far as 5–6 m between trees. Callitrichids (marmosets and tamarins) are small, diurnal, and live in family groups. They have good eyesight and hearing, and are usually active and agile. Their thumbs are not appposable and they have claw-like nails on all digits except the thumbs. Cebids (Cebidae) vary in weight, from 1 to 15 kg, and many have prehensile tails. Most are good jumpers and runners. The *Cercopithecidae* all have longer hind limbs than forelimbs, none have prehensile tails, and they range in weight from 1 to 55 kg. The upper canines are elongate, while the lower are curved slightly inward and backward. Hylobatidae include gibbons and siamangs. They all lack a tail, have a slender body, relatively long arms, and prominent canine teeth. For an extensive description of the various

species, the reader is referred to *Walker's Mammals of the World* (Nowak 1999).

PHYSIOLOGY

Primates have a large surface-area-to-body mass ratio; consequently, rapid body heat loss commonly occurs during anesthesia. This is compounded by drug suppression of hypothalamic thermoregulation and impairment of shivering. Heat loss is most pronounced in small species. Normal rectal temperature for rhesus macaques is listed as 36.7–38.9°C (Bourne 1975).

There are few reports of normal reference ranges for cardiovascular and respiratory values in primates. Values obtained while the primate is physically restrained are likely not representative of “normal” resting values. Unsedated rhesus macaques restrained in chairs had the following mean values: mean arterial pressure 113 mmHg, heart rate 174, cardiac output of 1.31 L/min, stroke volume 7.5 mL, blood volume 73 to 77 mL/kg, respiratory tidal volume of 12.5 mL/kg, respiratory minute volume 479 mL/kg, and a respiratory rate of 39/min (Bourne 1975). For cynomolgus macaques, also restrained in chairs, the mean arterial pressure is reported to be 87 mmHg, and the heart rate 227 beats/min (Morita 1995). Generally, heart rates are approximately 100–200 beats/min (bpm) for animals ≥ 1 kg, and 200–300 bpm for primates ≤ 1 kg (Bourne 1975; Haruo 1995; Johnson-Delaney 1994). For most species, the respiratory rate is 20–50 breaths/min. These physiological reference ranges are altered by anesthesia and restraint (Bush et al. 1977; Liu & DeLauter 1977).

Some hematology and serum biochemistry values might be altered by serial anesthesia, and should be

taken into account if animals are anesthetized many days in a row (Lugo-Roman et al. 2010).

HUMAN SAFETY

Most primates when restrained or confined deliver a nasty bite that may transmit several zoonotic pathogens. Herpes B virus is endemic and nonpathogenic in macaques, but can be fatal in humans (Hummeler et al. 1959; Ott-Joslin 1993). Therefore, a primary aim when handling primates is prevention of traumatic injury and transmission of zoonoses to humans.

VASCULAR ACCESS

Common vascular access sites are the femoral and the saphenous (popliteal) veins. The femoral vein is entered

Figure 38.1. Blood collection from the femoral vein of a squirrel monkey. The vein is located in the femoral triangle, medial to the artery. It is important to provide good hemostasis; a small primate can become hypovolemic and die from blood loss into a large hematoma.

just distal to the inguinal canal. With the animal on its back and its legs abducted, the pulsing femoral artery is palpated. The femoral vein lies caudal to the artery and just under the skin in the triangle formed by the abdominal, sartorius, and pectineus muscles (Fig. 38.1). The saphenous (popliteal) vein is located superficially on the caudal aspect of the lower leg. It is suitable for catheter placement in most primates, including callitrichids. Less common vascular access sites include the jugular and the cephalic veins. In monkeys with tails, the lateral coccygeal veins can also be used. They are palpable on the dorsolateral surface of the base of the tail.

PHYSICAL RESTRAINT

There are a variety of physical restraint techniques in primates that are safe, both for the handler and the primate. These include nets, squeeze cages, and head-lock devices. However, any restraint is stressful to the animal, and its duration must be minimized (Bush et al. 1977). Physical restraint also increases the possibility of human bites, and contact with secretions infected with zoonotic pathogens.

Hoop nets are useful for catching smaller species (≤ 4 kg). The animal is physically secured within the net by pinning it to the ground or closing off the entrance by twirling the net. The animal is then moved directly to a transport cage or induction box, injected with an anesthetic drug, or administered inhalant anesthetic through the net using a mask placed over the nose and mouth.

Manual restraint is excellent for small species like tamarins and marmosets. These species are caught in a hoop net and then secured by locking the head with thumb and index finger, the upper body with the other three fingers and the hind legs with the other hand.

This restraint technique is suitable for minor procedures such as inspection of wounds, to facilitate injection of drugs, and blood sampling. Leather gloves or a towel will reduce the risk of bite wounds.

Squeeze cages are indicated for animals too dangerous to handle by hand. Once in a squeeze cage, the animal is compressed for intramuscular (IM) injection of a parenteral anesthetic. A properly compressed primate will not be able to move allowing accurate injection.

PSYCHOLOGICAL RESTRAINT (TAMING)

Taming and training methods are used for “psychologically restraining” animals. This is a common method used for domestic animals, such as horses and dogs, but it can also be used on nondomestic animals to facilitate, for example, hand injection of drugs. Through positive reinforcement, many primates will accept an IM injection or even extend an arm out of the cage for blood collection (Phillippi-Falkenstein & Clarke 1992) or IV injection.

ENDOTHRACHEAL INTUBATION

Endotracheal intubation is readily achieved in most species with the aid of a laryngoscope and a suitable endotracheal tube. Intubation can be achieved with the primate positioned in dorsal recumbency on a table with the head flexed slightly backwards (Fig. 38.2a,b). Alternatively, the animal is placed in a sitting position and an assistant flexes the head backwards. The tongue is gently pulled outwards to visualize the glottis with a laryngoscope. The use of topical local anesthetic on the glottis will reduce laryngospasm and bucking after intubation. Lidocaine 2% can be diluted to 10 mg/mL or lower to ensure dosing of local anesthetic does not exceed 4 mg/kg.

Primates have a relatively short trachea, with the bifurcation located close to the neck. It is easy to introduce an endotracheal tube too far, intubating a main bronchus and ventilating only one lung (Horne 2001). To prevent this, the endotracheal tube length is pre-measured to the base of the neck, before placement. Once the tube is in position, the animal is ventilated and both the left and right thorax auscultated. If the tube is located in one bronchus, there will be no respiratory sound on the opposite side. In addition, if a pulse oximeter is used desaturation may be noted with one lung intubation. For species smaller than a squirrel monkey, an endotracheal tube can be made from a urinary catheter or infant feeding tube. For species the size of a squirrel monkey, an uncuffed 2.0- to 2.5-mm tube can be used. For most other species between 1 and 20 kg, a cuffed tube ranging in size from 3 to 5 mm is usually appropriate (Horne 2001).

PREANESTHETIC CONSIDERATIONS

Observing the animal prior to the anesthetic procedure will provide useful information about its health status. Social interaction, lethargy, diarrhea, vomiting, anorexia, body condition, and the presence of wounds can often be evaluated this way.

If possible, it is recommended to withhold food from primates for at least 12 hours prior to the anesthetic procedure. For smaller primates (≤ 1 kg), it is recommended food be withheld for only 6–8 hours prior to the procedure. These animals often have a higher metabolic rate and are more likely to develop hypoglycemia.

SEDATION AND GENERAL ANESTHESIA

There are several options for administering drugs to primates. Drugs can be administered orally, parenterally, or by inhalation of anesthetic gases.

Figure 38.2. (a and b) Endotracheal intubation in primates, as in this spider monkey, is facilitated by placing the animal in dorsal recumbency, extending the head and neck, using a laryngoscope and applying topical anesthetic to the glottis to reduce laryngospasm.

Oral Administration of Drugs

Drugs can be administered orally by squirting the sedative or anesthetic dose into the mouth, or mixing it in liquid or solid treats (Knottenbelt & Knottenbelt 1990; Martin et al. 1972; Miller et al. 2000; Ølberg 2004; Pulley et al. 2004; Winterborn et al. 2008). Ingestion of the full drug dose by the animal is a voluntary action, and depends primarily on palatability. It can also be influenced by person presenting the food and even if the food has been altered in any way. Another challenge with this route of administration is unpredictable absorption. There is a difference in bioavailability and absorption time of drug dose depending on how much is absorbed through the oral mucosa compared with the intestinal mucosa. If the drug is swallowed, first pass metabolism may have a significant effect on lowering the effective drug concentration (Paine et al. 1996; Thummel et al. 1996). Despite the positive aspect of a voluntary oral drug administration to sedate or anesthetize primates, there are no reports of using this as a consistent, safe, and reliable method.

Parenteral Anesthesia

Hand injection requires physical or psychological restraint. For larger species, the use of a projectile dart to deliver drugs is common practice, and darts typically are used for immobilizing primates in the wild (Burroughs 1993; Sapolsky & Share 1998) (Chapter 12). Darting is fast and effective, but has significant disadvantages, including stress, pain, and even trauma on injection. Primates have relatively small target areas for darting, and these can be difficult to hit, especially on a moving animal. Targets usually used for injection are the muscles in the hip and thigh area, or, in rare instances, the triceps or shoulder area of larger primates.

Several review articles describe parenteral anesthesia of primates (Beck 1972; Cohen & Bree 1978; Horne 2001; Martin et al. 1972; Sainsbury et al. 1989). Most recommendations include a dissociative anesthetic alone, or in combination with an α_2 -adrenoceptor agonist or benzodiazepine. It is common to combine two or more drugs to achieve immobilization of primates (Horne 2001; Jalanka 1989). This is done to minimize volume, increase potency, achieve a stable safe plane of anesthesia with adequate muscle relaxation and analgesia, improve recovery quality and time, and minimize side effects.

Alphaxolone/alphadolone, methohexitone, thiamylal, droperidol, acepromazine, butophanol, and propofol have been used, but are not included in this review. (For more information on these anesthetic agents see Bowden et al. 1974; Box & Ellis 1973; Connolly & Quimby 1978; Fowler et al. 2001; Kalema-Zikusoka et al. 2003; Marsboom et al. 1963; Porter 1982; Reed & Staple 1976; Sainsbury et al. 1989.). The drugs and combinations most commonly used for primate anesthesia are reviewed later.

Ketamine Ketamine has been used alone in a wide variety of primates, and most reports describe it as safe and reliable (Martin et al. 1972; Vercruyse & Mortelmans 1978). The duration of effect is relatively short (depending on dosage), mainly due to rapid redistribution from the central compartment and efficient metabolism in the liver. Ketamine causes reliable immobilization, and maintains stable cardiopulmonary function while maintaining the laryngeal reflex.

Effective intramuscular dosages vary from 5 to 12 mg/kg for chemical restraint, and up to 10–30 mg/kg for surgical anesthesia (Beck & Dresner 1972; Colillas 1978; Ochsner 1977). Some authors give a general recommendation of dosages from 5 to 40 mg/kg IM (Cohen & Bree 1978). A significant advantage of ketamine is its high therapeutic index. It has been given experimentally to five squirrel monkeys at dosages of 250 mg/kg without any deaths (Greenstein 1975). It can be administered safely several days in a row for repeated anesthesia (Bree et al. 1967).

However, there are several disadvantages to using ketamine alone, such as poor muscle relaxation, spontaneous movement, and hypersalivation. When high dosages of ketamine are used alone, the recovery period is prolonged and rough (Banknieder et al. 1978; Sun et al. 2003). A severe and common side effect of ketamine alone in humans is emergence delirium (Reich & Silway 1989), which occurs in approximately 5–30% of cases (White et al. 1982). This state is associated with visual, auditory, proprioceptive, and confusional illusions (Stoelting 1999). The same effects are likely the cause of poor recoveries with ketamine alone in monkey and gibbon species. There are no antagonists to ketamine.

The side effects and dosage of ketamine can markedly be reduced by adding sedative agents, such as α_2 -agonists or benzodiazepines (Levanen et al. 1995; Lilburn et al. 1978). In addition, both the α_2 -agonists and the benzodiazepines are reversible. Using these anesthetic drugs in combination with ketamine at lowered doses will likely reduce side effects and enhance safety of the procedure.

Ketamine/Benzodiazepine Immobilization of olive baboons with ketamine (10 mg/kg, IM) and diazepam (0.20–0.36 mg/kg, IM) was safe and efficient (Woolfson et al. 1980). This combination was preferred for procedures requiring good muscle relaxation compared with ketamine alone (10 mg/kg, IM).

The combination of ketamine (10 mg/kg, IM) and midazolam (1 mg/kg, IM) in common marmosets and black-tufted marmosets resulted in rapid immobilization and good muscle relaxation, with a duration of 30–45 minutes (Furtado et al. 2010).

Ketamine/ α_2 -Adrenoceptor Agonist The addition of an alpha-2 adrenoceptor agonist (alpha-2 agonist) to ketamine has several beneficial effects. It increases muscle

relaxation and analgesia and decreases the hypersalivation and required dose of ketamine. It also adds the possibility of reversing the effects of the α_2 -agonist with an α_2 -adrenoceptor antagonist. A disadvantage of the α_2 -agonists is their dose-dependent cardiovascular depressant effects. Many dosage variations have been tried in different species of primates in order to investigate the effects and give recommendations.

The combination of ketamine (5.25 mg/kg, IM) with xylazine (0.45 mg/kg, IM) enhanced analgesia, anesthesia, and muscle relaxation in rhesus macaques, compared with ketamine alone (Banknieder et al. 1978). Animals remained anesthetized for 44 minutes (range 23–63 minutes). However, an important observation with this combination is that anesthetic emergence was fast. Animals were alert and standing only a few minutes after the anesthetic period. The presence of the pedal reflex preceded the end of the anesthetic immobilization by only 2–3 minutes. This duration likely coincides with ketamine redistribution, and the quick recovery is probably due to the arousability noted with α_2 -agonists. Hence, the veterinarian needs to monitor depth closely and be aware of the procedure time with these combinations.

In rhesus macaques, the minimum effective IM dosages were 2.5 mg/kg of ketamine with 0.25 mg/kg xylazine (Naccarato & Hunter 1979). These investigators found a wide safety margin with this combination, although xylazine markedly reduced the thermoregulatory abilities of the animals. The IM dosages of 5 mg/kg ketamine and 0.5 mg/kg xylazine produced safe immobilization for 30 minutes, while increasing the dosage of xylazine to 1 and 2 mg/kg prolonged immobilization time to 60 and 80 minutes, respectively. Similar results were obtained with ketamine (5 mg/kg, IM) and xylazine (1 mg/kg, IM) in Japanese macaques (Hayama et al. 1989). Yellow baboons receiving ketamine (11 mg/kg, IM) and xylazine (0.5 mg/kg, IM) were easily intubated, and anesthesia lasted from 90 to 125 minutes (White & Cummings 1979). Other recommendations for wild savanna baboons are ketamine (10–15 mg/kg, IM) combined with xylazine (1 mg/kg, IM) (Sapolsky & Share 1998).

Medetomidine is a more selective, potent and specific α_2 -agonist than xylazine (Chapter 2). Medetomidine alone is not sufficient to immobilize rhesus macaques even at intravenous dosages as high as 0.2 mg/kg (Capuano et al. 1999). Intravenous dosages of 0.05, 0.10, 0.15, and 0.2 mg/kg of medetomidine produced similar and significant bradycardia, hypotension, loss of thermoregulation, decrease in respiratory rate, and inconsistent sedation. But the advantages of medetomidine with ketamine are similar to xylazine, such as enhanced analgesia, anesthesia, and muscle relaxation.

Ketamine/medetomidine has been used in several primate species (Horne et al. 1998; Jalanka 1989; Vie et al. 1998).

Resus macaques (*Macaca mulatta*) anesthetized with ketamine (2 mg/kg, IM) and medetomidine (0.075 mg/kg, IM) had a heart rate of 135 5 minutes after injection, declining to 115 25 minutes after injection. Mean arterial pressures were 70 and 65 mmHg respectively (Settle et al. 2010).

In cynomolgus macaques, there was little difference in the level of sedation, anesthesia time, and recovery time between ketamine alone (10 mg/kg, IM) or a combination of ketamine (2 mg/kg, IM) and medetomidine (0.05 mg/kg, IM). However, due to some unexpected quick recoveries, the investigators felt that this combination was unreliable and recommended caution in using it at the earlier dosages (Young et al. 1999). In the same species, a dosage of ketamine (3 mg/kg, IM) and medetomidine (0.15 mg/kg, IM) provided good muscle relaxation when compared with ketamine (10 mg/kg, IM) alone (Lee et al. 2010). Another study in capuchin monkeys demonstrated that ketamine (4 mg/kg, IM) combined with medetomidine (0.15 mg/kg, IM) provided rapid induction of anesthesia sufficient for handling, while ketamine (2 mg/kg, IM) and medetomidine (0.2 mg/kg, IM) was not sufficient for handling (Therriault et al. 2008). In this study, the evaluation of the lower dose of ketamine was based on only one capuchin monkey, and the monkeys were reversed shortly after induction.

Japanese macaques given ketamine (5 mg/kg, IM) and medetomidine (0.05 mg/kg, IM) had a mean induction time of 4 minutes and anesthetic duration of 65 minutes, with excellent muscle relaxation (Ølberg 2004). After induction they had an initial heart rate of 100 bpm that slowly decreased to 60 bpm during anesthesia. The mean arterial pressure also decreased slowly from approximately 110 mmHg after induction, to 70 mmHg at the end. The respiratory rates were 40 breaths per minute throughout anesthesia. Hypoxemia ($\text{PaO}_2 < 60 \text{ mmHg}$) was evident in the Japanese macaques after induction on room air. A normal SPO_2 and PaO_2 were measured when the monkeys were given supplemental oxygen through a face mask (4 L/min).

At lower dosages, the negative cardiopulmonary effects of α_2 -agonists are reported to be minor and not clinically noticeable (Capuano et al. 1999; Dyck et al. 1993; Horne et al. 1997), suggesting that low dose medetomidine might be favorable; however, further investigations are warranted to confirm.

In golden-headed lion tamarins (*Leontopithecus chrysomelas*), a combination of dexmedetomidine (0.01 mg/kg, IM) with ketamine (5 mg/kg, IM) produced anesthesia with good muscle relaxation for 45 minutes with minor cardiovascular effects and arterial oxygen saturation over 94% in room air (Selmi et al. 2004a). The same dosage of dexmedetomidine and higher ketamine (10 mg/kg, IM) had a similar effect but longer duration and a slight decrease in mean arterial pressure. In the same species, medetomidine (0.02 mg/kg, IM)

with ketamine (10 mg/kg, IM) had a similar effect and was evaluated as safe and reliable in this species (Selmi et al. 2004b). A lower dosage of dexmedetomidine (0.005 mg/kg, IM) with ketamine (10 mg/kg, IM) had poor muscle relaxation and anesthetic quality compared with the higher dexmedetomidine dose.

Based on these reports and clinical experience, ketamine ≤ 2 mg/kg may not be sufficient even in combination with medetomidine. In the protocols using a relatively low dosage of ketamine (2 mg/kg), the corresponding dose of medetomidine is relatively high (0.05–0.15 mg/kg). In the authors' opinion, higher dose of ketamine (>2 mg/kg, IM) and lower dose of medetomidine is preferable for cardiorespiratory stability, as well as anesthesia quality and time.

It is difficult to give minimum dose recommendations for the combination of ketamine and medetomidine. For most species, the author would recommend a ketamine dose of 5–8 mg/kg combined with a low dose medetomidine of 0.02–0.04 mg/kg for induction or short duration anesthesia.

Tiletamine/Zolazepam Tiletamine/zolazepam has been widely used in primates (Bree 1972; Bree et al. 1972; Gray et al. 1974; Horne 2001; Schobert 1987).

Wild black spider monkeys were anesthetized with dosages ranging from 11.6 to 18 mg/kg (Karesh et al. 1998), with the higher dosage resulting in more reliable and stable planes of anesthesia. Induction times were 2–4 minutes, with immobilization lasting from 80 to 150 minutes. Adult, free-living red howler monkeys were anesthetized with 22.5 mg/kg, IM, and juveniles received 30.5 mg/kg, IM. With these dosages, the induction period was 1–6 minutes, and immobilization varied from 40 to 300 minutes, with no apparent adverse effects (Agoramoorthy & Rudran 1994).

Other researchers also describe the use of tiletamine/zolazepam for field anesthesia in various species with a good overall effect (Glander et al. 1991; Sleeman et al. 2000). In cynomolgus macaques and vervet monkeys tiletamine/zolazepam (5–10 mg/kg, IM) was adequate for ophthalmologic surgery. These dosages produced a rapid onset and 30–50 minutes of surgical anesthesia, excellent muscle relaxation, absence of ocular movement, and a gradual emergence with no adverse effects (Kaufman & Hahnenberger 1975).

In rhesus monkeys, this combination induced little or no impairment of thermoregulation (Holmes & Hunter 1980).

Tiletamine/zolazepam has a high therapeutic index, as reflected by the variety of published dosage recommendations. There are likely species differences, but the dosages probably reflect the different subjective opinions of investigators, and no dose titration studies are available. Recommended dosages for capture of free-living animals are high compared with those used in captive animals. A major advantage of this combi-

nation is high potency, which allows a small drug volume.

There are no reversal agents for tiletamine; and prolonged recovery periods are common. Hence, the investigator may have to spend time monitoring the recovery of immobilized wild animals that cannot be abandoned in a sedated state.

Tiletamine/Zolazepam/Medetomidine Tiletamine/zolazepam (0.8–2.3 mg/kg, IM) with medetomidine (0.02–0.06 mg/kg, IM) have been used in Bornean orangutans, Bornean gibbons, and long-tailed and pig-tailed macaques (Fahlman et al. 2006). This combination results in rapid smooth induction within 1–7 minutes, good muscle relaxation, and anesthesia, although the data suggest hypotension and hypoxemia in some of the animals. For the gibbons and macaques, respiratory rates were 20–56 breaths per minute, heart rate ranged from 68 to 160 beats per minute and SpO₂ ranged from 88% to 99%. A major advantage observed by the investigators were that induction in wild orangutans with this combination resulted in a gradual descent from the trees, compared with rapid loss of consciousness and falling from the trees with tiletamine/zolazepam alone.

Medetomidine/Midazolam The combination of medetomidine and midazolam has been tried in Japanese macaques as an alternative to using dissociative anesthetics (Kimura et al. 2007). It was found that a dose of medetomidine (0.06 mg/kg, IM) with midazolam (0.3 mg/kg, IM) gave reliable immobilization within 13–19 minutes, with profound sedation and moderate muscle relaxation. The animals were given atipamezole 30 minutes after medetomidine/midazolam injection and completely recovered within 12 minutes. This drug combination might be useful for minor short procedures, although cardiovascular and pulmonary effects were not evaluated.

Benzodiazepines The main clinical effects of benzodiazepines are sedation, anxiolysis, anticonvulsive actions, spinal cord-mediated skeletal muscle relaxation, and anterograde amnesia (Ashton 1994). Benzodiazepines have few side effects and a high therapeutic index (Du Plooy et al. 1998). However, these drugs may cause mild respiratory depression, which may become significant when benzodiazepines are combined with other sedative or anesthetic agents (Gerak et al. 1998). When used in combination, they significantly decrease the minimum alveolar concentration (MAC) of inhalational agents, or dose of injectable, if used in combination with inhalational or injectable anesthetics in people (Melvin et al. 1982). With clinical doses, they have minimal effects on heart rate, blood pressure, cardiac output, and contractility, and blood pressure in veterinary species (Thurmon et al. 1996). There are

numerous benzodiazepine drugs on the market. They all have similar pharmacologic profiles, but vary in potency and duration of effect, related to their affinity for the benzodiazepine receptor and their pharmacokinetic properties (Stoelting 1999).

Flumazenil is a competitive benzodiazepine antagonist, and antagonizes the sedative and amnesic qualities of benzodiazepines (Stoelting 1999). Minimal information exists on the use of these drugs specifically in primates.

Inhalation Anesthesia

Inhalation anesthesia may be used alone or to maintain anesthesia after induction with injectable agents. The most commonly used inhalants, isoflurane, and sevoflurane, have a MAC in primates of 1.2% and 2%, respectively. The MAC of halothane in primates is approximately 0.9% (Soma et al. 1988). Small primates (i.e., tamarins and marmosets) can be manually restrained in a net and induced with an inhalant anesthetic through a facemask or in an induction chamber (Fig. 38.3). A clear advantage of inhalant anesthetics is reversibility and that oxygen is used as carrier gas. This normally ensures adequate partial pressure of oxygen in the arterial blood during anesthesia. As in other species, inhalants are expected to cause dose-related cardiovascular and respiratory depression in primate species (Thurmon et al. 1996).

MONITORING

A preanesthetic physical examination with full laboratory evaluation (CBC and biochemistry panel) is typically not possible without major sedation or general anesthesia. Once the animal can be restrained adequately or is induced, heart rate, respiratory rate, capillary refill time, mucous membrane color, peripheral pulse, and airway should be assessed. If available, pulse

Figure 38.3. Small primates, such as this cotton-top marmoset, can be manually restrained and masked induced with an inhalant anesthetic.

oximetry and indirect blood pressure will provide additional information on circulation and oxygenation. End-tidal CO₂ measurements will give valuable information about ventilation. An accurate body weight, rectal temperature, hematocrit, serum total protein, urea, and creatinine should also be obtained. Careful monitoring of cardiovascular and respiratory function, as well as reflexes, will give information of the anesthetic depth. Also, keeping track of time and record keeping is an important part of the monitoring procedure.

ANALGESIA

Opioid agonists are powerful analgesic agents, but one should exercise care when using them in primates due to their strong ventilatory depressant effects.

Opioids are mainly used for analgesia, and the μ receptor agonists are the ones producing the strongest effect, with regard to both supraspinal and spinal analgesia (Atcheson & Lambert 1994). Analgesia, sedation, and respiratory depression increase with increased plasma concentrations.

In rhesus monkeys, fentanyl IV produced respiratory depression and analgesia at dosages as low as 2 μ g/kg, and apnea was seen consistently at 60 μ g/kg (Nussmeier et al. 1991). There may be large differences in dosage requirements among different species, due to variations in concentration and distribution of opioid binding sites (Robson et al. 1985). This difference may be marked when compared with unrelated species, such as dogs, which do not develop apnea even at 3000 μ g/kg IV (Arndt et al. 1984; Bailey et al. 1987).

Butorphanol is an example of an agonist-antagonist opioid. However, it has significant respiratory depressant effects in primates (Liguori et al. 1996), compared with the minimal respiratory depressant effects seen in other animals, such as dogs and cats. Minute ventilation in rhesus monkeys is reduced 60–75% by butorphanol (0.1–0.3 mg/kg IM).

Buprenorphine, another opioid agonist-antagonist, has much less respiratory depressant effect in primates (Liguori et al. 1996). It is approximately 30 times more potent analgesic than morphine and the duration of action of at least 8 hours in humans (Stoelting 1999). A study in rhesus monkeys suggests that buprenorphine has a wide margin of safety in clinical use (Kishioka et al. 2000). It has been used for postoperative analgesia in a siamang monkey at a dose of 5 μ g/kg IM (Weiland et al. 2007).

Naloxone, naltrexone, and nalbuphine are μ opioid receptor antagonists, and effectively displace the agonists from the receptor-binding sites, reversing the effects (Stoelting 1999).

Ketamine and medetomidine have strong analgesic properties, and are often used in the anesthetic protocol.

COMPLICATIONS

Catching the animal and administering anesthetic agents for sedation or induction are two critical parts of primate anesthesia. There is a possibility of causing a traumatic injury when using projectile darts. Furthermore, there is a possibility that the primate will fall down if sitting in a tree or on a shelf once it becomes sedated. Nets can be used to catch the sedated primate before it hits the ground. Once induction of anesthesia is achieved, complications are often related to the health state of the animal, drugs used, and the delivered dose of each drug. Hypothermia is common and body temperature should be monitored throughout the procedure.

Hypoxemia may occur due to hypoventilation, pulmonary shunting, or ventilation-perfusion mismatch. The use of a pulse oximeter will help evaluate oxygen saturation throughout the procedure. Supplemental oxygen should be administered through a face mask or an endotracheal tube. Commonly used anesthetic agents, such as ketamine (5 mg/kg, IM) and medetomidine (0.05 mg/kg, IM), may cause mild to severe hypoxemia if the animals are breathing room air shortly after induction (Ølberg 2004). The use of reversible anes-

thetic agents adds safety to the procedure. A laryngoscope and a suitable endotracheal tube should always be available during anesthesia, as well as equipment necessary to give IV fluid.

RECOVERY

Recovery is performed in a quiet, confined space that prevents climbing and allows constant monitoring. A towel or other insulating material minimizes heat loss to the floor. The primate should not be reunited with its group until it is fully recovered.

FIELD IMMOBILIZATION (WILD CAPTURE)

Anesthesia of free-living primates comprises numerous challenges compared to controlled captive environments. One should carefully consider factors including environment, temperature, humidity, use of darts or traps, species, social groups, and potential for zoonotic diseases (Sapolsky & Share 1998).

It is possible to use traps (Aguiar et al. 2007), as well as remote darting equipment depending on the species and situation. With darting, one must consider the risk

Table 38.2. Recommended drugs and drug combinations for immobilization of monkeys and gibbons

Drug	Dosage (mg/kg)	Reversal Agent	Comments
Ketamine	10–30	None	Fast induction, high therapeutic index. Often hypersalivation, spontaneous movements, and rigidity. Not recommended to use as sole agent.
Ketamine/medetomidine	5–8/0.02–0.05	None for ketamine Atipamezole for medetomidine	Commonly used combination in many primate species for induction or short-term anesthesia. Fast induction and anesthesia for 30–45 minutes with good muscle relaxation. Be aware that recovery can be very fast. The low dosage 0.02 mg/kg medetomidine with ketamine has only been evaluated in golden-headed lion tamarins but probably works well for other species. A low dose medetomidine is preferred for cardiorespiratory stability.
Ketamine/xylazine	5/0.5–1	None for ketamine Yohimbine or atipamezole for xylazine	Approximately 30 minutes of immobilization with good muscle relaxation. Be aware that recovery can be very fast.
Ketamine/midazolam	10/1	None for ketamine Flumazenil for midazolam	Rapid immobilization, good muscle relaxation for 30–45 minutes in marmosets.
Ketamine/diazepam	10/0.2–0.4	None for ketamine Flumazenil for diazepam	Good muscle relaxation and described as safe and efficient in olive baboons.
Tiletamine-zolazepam	5–10	None for tiletamine Flumazenil for zolazepam	Commonly used for many species. High therapeutic index and large variation in dosage recommendations. Good muscle relaxation and anesthesia time of 30–50 minutes. Can be prolonged recoveries.
Tiletamine-zolazepam/ medetomidine	1–3/0.02–0.06	None for tiletamine Flumazenil for zolazepam Atipamezole for medetomidine	Rapid induction in macaques and gibbons, with a smooth induction. Good muscle relaxation. Data suggest some hypotension and hypoxemia with the highest dosages.
Medetomidine/midazolam	0.03–0.06/0.3	Atipamezole for medetomidine Flumazenil for midazolam	Reliable immobilization in Japanese macaques. Induction within 13–19 minutes. Totally reversible. Cardiovascular and pulmonary effects not evaluated.

that the animal will fall down from high trees during induction or get lost after darting. Other considerations are hyperthermia/hypothermia and aspiration of regurgitated food material. A small dart volume and fast induction times are favorable when darting free-ranging primates. Recommended drug combinations are tiletamine/zolazepam (Karesh et al. 1998), tiletamine/zolazepam/medetomidine (Fahlman et al. 2006), or ketamine/medetomidine (Vie et al. 1998). Remote areas may restrict the amount of equipment available, and one may not have oxygen supplementation during anesthesia. One should also keep the primate in a cage until fully recovered before release back into the wild.

SUGGESTED PROTOCOLS

Animals weighing less than or equal to 4 kg are manually restrained and anesthetized with isoflurane through a facemask or in an induction box. If inhalation anesthesia is not available, then 0.02–0.05 mg/kg of medetomidine and 5–8 mg/kg of ketamine is given IM.

Animals weighing greater than 4 kg are anesthetized with 5–8 mg/kg of ketamine and 0.02–0.05 mg/kg of medetomidine IM, by use of remote darting equipment (Table 38.2). Most primates will sleep with this combination for approximately 30–45 minutes, but be aware that they may awake suddenly. It is recommended to spray the epiglottis with lidocaine spray and intubate anesthetized primates, as well as giving them supplemental oxygen. Inhalation anesthesia with isoflurane is excellent for maintenance once induction is achieved. The primate should be kept in a separate cage without possibility to climb until fully recovered, before returned to the enclosure and other members of the group.

Great Apes

Shannon Cerveney and Jonathan Sleeman

INTRODUCTION

Anesthesia of great apes is often necessary to conduct diagnostic analysis, provide therapeutics, facilitate surgical procedures, and enable transport and translocation for conservation purposes. Anesthesia of great apes can be challenging due to their relatively large size, physical strength, agility, and intelligence. In particular, great apes can be very sensitive to changes in their normal environment. Even very subtle perturbations can cause apes to become excited or aggressive, such that anesthetic induction can be very distressing to both animal and anesthesiologist. However, there are sizeable populations of great apes in zoological collections and research institutions due to their endangered status and use as animal models for human diseases, respectively. Consequently, anesthesia is frequently performed on these species, which has resulted in the development of a body of knowledge. However, captive apes often suffer from medical conditions such as cardiomyopathy that can complicate anesthetic events. Recent studies have focused on orally administered, transmucosally absorbed, anesthetic agents as alternative, less stressful methods of premedication and anesthetic induction. Finally, there is increasing conservation management of *insitu* great ape populations, which has resulted in the development of field anesthesia techniques for free-living great apes for the purposes of translocation, reintroduction into the wild, and clinical interventions.

TAXONOMY, BIOLOGY, AND ANATOMICAL CONSIDERATIONS

Great apes include the bonobo (*Pan paniscus*), four subspecies of chimpanzees (*Pan troglodytes*), two species of

gorillas (*Gorilla gorilla* and *Gorilla beringei*), each with two subspecies, and two subspecies of orangutans (*Pongo pygmaeus*). They are all tropical Old World species, and all are considered endangered.

Bonobos are the smallest of the great apes, with an adult weight range of 25–45 kg. Chimpanzees usually weigh 40–90 kg, orangutans weigh 40–189 kg, and gorillas are the largest with an adult weight range of 70–340 kg. Males are larger than females for all species. All are social animals with complex social structures and behaviors, except for orangutans, which are solitary. Great apes have a close taxonomic relationship with humans. Consequently, there are many anatomical similarities, and human anesthetic equipment, such as facemasks, is often used in preference to veterinary equipment. In addition, there is a high potential for pathogen exchange between humans and great apes, necessitating appropriate disease preventive measures.

Their large size, agility and physical strength, as well as large teeth and strong jaws, create the potential for human injury during anesthetic procedures. For this reason, physical restraint and sedation of apes is generally not practical, and most procedures require the animal to be at least stage III of anesthesia. Human safety is of paramount importance during any anesthetic event involving great apes, and it is important to have an experienced, well-trained team of individuals. Due to the zoonotic disease concerns mentioned earlier, all persons in close proximity to apes must wear personal protective equipment, such as facemasks and latex gloves. It would also be prudent to establish escape and bite-wound protocols, as well as have access to a “bite-wound kit” for first aid treatment of persons who may be bitten.

Unique respiratory anatomical features of great apes include laryngeal air sacs, which are present in all

species, but are most extensive in gorillas and orangutans (Lawson et al. 2006; Nishimura et al. 2007; Raven 1950). In addition, great apes have relatively short tracheas, and care must be taken to ensure that a primary bronchus is not inadvertently intubated (Loomis 2003). Excessive caudal pharyngeal tissue, thick tongues, and long flaccid soft palates may create challenges for airway maintenance during anesthesia (Kenny et al. 2003). Captive apes are also prone to obesity, which may further complicate access to the airway.

Some Old World nonhuman primates in estrus will develop large genital tumescence. This swelling of the sexual skin can be quite prominent in chimpanzees, and is very vascular and friable. Care must be taken to avoid darting this area as severe hemorrhage may result (Fowler 1995).

Venous access can be accomplished at several sites. The femoral vein at the femoral triangle is readily available. In addition, the saphenous vein on the posterior surface of the lower leg and the cephalic vein are usually visible, especially in larger animals. Intravenous (IV) catheters are typically placed in the cephalic or saphenous vein. IV access is important for administration of fluids, and to provide a rapid route of anesthetic drug supplementation or emergency drug administration should the need arise (Fig. 39.1).

PREANESTHETIC CONSIDERATIONS

As with any species, a preanesthetic assessment is vital. However, this can be challenging in great apes and significant diseases may go unrecognized. Furthermore, estimated body weights are often inaccurate, with one study reporting that even experienced personnel overestimated the weights of chimpanzees by as much as 28% (Adams et al. 2003).

Figure 39.1. Intravenous catheter placed in the cephalic vein of a Bornean orangutan (courtesy Gary West).

Great apes should be fasted and water withheld for 12–24 hours prior to anesthesia. However, this is often a clue that a procedure is imminent and will result in increased agitation, vocalization, and aggression. Consequently, it is important to keep the environment as stress-free and close to the normal routine as possible to avoid this distress. In addition, some individuals will practice pica or coprophagy as a result of fasting (Loomis 2003). Furthermore, apes can remember and recognize individual persons, and the presence of the veterinarian will often induce a violent response.

PREANESTHETICS/SEDATIVES

Due to the stress of remote delivery injection of anesthetic agents, recent studies have focused on oral delivery and/or transmucosal absorption of preanesthetic and anesthetic agents. The techniques described can have variable and unpredictable results, but are a useful alternative method of delivery to consider. Despite the introduction of liquid or food material into the oral cavity immediately before anesthetic induction, potentially increasing the risk of aspiration, such complications have not been reported. Use of metoclopramide (0.4 mg/kg) orally to prevent emesis prior to orally administered anesthetic induction agents has been described (Miller et al. 2000).

Benzodiazepines

Benzodiazepines have minimal effects on cardiopulmonary function and are considered safe to use in primates (Horne 2001). Diazepam can be given orally as a preanesthetic agent and may provide some degree of sedation prior to anesthetic induction. Raphael et al. (2001) reported administering 5 mg diazepam orally to juvenile gorillas 2 hours prior to anesthetic induction with ketamine by hand injection. In addition, Miller et al. (2000) described the use of diazepam for its sedative effect at 0.2 mg/kg given orally 90–120 minutes prior to anesthetic induction. Premedication with midazolam (0.7–1.2 mg/kg PO) delivered in orange juice has been described in chimpanzees and orangutans (Hess et al. 2010). Effects ranged from slight to marked sedation.

Opioids

Transmucosal fentanyl formulations approved for human use have also been used in great apes. Hunter et al. (2004) trained animals to accept, after an overnight fast, a placebo candy lollipop and to suck on it slowly. After 4–6 weeks of training, the apes were then offered the fentanyl lollipop at an intended dose of 10–15 µg/kg. Orangutans and gorillas accepted the treated lollipops and displayed signs of adequate sedation in 30–45 minutes, and responded minimally to darting. However, the chimpanzees acceptance of the fentanyl lollipops was suboptimal and visible sedation

was not appreciated. The authors suggested a greater fentanyl concentration in the treated lollipop may be necessary to achieve sedation in chimpanzees. The resulting plasma concentrations of fentanyl in animals accepting treated lollipops supported transmucosal absorption. Success of this technique was dependent on an effective training program, cooperation of the keeper staff, and adequate housing facilities.

Neuroleptic Agents

For anxiolytic effects, the neuroleptic drug zuclopenthixol at dosages of 0.1–0.36 mg/kg by mouth twice daily was used in gorillas undergoing a prolonged journey (Vogelnest 1998). These animals were calm, traveled well, and maintained good appetites during their transportation.

Opioid/Neuroleptic Combinations

The administration of oral droperidol at a dose of 1.25 mg for a juvenile chimpanzee and 2.5 mg for adult chimpanzees 45 minutes prior to transmucosal carfentanil administration at 2.0 μ g/kg provided an effective premedication regimen that produced profound sedation prior to the IM delivery of tiletamine-zolazepam for anesthetic induction (Kearns et al. 2000). Carfentanil was administered by enticing the animal to the front of the cage and expelling the drug from a 0.5-mL syringe directly onto the oral mucosa. This combination produced smooth induction and heavy sedation or light anesthesia approximately 25 minutes after carfentanil administration (Kearns et al. 2000). At that time, naltrexone and tiletamine-zolazepam were combined into one intramuscular injection for anesthetic induction. Naltrexone was administered at 100 times the carfentanil dose in milligrams. The primary side effect noted was respiratory depression, but was adequately managed by administration of the narcotic antagonist at the time of anesthetic induction with tiletamine-zolazepam. However, the authors also recommended providing supplemental oxygen as well as preparing a naltrexone dart in advance as a precaution. In addition, a side-effect of facial pruritis was noted in some individuals.

Kearns et al. (2000) noted that during initial carfentanil dosing trials, direct application of carfentanil onto the oral mucosa produced the deepest level of sedation, followed by offering the drug in foods that contact the mucosa, such as marshmallow crème. When the drug was administered in fruit, only stage 2 or 3 of sedation was reached, which was attributed to the poor gastric absorption of narcotics compared with mucosal absorption.

Alpha-2 Agonists

Medetomidine transmucosally administered at 50–100 μ g/kg in marshmallow crème prior to immobilization with ketamine by injection resulted in variable effects

(Kearns et al. 1998). Some animals that had not had previous immobilization experience were noticeably sedated, whereas other more experienced chimpanzees showed little or no sedation.

Naples et al. (2010) compared chimpanzees receiving oral medetomidine at 0.1 mg/kg in marshmallow crème or applesauce prior to immobilization with tiletamine-zolazepam at 3 mg/kg IM by remote injection, with animals that were immobilized with medetomidine at 0.05 mg/kg and tiletamine-zolazepam at 3 mg/kg both given IM by remote injection. Although there was not a significant difference between the two groups in the time between tiletamine-zolazepam administration and a degree of sedation considered safe for human contact, animals receiving oral medetomidine exhibited less excitatory behavior and agitation associated with darting than animals that did not receive medetomidine as a premedication.

INDUCTION AGENTS

Intramuscular induction agents can be given by hand injection or remote delivery into a large muscle mass, such as the shoulder or thigh. Immobilization by darting can be very stressful for great apes. Urinary cortisol consistent with a stress response has been demonstrated in chimpanzees following ketamine administration by remote injection (Anestis et al. 2006). Animals scoring highly in the “mellow” behavioral component exhibited a higher peak cortisol and change in cortisol overall, contrary to what the authors predicted. The authors speculated that this behavioral type is an adaptive response, in which animals do not react to neutral situations, such as group member approaches, but will respond to perceived real threats, such as darting. Urinary cortisol was also demonstrated to be significantly higher in chimpanzees following remote injection with tiletamine-zolazepam, than other stressful events including restriction to an indoor enclosure due to a hurricane, and changes in group composition (Anestis 2009).

Operant conditioning to train individuals to present a muscle mass for hand injection of anesthetic agents may limit the stress experienced by the animal, but is not always possible. Otherwise, the agents are usually delivered in lightweight darts propelled by remote delivery systems, such as blow pipes or muzzle velocity adjustable dart guns. The least traumatic remote delivery system should be used to prevent injury. A pole syringe can also be used to administer supplemental drugs in a sedated animal. All attempts should be made to dart the animal without warning as once alerted the individual, or group, will become agitated and mobile, making darting very difficult. Protective clothing, including face shields may be necessary, as chimpanzees have a propensity to spit water, throw fecal matter and other material with surprising accuracy, as well as

returning darts with some force. In addition, apes have surprisingly long limbs and will grab at loose clothing, glasses, and even the dart gun. Ideally, potent drugs that require a small volume for injection should be used, as apes can remove a dart very quickly prior to full injection of the drug.

Darting individuals housed in a social group can be particularly challenging, and isolation of the targeted individual from the group prior to anesthesia may not be possible, or could be very stressful. Once alerted to the event the whole group may act aggressively toward humans in close proximity, which can be very intimidating. However, it is important to have a mechanism to isolate and retrieve the anesthetized individual, especially in the event of an anesthetic emergency. Appropriate facilities that allow shifting of animals, and securing areas or rooms, is very helpful. Removal of enclosure furniture and bedding prior to darting may be beneficial as apes can be very adept at hiding, or adopting body positions, to avoid the dart.

Injectable induction agents and dosages commonly used alone or in combination are listed in Table 39.1. The protocols described in this section pertain to captive great apes unless otherwise noted.

Ketamine Hydrochloride

Ketamine hydrochloride alone has been used successfully in chimpanzees with smooth and rapid induction (3–5 minutes) using standard IM dosages in Table 39.1 (April et al. 1982). Adequate muscle relaxation, good analgesia and minimal cardiopulmonary changes were reported. Recovery occurred 40–60 minutes after injection with signs of awareness at 20–30 minutes, and the majority of individuals were calm with minimal anxiety

and natural movements. Ketamine was also used as an induction agent in gorillas with some animals receiving a premedication of diazepam (Raphael et al. 2001). Ketamine is irreversible, has a short duration of action with sudden unexpected recoveries, and tolerance develops with repeated use (April et al. 1982; Lewis 1993). Conversely, incremental doses of ketamine to prolong anesthesia can result in an extended recovery time of several hours. Ketamine does maintain laryngeal reflexes to some extent, but this does not obviate the need for careful airway management. It can also induce hypersalivation, which can be prevented or controlled using an anticholinergic agent. Another disadvantage of ketamine when used alone is the large volume required. A concentrated 200 mg/mL solution may aid delivery in larger animals.

Ketamine and Alpha-2 Agonists

The disadvantages of ketamine resulted in the development of protocols combining ketamine with alpha-2 agonists. April et al. (1982) reported the use of a combination of ketamine (15–20 mg/kg) and xylazine (1 mg/kg) in chimpanzees delivered IM that resulted in similar induction time compared with ketamine alone, but with a greater depth of anesthesia characterized by greater muscle relaxation and analgesia, as well as cardiopulmonary stability, and longer but uneventful recoveries.

When medetomidine is delivered in combination with ketamine, the total ketamine dose can be reduced to at least one-fifth of the ketamine dose if it is used as the solo agent (Horne 2001). Lewis (1993), Horne et al. (1997), and Adams et al. (2003) have investigated the use of IM delivery of ketamine in combination with

medetomidine by remote injection. This combination provided a rapid and safe method of anesthetic induction, with complete immobilization achieved within 3–15 minutes for both chimpanzees and gorillas (Horne et al. 1997). Horne et al. (1997) reported that it was very important for the animal to be left undisturbed for the initial 10 minutes after administration as attempts to manipulate or move it prior to this time resulted in rapid arousal. Cardiovascular effects appeared to be minimal; the only noteworthy change was a modest increase in blood pressure soon after induction (Horne et al. 1997). However, IV administration of medetomidine may induce a transient bradycardia (Horne 2001). Reversal with atipamezole given IM, at five times the dose of medetomidine, was smooth and complete in chimpanzees but with variable recovery times (Adams et al. 2003). However, Horne et al. (1997) reported full recovery within 10–13 minutes in chimpanzees and gorillas following atipamezole administration with either a full dose given IM, or a partial dose administered IV with the remainder given IM. This combination also provided a smooth transition to inhalation anesthesia. Recoveries can be quite sudden, even without use of the reversal agent (J. Sleeman, unpubl. data, 1997–2000), which could create a dangerous situation for the unprepared anesthesiologist. Ketamine (100 mg) and medetomidine (1 mg) delivered IM have also been used to immobilize a bonobo (Halbwax et al. 2009).

Orally administered detomidine (0.32 mg/kg) and ketamine (9.6 mg/kg) have been investigated as anesthetic induction agents in gorillas (Miller et al. 2000). Some animals received diazepam (0.2 mg/kg PO) and metoclopramide (0.4 mg/kg PO) 90–120 minutes prior to delivery of other agents. The drugs were administered by keeper staff using husbandry training techniques. Lateral recumbency was achieved at 17 minutes in one animal that received a full dose of oral detomidine and ketamine, but supplemental tiletamine-zolazepam was administered (0.94 mg/kg) by remote injection. For the other animals that received partial doses, the first signs of sedation were seen around 15 minutes, and tiletamine-zolazepam was required to achieve lateral recumbency. In all cases, the gorillas had only mild responses to darting and were subjectively judged to be less stressed than darting alone based on decreased screaming, charging, and other stress behaviors.

Naphthylmedetomidine use has been investigated in chimpanzees and orangutans (Hess et al. 2010). Animals were premedicated with midazolam (0.7–1.2 mg/kg PO) and immobilized with ketamine (3 mg/kg IM) and hyaluronidase (150 M. U.) and either medetomidine (0.02–0.03 mg/kg) or naphthylmedetomidine (0.05–0.07 mg/kg IM). Immobilization with naphthylmedetomidine was less complete and shorter in duration than that with medetomidine, and was incompletely antagonized by

atipamezole. However, although cardiorespiratory parameters were not statistically evaluated, animals receiving medetomidine had lower heart rates after treatment than animals receiving naphthylmedetomidine. In addition, naphthylmedetomidine provided antiaggressive effects in the postoperative period.

Tiletamine-Zolazepam and Tiletamine-Zolazepam Combinations

Tiletamine, a cyclohexamine, and zolazepam, a benzodiazepine has been used widely in primates in a 1:1 combination (Telazol™) (Table 39.1). In addition, tiletamine-zolazepam has been used in combination with medetomidine for chimpanzees, (Horne et al. 1998) and free-ranging orangutans (Fahlman et al. 1999, 2006; see Field Anesthesia section). In all these studies, tiletamine-zolazepam alone, or in combination with medetomidine, produced smooth rapid induction within 1–15 minutes and with stable cardiopulmonary parameters, although significantly lower blood pressures were observed in chimpanzees induced with tiletamine-zolazepam/medetomidine and maintained with isoflurane, compared with animals anesthetized with ketamine/medetomidine and isoflurane (Horne et al. 1998). Furthermore, recoveries from tiletamine-zolazepam/medetomidine anesthesia in chimpanzees were prolonged (1–5 hours) and were characterized by signs of extreme drowsiness, dizziness, ataxia, and adverse gastrointestinal effects, such as vomiting. Flumazenil (0.025 mg/kg IV) transiently increased alertness in chimpanzees but did not significantly enhance the speed or quality of recovery (Horne et al. 1998). A similar effect after administration of flumazenil to gorillas has been noted (Sleeman et al. 2000).

Tiletamine-zolazepam delivered orally at a dosage of 16 mg/kg, administered in about 30 mL of a cola beverage was used to successfully immobilize a chimpanzee (Knottenbelt & Knottenbelt 1990). Lateral recumbency was achieved within 7 minutes with no response to external stimuli. Cardiopulmonary function was considered stable, and both pharyngeal and laryngeal reflexes were present. The chimpanzee began to respond to external stimuli after 40 minutes, and recovery was uneventful.

Fowler (1995) noted that the recovery time for tiletamine-zolazepam alone is dose dependent and recommended the use of low doses for quick procedures. The authors have observed excessive prolonged recovery times in silverback western lowland gorillas immobilized with tiletamine-zolazepam and maintained with inhalation agents (Cervený et al. 2012, J. Sleeman, unpubl. data). In one case, an initial dose of 4.36 mg/kg given intramuscularly was only partially received and two supplemental doses of 2.02 mg/kg (estimate 30% was received) and 2.45 mg/kg were given. Time from cessation of administration of inhalation agents until voluntary movement of the animal was 13.5

hours. Other gorillas supplemented with ketamine following tiletamine-zolazepam delivery did not experience profoundly prolonged recoveries, and the authors recommend ketamine supplementation if necessary.

Carfentanil

Preliminary trials with orally delivered, transmucosally absorbed carfentanil citrate alone at dosages of 2–4 µg/kg in chimpanzees provided nearly complete or complete immobilization after 22 minutes, but were accompanied by severe respiratory depression, including one case of respiratory arrest and death (Kearns et al. 1999). Consequently, administration of transmucosal carfentanil alone for immobilization of chimpanzees is not recommended.

Other Combinations

Ketamine/midazolam combinations have also been reported in a chimpanzee (2.5/0.25 mg/kg IM; D'Agostino et al. 2007) and in gorillas (9/0.05 mg/kg IM; Liang et al. 2005). Loomis (2003) also lists various other combinations in great apes, including ketamine/xylazine/tiletamine-zolazepam (1/0.25/1.25 mg/kg), as well as ketamine/medetomidine/butorphanol (2–3 mg/kg/20–30 µg/kg/0.2–0.4 mg/kg) and ketamine/butorphanol/midazolam (3/0.4/0.3 mg/kg), although no details were given. Hanley et al. (2006) also reported the use of a combination of ketamine (5.66 mg/kg) and tiletamine-zolazepam (3.4 mg/kg) delivered IM to induce anesthesia in an orangutan.

Use of adjuncts such as atropine sulfate at 2–5 mg IM for juvenile chimpanzees (April et al. 1982), 0.04 mg/kg IM for gorillas (Raphael et al. 2001), 0.01 mg/kg IM for an orangutan (Hendrix 2006), and glycopyrrolate at 0.01 mg/kg (Greenberg et al. 1999) IM also for an orangutan have been reported, presumably to control hypersalivation and/or bradycardia.

ANESTHETIC MAINTENANCE

Endotracheal Intubation

Maintenance of the airway and provision of oxygen is an important aspect of anesthesia in great ape species. At a minimum, flow-by oxygen should be provided. For prolonged procedures, intubation and maintenance of anesthesia using inhalation agents delivered in oxygen is recommended. For most of the induction agents mentioned earlier, the plane of anesthesia may not be adequate to allow intubation, and it may be necessary to deliver inhalation agents to the animal using a tightly fitting human facemask prior to intubation. Great apes are best intubated in dorsal recumbency with the head extended off the edge of the table which will help to extend the neck. Pulling the tongue forward may help to visualize the larynx. The base of the tongue should then be depressed using a Macin-

tosh laryngoscope blade. Great apes are prone to hypersalivation and laryngospasm, especially when ketamine is given at high doses as the sole anesthetic agent (Horne 2001). Applying small amounts of lidocaine to the glottis several minutes before intubation will help to prevent this (Adams et al. 2003; Horne 2001). A mucosal atomization device can be used for lidocaine application. Great apes require cuffed Murphy tubes ranging in size from 6–12 mm. As mentioned, the short tracheas predispose to intubation of a primary bronchus; thus, once the tube is in place both sides of the chest should be auscultated and monitored for air sounds.

Laryngeal Mask Airway

The laryngeal mask airway (LMA) is an alternative to endotracheal intubation that creates a seal around the larynx with an inflatable cuff (Brain 1983). LMA use has been reported in pediatric chimpanzees (Johnson et al. 2010), and one adult (Vilani et al. 2000). Cervený et al. (2012) found the LMA to be an effective device for airway control in western lowland gorillas (Fig. 39.2). Gorillas were immobilized with IM tiletamine-zolazepam, and anesthesia was maintained with sevoflurane delivery via either LMA or endotracheal tube. Arterial oxygen was significantly greater in the animals in which LMAs were placed 15 and 45 minutes after placement of the device. The authors speculate that this was due to intubation of a bronchus in the animals in which an endotracheal tube was placed. The LMA is easy to insert and can be used during spontaneous and intermittent positive pressure ventilation. In humans, lower anesthetic requirements have been reported for tolerance of placement, compared with endotracheal tubes (Brimacombe 1995). However, the LMA does not protect against aspiration and should not be used in animals that have not been fasted.

Figure 39.2. Removal of a laryngeal mask airway during anesthetic recovery of a western lowland gorilla.

Inhalatory Agents

Isoflurane is commonly used to prolong and maintain anesthesia in great apes (Adams et al. 2003; Cook & Clarke 1985; Hendrix 2006; Horne et al. 1997, 1998; Liang et al. 2005); however, it has potent vasodilatory properties that can cause severe hypotension (Horne 2001). In addition, as most animals will have received an anesthetic induction agent, the minimum alveolar concentration (MAC) of isoflurane must be reduced accordingly. For example, chimpanzees and gorillas induced with medetomidine and ketamine required masking with 2–3% isoflurane in 100% oxygen to permit intubation followed by 0.5–1.5% isoflurane for anesthetic maintenance using a nonrebreathing circuit (Horne et al. 1997). Blood pressures were elevated immediately following induction but steadily decreased and remained within normal limits after the first 15 minutes, as did heart rate, respiratory rate, hemoglobin saturation (SpO₂), and end-tidal CO₂. Animals induced with medetomidine and Telazol required a lower MAC and could be maintained at a mean level of 0.8% isoflurane in 100% oxygen (Horne et al. 1998). In addition, the latter anesthetic induction combination appeared to potentiate the vasodilatory effects of isoflurane, placing the animals at risk for hypotension, requiring close monitoring of blood pressure.

Sevoflurane is less noxious than isoflurane and can be useful for facemask delivery of an inhalant agent but is more expensive. Like isoflurane, sevoflurane had minimal effects on cardiac output at typical anesthetic concentrations (1.2 times MAC) in domestic dogs (Bernard et al. 1990). In humans, sevoflurane does not appear to sensitize the myocardium to catecholamines, a situation that may induce arrhythmias (Navarro et al. 1994). Cervený et al. (2012) reported use of sevoflurane for anesthetic maintenance of western lowland gorillas.

Intravenous Anesthesia

Injectable agents have also been used to maintain anesthesia in great apes. Fentanyl (10 µg/kg), midazolam (0.4 mg/kg), and vecuronium (0.1 mg/kg) were delivered IV as part of a balanced anesthesia for a juvenile orangutan undergoing heart surgery. Ketamine infusion (50 µg/kg/min) and low dose isoflurane between 0.2% and 1%, in a 1:1 air:oxygen mixture were used to maintain anesthesia in this patient (Greenberg et al. 1999). Historically, supplemental doses of ketamine have been used to prolong anesthesia, but this can result in a prolonged recovery (Lewis 1993).

Hendrix (2006) reported the use of thiopental (2.1 mg/kg IV) to allow intubation after anesthetic induction with IM ketamine (1 mg/kg) and midazolam (0.03 mg/kg) in an orangutan undergoing laparoscopic tubal ligation. After intubation, the animal was maintained on 1.5–2.25% isoflurane delivered in 100% oxygen at 1.5 L per minute via a rebreathing system.

Intermittent positive pressure ventilation at a rate of 10–20 breaths per minute, 800-mL tidal volume, and a peak inspiratory pressure of 20-cm water was used to overcome the respiratory compromise induced by the head down (Trendelenburg) position and abdominal insufflation. Hypertension (highest mean arterial blood pressure was 158 mmHg) was also noted and was thought to also be due to the insufflation or use of ketamine. Increasing the inhalant concentration improved the animal's relaxation and resolved the hypertension.

Use of propofol to maintain anesthesia has been reported in an orangutan at 50 mg/kg (total dose) IV in a drip, although this did not provide sufficient sedation (Kenny et al. 2003). Propofol has also been administered to an orangutan at 0.19 mg/kg/min IV in combination with intermittent supplemental boluses of ketamine (Hanley et al. 2006), as well as a gorilla (dose not reported; Raphael et al. 2001).

ANALGESIA

Although there is little pharmacological data available for great ape species, provision of analgesia is an important aspect of the anesthesia protocol for any procedure involving painful stimuli. Opioids and nonsteroidal anti-inflammatory drugs (NSAIDs) are often administered alone, or in combination to provide multi-modal analgesia. Human drugs and drug dosages are often used. Pollock et al. (2008) describe continuous IV administration of morphine and diazepam to an orangutan to facilitate postoperative management of intrapelvic abscess removal and to provide analgesia. Perioperative buprenorphine (0.005 mg/kg IM) was administered during an appendectomy in a chimpanzee (D'Agostino et al. 2007). During recovery, the chimpanzee was given butorphanol (0.01 mg/kg IM). When the animal was alert and able to accept food, the chimpanzee was offered acetaminophen (300 mg PO 3 times a day). Respiratory depression with opioid use has been reported in humans (Taylor et al. 2005), as well as other nonhuman primates (Carpenter 1998; Liguori et al. 1996), so caution is warranted when administering these drugs to great apes. Administration of opioid antagonists may ameliorate these effects.

Synthetic opioids are frequently administered in painful conditions in human medicine and may prove useful for great apes. One of the authors has administered tramadol at 1 mg/kg PO BID to a silverback western lowland gorilla (S. Cervený et al., unpubl. data). This appeared to have a mild sedative effect.

Peri-operative diclofenac was given to a bonobo (75 mg IM) during removal of a retained placenta. In addition, one of the authors has administered ibuprofen to western lowland gorillas (200–800 mg PO 2–3 times a day), and chimpanzees (400 mg PO twice a day), and ketoprofen (2 mg/kg IM) to a western lowland

Figure 39.3. Gorilla under anesthesia with monitoring equipment. Note pulse oximeter probe placement, use of side-stream capnography, and blood pressure cuff on the upper forelimb.

gorilla without any adverse effects (S. Cerveny et al., unpubl. data). NSAIDs should be administered with caution if dehydration or renal disease is suspected.

MONITORING

Careful and close anesthetic monitoring is warranted for great apes, whenever possible. A pulse oximeter probe can be placed on the tongue to monitor SpO₂ (Fig. 39.3). End-tidal CO₂ (capnography) can be obtained from an endotracheal tube or LMA.

A cuff can be placed on a limb for indirect oscillometric blood pressure measurement. Significant increases in blood pressure with increasing age have been reported in chimpanzees, necessitating closer monitoring in older individuals to detect possible hypertension (Eichberg & Shade 1987).

Cardiac electrical activity (ECG) can be monitored with leads in standard placement. ECGs were evaluated in three chimpanzees receiving a premedication of 30 mg diazepam and anesthetized with ketamine and xylazine (Erickson & Olsen 1985). Values were similar to previous studies of unanesthetized chimpanzees, although QT and PR intervals were slightly longer due to a lower heart rate in anesthetized chimpanzees. A retrospective study of ECGs from chimpanzees anesthetized with Telazol found ventricular premature contractions (VPCs) to be the most commonly detected arrhythmia (Doane et al. 2006). Other arrhythmias included: atrial premature contractions, second-degree AV block, right bundle branch block, trigeminy, and accelerated idioventricular rhythm. A significantly higher incidence of arrhythmias was found in males, animals with structural heart disease, and animals between 20 and 39 years as compared with those younger than 20 or older than 39.

Frequent analysis of arterial blood gases can also be very useful. Hendrix (2006) reports the use of the dorsal

pedal artery as a site for direct blood pressure measurement and blood-gas sampling in an orangutan. Arterial blood gas can also be sampled from the tibial or femoral arteries. Published cardiopulmonary parameters for great apes under various anesthetic regimens are summarized in Table 39.2. Hendrix (2006) also reports arterial blood-gas and end-tidal CO₂ values for an orangutan undergoing a laparoscopic procedure. Naples et al. (2010) reported arterial blood gas, end-tidal CO₂, and indirect blood pressure values in chimpanzees anesthetized with medetomidine and tiletamine-zolazepam.

ANESTHETIC RECOVERY

Injectable reversal agents and dosages commonly used are listed in Table 39.1. As noted previously, once reversed, recovery can be quite sudden. Consequently, except for emergency situations, these agents should only be administered once the animal is safely secured. The immobilized animal should be allowed to recover in isolation to prevent attack from other members of the group. If the procedure has lasted for only a few hours, then return to the group should be uneventful. If an animal must be separated for longer periods, then behavioral problems may ensue with reintroduction (Fowler 1995).

COMPLICATIONS

A retrospective study of anesthetized great apes in the United Kingdom and Ireland found a 30-fold risk of peri-anesthetic mortality in animals over 30 years of age when compared with animals between 10 and 30 years (Masters et al. 2007). Animals that were preanesthetically assessed as sick were associated with a 26-times greater risk. Overall, perianesthetic mortality risk was 1.35% when cases of euthanasia were excluded from the data, with 80% of deaths occurring in the postanesthetic period.

Cardiovascular diseases are a significant cause of morbidity in captive great apes. Fibrosing cardiomyopathy and aortic dissection are particularly common in older male gorillas (Kenny et al. 1994; Schulman et al. 1995). Unexpected death due to cardiovascular causes was reported in 13 chimpanzees at a captive facility, with systemic hypertension reported in two of the animals (Lammey et al. 2008). Cardiac dysrhythmia was speculated as the cause of death, as all of the animals had exhibited antemortem cardiac arrhythmias. Other cardiac conditions include, for example, idiopathic cardiomyopathy (Seiler et al. 2009), congestive heart failure, and coronary atherosclerosis (Loomis 2003). All of these conditions could complicate anesthesia or result in anesthetic death. Older apes, as well as animals with a history of cardiovascular disease, should be carefully evaluated prior to anesthesia, and carefully monitored during the procedure. Consulta-

tion with human anesthesiologists experienced with these medical conditions in human patients may be beneficial.

In a retrospective study of 226 great ape chemical restraint procedures at the San Diego Zoo, difficulty with airway maintenance was the primary reported problem (Robinson & Lambert 1986). Excessive salivation and upper airway obstruction caused by pharyngeal tissue were reported. Laryngeal air sac infections due to bacteria or yeast have been described frequently in great ape species (Hastings 1991; Hill et al. 2001; Lawson et al. 2006). Laryngeal air sacculitis could complicate general anesthesia due to the risk for fatal pneumonia from the aspiration of purulent material. Apes with air sacculitis should be intubated with cuffed endotracheal tubes, and the condition should be treated prior to any elective anesthesia.

Fatal acute respiratory distress syndrome due to negative pressure pulmonary edema was reported in an orangutan under Telazol-induced anesthesia (Kenny et al. 2003). The authors speculated that an acute upper airway obstruction was the precipitating factor. During early anesthetic induction, this orangutan was noted to be slumped forward, with the head flexed toward the chest. The propensity of orangutans for laryngospasm during anesthesia as well as the pharyngeal anatomy of this species may predispose these animals to this syndrome during anesthesia. Obesity and respiratory disease could also create further complications for respiratory function during anesthesia. Kenny et al. (2003) recommended that orangutans should be properly positioned with a patent airway during anesthetic induction, as well as the use of thick-walled, armored, or reenforced endotracheal tubes with a stylet to facilitate rapid intubation.

FIELD ANESTHESIA

There is increasing conservation management of *insitu* great ape populations, which has resulted in the devel-

opment of field anesthesia techniques for free-living great apes for the purposes of translocation, reintroduction into the wild, and clinical interventions. Anesthesia of great apes under field conditions is inherently riskier for the animals and humans conducting the procedure due to more variables and less control over the animal.

Sleeman et al. (2000) summarized the field anesthesia of 24 free-living human-habituated mountain gorillas (*Gorilla beringei beringei*) using either ketamine (dosage 7 mg/kg) or tiletamine-zolazepam (dose range 90–325 mg) delivered by remote injection. Anesthesia was mostly performed to facilitate medical treatment. Induction time for both agents was approximately 5 minutes, and recovery was significantly shorter for ketamine (mean = 42 minutes) compared with tiletamine-zolazepam (mean = 75 minutes). The authors concluded that anesthesia could be safely performed, even among a large group of gorillas, although the procedures frequently required the entire day. Success of the procedures was dependent on the assistance of local field staff, who had extensive knowledge of gorilla behavior as well as the landscape. Other key factors included darting the animals without warning; keeping the other gorillas away from the anesthetized animal by creating a visual barrier; remaining with the gorilla until it was fully recovered and able to rejoin its group; and reassuring the patient during recovery by grooming the animal and mimicking gorilla vocalizations. Neither drug appeared to produce novel physiologic effects, although some gorillas had low SpO₂ values (range = 86–88%). The authors reported that the relatively high altitude at which the procedures were performed may have contributed to the apparent hypoxemia, and consequently recommended providing supplemental oxygen (Fig. 39.4).

Habitat destruction and fragmentation results in scattered and isolated populations of orangutans, and translocation of isolated individuals to protected habitat is an important, albeit somewhat controversial,

Figure 39.4. Field anesthesia of a mountain gorilla (*Gorilla gorilla beringei*). It is important to wear personal protective equipment such as facemasks and latex gloves to prevent possible pathogen exchange. Note the visual barrier to keep the other gorillas away from the anesthetized animal (photo © Jonathan Sleeman).

conservation strategy (Andau et al. 1994; Kilbourn et al. 1997, 2003). The use of various anesthetic protocols to assist with orangutan translocations have been described, including tiletamine-zolazepam (3–6.9 mg/kg; Andau et al. 1994; Kilbourn et al. 1997, 2003), combined ketamine (5–7 mg/kg), and xylazine (1–1.4 mg/kg) (Andau et al. 1994; Kilbourn et al. 1997, 2003), as well as medetomidine (0.018–0.025 mg/kg) combined with tiletamine-zolazepam (0.8–2.3 mg/kg) (Fahlman et al. 1999, 2006). Kilbourn et al. (1997) recommended tiletamine-zolazepam due to shorter induction times and smaller dart volume. However, Andau et al. (1994) advised the use of ketamine/xylazine, where rapid recovery is desired due to the availability of the xylazine reversal agent, yohimbine hydrochloride. The induction time for both tiletamine-zolazepam and ketamine/xylazine was 4.38 minutes; however, if additional doses were required then induction time increased to 15.67 minutes (Andau et al. 1994). Recovery times were around 42 minutes for ketamine/xylazine and slightly longer for tiletamine-zolazepam.

In typical translocation operations, the orangutan was darted approximately 15 meters up a tree. Both Telinject and Distinject™ systems were used along with 1- or 3-mL plastic or metal darts with 19- to 20-mm needles with retaining collars. The animals were allowed to fall naturally to the ground (the tangle of vines providing natural cushioning), or nets were used to catch the animal. Andau et al. (1994) reported no mechanical injuries from the capture, handling, and transport of animals, although the authors cautioned against darting animals at a height of over 30 m. Two fatalities were recorded. One was due to hyperthermia as a result of an immobilized animal remaining high in the nest

fully exposed to the sun, and the other was a nursing infant that accidentally received the dart intended for its mother. The authors concluded that both Telazol and ketamine/xylazine provided satisfactory immobilization to facilitate the capture and translocation of orangutans, although the need to provide additional doses of drug in several animals suggested that a somewhat higher initial dose may be appropriate.

Medetomidine/Telazol combination delivered intramuscularly to semi-captive or free-ranging orangutans provided rapid smooth induction, with recumbency within 1–7 minutes (Fahlman et al. 1999, 2006). It was considered favorable for remote drug delivery to free-ranging orangutans when compared with Telazol alone due to low drug volume and more controlled descent from the trees. This combination resulted in the animals being able to grip branches during the descent down the tree, making the fall more gradual with less risk for injury. This is in contrast with Telazol alone in which the animals rapidly became immobilized and fell unconscious from the tree. Adequate anesthetic depth with good muscle relaxation was also reported. Heart and respiratory rates and hemoglobin oxygen saturation remained stable, although occasional SPO₂ measurements were below 90% and significant declines in systolic blood pressure (below 80 mmHg in some cases) and body temperature were recorded. The authors recommended using IV fluids and oxygen supplementation to prevent these side effects. One orangutan developed hyperthermia and apnea during translocation, but was successfully resuscitated. The authors reported that additional doses of Telazol were required during the orangutan translocations, and recommended further studies to determine optimal dosages in free-ranging orangutans. Atipamezole was administered intramuscularly at five times the dosage of medetomidine 23–54 minutes after injection of medetomidine/Telazol, or the last additional dose of Telazol. First signs of recovery from anesthesia were noted on average approximately 10 minutes (range 3–27 minutes) after reversal. The recoveries were reported to be smooth and calm.

Returning confiscated and orphaned chimpanzees to native habitat is also an increasingly considered as well as controversial conservation strategy. Tutin et al. (2001) described the successful release of 20 wild-born chimpanzees, and the use of anesthesia to facilitate this project. Capture of chimpanzees prior to release was performed by administering an anesthetic either by hand or remote injection. In addition, chimpanzees were maintained under anesthesia during the boat journey to the release site in order to minimize stress. While details of the anesthetic protocols used were not given, having an experienced team to decrease the risks of drowning as chimpanzees were often in trees overhanging a lagoon, as well as controlling aggression to humans was recommended.

40 Canids

R. Scott Larsen and Terry J. Kreeger

INTRODUCTION

The 36 species of nondomestic canids currently recognized by the World Conservation Union Canid Specialist Group (Sillero-Zubiri et al. 2004) are listed in Table 40.1.

SPECIES-SPECIFIC PHYSIOLOGY AND UNIQUE ANATOMIC FEATURES

The anatomy and physiology of nondomestic canids are similar to those of domestic dogs and do not warrant extensive review. The panting mechanism is important in evaporative cooling and thermoregulation. Lateral nasal glands supply moisture needed for evaporation and heat is dissipated as the animal breathes in through the nose and out through the mouth (Kennedy-Stoskopf 2003). This panting mechanism may be compromised during anesthesia, so careful attention to body temperature is warranted, especially if the mouth is held closed. Body temperature may become markedly elevated during restraint, so other methods must be used to prevent severe persistent hyperthermia if the animal cannot pant.

Cardiac parameters are generally presumed to be similar to those for comparably sized domestic dog; there are a few studies documenting cardiac values in nondomestic canid species (Estrada et al. 2009; Guglielmini et al. 2006). In a study evaluating maned wolves, several have had low-grade systolic murmurs due to mitral insufficiency (Estrada et al. 2009). There was increased contact with the sternum as maned wolves aged, and many animals >6 years old had mitral thickening.

A few canids go through seasonal torpor or hibernation. Raccoon dogs hibernate during the coldest winter

periods. At these times, they have increased fat deposits and lower basal metabolic rates, as well as lower cortisol, thyroid, and insulin levels (Asikainen et al. 2004), all of which may influence the species' response to anesthetic drugs.

PHYSICAL RESTRAINT

Canids are strong, fast, and agile. Their teeth are large and sharp, their jaw muscles are strong, and most canids can bite through heavy leather gloves. Gloves may be worn to handle canids, not to protect the handler from bite injuries but to protect against scratches from the nails. However, gloves may restrict hand agility and decrease grip control, so some handlers prefer not to use gloves.

Many noninvasive procedures can be performed without anesthesia in smaller species such as foxes (Brash 2003). Canids can be caught and temporarily restrained in large fishing nets, but substantial proficiency is needed to safely restrain large canids this way. Once in the net, animals can be pinned behind the head using a soft broom, forked stick, net, or catch pole. Canids should be pinned while injections are made (Kreeger 1992). A towel or cloth should be placed over the eyes to decrease visual stimulation, calm the animal, decrease stress, and speed induction for chemical sedation/immobilization.

Small-to-medium-sized canids can be grabbed from behind and held by the scruff (Brash 2003) or by grabbing around the neck, with the fingers closing underneath the jaws. If grabbing around the neck, care should be taken not to damage the trachea. At the same time that the neck is grabbed, the body is pushed firmly and gently against the ground by the handler or an assistant. Once in hand, a muzzle can be applied using

Table 40.1. Taxonomic and biologic information for canids

Genus	Species	Common Name	Adult Body Wt (kg)			Longevity (year)	
			Female	Male	Combined	Captive (Wild)	
<i>Alopex</i>	<i>lagopus</i>	Arctic fox	2.4–4.8	2.7–5.4		11	
<i>Atelocynus</i>	<i>microtis</i>	Short-eared dog			9–10	9–11	
<i>Canis</i>	<i>adustus</i>	Side-striped jackal	7–10	7–12		10–12	
	<i>aureus</i>	Golden jackal	6.5–7.8	7.6–9.8		14	
	<i>latrans</i>	Coyote	7.7–15	7.8–15		21 (16)	
	<i>lupus</i>	Gray wolf			23–60 ^a	16 (13)	
	<i>lupus dingo</i>	Dingo	8–17	7–22		13 (7–8)	
	<i>mesomelas</i>	Black-backed jackal	6–10	6–12		(10–12)	
	<i>rufus</i>	Red wolf	20–30	22–34		(13)	
	<i>simiensis</i>	Ethiopian wolf	11–14	14–19		(12)	
	<i>Cerdocyon</i>	<i>thous</i>	Crab-eating fox			4.5–8.5	(9.2)
<i>Chrysocyon</i>	<i>brachyurus</i>	Maned wolf			21–30	16	
<i>Cuon</i>	<i>alpinus</i>	Dhole	10–13	15–20		16 (7–8)	
<i>Lycaon</i>	<i>pictus</i>	African hunting dog	19–27	25–35		(11)	
<i>Nyctereutes</i>	<i>procyonoides</i>	Raccoon dog	3–13	3–12		13	
<i>Otocyon</i>	<i>megalotis</i>	Bat-eared fox	3.2–5.4	3.4–4.9		13	
<i>Pseudalopex</i>	<i>culpaeus</i>	Culpeo (Andean fox)	4–10	3.4–14		(11)	
	<i>fulvipes</i>	Darwin's fox	1.8–3.7	1.9–4.0		(7)	
	<i>griseus</i>	Chilla	2.5–5	3.1–4.9		5	
	<i>gymnocercus</i>	Pampas fox	3.0–5.7	4.0–8.0		14	
	<i>sechurae</i>	Sechuran fox			2.6–4.2		
	<i>vetulus</i>	Hoary fox	3.0–3.6	2.5–4.0		8	
	<i>Speothos</i>	<i>venaticus</i>	Bush dog			5–8	13
	<i>Urocyon</i>	<i>cinereoargenteus</i>	Gray fox	2.0–3.9	3.4–5.5		14–15
		<i>littoralis</i>	Island gray fox	1.3–2.4	1.4–2.5		(10)
<i>Vulpes</i>	<i>bengalensis</i>	Indian fox	>1.8	2.7–3.2		6–8	
	<i>cana</i>	Blanford's fox	0.8–1.5	0.8–1.4		6 (4–5)	
	<i>chama</i>	Cape fox	2.0–4.0	2.0–4.2			
	<i>corsac</i>	Corsac fox	1.9–2.4	1.6–3.2		9	
	<i>ferrilata</i>	Tibetan sand fox	3.0–4.1	3.8–4.6			
	<i>macrotis</i>	Kit fox	1.6–2.2	1.7–2.7			
	<i>pallida</i>	Pale fox			2.0–3.6	3	
	<i>rueppelli</i>	Sand fox	1.1–1.8	1.1–2.3		6 (7)	
	<i>velox</i>	Swift fox	1.6–2.3	2.0–2.5		(8)	
	<i>vulpes</i>	Red fox	3.6–6.5	4.4–7.6		(9)	
<i>zerda</i>	Fennec fox	1.0–1.9	1.3–1.7		13–14		

^aData from Kreeger & Arnemo 2007; all other data from compiled information in Sillero-Zubiri et al. 2004.

a small rope, gauze bandage, or tape. Caution must be used with muzzles because they impair the animal's ability to pant (see earlier). If an animal appears overheated or distressed, the muzzle may need to be removed.

Appropriately sized squeeze chutes can be used for any canid, but care should be taken that the animal cannot get its mouth or legs through the spaces in the chute. Many canids can be trained to walk into a chute.

Box traps, padded-jaw traps, or offset-jawed foothold traps are typically used. Although coyotes do not usually fight a trap for long (Kreeger 1992), other canids may fight against the trap frantically (especially when approached by humans) and may pull out of the trap and/or injure themselves. Leg fractures may occur when steel-jawed traps are used to capture red foxes, but are not common (White et al. 1990). Box traps may be used on naïve fox populations, but are ineffective

on many red foxes. Leg snares may be useful for this species (Jessup 1982). Small leg snares will also capture coyotes and other canids. Leg snares are more likely to result in compromise of blood supply and edema of the paw, but are less likely than jawed traps to cause crushing, contusion, lacerations, or fractures. In colder climates, snares may result in frostbite-type lesions and should not be used. Always check for trap injuries when such means of capture are employed. A restraint pole and double leather gloves can be used to remove animals from traps (Jessup 1982).

Animals in traps are sometimes administered oral medication through "tranquilizer tabs" (Balser 1965). The device is attached to the jaw of the trap and the tablet is ingested when the animal bites at the trap, resulting in sedation. Such sedation may decrease the chance of the animal injuring itself, but is insufficient for handling (Jessup 1982). This technique was

originally described in coyotes using high doses of powder-form diazepam (48–96 mg/kg) wrapped in semirotten cloth; ataxia often lasted 18–36 hours and sedation could last days (Balser 1965). Some deaths were reported using this technique, but it is unknown what effect the drug has had on mortality as compared with other factors (Balser 1965). Modifications to these “tranquilizer tabs” have since been made. One device includes a balloon with 3 mL of petroleum jelly, covered by two layers of gauze (Jessup 1982). If the trap may get wet, the tabs can be sealed by dipping them repeatedly in a melted mixture of 25% refined beeswax and 25% paraffin wax (Balser 1965). Tablets of diazepam (6–7 mg/kg), midazolam (3–4 mg/kg), or acepromazine (5 mg/kg) have also been used. Acepromazine interferes with thermoregulation, so this drug should not be used if trapping is conducted at high ambient temperatures or if the traps are infrequently checked. When using tablets, doses are relatively high because of the likely loss of drug during chewing (Jessup 1982). More recently, propiomazine has been used, to good effect, in gray wolves (Sahr & Knowlton 2000). Gray wolves in traps with propiomazine had less trap-associated trauma on their legs than those that received no tranquilizers; no mortality was associated with use of this drug, even when doses of 1000 mg were consumed by wolf pups or smaller nontarget species (Sahr & Knowlton 2000).

VASCULAR ACCESS

Arterial and venous access sites are comparable with those of domestic dogs. Medetomidine often causes vasoconstriction and may predispose to vasospasm, so vascular access may be more difficult with the use of this drug. Xylazine exerts similar changes, although vasodilation may follow the initial period of vasoconstriction. Venipuncture and catheterization should be done as soon as possible if medetomidine is used, preferably within the first 15–20 minutes post induction, because vasospasm makes these procedures more difficult later during the immobilization. Typical sites for phlebotomy are the jugular, cephalic (brachial), and lateral saphenous veins. Venous catheters are typically placed in the cephalic or saphenous veins. For blood gas analysis, arterial samples are readily obtained from the femoral artery (Larsen et al. 2002).

INTUBATION

Intubation of the anesthetized canid is not always essential, but should be performed during prolonged procedures (especially if inhalant anesthetics are used), if animals are hypoxemic, or if they are hypoventilating. Intubation is as described for domestic dogs. Endotracheal sizes increase in proportion to the size of the animals: 3–4 mm for adult fennec foxes, 5–6 mm for adult red foxes (Bertelsen & Villadsen 2009), 9–10 mm

for adult red wolves (Sladky et al. 2000), and 10–12 mm for adult gray wolves.

PREANESTHETIC CONSIDERATIONS

Anticipation and avoidance of potential complications are key points in preparation for canid anesthesia. Respiratory depression is a common complication for immobilized canids and can be induced by alpha-two adrenoceptor agonists or opioids. Respiratory depression often manifests as hypoxemia and hypercapnia. Hypoxemia can be addressed by providing supplemental oxygen in the nares or through an endotracheal tube. Hypopnea and hypercapnia may be corrected through intubation and assisted ventilation. Opioids and alpha-two agonists may be antagonized, but the animal may not remain anesthetized and effects from residual dissociative agents may occur. A respiratory stimulant, such as doxapram, may increase respiratory rate and ventilation, at least transiently.

Prolonged exertion may result in hyperthermia, which needs to be treated quickly. Heavily furred animals can also become hyperthermic when under a warm sun, even with cold ambient temperatures. Most canids dissipate heat through panting, which is often compromised during immobilization. Hyperthermia should be suspected if rectal temperature is $>40^{\circ}\text{C}$ and treatment is mandatory if the temperature is $>41^{\circ}\text{C}$. Hyperthermic animals should be moved out of direct sunlight. Cooling measures may be warranted such as spraying the body with water, packing with ice packs, application of isopropyl alcohol to proximal legs and ears, cold water enemas, and administration of cool IV fluids. Be careful to remove these cooling methods as body temperature declines to prevent hypothermia.

Hypothermia occasionally occurs under cold conditions, prolonged immobilizations, or in animals with hair loss or debilitated body condition. Warm water containers, warm blankets, heat pads, heat lamps, and hand warmers can be used to increased body temperature. Recovery will be slowed if the animal remains below normal body temperature.

Severe sustained hypertension may be seen with concurrent use of dissociative agents and alpha-two adrenoceptor agonists. Ketamine-medetomidine-induced hypertension can be particularly severe, but this can also be seen with ketamine-xylazine, or with alpha-two agonists in the absence of a dissociative agent (Kreeger et al. 1986; Larsen et al. 2002; Sladky et al. 2000). Blood pressure typically declines over time and is less severe in calm animals. Anticholinergics should be used sparingly and judiciously to avoid exacerbating hypertension.

Vomiting may occur and can result in aspiration of stomach contents. To prevent this problem, captive animals should be fasted 12–24 hours prior to immobilization, but this is not an option for free-ranging

animals. Water can be withheld up to 12 hours in advance, but 2 hours is typically sufficient. Vomiting upon recovery is typically less hazardous than at induction because the animal has control of its glottis and is less likely to aspirate. If an animal vomits when anesthetized, it should be placed in sternal recumbency with the neck extended and the nose pointed down.

Seizures may occur with the use of dissociative anesthetics, although they may be seen with less frequency as lower doses of dissociatives are used and as benzodiazepines are more commonly used as part of immobilization combinations. If the animal only experiences one or two short seizures, treatment is not necessary, but if more seizures occur, or if seizures are sustained, diazepam or midazolam should be administered IV or IM. Remember to administer diazepam over 10–20 seconds IV to prevent cardiac arrest from the propylene glycol.

Wounds are common and should be treated with appropriate medical care. All anesthetized canids should be checked for wounds from traps, needles, and conspecifics. Removal of hair should be minimized if the coat is needed for thermoregulation.

Gastrointestinal dilatation (bloat) may sometimes occur in larger canids, particularly in animals that have recently eaten (and especially if the food ingested was rotten). Although rare, gastrointestinal dilatation and volvulus may also occur. Care should be taken to avoid unnecessary rolling of animals, particularly onto their backs.

There is much discussion in the literature regarding the stress of capture and immobilization of African wild dogs, with speculation that handling-induced stress contributed to mortality in this species through elevated corticosteroids and recrudescence of latent viruses. The evidence for this is scant and analysis of the pertinent data suggests that handling does not increase the likelihood of disease in this species (de Villiers et al. 1995).

CHEMICAL RESTRAINT AND ANESTHESIA

Monitoring and Supportive Care

Approach the recumbent animal quietly and cautiously. The ear seems to be one of the more sensitive parts of the canid body to stimulation, so attempting to elicit an ear twitch with a stick or pole can be a good way of assessing anesthetic depth. If an ear twitch is still present 10–15 minutes after agent administration, supplemental drugs may be warranted. Keep in mind, however, that some animals will maintain an ear twitch despite being otherwise adequately immobilized, so supplement judiciously. Jaw tone should always be assessed and is highly predictive of an animal's depth. Deeply sedated or anesthetized animals do not have appreciable jaw tone. Animals with some degree of residual jaw tone may not be adequately anesthetized

and are more prone to become reactive and cause injury from teeth.

The animal should be placed in lateral recumbency with the head and neck extended to provide a clear airway. Respiratory rate and depth are the most important parameters to monitor. These should be checked immediately and monitored throughout the procedure. Body temperature should also be checked and the animal should be kept out of direct sunlight, if possible, to avoid hyperthermia. Efforts to cool the animal should be instituted if rectal temperature exceeds 40°C.

Once respiration and body temperature are evaluated, heart rate and rhythm should be checked. Any necessary ophthalmic exam should be performed early in the procedure so that lubrication can be applied to the cornea and the eyes can be covered. Muzzling the animal and hobbling the legs may be necessary if the animal is only sedated or lightly anesthetized.

Monitoring the Respiratory and Cardiovascular Systems

Regular monitoring should be performed, with respiratory rate and depth assessed constantly. Heart rate, heart rhythm, and body temperature should be regularly evaluated every few minutes. Portable monitors that gauge blood pressure, peripheral oxygen saturation, end-tidal carbon dioxide, and electrocardiogram (ECG) profile are quite helpful in better monitoring each patient. These portable devices can be expensive and are not always essential for procedures (especially field immobilizations), but they tend to work well in canids of all different sizes and may contribute substantially to good anesthetic management. Their use would be more important for prolonged procedures, clinical settings, and high-risk animals.

Recovery Considerations The immobilized animal should not be left unattended until it has recovered, unless it is in captivity or held such that it can be kept away from other animals and hazards. Monitoring should intensify when hazards such as water and precipices are in the immediate area. For these reasons, immobilization combinations that can be antagonized are ideal. Yohimbine may be given IV to rapidly antagonize xylazine; similarly naloxone or naltrexone may be given IV to antagonize butorphanol. Some authors advocate IV atipamezole, but this may put undue strain on the cardiovascular system due to the drug's potent and specific nature. Atipamezole IM appears to result in acceptably swift recovery times. Once antagonists are administered, the animal should be left undisturbed in a shaded quiet area; if moved after antagonists are administered, the animal may become agitated and tend to stand and run before having fully recovered.

Dissociative Agents

The dissociative anesthetic, ketamine, is a mainstay of canid anesthesia. Tiletamine is also used commonly,

but this drug is only available in combination with zolazepam (in Telazol[®]) and recoveries are typically long with this drug combination. Phencyclidine was commonly used many years ago (Seal & Erickson 1969), but is no longer available. Ketamine has been used alone to immobilize African hunting dogs, gray wolves, coyotes, red foxes, gray foxes, and kit foxes (Ebedes & Grobler 1979; Jessup 1982; Kreeger & Seal 1986a). Induction times are rapid (3–6 minutes), but immobilization times are short (18–22 minutes) relative to recovery times (50–90 minutes) (Kreeger & Seal 1986a). Typically only light anesthesia is achieved, but heart rate and respiratory rate are stable (Ebedes & Grobler 1979). Increasing doses do not decrease induction times or substantially increase immobilization times, but recoveries are longer (Jessup 1982).

If used alone, dissociative agents induce rough inductions and recoveries, hyperthermia, skeletal muscle hypertonicity, muscle spasms, uncontrolled head movements, ptialism, and convulsions (Jessup 1982; Kreeger 1992), so they are typically combined with alpha-two agonists, benzodiazepines, and/or opioids. Dissociatives cannot be antagonized, although yohimbine was tried in gray wolves (Kreeger & Seal 1986a). Wolves that received yohimbine had their heads up more quickly, but took longer to stand, than those receiving a placebo (Kreeger & Seal 1986a). If ketamine is given with other agents that can be antagonized, the antagonists should not be administered until most of the dissociative has been metabolized. Early reversal may result in convulsions, tremors, hyperthermia, or rough recoveries due to residual ketamine. A 45-minute wait generally appears adequate. Waiting times seem less critical with the use of Telazol because zolazepam ameliorates the effects of the dissociative.

Alpha-Two Adrenergic Agonists

Alpha-two adrenoceptor agonists, including xylazine and medetomidine, are potent, reversible sedatives that are commonly used to smooth induction and recovery when either ketamine or tiletamine-zolazepam is used. Alone these agents can heavily sedate canids to the point of relatively safe handling, but these animals may also be aroused with stimulation and are capable of directed attack. For these reasons, it is usually preferable to combine an alpha-two agonist with at least one other drug.

Xylazine Xylazine has been used alone in wolves, coyotes, red foxes, gray foxes, and kit foxes (Jessup 1982; Philo 1978). Doses need to be higher for excited animals because they have higher sympathetic tone that can override the adrenergic agonist. Use of xylazine alone is best for short procedures requiring only moderate handling (Kreeger et al. 1988); for longer, or more stimulatory procedures, additional drugs are warranted. Initial effects occur in 2–3 minutes, animals are

sternal in 4–10 minutes, and maximal effect is in 15 minutes (Philo 1978). Induction is no quicker with higher doses, but respiration is more depressed and there is a greater chance of apnea (Philo 1978). Animals can be approached and safely handled if there are no loud noises and contact with the animal is not abrupt (Kreeger et al. 1988). Vomiting may occur shortly after xylazine administration (Jessup 1982; Philo 1978). Low heart rates may occur; historically, this has been counteracted by use of the anticholinergic drug, atropine (Philo 1978), but low heart rates do not necessarily need to be treated if cardiac output and perfusion are good. Xylazine sedation typically lasts 30–60 minutes, but complete recovery takes 2–3 hours without reversal (Kreeger et al. 1988; Philo 1978). Yohimbine is usually used for reversal, but tolazoline and atipamezole are other options. Recovery typically occurs 4–6 minutes after IV administration of yohimbine (Kreeger et al. 1988).

Medetomidine Medetomidine is more potent and specific than xylazine. Like xylazine, high doses of medetomidine alone can effect complete immobilization in relatively calm canids. Complete immobilization was achieved in farmed Arctic foxes using 0.1 mg/kg (Jalanka 1990). Similarly, calm, habituated gray wolves have been induced with 0.05 mg/kg. Medetomidine has even been effective in field settings with coyotes (0.12 mg/kg) and red foxes (0.14 mg/kg), although it should be noted that only noninvasive and minimally stimulating procedures could be accomplished using medetomidine alone (Baldwin et al. 2008). At high doses of medetomidine, there is better muscle relaxation and less chance of spontaneous recovery, but mucous membranes may be cyanotic, oxygenation may be poor (as low as 74%), and respiration may be impaired (Kreeger et al. 1996). Second-degree atrioventricular heart blocks are common with the use of medetomidine and occur with increased frequency at higher doses. Atropine has been administered to relieve bradycardia; although the anticholinergic drug may double the heart rate, oxygen saturation does not necessarily improve. Without administration of reversal agents, immobilization with medetomidine lasts about 60 minutes (Kreeger et al. 1996). Recoveries are quick (2–5 minutes) with the administration of atipamezole (0.25 mg/kg, IV) and are slower if yohimbine (0.2 mg/kg, IV) is used (Kreeger et al. 1996). Although some sources advocate IV administration of atipamezole, we do not. IV atipamezole appears to effect extremely rapid changes in cardiovascular parameters, with potentially deleterious consequences; such changes are not as rapid with IM atipamezole or IV yohimbine (Ambrisko & Hikasa 2003).

Phenothiazine Derivatives

The phenothiazine derivative, acepromazine, is a tranquilizer that is occasionally used alone to calm canids that are trapped (5 mg/kg; McKenzie 1993). Since

acepromazine interferes with thermoregulation, it should not be used if ambient temperatures are high or if traps are not checked frequently. Acepromazine is not effective alone as an immobilizing agent, but has occasionally been used successfully for South American canids in combination with ketamine (Pessutti et al. 2001).

Opioids

Some opioids can be useful in combination with other drugs for sedation, immobilization, and anesthesia. Butorphanol is used most often as it is inexpensive, has relatively mild respiratory effects, and is readily absorbed via intramuscular injection. Fentanyl and morphine have also been used. By itself, butorphanol has produced "apathetic sedation" in wolves (Kreeger 1992). Anesthesia can be achieved when butorphanol is combined with an alpha-two agonist, but these combinations work best on calm, captive animals and are not potent enough to anesthetize free-ranging or otherwise highly excited canids (Kreeger 1992).

Ultrapotent opioids (etorphine, carfentanil, sufentanil) have been used historically in large canids, but the human and animal hazards of these drugs, along with the availability of safer options, make it less likely that they would be used for canids today (Kreeger & Seal 1990).

Benzodiazepines

Benzodiazepines, such as diazepam, midazolam, and zolazepam, are useful sedatives for facilitating muscle relaxation and preventing convulsions, particularly in combination with dissociative agents. They are also helpful in treating animals experiencing seizures or convulsions. Both diazepam and midazolam have been used with ketamine; zolazepam is combined with tiletamine in Telazol. Benzodiazepines are reversible with flumazenil; however, flumazenil is relatively expensive and in many situations, benzodiazepine reversal is probably not necessary. Benzodiazepines have minimal adverse cardiorespiratory effects and residual sedation is the most commonly observed occurrence post immobilization. Flumazenil administration may be warranted in animals that are going through cardiorespiratory decompensation or when animals are to be immediately released into the wild after immobilization.

Ketamine-Xylazine Ketamine-xylazine combinations were the standard protocols used for many canid species for several years. Small canids generally need higher doses of ketamine than large canids, but doses for xylazine tended to remain constant for different body weights. Some have advocated administration of xylazine 10 minutes prior to administration of ketamine (Cornely 1979), but this is often impractical in the field setting and it is our experience that temporal

separation of the drugs is not needed. Lower doses of ketamine with higher doses of xylazine result in quicker recoveries by taking advantage of the reversibility of the alpha-two agonist while minimizing the amount of ketamine that persists; quicker recoveries often occur even without reversal (Kreeger & Seal 1986b). In coyotes, if the dose of ketamine is decreased from 4 to 2 mg/kg, the recovery time is shortened from 2–3 to <1 hour (Kreeger & Seal 1986b).

Induction with ketamine-xylazine is variable, occurring in 2–20 minutes; faster inductions occur when using relatively high doses of ketamine and relatively low doses of xylazine. Working times are typically 20–40 minutes, and complete recovery occurs in 1–2 hours (Cornely 1979; Kreeger & Seal 1986b). Heart rate may be either slowed or elevated; tachycardia is seen with high doses of ketamine; bradycardia is seen with high doses of xylazine (Kreeger & Seal 1986b). Premature ventricular contractions (PVCs) may occasionally occur, but do not typically cause clinical problems (Kreeger & Seal 1986b). It is less common to see PVC arrhythmias if atropine is administered (Fuller & Kuehn 1983), but it is more common to see hypertension and mean arterial blood pressures may be over 170 mmHg (Kreeger & Seal 1986b). Since atropine will exacerbate this hypertension without improving oxygenation, the use of an anticholinergic drug is usually contraindicated. Oxygenation is typically stable, but may be lower than desired (83–94%; Osofsky et al. 1996). Blood pressure values tend to normalize after antagonists are administered (Kreeger et al. 1986). Respiratory rate is often elevated when ketamine-xylazine is used (Sladky et al. 2000). Canids immobilized with ketamine-xylazine have poor thermoregulatory ability and hyperthermia is also frequently observed (Fuller & Kuehn 1983), although temperatures tend to decrease over the course of the immobilization (Fuglei et al. 2002; Sladky et al. 2000).

The xylazine component can be antagonized with yohimbine (0.1–0.2 mg/kg) or tolazoline (8 mg/kg) (Kreeger et al. 1986, 1990b), but antagonists should not be administered until 45 minutes after the last injection of ketamine; otherwise, tachycardia, severe hypotension (<30 mmHg), mouth gaping, face scratching, twitching, and hyperreflexia may occur (Kreeger & Seal 1986b). With yohimbine, arousal occurs in 1–8 minutes, sternal recumbency in 5–6 minutes, and uncoordinated ambulation in 10–25 minutes (Kreeger & Seal 1986b). Doses of yohimbine higher than 0.2 mg/kg do not improve or hasten reversal, but instead cause ataxia, hyperreflexion, tachycardia, and hypersalivation (Kreeger et al. 1990b). Yohimbine may be given IV, IM, or a percentage by both routes (Osofsky et al. 1996).

Some immobilization-associated deaths have been reported with ketamine-xylazine, but the reasons for these deaths were not clear (Fuller & Kuehn 1983).

Ketamine-Medetomidine In the past decade, many clinicians have switched from using ketamine-xylazine to ketamine-medetomidine. Much is similar about the two protocols; however, medetomidine is more potent and specific than xylazine so lower doses of ketamine are effective and reversal is quicker and more complete. For canids, some authors have recommended ketamine (2.5–3 mg/kg) and medetomidine (0.06–0.1 mg/kg), to insure complete immobilization and operator safety (Jalanka & Röken 1990); however, in our experience, slightly higher doses of ketamine (4–6 mg/kg) can be safely combined with lower doses of medetomidine (0.02–0.04 mg/kg) to provide effective immobilization with fewer adverse cardiopulmonary effects.

Animals are typically ataxic in 1–5 minutes, recumbent in 5–10 minutes, and induced in 10–15 minutes. Inductions may be much faster in captive animals that are accustomed to handling than in less acclimated individuals (Fuglei et al. 2002; Jalanka 1990). Animals should be kept as calm as possible during induction. Vomiting occasionally occurs (Arnemo et al. 1993; Fuglei et al. 2002; Holz et al. 1994), particularly if animals have not been fasted. Animals acclimated to handling and people may have stable body temperatures, but hyperthermia is common and temperatures tend to decrease over time (Arnemo et al. 1993; Jalanka 1990; Sladky et al. 2000). Decline in body temperature may be substantial in raccoon dogs that are anesthetized during the winter when they hibernate; this decrease may critically affect their metabolism so special care to body temperature should be paid in this species (Arnemo et al. 1993).

Heart rate may increase or decrease over time in canids (Aguirre et al. 2000; Arnemo et al. 1993; Fuglei et al. 2002; Sladky et al. 2000). Heart rate is increased by atropine administration (Holz et al. 1994), but use of this drug is not typically warranted for the reasons described with ketamine-xylazine. Oxygenation is typically stable, but may be somewhat low. Arctic fox pups anesthetized with ketamine-medetomidine had SpO₂ values of 78–95% (Aguirre et al. 2000), while mean values were 92–94% in red wolves (Sladky et al. 2000). Respiratory rate tends to increase over time (Aguirre et al. 2000; Jalanka 1990; Sladky et al. 2000). Raccoon dogs anesthetized with ketamine (5 mg/kg) and medetomidine (0.1 mg/kg) exhibited intermittent apnea and tachypnea, but breathing became more regular as time went on (Arnemo et al. 1993). These respiratory effects may have been due to the relatively high dose of medetomidine that was used.

Some authors have cited excess salivation as a reason for use of atropine in immobilization protocols (Holz et al. 1994). It is true that animals salivate less if an anticholinergic is administered; however, we have not appreciated hypersalivation to be a clinically important problem.

Ketamine-medetomidine immobilization typically lasts approximately 60 minutes after initial injection, although individual animals may rouse more quickly (Jalanka 1990) and some animals do not regain corneal or pedal reflexes until >120 minutes (Arnemo et al. 1993). Recovery is usually rapid, with animals standing 5–20 minutes post antagonist and fully recovered 10–35 minutes post antagonist (Aguirre et al. 2000; Arnemo et al. 1993; Jalanka 1990). Without antagonist agents, complete recovery occurs in about 3 hours (Arnemo et al. 1993). Medetomidine is typically antagonized with atipamezole (5 mg/mg medetomidine 5:1). For most species, high doses of atipamezole are contraindicated; foxes given 0.25 mg/kg atipamezole were reported to be nervous, overalert, and developed muscle fasciculations (Jalanka 1990). However, it is important to note that raccoon dogs were not effectively antagonized when given 5:1 atipamezole:medetomidine and 10:1 was needed instead (Arnemo et al. 1993). Although this dose is higher than for any other canid, it did not cause raccoon dogs to be excited or overly alert (Arnemo et al. 1993). Antagonism may be quicker with IV administration of atipamezole than with IM delivery, but the difference is a matter of 2–5 minutes. In blue foxes, IV atipamezole caused a 200% increase in heart rate 1.5 minutes post administration (Jalanka 1990). Given the rapid and dramatic changes in blood pressure and cardiovascular output that occurs when atipamezole is given IV, this route of administration poses unnecessary risks and should not be performed. Theoretically, yohimbine may also be used to antagonize medetomidine, but even in domestic dogs, there is sparse literature about dosing.

Unexplained mortalities have been seen with use of ketamine-medetomidine. Of 20 Arctic foxes anesthetized with ketamine (3 mg/kg)-medetomidine (0.5 mg/kg) for implantation of heart-rate transmitters, two died 30–35 minutes into surgery (Fuglei et al. 2002). The cause of death was not explained so surgical factors cannot be discounted.

Xylazine-Butorphanol Butorphanol (0.4 mg/kg) has been combined with xylazine (2 mg/kg) to immobilize gray wolves (Kreeger et al. 1989). Animals were induced in 12 minutes; bradycardia, respiratory depression, and normotension were observed. Immobilization was rapidly antagonized with yohimbine and naloxone. After antagonists were administered, heart rate and respiratory rate rapidly increased (Kreeger et al. 1989).

Medetomidine-Butorphanol Butorphanol has also been combined with medetomidine in canids; this drug combination can be fully antagonized, with few side effects, but requires minimal visual and auditory stimulation to be effective. Medetomidine (0.04 mg/kg) with butorphanol (0.4 mg/kg) was successfully used to immobilize 23 of 24 red wolves (Larsen et al. 2002).

Induction times were 5–15 minutes. Some wolves received supplemental diazepam (0.2 mg/kg, IV) at induction, others received ketamine (1 mg/kg, IV) 30 minutes post induction, and others received no additional anesthetics. A few red wolves experienced bradycardia (<40 beats/min); heart rate and blood pressure increased when ketamine was given. Second-degree heart block and sinus arrhythmia were observed, but there were no other cardiac arrhythmias. Initial blood pressure values were high (98–194 mmHg), but decreased over time. Oxygenation was initially poor in a few animals, but improved over time and was generally good ($\text{SpO}_2 > 93\%$). Effects of the medetomidine-butorphanol lasted 30–40 minutes; longer recumbency times were achieved with addition of diazepam or ketamine. Antagonism with atipamezole (0.2 mg/kg)-naloxone (0.02 mg/kg) effected quick recovery times, with animals fully recovered in about 7 minutes. Flumazenil (0.04 mg/kg) was also administered to wolves that had received diazepam. When low doses of glycopyrrolate were added, there appeared to be a threshold effect on heart rate and blood pressure. At low doses (0.0025–0.005 mg/kg), heart rate and blood pressure did not change, but at higher doses (0.0075–0.0175 mg/kg), acute tachycardia and severe sustained hypertension occurred (Larsen et al. 2001).

Xylazine-Fentanyl Similar to xylazine-butorphanol, xylazine (1 mg/kg)-fentanyl (0.1 mg/kg) has been used successfully to immobilize canids, African wild dogs, in particular (de Villiers et al. 1995; Hattingh et al. 1995). This combination can be antagonized with yohimbine (0.125 mg/kg) and naloxone (1.2 mg/animal). Animals were ataxic in 1.5–3 minutes and recumbent in 5–7.5 minutes (Hattingh et al. 1995). If approached too soon, animals would respond to touch by getting up and running with ataxia. With any alpha-two agonist-opioid combination, canids should be left as undisturbed as possible until 10 minutes post darting. Immobilization with xylazine-fentanyl typically lasts 45–60 minutes. During this time, canids are normoemic, but hypercapnic ($[\text{pCO}_2] = 64 \text{ mmHg}$) and acide-mic ($\text{pH} = 7.18\text{--}7.28$). Supplementation with small doses of xylazine-fentanyl can extend the immobilization by 45–60 minutes. Once antagonists are administered (IV), complete antagonism occurs within 1–2 minutes (Hattingh et al. 1995). Detomidine-fentanyl has been used in African wild dogs in a similar manner (Hattingh et al. 1995).

Ketamine-Medetomidine-Butorphanol These three drugs have been combined together to take advantage of the properties of each agent while minimizing side effects. This combination was compared with ketamine-xylazine, ketamine-medetomidine, and ketamine-medetomidine-acepromazine in red wolves (Sladky et al. 2000). While all combinations were effective,

hypertension was not as severe in the ketamine-medetomidine-butorphanol group and recoveries were faster and smoother. In some animals, mild hypoxemia ($\text{SaO}_2 = 87\text{--}90\%$) was observed early in the procedures, but improved over time (Sladky et al. 2000). Although respiration rate was lower in this group, hypercapnia was not observed.

A recent study reported minimal hypertension with mild cardiac changes (first- and second-degree atrio-ventricular blocks, sinus arrhythmia, and depressed left ventricular systolic function) using a combination of ketamine (2 mg/kg)-medetomidine (0.03 mg/kg)-butorphanol (0.2 mg/kg)-acepromazine (0.02 mg/kg)-isoflurane (1–2%) in gray wolves (Valerio et al. 2005). However, this report did not measure blood pressure or assess arrhythmias until 35 minutes post injection, and recovery times were not reported, so it is difficult to compare these results with other investigations (Guglielmini et al. 2006; Valerio et al. 2005).

Ketamine-Midazolam This combination has been reported in red foxes, with induction times of 4–6 minutes and head-up times of 14–23 minutes. Compared with other drug regimens, inductions were longer and there were more spontaneous recoveries (Kreeger et al. 1990b). Ketamine-midazolam has not been a combination that been extensively investigated for wild canids, probably because of the availability of Telazol, a relatively inexpensive, high concentration dissociative-benzodiazepine alternative.

Tiletamine-Zolazepam Tiletamine-zolazepam (Telazol) has been used in a wide variety of species and may be the preferred agent for helicopter captures or escape situations where accurate dosing may be compromised and quick induction is essential. Induction in gray wolves was no shorter using 10 versus 5 mg/kg (5–8 minutes), but arousal time was twice as long with the higher dose (Kreeger et al. 1990a). For helicopter captures, doses over 10 mg/kg may need to be used in order for wolves to be adequately induced (Ballard et al. 1991). Telazol has also been effectively combined with xylazine in wolves (Kreeger et al. 1995).

High stepping was often the first drug response observed, followed by disoriented gait, loss of use of hind legs, licking lips, loss of use of forelegs, loss of head and neck movement, nystagmus, and loss of tongue movement (Ballard et al. 1991). In maned wolves anesthetized with 3 mg/kg tiletamine-zolazepam, many had compulsive licking, excessive salivation, muscle twitching, or muscle tremors (Furtado et al. 2006). In other canids, extreme salivation may occur and mild seizures are not uncommon (Ballard et al. 1991; van Heerden et al. 1991). Within reason, differences in Telazol doses do not seem to have a substantial effect on heart rate, respiratory rate, blood pressure, or temperature. Working times are typically 60–90 minutes at these

doses and recovery time is highly variable (25–300 minutes) (Ballard et al. 1991). Complete recovery times have been reported to be as long as 5–6 hours with 5 mg/kg Telazol and some wolves have very rough recoveries with ataxia, paddling, falling backward, and severe mutilation (Kreeger et al. 1990a). When supplementing canids induced with Telazol, it is generally recommended to administer ketamine, rather than additional Telazol, if only injectable anesthetics are given. Supplemental ketamine has produced substantially shorter arousal times (30–45 minutes post injection) than equivalent doses of Telazol (80–130 minutes post injection) (Kreeger et al. 1990a).

Tiletamine-Zolazepam-Medetomidine Recovery qualities may be much improved with lower doses of Telazol combined with medetomidine. When tiletamine-zolazepam (2 mg/kg) was administered to red foxes in combination with medetomidine (0.04 mg/kg), the anesthetic quality and recovery times (6 minutes) were similar to procedures performed using ketamine-medetomidine (Bertelsen & Villadsen 2009). Other cardiorespiratory changes also appear to be similar to ketamine-medetomidine as an initial tachycardia gradually decreased during anesthesia, an initial moderate hypertension decreased over time, and an initially low respiratory rate gradually increased to normal. Telazol-medetomidine has also been used with success in dingoes (Vogelnest 1999).

Medetomidine-Midazolam Medetomidine (0.06 mg/kg)-midazolam (0.5 or 1 mg/kg) has been used successfully in red foxes (Shilo et al. 2010) with faster induction times in animals given 1 mg/kg midazolam than those given 0.5 mg/kg midazolam (Table 40.2). Recovery times were similar between the two doses and were approximately 10 minutes post-atipamezole-administration. In that study, blood pressure values were suggestive of mild hypertension and were similar between animals given ketamine-medetomidine and those given medetomidine and 0.5 mg/kg midazolam; interestingly, foxes given medetomidine and 1 mg/kg midazolam had higher blood pressure values than animals given ketamine-medetomidine.

Medetomidine-midazolam has been similarly effective in golden-backed jackals (King et al. 2008). In that study, recovery times were slightly longer than with ketamine-medetomidine, but were also smoother. It is notable that medetomidine doses were particularly high (0.09 ± 0.02 mg/kg), but bradycardia was not observed and hypertension was not severe.

Medetomidine-Midazolam-Butorphanol Medetomidine-midazolam-butorphanol has been used in red foxes, but with lower doses of medetomidine (0.04 mg/kg) and midazolam (0.3 mg/kg) than with medetomidine-midazolam and no butorphanol (Bertelsen & Villadsen

2009). Induction times with this protocol were slower (9 minutes) compared with combinations that included ketamine (3–4 minutes) or Telazol (4 minutes); similarly, recovery times were longer post atipamezole (10 minutes) than with combinations that included a cyclohexamine (6 minutes). More important to note is that inductions and recoveries with medetomidine-midazolam-butorphanol were more variable, with some animals becoming rousable before atipamezole was administered and others still sedate long after atipamezole administration (Bertelsen & Villadsen 2009). Medetomidine-midazolam-butorphanol has also been used with success in free-ranging African wild dogs (Fleming et al. 2006).

Drug Choice

As with any group of animals, drugs used for immobilization of canids will vary by the species and situation, as well as the preferences and experience of personnel.

For small canids, induction and maintenance with isoflurane or sevoflurane (Crawshaw et al. 2007) is an easy way of quickly providing anesthesia from which animals can rapidly recover. Animals can either be manually restrained and induced via face cone or induced via chamber. Mask induction can be accomplished with animals up to the size of red wolves and coyotes, if there are trained personnel capable of good manual restraint. Chamber induction can occur in purpose-built plastic induction chambers or by placing a plastic bag around a transport kennel. When using these devices, the patient must be closely monitored to insure that the animal does not have complications or become overanesthetized. Animals can become overheated in induction chambers, so these devices should not be used if temperatures cannot be controlled. Some people prefer to use clear bags when placing plastic bags around kennels, so that the animals can be observed throughout induction. By using isoflurane induction, there is increased risk of exposure of personnel to inhalant anesthetics.

Isoflurane can also be used for maintenance of anesthesia. Animals may be maintained with a face mask over the mouth or through an endotracheal tube after intubation. There will be less environmental release of isoflurane if an endotracheal tube is used. Intubation is recommended for animals with complications or for any prolonged immobilization procedure. Sevoflurane can probably be used with equal efficacy and safety, but there is less experience with this drug as it has been more expensive and requires a vaporizer with different calibration settings.

Injectable anesthetic drugs may also be used safely and are particularly appropriate for larger canids and for remote anesthetic delivery. Recommended doses from the literature are to be listed later. Although there have been many anesthetic combinations

Table 40.2. Injectable immobilization drug dosages for canids

Alopex lagopus (Arctic fox)
Ketamine (2.5 mg/kg)-medetomidine (0.05 mg/kg); atipamezole (0.25 mg/kg) (Aguirre et al. 2000; Jalanka 1990)
Medetomidine (0.025–0.1 mg/kg) (Jalanka 1990)
Telazol® (10 mg/kg) (Kreeger & Arnemo 2007)

Atelocynus microtis
Telazol (10 mg/kg) (Kreeger & Arnemo 2007)

Canis audustus, *Canis aureus*, *Canis mesomelas* (jackals)
Medetomidine (0.09 mg/kg)-midazolam (0.5 mg/kg); atipamezole (0.45 mg/kg) (King et al. 2008)
Ketamine (2 mg/kg)-medetomidine (0.11 mg/kg); atipamezole (0.55 mg/kg) (King et al. 2008)
Ketamine (5–8 mg/kg)-xylazine (0.5 mg/kg) (McKenzie & Burroughs 1993)
Telazol (3–4 mg/kg, 6–8 mg/kg if not enclosed) (McKenzie & Burroughs 1993)

Canis latrans (coyote)
Medetomidine (0.06–0.12 mg/kg); atipamezole (0.6 mg/kg) (Baldwin et al. 2008; Miller et al. 2009)
Ketamine (4 mg/kg)-xylazine (2 mg/kg); yohimbine (0.15 mg/kg) (Kreeger & Seal 1986b)
Telazol (10–11 mg/kg) (Gray et al. 1974; Kreeger & Arnemo 2007).

Canis lupus (gray wolf)
Ketamine (3–4 mg/kg)-medetomidine (0.06–0.08 mg/kg); atipamezole (0.3–0.4 mg/kg IM) (Holz et al. 1994; Kreeger & Arnemo 2007).
Medetomidine (0.05 mg/kg); atipamezole (0.25 mg/kg IM) (Kreeger et al. 1996)
Xylazine (2 mg/kg)-butorphanol (0.4 mg/kg); yohimbine (0.125 mg/kg IV)-naloxone (0.05 mg/kg IV) (Kreeger et al. 1989).
Ketamine (4–10 mg/kg)-xylazine (1–3 mg/kg); yohimbine (0.15 mg/kg IV), (Kreeger 1992; Kreeger et al. 1987)
Xylazine (2 mg/kg captive, 3–4 mg/kg wild); yohimbine (0.15 mg/kg IV) (Kreeger et al. 1988; Philo 1978)
Telazol (10 mg/kg)-xylazine (1.5 mg/kg) (Kreeger & Arnemo 2007)
Telazol (3–10 mg/kg, 10–13 mg/kg for helicopter captures) (Ballard et al. 1991; Boever 1977; Kreeger et al. 1987)

Canis lupus dingo (dingo)
Telazol (1–2 mg/kg)-medetomidine (0.04 mg/kg) (Vogelnest 1999)
Ketamine (7.5 mg/kg)-xylazine (1 mg/kg) (Wentges 1975)
Telazol (7–10 mg/kg) (Vogelnest 1999)

Canis rufus (red wolf)
Medetomidine (0.04 mg/kg)-butorphanol (0.4 mg/kg), supplement with diazepam 0.2 mg/kg IV or ketamine (1 mg/kg IV);
atipamezole (0.2 mg/kg)-naloxone (0.02 mg/kg) ± flumazenil (0.02 mg/kg) (Larsen et al. 2001)
Ketamine (2 mg/kg)-medetomidine (0.02 mg/kg)-butorphanol (0.2 mg/kg); atipamezole (0.2 mg/kg) (Sladky et al. 2000)
Ketamine (2 mg/kg)-medetomidine (0.04 mg/kg); atipamezole (0.2 mg/kg) (Sladky et al. 2000)
Ketamine (8–10 mg/kg)-xylazine (2 mg/kg); yohimbine (0.1 mg/kg) (Kreeger & Arnemo 2007; Sladky et al. 2000)
Telazol (10 mg/kg) (Kreeger & Arnemo 2007)

Canis simienseis (Ethiopian wolf)
Telazol (2–7 mg/kg) (Sillero-Zubiri 1996)

Cerdocyon thous (crab-eating fox)
Ketamine (10 mg/kg)-xylazine (0.5–1 mg/kg) (Pessutti et al. 2001)
Telazol (10 mg/kg) (Kreeger & Arnemo 2007)

Chrysocyon brachyurus (maned wolf)
Ketamine (2.5 mg/kg)-medetomidine (0.08 mg/kg); atipamezole (0.4 mg/kg) (Kreeger & Arnemo 2007)
Telazol (1.2–5 mg/kg), supplement with ketamine (25–50 mg) or isoflurane (Deem & Emmons 2005; Estrada et al. 2009; Norton 1990)
Ketamine (6–9 mg/kg)-xylazine (0.5–2 mg/kg); yohimbine (0.1–0.2 mg/kg) (Norton 1990; Pessutti et al. 2001)

Cuon alpinus (dhole)
Telazol (10 mg/kg) (Kreeger 1992)

Lycaon pictus (African wild dog)
Ketamine (3–5 mg/kg)-medetomidine (0.05–0.1 mg/kg); atipamezole (0.15 mg/kg) (Cirone et al. 2004; van Heerden 1993)
Medetomidine (0.045 mg/kg)-butorphanol (0.24 mg/kg)-midazolam (0.3 mg/kg); atipamezole (3 mg)-naltrexone (10 mg)-flumazenil (0.2 mg) (Fleming et al. 2006)
Xylazine (0.7–1.1 mg/kg)-fentanyl (0.1 mg/kg); yohimbine (0.125 mg/kg)-naloxone (0.04 mg/kg), supplement with xylazine (10 mg)-fentanyl (0.5 mg) (de Villiers et al. 1995; van Heerden 1993)
Ketamine (1.6 mg/kg)-xylazine (2.2 mg/kg); yohimbine (0.2 mg/kg IV/IM) (Osofsky et al. 1996)
Telazol (1–4 mg/kg, ild African wild dogs are more sensitive than captive ones) (Hattingh et al. 1995; van Heerden 1993)

Nyctereutes procyonoides (raccoon dog)
Ketamine (5 mg/kg)-medetomidine (0.1 mg/kg); atipamezole (1 mg/kg) (Arnemo et al. 1993)
Telazol (7 mg/kg) (Gray et al. 1974)

Otocyon megalotis (bat-eared fox)
Ketamine (5–8 mg/kg)-xylazine (0.5 mg/kg) (McKenzie & Burroughs 1993)
Telazol (5 mg/kg) (McKenzie & Burroughs 1993)

Pseudalopex culpaeus (South American fox)
Telazol (10 mg/kg) (Kreeger 1992)

Pseudalopex vetulus (hoary fox)
Ketamine (3–5 mg/kg)-xylazine (0.6–0.8 mg/kg) (Pessutti et al. 2001)

Speothos venaticus (bush dog)
Telazol (10 mg/kg) (Pessutti et al. 2001)

Table 40.2. (Continued)

<i>Urocyon cinereoargenteus</i> (gray fox)
Ketamine (11–15 mg/kg)-xylazine (2–3 mg/kg) (Jessup 1982)
Telazol (9 mg/kg) (Gray et al. 1974)
<i>Vulpes chama</i> (Cape fox)
Ketamine-xylazine (5–8 and 0.5 mg/kg) (McKenzie & Burroughs 1993)
Telazol (5 mg/kg) (McKenzie & Burroughs 1993)
<i>Vulpes macrotis</i> (kit fox)
Telazol (10 mg/kg) (Kreeger & Arnemo 2007)
<i>Vulpes pallida</i> (pale fox)
Telazol (10 mg/kg) (Kreeger 1992)
<i>Vulpes velox</i> (swift fox)
Ketamine (10 mg/kg)-xylazine (1 mg/kg); yohimbine (0.125 mg/kg) (Telesco & Sovada 2002)
Telazol (10 mg/kg) (Kreeger & Arnemo 2007).
<i>Vulpes vulpes</i> (red fox)
Ketamine (2–4 mg/kg)-medetomidine (0.04–0.07 mg/kg); atipamezole (0.20–0.35 mg/kg) (Bertelsen & Villadsen 2009; Shilo et al. 2010)
Medetomidine (0.14 mg/kg); atipamezole (0.80 mg/kg) (Baldwin et al. 2008)
Medetomidine (0.04 mg/kg)-midazolam (0.3 mg/kg)-butorphanol (0.1 mg/kg); atipamezole (0.15 mg/kg) (Bertelsen & Villadsen 2009)
Medetomidine (0.07 mg/kg)-midazolam (0.8 mg/kg); atipamezole (0.35 mg/kg) (Shilo et al. 2010)
Ketamine (4 mg/kg)-medetomidine (0.02 mg/kg)-butorphanol (0.04 mg/kg), reversed with atipamezole (0.1 mg/kg) (Brash 2003)
Ketamine (25–30 mg/kg)-midazolam (0.6 mg/kg) (Kreeger & Arnemo 2007; Kreeger et al. 1990b)
Ketamine (20–23 mg/kg)-xylazine (1–1.2 mg/kg); yohimbine (0.15 mg/kg) (Brash 2003; Kreeger et al. 1990b)
Telazol (2 mg/kg)-medetomidine (0.04 mg/kg); atipamezole (0.2 mg/kg) (Bertelsen & Villadsen 2009)
Telazol (4–10 mg/kg) (Boever 1977; Brash 2003; Kreeger et al. 1990b)
<i>Vulpes zerda</i> (fennec fox)
Telazol (10 mg/kg) (Kreeger & Arnemo 2007)

Note: Drugs or drug combinations are listed in order in which they are recommended

recommended in the literature (see previous section), the following list only incorporates those that we recommend. These recommendations are based on literature reports, current drug availability, and personal experience.

For most routine procedures, on young healthy animals in a controlled environment, we recommend medetomidine-butorphanol. This combination provides profound sedation and 45–60 minutes of working time for many canids. Induction times with medetomidine-butorphanol are typically 5–15 minutes; it is not a highly potent combination, so this is not an appropriate combination for situations where the animals are uncontained, such as darting from a helicopter. One of the authors prefers to use medetomidine-butorphanol for short procedures in medium-to-large *Canis* spp. (wolves, red wolves, and coyotes) particularly in situations where the animal is to be released immediately back into the wild (RSL). Medetomidine-butorphanol induces profound sedation, and procedures such as phlebotomy, radio collar attachment, measurements, and skin biopsies can be performed. However, this combination should not be used for more invasive procedures as there is no general anesthetic incorporated. It should be noted that there will be a subset of the population that will not be adequately immobilized with this combination. For these animals, another agent, such as ketamine, diazepam, or midazolam, may be needed. If ketamine is used, atipamezole-naloxone should not be administered for 30–45 minutes, but there is still rapid, smooth recovery.

In a less controlled situation, such as emergency captures or helicopter darting, Telazol, ketamine-medetomidine, or ketamine-xylazine may be more appropriate since there is a lower volume of drug and induction is more rapid. Induction with medetomidine-butorphanol is often 10–15 minutes, whereas induction with Telazol is typically <5 minutes.

In animals that are ill or aged, particularly if cardiac or respiratory disease is suspected, it is probably not advisable to use medetomidine or other alpha-two agonists. Although these agents can be rapidly antagonized, their effects on blood pressure, heart rate, and respiration make them unnecessarily risky in high-risk patients. For compromised patients, inhalant induction may be the safest option. However, clinical judgment must be used to determine if the stress of handling will be detrimental to the animal's condition. Injectable combinations such as ketamine-midazolam, ketamine-midazolam-butorphanol, or Telazol can also be used.

Field Immobilization Considerations (Wild Capture)

Most canids are fast, elusive, and cunning, making them challenging to successfully immobilize in the wild. Some are also nocturnal. Free-ranging canids are typically trapped before drugs are administered (Kreeger 1992), although field-darting occurs in some cases. Jackals have extremely fast reaction times to sound and can move out of the path of slow-moving darts (McKenzie & Burroughs 1993).

Injectable anesthetic drugs are most commonly administered intramuscularly by hand injection, pole syringe, or dart. Hand injection during physical restraint should be performed in smaller species to avoid errant needle placement and unnecessary tissue trauma. Larger canids can be safely darted with a blowpipe or dart gun.

Gray wolves can be relatively safely pursued and darted from helicopters because they are large and inhabit areas with open country. For this type of a procedure, a pilot and a shooter are typically needed. Rapid projectile dart rifles are needed to insure accurate dart placement. Complications of helicopter darting may include pneumothorax secondary to inadvertent thoracic dart placement (Kreeger et al. 1995) or exhaustion. Coyotes have also been effectively captured in this manner (Baer et al. 1978), and with helicopter-launched net guns, although the impact of the net may cause mortality using this latter technique (Gese et al. 1987).

African wild dogs can be darted from a vehicle at a range of 15–30 m (van Heerden 1993) and should be darted in the upper hind leg. Wild dogs can also be captured by using a helicopter to chase a pack into a funnel-shaped boma. Jackals have occasionally been darted from vehicles to which they have been habituated, but trapping is a much more practical method of capturing these animals (McKenzie & Burroughs 1993). Small animals such as foxes will not normally approach to within darting distances. These animals have small muscle masses and damage to vital organs is very possible, even with light darts (McKenzie & Burroughs 1993). Bat-eared foxes may retreat into burrows if darted; they also have a bushy coat that makes accurate dart placement difficult, so darting is not recommended (McKenzie & Burroughs 1993). In some cases, capture collars (Wildlink Capture Collar, Advanced Telemetry Systems, Isanti, Minnesota 55040, USA) have been used to facilitate immobilization through the automated injection of drugs using a remote signal (Federoff 2001).

POSTANESTHETIC CHALLENGES

Many canids are pack animals. Reintroduction after prolonged separation (>12 hours) may result in extensive fighting, so animals should be kept with the pack as much as possible. Even if it is necessary to perform frequent immobilizations on an individual, it is generally preferable to perform procedures as quick as possible and return the animal to the pack each time, rather than separating the animal and then attempting reintroduction (Kreeger 1992).

Ursids (Bears)

Nigel Caulkett and Åsa Fahlman

SPECIES-SPECIFIC PHYSIOLOGY

In the wild, free-ranging bears are often subject to physical restraint via snares or traps prior to anesthesia. Physical restraint can result in stress, hemoconcentration, or injury (Cattet et al. 2003a). In Scandinavia, free-ranging brown bears (*Ursus arctos*) are only captured by helicopter darting, whereupon hyperthermia, hypoxemia, and lactic acidemia are commonly recorded during anesthesia (Fahlman et al. 2011). A careful physical examination should be performed as part of any capture to identify capture-related injuries. Bears are monogastrics, as such, they are prone to vomiting on induction, or regurgitation during anesthesia. It is best to avoid anesthetizing bears that have recently eaten. This is not always possible in management situations, but may be an option in research situations, and should be adhered to with captive animals. Despite previous fasting, vomiting is a common adverse effect during induction of captive sun bears (*Helarctos malayanus*) with medetomidine-zolazepam-tiletamine (MZT) (Onuma 2003). On the contrary, vomiting has not been observed in free-ranging brown bears (thus not fasted) anesthetized with the same drug combination (Fahlman et al. 2011).

Human safety must always be considered during capture and anesthesia of bears. It is important to know the behavior of the target species. With free-ranging bears, it is also important to consider other bears in the vicinity; these animals can pose a threat to the anesthetized bear or to the capture personnel.

Physical Capture and Restraint

In forested areas without large clear cuts, aerial capture is generally not a safe option. Physical capture techniques are often employed in these situations. The two

most common methods, in North America, are culvert traps and snares. Following physical capture, the animal may be anesthetized without the risk of losing it in a forest environment. Bears captured in culvert traps may experience hemoconcentration (Cattet et al. 2003a). Brown bears captured with snares demonstrated a stress leukogram, hemoconcentration, and muscle damage, evidenced by elevations in serum muscle enzymes (Cattet et al. 2003a). Snared bears often exhibit increased serum myoglobin and pathological lesions indicative of capture myopathy have been observed (Cattet et al. 2005, 2008). Fractures and soft tissue injuries may also be encountered in snared animals. If used, snares should be checked frequently, to minimize time spent in the snare, and snared animals should be closely examined to identify and treat snare-related injuries.

CHEMICAL RESTRAINT AND ANESTHESIA

Vascular Access

Venous blood can be sampled from the jugular or medial saphenous vein. IV catheters may be placed in the jugular or cephalic vein. The femoral pulse can easily be palpated in the groin for collection of arterial blood samples for blood gas analysis. A pulsating flow confirms insertion of the needle into the femoral artery. Firm pressure must be applied to the arterial sample site for a minimum of 2 minutes post sampling to avoid development of a hematoma (Fig. 41.1).

Intubation

Intubation of bears is not difficult if the bear is in a sufficiently deep plane of anesthesia. The oral and pharyngeal anatomy is similar to that of a canid. Intubation is easiest with the bear positioned in sternal recumbency. A long laryngoscope and a light source

Figure 41.1. Grizzly bear, with IV catheter placed in the cephalic vein.

Figure 41.2. Intubation of a sloth bear at the Bannerghatta Bear Rescue Center. International Animal Rescue; Wildlife SOS India.

will facilitate visualization of the glottis prior to intubation. Endotracheal tube size is dependent on size of the bear. We typically carry size 8–14 tubes (internal diameter in millimeters) for black bears and 8–18 tubes for brown bears (Fig. 41.2).

Preanesthetic Concerns

There are two major methods to facilitate capture of wild bears. Bears can be pursued and darted from a helicopter in open areas, such as tundra, alpine meadows, frozen lakes, marshland, or on large clear cuts in the forest. Management situations may dictate that a free-ranging animal is darted by a ground based capture team. These situations can be risky as there is a possibility that the capture team will lose track of the

animal during the induction period. Trained dogs should be available to track the bear if it is lost out of sight after darting.

Aerial capture techniques are best suited for capture of polar bears (*Ursus maritimus*) and brown bears. It is important to assess the terrain for any hazards prior to pursuit. If the bear is in unsuitable terrain, the helicopter can fly at a distance to slowly drive the bear to an area where darting can take place. The dart is delivered at close range (4–6 m). The time of intensive helicopter pursuit, when the helicopter approaches the bear for the actual darting, is usually less than 30 seconds. If a darted bear during the induction period moves toward risky terrain, such as open water, a second dart might be needed to rapidly induce recumbency. In Scandinavia, helicopter darting of family groups including radio-marked mother and dependent offspring (yearlings or 2-year-old cubs, no cubs of a year are being darted) are conducted. Up to four brown bears are captured at once. The cubs are darted one after the other, with the mother being darted last. After successful darting of the first cub, it is being observed from the helicopter at a high altitude throughout the induction period until recumbency, before darting of the next family member. When a darted cub starts to slow down, as the drugs starts to have an effect, the other family members usually leave it and are then not followed by the helicopter for a while. It is often 10–20 minutes between the intensive pursuits for darting of different family members (Fahlman et al. 2011).

The major complications encountered with helicopter darting of bears are hyperthermia and acidosis (Cattet et al. 2003a; Fahlman et al. 2011). The risk of these complications can be minimized by keeping pursuit and induction times as short as possible. Other factors that can influence the degree of exertion during the induction include pursuit intensity (distance and elevation gained), the type of terrain, snow depth, and the ambient temperature.

Drug Delivery

Drug delivery systems must be reliable and accurate. Systems that have low impact energy and deliver drugs at a low velocity are generally preferable. Captive bears may be injected with a pole syringe or blow dart. Volume limitations with blow darts necessitate the use of potent drug combinations for large bears. Potent drugs may be incorporated into a sticky bait, to facilitate capture in zoological settings.

It is advisable to dart free-ranging bears from a safe distance. Dart rifles will facilitate drug delivery in these situations. Many bear species will demonstrate seasonal variation in fat distribution. Black bears and brown bears will deposit a thick layer of fat over the rump in fall, and the shoulder or neck is the preferred location for dart placement. In spring, these animals can be darted in the hindquarters. Polar bears may have a

thick layer of fat at any time of the year and the shoulder or neck should be targeted.

MONITORING ANESTHESIA AND SUPPORTIVE CARE

Anesthetic Depth

Depth of anesthesia should be closely monitored as some drug combinations have proven to be unreliable in bears. Sudden recoveries have been encountered with xylazine-ketamine and medetomidine-ketamine (Cattet et al. 1999b; Jalanka & Roeken 1990). These combinations are best avoided in most situations. Factors that increase the risk of sudden arousal include loud noise, particularly distress vocalization of cubs (Jalanka & Roeken 1990). Other factors that can induce arousal include movement of the bear, that is, changing the body position or location of the anesthetized animal, or painful stimuli, such as tooth extraction. Local anesthesia should be considered whenever possible to decrease pain-related stimulation during painful procedures.

Techniques for monitoring depth of anesthesia will depend on the agent used. Zolazepam-tiletamine (Telazol®, Zoletil® [ZT]) will produce reliable anesthesia with predictable signs of recovery. Lightening of anesthesia is evidenced by spontaneous blinking, increased jaw tone, chewing, and paw movement. As the depth of anesthesia further decreases, animals will demonstrate head movement. Animals anesthetized with ZT alone with significant head movement generally require a “top-up” of tiletamine-zolazepam or ketamine, unless they are to be left to recover. Top-up doses of tiletamine-zolazepam can significantly prolong recovery and should only be used if >30 minutes of additional anesthetic time is required. Ketamine is a better choice if 5–20 minutes of additional time is needed.

In xylazine-ketamine or medetomidine-ketamine anesthetized bears, head lifting or limb movement signals that the bear is extremely light and should not be approached or manipulated. Increased intensity of the palpebral reflex or nystagmus are early indicators that the bear is light.

With both xylazine-zolazepam-tiletamine (XZT) or MZT, head lifting should be absent before the bear is approached. The palpebral reflex can be used to determine depth of anesthesia. Lightly anesthetized bears will begin to breathe deeply, and may sigh. They may start to lick, and will develop a spontaneous palpebral and an increased jaw tone. Head lifting or paw movement should be a sign to be extremely cautious, as the bear may soon rouse.

Pulmonary Function

Hypoxemia can occur in bears during anesthesia with different drug protocols, as demonstrated by arterial

blood gas studies in brown bears, black bears, and polar bears (Caulkett & Cattet 1997; Caulkett et al. 1999; Fahlman et al. 2011). Both free-ranging and captive brown bears anesthetized with MZT developed hypoxemia, despite lower drug doses used in the captive bears (Fahlman et al. 2011).

Oxygenation can be monitored with a pulse oximeter with the probe placed on the tongue. Pulse oximetry readings may be difficult to achieve in bears lightly anesthetized with ZT, as they tend to chew. A hemoglobin saturation below 95% is indicative of hypoxemia, which can generally be treated with supplemental inspired oxygen. It is important to note that pulse oximetry may not reliably indicate hypoxemia or normoxemia. Inconsistent pulse oximetry values have been reported in polar bears anesthetized with ZT and in brown bears anesthetized with MZT (Cattet et al. 1999a; Fahlman et al. 2010). Since pulse oximeters tend to overestimate saturation at lower ranges of partial pressure of arterial oxygen (PaO₂), hypoxemia can be missed if arterial oxygenation is evaluated only by pulse oximetry (Fig. 41.3).

Portable equipment available to facilitate oxygen delivery include oxygen cylinders and oxygen concentrators. An ambulance-type regulator and aluminum D-cylinder is lightweight, portable, and sturdy. Portable battery driven oxygen concentrators are small, lightweight, and easy to operate. They produce oxygen on site and thus less logistic is necessary compared to when using oxygen cylinders (see Chapter 5 on Oxygen Therapy). A nasal catheter is a simple method to provide supplemental inspired oxygen. Oxygen flow can be adjusted to maintain a saturation of 95–98% with the minimum required oxygen flow. Low flow rates of intranasal oxygen effectively treats hypoxemia in brown bears anesthetized with MZT (Fahlman et al. 2009, 2010). In relation to the body weight of the bears, the following flow rates are recommended: 0.5L/min to bears up to 25kg, 1L/min to bears from 25–100kg,

Figure 41.3. Grizzly bear receiving supplemental inspired oxygen.

2L/min to bears from 100–200 kg, and 3L/min to bears from 200–250 kg.

Intranasal oxygen administered by pulsed delivery from a portable oxygen concentrator (EverGo™ Portable Oxygen Concentrator, Respironics®) effectively treats hypoxemia in anesthetized brown bears (Fahlman et al. 2012). This concentrator weighs 4.5 kg and it delivers oxygen in a pulsed flow with pulse volumes from 12–70 mL up to a maximum capacity of 1.05 L/min. With pulse dose technology, the negative pressure of the patient's inspiration triggers oxygen delivery. Thus oxygen is provided during the inspiratory phase, which is the crucial time for participation of gas exchange in the lungs. The arterial oxygenation in brown bears improved significantly from mean \pm SD (range) pre-O₂ PaO₂ values of 73 \pm 11 (49–93) to 134 \pm 29 (90–185) mmHg during supplementation (Fahlman et al. 2012).

Monitoring the Cardiovascular System

The cardiovascular system should be closely monitored. Polar bears, black bears, and brown bears anesthetized with ZT commonly have heart rates of 70–90 beats/min. Heart rate is slightly lower with XZT and MZT, 50–70 beats/min. Bradycardia is common with medetomidine-ketamine, and heart rates of 30–40 beats/min are not uncommon in polar bears. The femoral artery is the best location to palpate a pulse, but the brachial artery can also be used.

Blood pressure can be measured directly from the femoral artery. Oscillometric monitors can be useful in smaller bears. The cuff width should be approximately 0.4 times the limb circumference. Mean arterial pressure (MAP) in polar bears anesthetized with ZT was approximately 150 mmHg (Caulkett et al. 1999). Polar bears anesthetized with MZT are hypertensive (MAP > 200 mmHg) (Caulkett et al. 1999). Black bears are also hypertensive with this combination (Caulkett & Cattet 1997).

Thermoregulation

Rectal temperature should be closely monitored. Rectal temperature tends to decrease over time with ZT, whereas it tends to increase with XZT and MZT. In hot ambient temperatures, after intense physical activity, and in stressed animals, body temperature can increase to dangerous levels (>41°C). Treatment of hyperthermia may include cooling the animal with snow or water, fanning, intravenous drip, cold water enema, and intranasal oxygen.

Supportive Care

The eyes should always be lubricated, and caution must be exercised to avoid corneal abrasions or ulceration. A blindfold should be placed to protect the eyes and decrease visual stimuli.

Bears can be positioned in sternal or lateral recumbency, but can also be positioned in dorsal recumbency with few adverse effects.

When possible, anesthesia should be reversed in free-ranging animals. This is particularly important for sows with cubs, and in areas where high concentrations of bears are present.

Translocation of bears in cargo nets, by helicopter, can result in mortality (Cattet et al. 1999a). Slings in a cargo net can induce hypertension and hypoxemia (Cattet et al. 1999a). Ideally, these bears should be transported or weighed with their head and neck extended and their body extended (Cattet et al. 1999a). We have used a stretcher-type sling or a “wooden board” to facilitate this positioning. If bears are to be relocated in culvert traps, they should be awake before transport (Fig. 41.4a,b).

PHARMACOLOGICAL CONSIDERATIONS

The following section deals with drug combinations that can be used to anesthetize bears. Mean doses of these combinations can be found in Table 41.1.

Xylazine-Ketamine

This combination may be suitable for short procedures in small bears, but the risk of sudden arousal limits its utility in larger, more aggressive bears. Xylazine can be antagonized with atipamezole or yohimbine, but since a high dose of ketamine is required, adverse effects of the ketamine (rigidity, convulsions, hyperthermia) are unmasked (Ramsay et al. 1985).

Medetomidine-Ketamine

The major advantages of medetomidine-ketamine over xylazine-ketamine are that small volumes are required. Since a low dose of ketamine is used, reversal of the effects of medetomidine with atipamezole is less likely to induce rigidity or convulsions due to ketamine residual effects. Medetomidine-ketamine may be useful for small bears, but should not be used in larger potentially aggressive bears. Sudden recoveries have occurred in brown bears (Jalanka & Roeken 1990), and polar bears (Cattet et al. 1999b). This combination should only be used by experienced personnel, for short procedures, and depth of anesthesia should be closely monitored.

Zolazepam-Tiletamine (Telazol, Zoletil)

This drug combination produces reliable anesthesia in bears. Recovery is usually slow, smooth, and predictable. ZT produces minimal adverse effects on the respiratory or cardiovascular systems; therefore, it has a high margin of safety (Caulkett et al. 1999). The major disadvantages of ZT are lack of analgesia (Caulkett et al. 1999) and lack of reversability (Cattet et al. 1999b; Caulkett et al. 1999). Recovery can be prolonged,

Figure 41.4. (a and b) Intranasal oxygen supplementation from an oxygen cylinder, and positioning on a pallet during translocation of a brown bear.

Table 41.1. Recommended mean doses (mg/kg) of immobilizing agents used to facilitate capture of free-ranging American black bears, brown bears, and polar bears

Drug Combination	Black Bear	Brown Bear	Polar Bear
Xylazine/ketamine	2/4	NR	NR
Medetomidine/ketamine	0.04/1.5	NR	NR
Medetomidine/zolazepam-tiletamine	0.05/2	Free ranging 0.08/4.1 Captive 0.03/2.2	0.06/2.2
Xylazine/zolazepam-tiletamine	2/3	2.5/3.8	2/3
Zolazepam-tiletamine	7	8	8

NR, not recommended in this species.

particularly in large bears, and if repeated doses are administered.

Medetomidine-Zolazepam-Tiletamine (MZT)

This combination can be delivered in small volumes, which increases its utility in large polar bears or brown bears. MZT provides better analgesia than ZT alone (Caulkett et al. 1999). The major advantage of this combination is that it is readily and rapidly reversible with atipamezole, administered IM at three to five times the medetomidine dose. The major disadvantages of MZT are hypertension and hypoxemia (Caulkett & Cattet 1997; Caulkett et al. 1999; Fahlman et al. 2011). Hypoxemia can be offset by the provision of supplemental oxygen (Fahlman et al. 2010). MZT has been used in black bears (Caulkett & Cattet 1997), polar

bears (Cattet et al. 1999b), and brown bears (Arnemo et al. 2001; Fahlman et al. 2011).

Xylazine-Zolazepam-Tiletamine (XZT)

XZT has many of the same characteristics as MZT (Cattet et al. 2003b, 2003c). It provides analgesia and can be delivered at approximately half the volume of ZT alone. XZT produces hypertension and hypoxemia (Cattet et al. 2003b). Hypoxemia is generally not severe and responds well to supplemental inspired oxygen. XZT will produce effective immobilization. It is important to note that quality of anesthesia is different from ZT alone, and head lifting or limb movement may immediately precede arousal. This combination is potentially reversible with yohimbine or atipamezole, whereas tolazoline appears to be ineffective. Our

current experience is that although recovery is not as rapid as with medetomidine-ketamine or MZT, it is still faster than with ZT alone. The longer recovery is probably a result of the higher ZT requirement with this mixture, compared with MZT. We generally use 0.1–0.2 mg/kg of yohimbine or 0.1 mg/kg of atipamezole to antagonize the xylazine component of this mixture.

Oral and Intranasal Drug Administration

Oral or intranasal drug administration may be preferable in captive bears, when injection is not desired. Carfentanil has been used orally in captive bears (Mama et al. 2000; Mortenson & Bechert 2001; Ramsay et al. 1995). The drug can be mixed in honey. The sticky base will coat the mouth and allow for sublingual absorption. In black bears, oral carfentanil produced effective immobilization that was accompanied by rigidity and muscle tremors (Ramsay et al. 1995). Diazepam was administered at a dose of 25 mg IV to treat these tremors (Ramsay et al. 1995). Bears immobilized with oral carfentanil were hypoxic; this was readily treated with supplemental inspired oxygen (Ramsay et al. 1995).

Volatile Anesthesia

Volatile anesthesia may be required for invasive or prolonged procedures. The bear is induced with one of the earlier injectable drug combinations, intubated, and maintained on volatile anesthesia delivered via an appropriately sized circuit. Bears under 150 kg body weight may be maintained on a small animal circle system. A large animal machine should be used for heavier animals. Isoflurane is a good choice for maintenance of anesthesia. Isoflurane-induced vasodilation tends to offset the hypertension that can result from administration of potent alpha-2 agonists. The major side effects of isoflurane are hypotension and respiratory depression. It is advisable to monitor blood pressure and end tidal or arterial CO₂ in bears anesthetized with isoflurane (Fig. 41.5).

Recovery from isoflurane is generally smooth. Alpha-2 agonist drugs should be antagonized at the termination of surgery to hasten recovery.

SPECIES-SPECIFIC CONCERNS

Polar Bear (*U. maritimus*)

Polar bears can have substantial fat deposits throughout the year. The shoulder and neck are the best sites for drug delivery. Male polar bears can be large and heavy. Potent drug combinations are required to keep drug volume and dart size to a minimum. Polar bears should be positioned carefully to avoid excessive pressure on limbs that could result in compartment syndrome. In summer, polar bears enter a hypometabolic state. At this time of the year, animals are fasting and body temperature is decreased (34–35°C). Immobilizing

Figure 41.5. Maintenance of anesthesia with isoflurane in a black bear.

drug requirements may also be decreased at this time of the year. In areas where large numbers of polar bears congregate, reversible anesthetic protocols should be considered. This will decrease the risk of predation from other bears. Reversible protocols should also be considered for mother bears with cubs.

Zolazepam-tiletamine (Table 41.1) will produce reliable immobilization, but can also result in prolonged recoveries. Volume requirements are high, which will necessitate the use of large darts, and this can result in excessive tissue trauma.

Xylazine-zolazepam-tiletamine (Table 41.1) can be delivered at approximately half the volume of ZT alone. Although potentially reversible with yohimbine or atipamezole, reversal of this mixture is not reliable. This is probably due to residual ZT sedation. Animals immobilized with this mixture will benefit from supplemental inspired oxygen.

Medetomidine-zolazepam-tiletamine (Table 41.1) will produce reliable immobilization. This combination will produce rapid onset of immobilization; it can be delivered in a small volume and it is readily reversible with atipamezole, administered at five times the medetomidine dose. Animals will benefit from supplemental inspired oxygen (Caulkett et al. 1999).

Brown Bear (*U. arctos*)

A variety of techniques can be used to anesthetize brown bears. Drug combinations should be reliable and potent. Reversible combinations are desirable in certain situations, particularly in free-ranging sows with cubs. Brown bears enter a hypometabolic state in the winter. Drug requirements are decreased at this time (Evans et al. 2010).

Zolazepam-tiletamine (Table 41.1) is routinely used for management of brown bears in North America. ZT will not only produce reliable immobilization but can also result in prolonged recoveries. High volume requirements necessitate the use of large darts, which can produce excessive tissue trauma.

Xylazine-zolazepam-tiletamine (Table 41.1) is potentially reversible with yohimbine or atipamezole. Reversal of this mixture is not reliable. This is probably due to residual effects of ZT. Animals immobilized with this mixture will benefit from supplemental inspired oxygen.

Medetomidine-zolazepam-tiletamine (Table 41.1) will induce a rapid onset of immobilization and it can be delivered in a small volume. It is readily reversible with atipamezole, administered at five times the medetomidine dose. MZT is the drug combination of choice used for immobilization of brown bears in Scandinavia (Arnemo et al. 2001; Fahlman et al. 2011). Doses and physiological evaluation of capture and MZT anesthesia in brown bears have been described in detail (Fahlman et al. 2011).

Low doses of MZT + ketamine (MZTK) can be used for anesthesia of free-ranging brown bears during hibernation in the wild (Evans et al. 2010). Two to 4-year-old bears were darted in their dens with medetomidine at 0.02–0.6 mg/kg, ZT at 0.9–2.8 mg/kg, and ketamine at 1.1–3.0 mg/kg. Hypoxemia was corrected with intranasal oxygen therapy. One bear that was darted with the higher dose of MZTK developed apnea and was intubated followed by manual ventilation with a bag valve mask.

Oral carfentanil has been used at a dose of 8 µg/kg in a captive brown bear. This dose-induced deep sedation, sufficient for intubation to maintain anesthesia on isoflurane and oxygen. The bear also received 0.02 mg/kg of atropine IM. Naltrexone was administered at a dose of 0.42 mg/kg split IM and IV to speed recovery (Mama et al. 2000).

American Black Bears (*U. americanus*)

These bears have a more placid nature than brown bears; dose requirements are lower with ZT. A variety of drugging techniques can be used. Black bears are frequently immobilized for management purposes in North America. The bear may be snared or captured in a culvert trap prior to drug administration. Physical capture of the bear will facilitate drug administration and limit mobility on induction. Free-ranging bears are often treed prior to drug administration. This will also facilitate drug administration and decrease mobility on induction. Ideally, a coniferous tree should be picked, as the boughs will help to break the bear's fall on induction. Air filled bags or mattresses can be placed at the base of the tree to soften the landing. Bears that remain in the tree, after induction, may need to be placed in a sling and lowered with ropes.

Zolazepam-tiletamine (Table 41.1) will produce reliable immobilization and can be delivered at a relatively low volume in most bears.

Xylazine-zolazepam-tiletamine (Table 41.1) is a useful combination in black bears. The dose we have used is similar to a brown bear or polar bear dose. The dose could possibly be lowered. Further work is needed to determine an appropriate dose for this species.

Medetomidine-zolazepam-tiletamine (Table 41.1) will induce a rapid onset of immobilization; it can be delivered in a small volume and it is readily reversible with atipamezole, administered at five times the medetomidine dose. Animals will benefit from supplemental inspired oxygen (Fahlman et al. 2010).

Xylazine-ketamine (Table 41.1) can be used, cautiously, in black bears. It is important to monitor the bear closely for signs of arousal. Rapid nystagmus and brisk tongue withdrawal are signs of light anesthesia. An IV top up of xylazine-ketamine at one-third of the original dose may be considered, or procedures may be terminated.

Oral carfentanil has been used in captive black bears. A dose of 6.8–18 µg/kg was administered in honey. Bears demonstrated muscle rigidity that was readily treated with diazepam (10–25 mg IV). Bears also developed hypoxemia that resolved with 5 L/min of supplemental oxygen (Ramsay et al. 1995).

Sloth Bear (*Melurus ursinus*), Sun Bear (*Ursus malayanus*), Asiatic Black Bear (*Ursus thibetanus*), Spectacled Bear (*Tremarctos ornatus*), and Giant Panda (*Ailuropda melanoleucia*)

These species are grouped at the end of the section because there is a paucity of information in the literature about anesthesia of these animals. It is very probable that XZT, MZT, or oral carfentanil will be as effective in these species as in other bear species. ZT has been used in sun bears at a dose of 4.0–5.5 mg/kg, in sloth bears at a dose of 5.5–6.6 mg/kg, in Asiatic black bears at a dose of 2.8–4.4 mg/kg, and in spectacled bears at a dose of 3.2–11.1 mg/kg (Schobert 1987). Sloth bears have been anesthetized with 1.4–2.4 mg/kg of xylazine, combined with 5.8–9.7 mg/kg of ketamine (Page 1986). Sun bears have been anesthetized with 60–80 µg/kg of medetomidine + 2–3 mg/kg of ketamine (Jalanka & Roeken 1990). Giant pandas have been anesthetized with a variety of drug combinations. Ketamine at a dose of 4.8 mg/kg in combination with xylazine at 0.43 mg/kg has been described as a suitable protocol for healthy pandas (Kreeger et al. 2002). Alternatively, 5.8 mg/kg of ZT can be used (Kreeger et al. 2002).

Procyonids and Mustelids

George V. Kollias and Noha Abou-Madi

INTRODUCTION

Chemical restraint and anesthesia techniques and protocols applicable to captive mammals in the families Mustelidae and Procyonidae are similar in many respects to the techniques used for domestic dogs and cats. Chemical restraint and anesthesia of free-ranging members of these families present challenges not dissimilar to those encountered for mammals in other families and genera, including the capture techniques employed and stress associated with capture and restraint. The metabolic impact of physical restraint and general anesthesia on animals is often underestimated. As an example, ferrets manually restrained showed significant increase in their plasma concentration of cortisol and adrenocorticotropic hormone (ACTH) and a decrease in alpha-melanocyte stimulating hormone (MSH), while isoflurane anesthesia resulted in significant increase in plasma MSH directly after induction (Schoemaker et al. 2003). Applying the basic principles of restraint and anesthesia are essential to insuring a successful outcome. Specialized equipment and supplies (small endotracheal tubes, special face masks, small intravenous and intraosseous catheters, and cannulas) should be on hand at the outset of the procedure. Additionally, emergency drug doses should be calculated and drawn up in labeled syringes or vials prior to beginning the anesthetic procedures. Attempting to calculate, draw up, and administer emergency drugs for a 50g (1.8oz) ermine can be problematic at the time of an anesthetic emergency. Drug dosages used are extrapolated from the dog or cat unless specific doses are available for species such as the ferret (Carpenter & Marion 2013).

BIOLOGY

Mustelidae

Mustelids are members of the order Carnivora, which contains six additional families. There are 67 species of mustelids in 27 genera that include the wolverine, fisher, nearctic otter, sea otter, polecat, marten, ferret, badger, tayra, grison, and skunk. Mustelids are distributed in all continents except Antarctica and Australia. The otters have the widest distribution, being found in North, Central, and South America as well as in Africa, Europe, and Asia. Mustelid habitats range from Arctic tundra to tropical rainforest and they are terrestrial, arboreal, fossorial, and found on the open seas, as with the sea otter. Many are small (<1kg or 2.2lbs), while some are relatively large (45kg or 99lbs) when compared to members of other mammalian families. The smallest, the weasel, rarely exceeds 19cm (7.5in) in length. The giant river otter is the longest mustelid reaching a length of up to 190cm (6.2ft). Most are carnivorous (otter and fisher) but some are omnivorous (skunk). All have five toes on each foot with non-retractable claws. Sexual dimorphism is marked in most mustelids but is less apparent in badgers, otters, and skunks. Male skull size may range 5–25% longer than that of females. Mustelids possess prominent sharp canines, cutting carnassials, heavy premolars, and powerful jaws that are capable of crushing thick bones. The dental formula varies within and between subfamilies. As examples, the European common weasel has the dental formula of $I \frac{3}{3}, C \frac{1}{1}, P \frac{3}{3}, M \frac{1}{2} = 36$, whereas the dental formula of the wolverine is $I \frac{3}{3}, C \frac{1}{1}, P \frac{4}{4}, M \frac{1}{2} = 36$. Mustelids lack both a clavicle and an appendix. The otters, like other

aquatic carnivores, have a multilobulated (reniculated) kidney (Baitchman & Kollias 2000). The renal lobules are firmly compressed against each other, forming a somewhat solid kidney. Musk is present in most species and produced by modified sebaceous glands present and stored in perianal sacs. The composition of musk varies between species and is used for demarcation of territory often for generations. In the case of skunks, musk is used for defense purposes. The reproductive biology of mustelids also varies between species, with males and females of most species living separately the majority of the year. Mustelids are induced ovulators and require vigorous copulation for ovulation. Males have a baculum (os penis) and females an os clitoris. Delayed implantation, up to 10 months, is exhibited in 16/67 mustelid species. The mediators of delayed implantation are largely unknown and may include environmental factors such as photoperiod. Delayed implantation can occur in semidormancy.

Procyonidae

The Procyonidae are small- to medium-sized, long-bodied, and long-tailed mammals in the order Carnivora. There are 16 New World species including the raccoon, white-nosed coati, kinkajou, and so on. New World procyonids inhabit temperate, tropical, and neotropical regions. Procyonids are generally omnivores but are known to be opportunistic carnivores. The dental formula is $I\ 3/3, C\ 1/1, P\ 4/4, M2/2 = 40$. An exception to this formula is the kinkajou which has $P3/3$. The molars of all procyonids are large and well adapted to crushing. There is some interspecies variation in dentition which relates to food preferences. Subsequently procyonids have highly specialized gastrointestinal systems with all members of the family lacking a cecum. The feet of procyonids have five toes and they walk partly or wholly on the soles of their feet (plantigrade). Claws are nonretractable, except the ring-tails which have semiretractable claws on their front feet. All procyonids have agile front feet which make them excellent climbers. Excepting the coati, procyonids are generally nocturnal or crepuscular. Females usually breed in the spring of their first year and males from their second year on. The small procyonids live 10–15 years in captivity. The authors are aware of a male kinkajou that lived until 32 years of age in a zoo. In the wild, it is unusual for procyonids to exceed 7 years of age.

CHEMICAL RESTRAINT, IMMOBILIZATION, AND ANESTHESIA

Delivery of injectable agents to procyonids and mustelids, as with other wild mammals, often requires physical restraint and specialized supplies and equipment (see Chapters 8 and 12). Squeeze cages or boxes and transfer boxes (Fig. 42.1 and Fig. 42.2) greatly facilitate delivery of injectable drugs and help to minimize stress

Figure 42.1. Large procyonids and mustelids are restrained in squeeze cages to facilitate intramuscular injection of parenteral anesthetic drugs.

Figure 42.2. A transport cage for a Nearctic river otter (*L. canadensis*). Note the solid wood sides to reduce visual stimulation and prevent damage to the teeth and feet that can occur when confined to a wire cage. A clear door allows inspection of the animal during transport.

while maximizing the quality of induction, immobilization, and recovery of procyonids and mustelids. As an example, when recently captured nearctic river otters (*Lontra canadensis*) are transferred from their holding cages to a small squeeze cage, injected, and the squeeze cage is then covered with a drape or towel and minimal environmental noise occurs, the otters are consistently immobilized in 10–12 minutes and remained so for 35–45 minutes. If this protocol is not consistently adhered to otters never reach an acceptable level of immobilization, complications such as hyperthermia occur due to excessive movement, and recovery is unacceptable due to hyperkinesia vocalization and disorientation (Kollias 1999). Numerous general and specific single drugs or drug combinations have been reported for chemical restraint, immobilization, and anesthesia of procyonids (Table 42.1 and Table 42.2) and mustelids (Table 42.3 and Table 42.4).

Table 42.1. General Procyonidae chemical restraint agent doses (IM)

Agent(s) and Dose(s)	Reversal Agent	Comments
Ketamine (10–30 mg/kg) ^a	None	High end of dose range used for smaller animals
Ketamine (10 mg/kg) + diazepam (0.5 mg/kg) ^a		Minimal respiratory depression
Ketamine (10 mg/kg) + midazolam (0.25–0.5 mg/kg) ^a		Minimal respiratory depression
Ketamine (10 mg/kg) + xylazine (1–2 mg/kg) ^b		Good muscle relaxation
Ketamine (2.0–5.0 mg/kg) + medetomidine (0.025–0.05 kg) ^c	Antipamezole (0.1 mg/kg) Ketamine: none	
Ketamine (5–15 mg/kg) + xylazine (1–2 mg/kg) + atropine (0.04 mg/kg) ^d		Induction: 3–5 minutes Anesthesia: 15–20 minutes Recovery: 60–90 minutes
Tiletamine/zolazepam (10–25 mg/kg) ^a	Tiletamine: none Zolazepam: flumazenil	Chemical capture and minor surgery
Tiletamine/zolazepam (3–5 mg/kg) ^e	Tiletamine: none Zolazepam: flumazenil

Table 42.4. Specific mustelid chemical restraint agent doses (IM)

Adult Weight Range (kg)	Agents and Doses (mg/kg)	Reversal Agent (mg/kg)	Comments
Badger, European (<i>Meles meles</i>) 5.5–12.5 0 = 9.3	Ketamine (20) ^a Ketamine (15) + midazolam (0.4) ^a Ketamine (10) + midazolam (1.0) ^a Ketamine (5) + medetomidine (0.808) ^a	None None given None given Medetomidine: atipamezole (0.80)	Recovery considered prolonged; 0h = 170 beats/min Few advantages over ketamine alone; 0h = 150 beats/min Few advantages over ketamine alone; 0h = 160 beats/min Best quality of maintenance; lower mean HR than other agents used (0 = 100 beats/min); 0 arterial blood pressure = 150 mmHg was higher than other agents used; early reversal with atipamezole may cause excitement Preferred combination
10–16	Ketamine (5–10) + medetomidine (0.05–0.10) ^b Tiletamine/zolazepam (2.5) + medetomidine (0.04) ^b Tiletamine + zolazepam (10) ^c	Medetomidine: atipamezole (0.25–0.50) Medetomidine: Atipamezole (0.20)	Alternative combination Supplement with ketamine (5 mg/kg)
n = 93 5.5–12.5	Ketamine (15) + acepromazine (0.4) ^c Ketamine (16) xylazine (6) ^c Medetomidine (0.02) + ketamine (0.04) + butorphanol (0.08) ^d Medetomidine (0.02) + ketamine (0.04) + butorphanol (0.06) ^d Medetomidine (0.02) + ketamine (0.06) + butorphanol (0.04) ^d	None given None given None given	Induction slower than ketamine, but quality of induction similar (range = 3–22 minutes 0 = 6 minutes); paler mucous membranes than ketamine alone; recovery 37–39 minutes; sudden arousal or recovery occurred in 14/93 (15%) of the badgers using these combinations and was statistically linked to increasing rectal temperature
Badger, Chinese ferret (<i>Melogale moschata</i>) 1–3	Tiletamine/zolazepam (5) ^e		Supplement with ketamine (5 mg/kg)
Badger, hog (<i>Arctonyx collaris</i>) 7–14	Tiletamine/zolazepam (4.4) ^c		Supplement with ketamine (2.2 mg/kg)
Badger, honey (ratel) (<i>Mellivora capensis</i>) 7–13	Tiletamine/zolazepam (2.2) ^e Ketamine (6) + xylazine (0.5) ^e		Supplement with ketamine (2.2 mg/kg)
Badger, American (<i>Taxidea taxus</i>) 4–12	Tiletamine/zolazepam (4.4) ^f Ketamine (15) + xylazine (1) ^f		Supplement with ketamine (4.4 mg/kg) Alternative choice
Ermine (<i>Mustela erminea</i>) 0.05–0.365	Ketamine (5) + medetomidine (0.0001 mg/gm) (0.1) ^c Tiletamine/zolazepam (0.011–0.022 mg/gm) (11–22) ^b	Atipamezole (0.0005 mg/gm) (0.5); 1/2 IV + 1/2 IM	Supplement with ketamine (2.5)
Black-footed ferret (<i>Mustela nigripes</i>) 0.7–1.5	Ketamine (3) + medetomidine (0.075) ^b	Medetomidine: atipamezole (0.375); 1/2 IV + 1/2 IM	
Ferret (<i>Mustela putorius</i>)	Ketamine (35) + diazepam (0.2)		

Table 42.4. (Continued)

Adult Weight Range (kg)	Agents and Doses (mg/kg)	Reversal Agent (mg/kg)	Comments
2.6–5.5	Ketamine (20) + medetomidine (0.040) ^c	Medetomidine: atipamezole (0.02)	Supplement with ketamine (10)
	Ketamine (20) + acepromazine (0.10) ^c	None	
Marten (<i>Martes americana</i>)			
0.5–1.5	Ketamine (10) + medetomidine (0.2) ^c	Medetomidine: atipamezole (1; 1/2 IM, 1/2 SC)	Prone to hyperthermia; supplement with ketamine (5)IM if indicated
	Ketamine (18) + xylazine (1.6) ^c	Xylazine: atipamezole (0.02–0.06) or yohimbine (0.2–0.5) IM	
Mink, American (<i>Mustela vison</i>)			
1.13–1.81	Ketamine (22.1–24.8) + 0 = 23.2 ^m	None	Ranch raised and bred adults (<i>n</i> = 22); time to immobilization (lateral recumbency with no purposeful movements) = 2–4 minutes; time to anesthesia (no movement in response to [unspecified] pain) = 5–10 minutes; time to recovery (period from initial injection until mink could stand unaided) = 60 minutes; muscle relaxation improved over 60 minutes period of immobilization
0 = 1.51 (males or females)			
0.8–1.1	Tiletamine/zolazepam (15) ^c	None specified	Supplement with Ketamine IM (15) if appropriate
	Ketamine (5) + medetomidine (0.1) ^c	Atipamezole (5), 1/2 IM, 1/2 SC	Alternative
	Ketamine (40) + xylazine (1)	Xylazine: as above for Marten	Alternative
Mink, European (<i>Mustela lutreola</i>)			
Males (<i>n</i> = 6)	Ketamine (10) + medetomidine (0.20) ^f	Medetomidine: Atipamezone (1.0) IM injected	Free-ranging mink captured for clinical examination, blood collection and placement of intra-abdominal radio transmitters. Induction smooth and rapid (0.7–3.9 minutes); degree of anesthesia and muscle relaxation satisfactory in most individuals; all animals exhibited decreased heart rate and respiratory rate, and rectal temperature. Hypotermia was significant and was controlled/prevented by placing animals on a warmed plastic table (37°C)
0.77–1.03		28.1–54.0 minutes after ket/med injection; standing in	
Females (<i>n</i> = 8)		1.5–9.4 minutes; ambulatory in 10–25.7 minutes	
0.42–0.54			

<p>Otter Nearctic (American River) (<i>Lontra canadensis</i>)</p> <p>Males</p> <p>2.90–9.30</p> <p>0 = 5.64</p> <p>Females</p> <p>3.6–8.0</p> <p>0 = 5.50</p>	<p>Ketamine (15) + midazolam (0.3) or diazepam (0.5)</p> <p>(male and female > 4.5 kg)ⁿ</p> <p>Ketamine (20) + midazolam (0.30) or diazepam (0.5)</p> <p>(male and female < 4.5 kg)ⁿ</p>	<p>None used</p> <p>None used</p>	<p>Wild-caught otters immobilized 1–5 days post capture. Conditions of immobilization: restrained in portable squeeze cage, which was covered with a drape to block light and injected IM. Room lights out and no sound stimulation. Induction reached (lateral decubency and no response to touch) in 10–12 minutes. Immobilization time: 30–45 minutes. Procedures (physical examination, wound care, bandaging, and blood collection) sometimes required administration of one additional 20–30 mg dose of ketamine HCl IV or isoflurane (0.5–1%) via face mask. This provided an additional 20 minute working time. If procedures extended beyond this 20 minute time frame, the otters were intubated, maintained on isoflurane (0.5–1.5%), and given intermittent positive pressure ventilation every 15 seconds if they were hypoventilating. Monitoring included HR (range = 120–264 beats/min; mean = 166), RR (range = 12–56/minutes; mean = 30/minutes) and rectal temperature (range = 99.80–104.7°F; mean = 101.8°F). Otters were recovered in their holding cage (room temp = 60°F) which was padded with towels and the front draped with a sheet to decrease light and sound stimulation. Complete recovery times (normal ambulation and mentation) ranged from 30 to 90 minutes. Hyperthermia may be an issue if otters become hyperactive during recovery. If this occurs, sedation and other corrective measure may be necessary (midazolam IM, placing a fan directed through the cage cars, decreasing ambient temperature). No mortalities, and few complications, occurred using this protocol in over 250 immobilizations and anesthetic episodes.</p> <p>Highly recommended</p> <p>Avoid in hypothermic otters. May need higher doses (Ket 3.5 + Med 0.035 mg/kg) but respiratory depression more likely</p> <p>Recovery may be prolonged without flumazenil</p> <p>Expect muscle rigidity and variable duration</p> <p>Prolonged recovery compared with ketamine + midazolam</p> <p>Variable effects from heavy sedation to immobilization. May get respiratory depression.</p> <p>Not recommended. Reports of fatal complications.</p>

In the authors' experiences, the doses listed are guidelines for use and often require modification when applied to specific individuals or collections of animals and whether they are used for captive, recently captured, or free-ranging procyonids or mustelids.

INHALATION ANESTHESIA

Generally, induction of inhalation anesthesia is facilitated by prior administration of injectable agents recommended in Table 42.1, Table 42.2, Table 42.3, and Table 42.4, and in standard veterinary anesthesia texts for domestic dogs and cats (Muir & Hubbell 2007; Seymour & Gleed 1999). The polecat and ferret are mustelid species for which a number of injectable and inhalation anesthesia protocols have been published (Table 42.3 and Table 42.4; Cantwell 2001; Evans & Springsteen 1998; Gaynor et al. 1997; Imai et al. 1999; MacPhail et al. 2004; Vastenburger et al. 2004). Isoflurane and sevoflurane have been shown to be safe and efficacious and are agents of choice in both procyonids and mustelids (Denver 2000; Gaynor et al. 1997; Schumacher 1996). Following administration of preanesthetic agents or parenteral drugs, some animals may still require restraint. They can be held in a towel or with gloves and provided the inhalant agent via face mask or induction chamber. Once the animal loses its righting reflex, it is masked until it is intubated or maintained on a face mask. With intubation or face mask maintenance, inhalants should be administered using a non-rebreathing circuit (Ayre's T-piece or Bain system). Oxygen flow should be two to three times the minute ventilation (approximately 200–350 mL/kg/min) (Cantwell 2001). Anesthesia monitoring, thermoregulation, and cardiopulmonary support, resuscitation, and recovery for these species are as discussed in Chapters 3–5 and 9.

Viverrids

Anneke Moresco and R. Scott Larsen

INTRODUCTION

Viverrids are small- to medium-sized carnivores and their natural habitat spans Southwestern Europe, Southern Asia, the East Indies, and Africa, including Madagascar. The phylogeny is challenging as there is a fair bit of convergence in this taxon (Gaubert & Veron 2003). Therefore, as new molecular techniques become available, the taxonomic classification of the Viverridae continues to change. This chapter follows the taxonomy detailed by the Integrated Taxonomic Information System (ITIS). Within the Viverridae family, there are now 4 subfamilies and 35 species listed. Latin names, common names, weight ranges, and longevities are given in Table 43.1. The International Union for Conservation of Nature (IUCN) lists the genus *Prionodon* in its own family Prionodontidae. The Euplerinae and Nandininae are now listed as distinct families (Eupleridae and Nandinidae, respectively) rather than within the Viverridae. The family Eupleridae contains the genera *Cryptoprocta*, *Eupleres*, and *Fossa*, formerly classified in the Viverridae (IUCN 2011).

The fossil record for Viverridae is the oldest among the families classified in the order Carnivora. Phylogenetically, they are classified as part of the Feliformia group and are more closely related to felids than to canids (Veron & Heard 2000).

Most viverrid species are nocturnal or crepuscular, making observations difficult. Therefore, the ecology of many species in this group is poorly understood. With the advent of smaller devices, more radiocollaring studies are being done, thus providing more data on their behavior and diet (Grassman et al. 2005). The natural social structure is typically solitary (Kingdon 2003); however, in captivity, they can be housed in pairs or small groups. This needs to be taken into

account during induction and recovery, since brief separation and reintroduction will be necessary.

SPECIES SPECIFIC PHYSIOLOGY

As their taxonomic classification indicates, most viverrids are carnivorous and a high percentage of their diet (70%) consists of meat (Ray & Sunquist 2001). Binturongs (*Arctictis binturong*) and many civet species are more omnivorous, with up to 40% of their diet consisting of fruit. However, for many species, details about their diets in the wild remain unknown.

Viverrids are skilled climbers with strong, sharp, retractile or semiretractile claws, and tend to be arboreal. A few are primarily terrestrial (e.g., oriental civets) and will dig burrows, use burrows dug by other animals, or seek shelter within human-built structures (Nowak 2005). One should remember their raking power when physically restraining and handling these animals (Rettig & Divers 1986). In addition to personnel safety, nails are an important consideration when choosing a net to catch and restrain as they can injure themselves or may tear the net trying to escape.

The binturong is unique among viverrids in that it has a truly prehensile tail. It is a very thick (up to 15 cm diameter at the base) and strong appendage that can be used with great dexterity, which should be kept in mind when handling binturongs, even when they are sedated.

Mammals that consume exclusively vertebrate diets tend to have higher metabolic rates than those that also consume fruit and invertebrates (McNab 1995). The binturong, the largest of the viverrids, has a slightly lower body temperature (37–38°C) than similarly sized dogs and tends to maintain normal body temperature during anesthesia (Moresco & Larsen 2003; Mudappa

Table 43.1. Latin names, common names, body weights, and longevity of viverrid species

Latin Name	Common Names	Weight	Reference
Hemigalinae			
<i>Chrotogale owstoni</i>	Owston's palm civet	2.5–4.0 kg	King (2002); Kingdon (2003)
<i>Cynogale bennettii</i>	Sunda otter civet	3–5 kg	Nowak (2005)
<i>Diplogale hosei</i>	Hose's palm civet	Wt unk	Nowak (2005)
<i>Hemigalus derbyanus</i>	Banded palm civet	1.75–3.0 kg	Nowak (2005)
Paradoxurinae			
<i>Arctictis binturong</i>	Binturong, Asian bear cat	14 kg, in captivity up to 30 kg	Moresco & Larsen (2003); Nowak (2005) A. Moresco, pers. obs.
<i>Arctogalidia trivirgata</i>	Small-toothed, three-striped civet	2.0–2.5 kg	Nowak (2005)
<i>Macrogalidia musschenbroekii</i>	Sulawesi palm civet	3.8–4.5 kg	Nowak (2005)
<i>Paguma larvata</i>	Masked palm civet	3.6–5 kg	Nowak (2005)
<i>Paradoxurus hermaphroditus</i>	Asian palm civet, common palm civet, musang, toddy cat		
<i>Paradoxurus jerdoni</i>	Jerdon's palm civet, musang, toddy cat, brown palm civet	1.2–3.5 kg	Mudappa and Chellam (2001)
<i>Paradoxurus zeylonensis</i>	Golden palm civet		
Prionodontinae			
<i>Prionodon linsang</i>	Banded linsang	0.6–1.2 kg	Nowak (2005)
<i>Prionodon pardicolor</i>	Spotted linsang	7–20 kg	Kingdon (2003)
Viverrinae			
<i>Civettictis civetta</i> (<i>V. civetta</i>)	African civet	7–20 kg	(Kingdon 2003)
<i>Genetta abyssinica</i>	Ethiopian or Abyssinian genet	1.3–2 kg	Kingdon (2003)
<i>Genetta angolensis</i>	Angola or Miombo genet	1.3–2 kg	Kingdon (2003)
<i>Genetta genetta</i>	Small spotted- or common genet	1.3–2.25 kg	Haltenorth and Diller (1984)
<i>Genetta johnstoni</i>	Johnston's genet	1–3 kg	Kingdon (2003)
<i>Genetta maculata</i>	Rusty spotted genet	1.2–3.1 kg	Haltenorth and Diller (1984)
<i>Genetta servalina</i>	Servaline genet	1–2 kg	Kingdon (2003)
<i>Genetta thierrii</i>	Hausa genet	1.3–1.5 kg	Kingdon (2003)
<i>Genetta tigrina</i>	Large-spotted- or rusty-spotted genet	1.2–3.1 kg	Kingdon (2003)
<i>Genetta victoriae</i>	Giant genet	2.5–3.5 kg	Kingdon (2003)
<i>Genetta cristata</i>	Crested servaline genet		
<i>Genetta piscivora</i>	Aquatic genet	1.2–2.5 kg	Kingdon (2003)
<i>Poiana richardsoni</i>	African linsang or oyan	0.5–0.7 kg	Kingdon (2003)
<i>Viverra civettina</i>	Malabar civet	5–11 kg	Nowak (2005)
<i>Viverra megaspila</i>	Large spotted civet	5–11 kg	Nowak (2005)
<i>Viverra tangalunga</i>	Malay civet	Male: 2.45–4.3 kg; female: 3.62–3.95 kg	Colón (2002)
<i>Viverra zibetha</i>	Large Indian civet	5–11 kg	King (2002); Nowak (2005)
<i>Viverricula indica</i>	Lesser oriental civet, rasse	2–4 kg	Nowak (2005)

& Chellam 2001). The smaller viverrids have a larger surface-to-volume ratio, making them more susceptible to heat loss during anesthesia.

In the wild, the fanaloka (*Fossa fossana*) and the falanouc (*Eupleres goudotii*) can lay down fat reserves in preparation for winter. Fat may make up a significant percentage of their body weight and is laid down especially in the tail (Garbutt 1999). Therefore, the tail is not recommended as a site for intramuscular anesthetic injection in viverrids because absorption can be inconsistent (Moresco, unpublished data, 2002).

PHYSICAL RESTRAINT

In most cases, it is difficult to safely handle viverrids for examination and sample collection solely using

physical restraint techniques. Typically, the goal is to choose the restraint technique that will be the least stressful and will allow the most reliable drug delivery. Recently transported animals are best left to acclimate before restraint is attempted; restraint (physical or chemical) should not be attempted if ambient temperature is above 32.2°C (90°F) (Fowler 1986).

Nets

Advantages: Net capture can be low stress if performed by well trained staff; transfer out of the net may not be necessary to administer drugs because these can be delivered through the mesh. Nets can be used to capture animals in a tree or in a den in their exhibit. With appropriately sized nets and trained personnel, nets can be used even for binturongs, the largest of the

viverrids. Animals can be transferred to a kennel after injection of anesthetics and kept quiet and dark to minimize stimulation. This is particularly important when using alpha-two agonists for chemical restraint, as catecholamines released due to stress or excitement can overwhelm the sedative effect of alpha-two adrenergic agonists. If left in the net while the injectable anesthetics take effect, the animal's eyes should be covered and noise should be minimized.

Disadvantages: There is the potential for claws or teeth getting caught in mesh. Nets are not typically useful in free-ranging situations.

Trap/Kennel/Squeeze Cage

Advantages: Squeeze cages or small kennels can be low stress if the animals have been habituated to enter them voluntarily (operant conditioning). These have been used successfully in animals as small as Owston's palm civet (Streicher 2001). Transfer for drug delivery is usually not necessary because drugs can be delivered through the mesh (via pole syringe, blow pipe, or low-power dart gun if trap is not a squeeze cage). If the animal is small enough, it can be transferred to a chamber for induction with inhalant anesthesia or the entire cage can be covered with a plastic bag and inhalant anesthetics can be administered. In the field, box traps are typically used to capture small- to medium-sized carnivores (Colón 2002; Mudappa & Chellam 2001). Trap success improves if traps are located near areas such as latrines where signs of activity have been recorded. Traps should be baited, but left locked open for several days before setting the trap to close, to habituate the animals (Mudappa & Chellam 2001). Many viverrids have nocturnal habits, so traps should be set at night and checked frequently to minimize the amount of time the animals spend inside. Checks can be less frequent if traps are equipped with devices that signal when they are triggered. Animals should spend minimal time in the traps because this can increase stress and thereby affect the quality of anesthesia, as well as increase the likelihood of self injury.

Disadvantages: When trapping animals in the wild, keep in mind the presence of potential predators that may attack and kill the trapped animal. Trap-related injuries may include self-mutilation, nose trauma, or traumatized digits and limbs. Free-ranging animals will not be habituated to squeeze cages and kennels and will be stressful; in the captive setting, it can also be stressful if the animals are not habituated (see advantages).

Handling Bag

Advantages: Animals can be transferred from a trap to a handling (burlap) bag prior to injection; this facilitates hand injection and decreases visual stimulation. Appropriate gloves (e.g., Kevlar®) should be used when handling the bag containing an animal.

Disadvantages: Any additional manipulation of the animal can increase the stress to the animal as well as the risk of escape or injury to the animal or personnel.

CHEMICAL RESTRAINT AND ANESTHESIA

Vascular Access

In many viverrids, the skin is thick, the hair is coarse, and subcutaneous tissue is abundant (especially in obese captive animals), all of which makes visualization of veins difficult.

Jugular Vein The preferred site for phlebotomy is the jugular vein due to its accessibility and the possibility of obtaining relatively large amounts of blood. The neck of viverrids tends to be cylindrical, rather than cone shaped. In binturongs, the jugular vein appears to be small relative to body size and is located more lateral than in dogs and cats, similar to ferrets. In overweight animals, it is difficult to palpate or visualize the jugular vein unless the head of the animal is held slightly below the body by briefly extending the head and neck beyond the edge of the examination table (the head should remain supported). This technique can put some additional pressure on the lungs, and it is important to evaluate the cardiorespiratory status of the animal before using it. Arterial oxygen saturation can be monitored with a pulse oximeter. If using an anesthetic combination that includes medetomidine, veins are best visualized and accessed within 20 minutes after drug administration (Moresco & Larsen 2003).

Cephalic Vein The cephalic vein is a valuable site for catheterization. In binturongs, the cephalic vein courses medially and it is often large enough to place a 20-gauge 3/4-in or 1-in IV catheter. This vein is visible after clipping hair and/or moistening with isopropyl alcohol.

Femoral Vein Frequently, the femoral vein is not visible, but can be found adjacent to the easily palpable femoral artery. It is not recommended as the primary site of venipuncture because the artery can be inadvertently punctured, which may lead to formation of a large hematoma. If the femoral artery is punctured, direct pressure should be applied for several minutes to minimize hematoma formation. If accessing the femoral vein, attempt to isolate the vein between two fingers and insert the needle perpendicular to the skin and vessel. Use a small gauge needle (23–25 gauge) to minimize vascular trauma. Some viverrids have large fat deposits in the hind leg, which may make it difficult to access the femoral artery and vein.

Saphenous Vein In binturongs, the saphenous vein can be accessed on the distolateral aspect of the hind leg over the tarsus, similar to its location in dogs. It can vary considerably in size between individuals.

Tail Vein In some viverrids, the tail vein can be accessed for small amounts of blood; however, it is not useful for drug administration. This vein can neither be seen nor palpated. The needle is inserted medially on the ventral aspect of the tail, perpendicular to the long axis; the needle is “walked” cranially, similar to the technique used in cattle. In binturongs, success is most likely when inserting the needle about 10 cm caudal to the tail base.

ENDOTRACHEAL INTUBATION

Endotracheal intubation of viverrids is not described in the literature, but it is generally straightforward because the mouth can be opened wide. In binturongs, the glottis is usually easily visualized and endotracheal tube insertion is similar to cats. In contrast to felids, there is minimal laryngospasm, so topical lidocaine is generally not needed. Due to the small size of the animals, it is important not to overinflate the cuff to avoid pressure necrosis. Since many viverrids are small in size, small internal diameter endotracheal tubes are needed, making it more likely that a small amount of saliva, blood, or foreign material can obstruct the tube. If intubation is not performed, nasal insufflation may be used for oxygen supplementation.

Preanesthetic Considerations

Preanesthetic considerations are similar to other small mammals. Similar to other members of the order Carnivora, viverrids have simple stomachs and relatively short gastrointestinal tracts; in some species, the cecum is absent or vestigial (Crapo et al. 2002; Mitchell 1905). In general, hind gut fermentation does not seem to be

significant despite the large amount of fruit consumed by some species (Mitchell 1905). They have correspondingly short gastrointestinal transit times and preanesthetic fasting periods of 24 hours are typically appropriate; water can be withheld for 4–8 hours.

Induction/Maintenance Protocols

Anesthetic induction is often achieved with injectable drugs. The most commonly used combinations include a dissociative agent (ketamine or tiletamine) and either an alpha-two adrenergic agonist (medetomidine or xylazine) or a benzodiazepine (diazepam or midazolam). Sometimes, an opioid (butorphanol) is added to further reduce the needed doses of other drugs.

The dissociative agent phencyclidine was successfully used in combination with promazine (a phenothiazine) in a large number of viverrids: *A. binturong*, *Arctogalidia trivirgata*, *Cryptoprocta ferox*, *Genetta genetta*, *Hemigalus derbyanus*, *Nandinia binotata*, *Paradoxurus hermaphroditus*, *Paguma larvata*, *Prionodon linsang*, *Viverra civetta*, *Viverricula indica*, and *Viverra zibetha* (Seal & Ericksson 1969). Although phencyclidine is no longer available in the United States, ketamine and tiletamine are other dissociative agents that are commonly used in viverrids. If dissociative agents are used alone, high muscle tone, persistent movement, rough inductions, and rough recoveries may occur (Seal & Ericksson 1969). These effects have been documented with phencyclidine use in viverrids and with the use of other dissociatives in other carnivore species. Therefore, the use of dissociative agents by themselves is not recommended. Instead, it is recommended to use a dissociative in combination with a sedative to improve muscle relaxation (see Table 43.2).

Table 43.2. Anesthetic drug combinations used in viverrids

Drug Combination (dose)	Species	Comment	Reference
Ketamine (10–15 mg/kg)	(1) Viverrids	(2) Induction: 3–15 minutes.	(1) Denver (2003)
Xylazine (1–2 mg/kg)	(2) <i>Paradoxurus jerdoni</i>	Recovery: 49–138 minutes.	(2) Mudappa and Chellam (2001)
Ketamine (3–8 mg/kg)	<i>Arctictis binturong</i>	Lower ketamine and higher medetomidine doses provide shorter recovery	Moresco and Larsen (2003)
Medetomidine (0.02–.06 mg/kg)			Klaphake et al. (2005)
Butorphanol (0.2–0.5 mg/kg)			
Ketamine (10 mg/kg)	Viverrids		Denver (2003)
Diazepam (0.5 mg/kg)			
Ketamine (10 mg/kg)	Viverrids		Denver (2003)
Midazolam (0.25–0.50 mg/kg)			
Tiletamine/zolazepam			
(1) 3–5 mg/kg	(1) Viverrids	(2) Induction: 15–20 minutes. Need redosing if excited, silence during induction. Recovery: 60–120 minutes. More docile in trap than <i>Arctictis binturong</i> or <i>Paguma larvata</i>	(1) Denver (2003)
(2) 5 mg/kg	(2) <i>Viverra tangalunga</i>		(2) Colón (2002) and Colon, pers. comm.
(3) 15 mg/kg	(3) Madagascar carnivores		(3) Louis, pers. comm.
Ketamine (17 mg/kg)	<i>Chrotogale owstoni</i>	Induction: 9 minutes, No vomiting, ↓ in body temp. Only HR and temp were monitored.	King (2002)
Acepromazine (0.73 mg/kg)			
Atropine (0.04 mg/kg)			
Ketamine (17.9 mg/kg)	<i>Viverra zibetha</i>	Induction: 11 minutes, No vomiting, Only HR and were temp monitored	King (2002)
Acepromazine (0.77 mg/kg)			
Atropine (0.04 mg/kg)			

The combination of ketamine-medetomidine-butorphanol has been successfully used for anesthetizing binturongs. Doses ranged from 2 to 8 mg/kg ketamine, 0.02 to 0.06 mg/kg medetomidine, and 0.2 to 0.5 mg/kg butorphanol; lower doses of ketamine were used with higher doses of medetomidine (Klaphake et al. 2005; Moresco & Larsen 2003). This combination worked well in binturongs, with good inductions, stable cardiopulmonary values, and fast, reversible recoveries. Ketamine-medetomidine-butorphanol has been used in African palm civets at similar dosages. Although ketamine-medetomidine-butorphanol is recommended as an anesthetic protocol in viverrids, there may be other combinations that offer more consistent inductions while retaining reversibility.

Ketamine (6 mg/kg) has been used in combination with a relatively high dose of xylazine (10 mg/kg) in the common genet (Palomares 1993). This combination used much lower doses than that reported for ketamine alone (66 mg/kg) (Maddock 1989). However, the actual doses used by Maddock varied widely, and 4 of 10 animals needed supplemental doses. In brown palm civets, 15 mg/kg of ketamine and 1.5 mg/kg of xylazine achieved greater induction success (Mudappa & Chellam 2001), see Table 43.2. Metoclopramide may be used during ketamine-medetomidine immobilization to counter vomiting associated with medetomidine administration (Moresco, unpublished data, 2002).

Acepromazine has also been used in combination with ketamine in viverrids (Fuller et al. 1990; Maddock 1989); however, acepromazine has a long duration of action and is nonreversible. One study in Owston's palm civets (*Chrotogale owstoni*) and large Indian civets (*V. zibetha*) used ketamine-acepromazine-atropine as a combination mixed in the bottle prior to administration (King 2002). Acepromazine was chosen to decrease the risk of vomiting, as had been reported with the use of xylazine (Mudappa & Chellam 2001; Streicher 2001). Inductions were relatively quick (~7–9 minutes) and no vomiting was observed; however, temperatures decreased substantially in spite of measures taken. No other adverse effects were noted; however, only temperature, heart rate, and recovery were evaluated. The main disadvantage of this combination is that acepromazine has a long duration of action, and that none of the drugs used are reversible.

Tiletamine-zolazepam has been recommended for several different species of viverrids, including *N. binotata*, *C. civetta*, *H. derbyanus*, *Viverris indica*, *F. fossa*, *Pag. larvata*, *V. zibetha*, and *Par. hermaphroditus*. Dosages used for these species range from 4 to 9 mg/kg (Kreeger 1999). Smaller species often require higher dosages, up to 12 mg/kg (McKenzie & Burroughs 1993).

Isoflurane can be administered via face mask as an induction agent to small species or young animals. For small- to medium-sized animals, chamber induction

can also be readily performed if adequate equipment is available.

Body Weights

See Table 43.1.

Monitoring

Ideally, heart rate, respiratory rate, temperature, blood pressure, oxygenation, ventilation (CO₂), and electrocardiogram (ECG) should be monitored during an anesthetic procedure. It is not always possible to monitor all these parameters. However, minimum monitoring equipment in captive as well as field settings should include a stethoscope for monitoring heart rate, cardiac rhythm, respiration rate, and lung field quality, as well as a thermometer for measuring temperature. Cardiac and respiratory function as well as mucous membrane color should be evaluated as soon as the animal is unconscious to assess physiologic stability before continuing with the procedure. Temperature should be taken frequently because the small species of viverrids are at increased risk for rapid loss of heat. A pulse oximeter can provide trends in oxygenation over the course of anesthesia. End tidal CO₂ (ETCO₂) measurements are useful to determine if the animal is properly intubated as well as to monitor ventilation. However, if the animal is small, some capnographs may have difficulty providing accurate readings.

Blood pressure can be profoundly affected by the initial excitement of capture and also by the drugs chosen. Combinations of ketamine with medetomidine have been reported to cause hypertension in canids and ursids (Caulkett et al. 1999; Larsen et al. 2002; Sladky et al. 2000). Since changes in blood pressure are difficult to assess clinically, a means of monitoring blood pressure contributes to the ability to improve the quality of the anesthesia. In animals that are subject to regular physical examinations, recording ECGs provides a baseline for that individual; additionally, in the case of viverrids, baseline ECGs would provide valuable data for the taxon as there are no such normal values published.

Recovery Considerations

The main consideration during an anesthetic event is safety for the animal and personnel. In cases where the animal needs to go back to a group or to fend for itself in the wild, it is important that animals are fully conscious and have good motor coordination.

During recovery, the animal should be in a quiet place and isolated from other animals, but where it can be observed as it recovers. The antagonists (if any) may be given after transport to the recovery area to ensure that the patient does not start to recover prior to it being contained. Animals should be monitored continuously until they have been extubated and they can lift their head. After extubation, visual monitoring can

be done at short intervals until the animal is standing, then at longer intervals until it is fully recovered. Although animals recovered in a quiet place may appear to take longer to recover than when stimulated, stimulating them into activity before the anesthetics have been fully metabolized results in activity that is uncoordinated and leads to unnecessary stress or injury.

Recovery should take place in a kennel, cage, or area from which the animal does not need to be moved once awake. Even for binturongs, the largest viverrid, a kennel can be used if the door can be opened with minimal risk to personnel. Food and water should not be provided until the animal is fully recovered.

Field Immobilization Considerations (Wild Capture)

Darting: When darting free-ranging animals, the period of time between the administration of drugs and recumbency is particularly dangerous because the animal is still ambulatory but has lost some motor coordination. If anesthesia is administered via dart, and the animal is not contained, they will attempt to escape. Many viverrids will climb trees, increasing the chance of escape or fall. It is important to make sure that the darting does not occur near water because sedated animals can easily drown if they fall into a pond, lake, or stream.

Monitoring: Similar to anesthesia in captive animals, safety of free-ranging animals and personnel should be key. Close monitoring of the patient allows for early detection of problems. There are now monitors that can provide heart rate, respiration rate, temperature, blood pressure, oxygenation, ETCO₂, and ECG in one machine, weighing less than 5 kg. With monitors this small, close monitoring of anesthetized patients is no longer restricted to a clinic. Because free-ranging animals cannot be fasted, the possibility of regurgitation should be considered and additional precautions to address regurgitation should be taken. In the field, age and health status of the animals are usually not known ahead of time so problems can arise once the animal is anesthetized; emergency drugs should be on hand and dosages should be calculated prior to induction.

Recovery: Release of the animal should only happen once the animal is fully recovered. Timing of the release should be such that the animal will still have enough time to find a safe area for sleeping. Release of diurnal animals should occur well before sunset. Conversely, release of nocturnal and crepuscular animals should be timed according to their behavior.

Postanesthetic Complications

Postanesthetic complications can occur due to the presence of undetected disease. Animals that have otherwise masked disease conditions decompensate due to the effects of anesthesia and may be affected by heart

failure, renal disease, or hepatic disease. Not only may these conditions contribute to physiologic problems but they may also change how anesthetic agents are metabolized.

Other things to consider are group dynamics when returning an animal to the group with which it is housed. Group dynamics can be altered by separation and reintroduction, with increased fighting occurring during reintroduction. This is less likely in viverrids that are housed in pairs. If returning to the wild, animals should always be returned to the same place they were captured. Releases should also happen only after complete recovery has occurred. Complications from premature release can include injury sustained from falling, drowning, or being predated. Animals should be held until the next day if they have not fully recovered in time for an appropriate release.

Hyenidae

Nina Hahn, John M. Parker, Gregory Timmel,
Mary L. Weldele, and Wm. Kirk Suedmeyer

INTRODUCTION

A breeding colony of spotted hyenas (*Crocuta crocuta*) was established at the University of California, Berkeley (UCB) in 1985 with wild cubs collected in Kenya. The spotted hyena was selected for research because of unique morphological and behavioral characteristics. Female spotted hyenas are larger than, and dominant to, males. They lack an external vagina, and instead have a hypertrophied, penis-like clitoris through which they urinate, copulate, and give birth. This makes them a useful research model in which to study the general mechanisms of sexual differentiation, and the differential development of morphology and behavior.

Colony management has included annual physical exams, which are always performed on anesthetized animals. Hyenas are also anesthetized for longer-term procedures including dentistry, diagnostic imaging, and surgery. They are also routinely immobilized to collect blood and measurements essential to research. Nearly 2000 anesthetic procedures have been performed in the over-20 years that the UCB colony has been existent, and no mortality has resulted from anesthesia. Unique characteristics of hyena anesthesia are outlined in the following chapter.

TAXONOMY AND BIOLOGY RELATED TO ANESTHESIA AND HANDLING

Hyenas resemble large canids, but because they belong to the suborder Feloidae (with cats and mongooses), they are more closely related to domestic cats (*Felis sylvestrus catus*) than dogs (*Canis familiaris*). Reports of hyena anatomy and physiology indicate similarities to cats as well as dogs in terms of retinal anatomy (Calde-

rone et al. 2003) and susceptibility to pathogens (East et al. 2004; Ferroglio et al. 2003; Hahn et al. 2003; Harrison et al. 2004; Troyer et al. 2005). Hyenas, however, are more cat-like in several ways including dentition as well as physiological responses to xylazine and ketamine (see discussion later).

It is therefore appropriate that veterinarians utilize physical anesthetic techniques suitable for large dogs, yet rely on domestic cat references for drug choices and dosages.

VASCULAR ACCESS AND SAMPLE COLLECTION SITES

Fore- and hind-limb veins are both readily accessible for catheterization (Fig. 44.1 and Fig. 44.2). The venous anatomy as it pertains to catheterization of the fore limb is comparable with that of the domestic cat (Fig. 44.1). Catheterization of the cephalic vein can be performed with the relative ease of that of a large dog. However, care should always be taken when positioning the catheter to avoid the extensive branching and anastomoses of the superficial fore-limb vessels (Fig. 44.1).

The jugular, cephalic, and saphenous veins are accessible for blood collection and cannulation. Sublingual vessels are prominent and can provide quick vascular access for electrolyte and blood gas analysis during anesthetic procedures. Arterial pulses can be palpated midline on dorsal metacarp; however, arterial cannulation has not been attempted by these authors. Cerebral spinal fluid can best be collected by cisternal puncture. The occipital protuberance, spinous process of axis, and wings of the atlas can be palpated in an intubated hyena despite the thick neck muscles.

Figure 44.1. Three photographs of the spotted hyena forelimb. (a) A hyena in left lateral recumbency. Note the right antebrachium for panel (b) orientation. (b) An *in situ* cranial–medial view from the level of midelbow to proximal carpus. Note the prominent superficial veins (visualization aided by manual occlusion). (c) The venous anatomy *in situ*. Only the skin and superficial fascia have been removed. In both panels (b) and (c), extensive anastomoses and bifurcations can be observed.

Figure 44.2. Catheter placement in the saphenous vein of a hyena.

RESTRAINT

Chemical restraint (anesthesia) is always necessary prior to performing any procedures on adult hyenas. Cubs less than 1 month of age can be manually restrained for examination and minor procedures such

as blood collection and vaccinations. Hyena cubs 2–6 months of age may be placed in a “squeeze-back” cage for hand injection with anesthetics as will be described later.

FIELD TECHNIQUES

The anesthetic procedures described for anesthesia in captive hyenas (see Captive Hyena Immobilization and Anesthesia) are also used in the field (Berger et al. 1992; Place et al. 2002). The most commonly used agent for immobilization in the field, however, is a combination of tiletamine hydrochloride and zolazepam hydrochloride (Telazol®, A.H. Robbins, Richmond, VA), given at an estimated dose of 6.5 mg/kg (K. Holekamp, pers. comm., 2005; Van Horn et al. 2004). For field use in hyenas, Telazol (500-mg vial) is reconstituted with 2.5 mL of diluent instead of the label-recommended 5 mL. The resulting solution provides 86.2 mg/mL of each, tiletamine and zolazepam (combined 172.4 mg/mL of Telazol). Adult hyenas receive 1.8–2.0 mL, subadults 1.4–1.6 mL, and cubs ~1 mL of this solution. The actual dose used is probably <6.5 mg/kg, and 5 mg/kg of Telazol is recommended for captive hyenas. Hyenas can be darted with either a blow pipe or a CO₂-powered

rifle. The blow pipe is only useful at distances of 1–5 m and only practical for animals that are very comfortable around the vehicle. It is always preferable to use the CO₂ rifle since it is silent and allows the dart to hit the animal with a smaller, less traumatic impact. Hyenas are darted in the early morning hours. They are allowed to recover in the shade and are attended until able to walk. The Telazol dose for field use has also been reported as 2.5 mg/kg (Harrison et al. 2004; Holekamp & Sisk 2003), but this is likely an error.

BODY WEIGHTS AND BLOOD VALUES

Adult colony-born female hyenas weigh 50 kg on average (range 49.5–90 kg). Adult males weigh slightly less than females, averaging 47.6 kg (range 44.5–54.5 kg). Serum chemistry, blood gas analysis, and complete blood count are similar to both cats and dogs (Table 44.1 and Table 44.2). Clot formation is frequently encountered in specimens treated with ethylenediaminetetraacetic acid (EDTA) and therefore heparin is the preferred anticoagulant.

Table 44.1. Serum chemistry ranges for captive adult spotted hyenas under KXA anesthesia

Serum Chemistry	Range	Units
Alk phos	14–136	U/L
ALT	65–162	U/L
AST	76–142	U/L
CK	149–419	U/L

ALT, Alanine transaminase; AST, aspartate aminotransferase; CK, creatine kinase; GGT, gamma-glutamyl transferase; BUN, blood urea nitrogen; A/G, albumin to globulin; A/C, albumin to creatinine; NA/K, sodium to potassium.

CAPTIVE HYENA IMMOBILIZATION AND ANESTHESIA

The anesthetic regime established 20 years ago at UCB remains the protocol of choice for captive hyenas. It consists of 4–6 mg/kg ketamine, 1 mg/kg xylazine, and 0.045 mg/kg atropine (KXA). The ketamine dose has been incorrectly reported as 10 mg/kg (Berger et al. 1992; Hahn et al. 2003). Hyenas 9 months of age and older are anesthetized using a reusable, air-charged dart/blow gun system prior to handling. Telinect and Daninject systems have both been used successfully at UCB.

Prior to darting, it is usually best to isolate the hyena in a small enclosure. Hyenas are fasted overnight prior to anesthesia. Xylazine appears to be an emetic in hyenas, as in cats (Plumb 2005), and they frequently vomit after successful darting.

The hind quarters are the preferred anatomic site for dart placement. The excitement preceding darting often induces pronounced side-to-side whipping of the hyena's neck. This precludes the neck/shoulder region from being the preferred target site. Hyenas appear to undergo segmental anesthesia following KXA inoculation delivered into hind quarters; loss of function is first evident in the caudal region (lumbrosacral region, pelvic limbs, and tail).

Mature hyenas are anesthetized with KXA utilizing 3 mL darts and drug preparations of 100 mg/mL ketamine, 100 mg/mL xylazine, and 15 mg/mL atropine. Dart preparation time can be safely performed by first

Table 44.2. Complete blood count ranges for captive adult spotted hyenas under KXA anesthesia

Blood Value	Range	Units
WBC	7200–23,200	Thous./ μ L
RBC	4.74–8.73	Million/ μ L
HCT	23–46.5	%
MCV	43–65	fL
MCH	14.4–22.5	pg

adding calculated doses of xylazine and atropine based on previous weights to the dart syringe, then adding ketamine to fill the remaining 3 mL volume (2.2–2.4 mL). Heavier hyenas will therefore receive a lower dose and will often need supplemental doses of ketamine (1–2 mg/kg) for full sedation. In contrast, low weight animals often require supplemental sedatives to counter the side effects associated with ketamine, such as rigidity and twitching. Intravenous diazepam (0.1–0.5 mg/kg) is commonly used for this purpose. When supplementing KXA anesthesia, diazepam causes a transient respiratory depression evident by prolonged periods of apnea. Subadult animals may not require the amount of ketamine needed to fill the dart to capacity. Less concentrated preparations of xylazine (20 mg/mL) and atropine (0.54 mg/mL) should be used for small cubs. Hyena cubs can be either hand or squeeze-cage restrained and drugs can be delivered via hand injection. Additionally, cubs generally require approximately 80% of the weight-calculated adult ketamine and xylazine doses. The previously stated adult dose of atropine, however, is used for cubs.

Hyenas must be muzzled upon immobilization, and when applicable, remained muzzled for duration of procedure when maintained on injected anesthetics. The bite response is not as readily abolished by ketamine anesthesia, as it is with dogs, cats, and primates. Jaw tone should be cautiously and properly assessed prior to endotracheal intubation.

Yohimbine (0.11 mg/kg), up to a maximum dose of 6 mg, is administered intramuscularly to reverse the xylazine at the conclusion of the procedure, at least 20 minutes after the last injection of ketamine. The time delay and route of administration decrease the likelihood of negative reaction due to the presence of ketamine.

Telazol (5 mg/kg) has been used successfully to anesthetize “ketamine reactors” (see discussion later) but was associated with a rough, prolonged recovery in the captive colony and therefore is not recommended.

ANESTHETIC MAINTENANCE

For long-term and major surgeries, hyenas are catheterized, intubated, and maintained on isoflurane anesthesia (1–2%) after darting with KXA, as described earlier. Yohimbine given after isoflurane stabilization may help prevent xylazine-induced adverse effects such as bradycardia, respiratory depression respiratory, and loss of thermoregulation, as will be described later.

Intubation of the hyena can be performed using a size 11–12 endotracheal tube with the relative ease of a large dog. The hyena is best intubated while in sternal recumbency. The larynx is easily visualized through the mouth using a large-bladed laryngoscope. Unlike cats, laryngeal spasm during intubation has not been observed.

ANALGESIA

Analgesia is always provided following major surgeries and dental procedures. Buprenorphine (0.01 mg/kg SQ or IM) is administered at the time of intubation and repeated following the end of surgery. If additional analgesia is indicated, 10 mg/kg etodolac (Etogesic®) is administered orally once daily in food. No ill effects have been observed in any hyena receiving etodolac, including one hyena given 9 mg/kg daily for 1 month. Meloxicam (0.2 mg/kg SQ) has been used for endodontic procedures. It is given once at the completion of the procedure.

COMPLICATIONS

Xylazine frequently induces emesis, pronounced bradycardia, and loss of thermoregulation in hyenas. Atropine is included to reduce salivation typical of ketamine and offset bradycardia associated with xylazine administration. Aspiration of regurgitate was noted on necropsy in one geriatric animal (21 years old) with biliary carcinoma following immobilization with KXA, but aspiration following KXA administration has never been a clinical problem in hyenas. As a precaution, however, hyenas are always fasted prior to immobilization.

Hyenas' eyes remain open after ketamine administration, as do cat eyes (Plumb 2005), and should always be treated with ophthalmic lubricant (e.g., Lacri-lube®). Prolonged apnea is noted infrequently following bolus diazepam and ketamine/diazepam administration as occurs in cats.

Hyperthermia in response to KXA administration has been observed. Care is taken to avoid darting during hot weather, but hyperthermia has been noted on days when ambient temperature is not a contributing factor. Hyperthermia has been attributed to agitation and increased activity prior to darting; however, this may be a response to ketamine as has been observed in cats (Plumb 2005). Xylazine causes loss of thermoregulation in many animal species (Plumb 2005) and this may also contribute to hyperthermia in anesthetized hyenas.

Very rarely, respiratory depression after KXA administration is noted. Reversal of the xylazine with yohimbine will correct this. Heart rates as low as 48 beats/minute are often observed, but as clinical outcome for these animals is no different from animals with higher heart rates, this has been attributed to the effects of xylazine and considered normal. Systolic heart murmurs have been occasionally identified during physical exam under KXA anesthesia. Follow-up cardiac ultrasound examinations identified a decrease in ventricular myocardial contractility in the three animals examined. This was attributed to the xylazine component of the anesthetic combination and not considered clinically significant.

There are two types of adverse reaction to KXA anesthesia that have been observed. Some hyenas display tonic-clonic-like movements and extensor rigidity after KXA administration. This response is not uncommon in male hyenas. Male hyenas weigh on average less than female hyenas and therefore may receive the high end of the 4- to 6-mg/kg ketamine range when following the UCB KXA protocol. The adverse ketamine reaction observed in these hyenas may be due to the ensuing relatively high ketamine to xylazine ratio. This reaction may be similar to what has been described in captive macaque monkeys (*Macaca mulatta*), which undergo frequent exposure to ketamine anesthesia. In macaques, ketamine causes varying degrees of muscle rigidity in susceptible individuals. These animals may have a tonic-clonic or psychotomimetic response to the administration of ketamine (UC Davis Veterinary School, Clinical Medical Primatology lecture notes). Cats also demonstrate “myoclonic jerking and/or tonic/clonic convulsions” (package insert of Ketaset®) with ketamine administration.

Two male hyenas (brothers with the same parents but from different litters) developed generalized seizures after KXA administration. They both had been anesthetized with KXA numerous times. Both of these animals developed generalized seizures when anesthetized with KXA in their fourth year. Prior to having seizures, neither of these two animals demonstrated the tonic-clonic movements as described earlier. Hyenas at the UCB colony are routinely immobilized for research purposes seven times the first year, four times the second year, twice the third year, and yearly thereafter. Seizures have been reported to occur in 20% of cats anesthetized with therapeutic doses of ketamine (Plumb 2005). Ketamine is known to be epileptogenic (Plumb 2005), and there may be individual susceptibility to the effects of ketamine in hyenas, but the mechanism of both the seizure activity and tonic-clonic movements are purely speculative.

Diazepam (0.5–1 mg/kg IV to effect) will eliminate seizures as well as tonic-clonic muscle activity in hyenas. Diazepam should always be kept close at hand when anesthetizing hyenas.

RECOVERY

Hyenas are placed in a straw-bedded, enclosed cage for postsurgical recovery. Animals are allowed to fully recover from anesthesia prior to being reintroduced to cage mates. After short-term procedures using xylazine reversal, this can generally be within 1–2 hours of anesthesia. In longer term or major surgical procedures when xylazine reversal is not used, or if opioid analgesics are used, hyenas are allowed overnight recovery prior to reintroduction to cage mates. After laparotomy hyenas are kept separate from cage mates for up to 2 weeks.

DISEASE ISSUES (AFFECTING ANESTHESIA)

Acute and peracute pain has dramatic effects on dosage requirements and induction time. Beyond this, there are no known disease issues that affect anesthesia in hyenas.

FIELD IMMOBILIZATION OF THE BROWN HYENA (*HYAENA BRUNNEA*) IN NAMIBIA

Wm. Kirk Suedmeyer

Few references for field immobilization techniques of the brown hyena are reported in the literature. An understanding of the natural history and habits facilitates successful capture. Health assessment, placement of tracking devices, evaluation of reproductive status, and morphometric measurements are only accomplished by immobilization (Fig. 44.3).

The brown hyena is a nocturnal, cautious, silent, and solitary forager (Estes 1992; Mills 2003; Nowak 1991). However, large carcasses will attract several hyenas. As opposed to the spotted hyena (*C. crocuta*), brown hyenas generally feed singly, rather than as groups, even on larger carcasses; individuals will wait patiently in the distance until a conspecific finishes. In most instances, black-backed jackals (*Canis mesomelas*) will arrive at the site first; vocalization and activity of larger groups of jackals may attract hyenas to the location. Jackals will commonly telegraph a hyenas approach by nervously looking in the direction of the approaching animal. In some areas, hyenas disperse jackals from the site, whereas in other locations, jackals antagonize hyenas from the carcass. Use of camouflage, a low profile silhouette, and absolute stillness are paramount to success. The field marksman should be in

Figure 44.3. A GPS collared brown hyena (*Hyaena brunnea*) inadvertently disturbed from its daytime den. Brown hyenas are rarely observed during daylight hours.

place prior to sunset as brown hyenas are very aware of movement and changes in the environment. Utilization of enhanced lighting in the form of infrared technology facilitates darting during moonless nights. Dart placement is key to efficient immobilization. Commercially available remote delivery systems work well. A well-aimed dart placed in the shoulder or neck affords consistent success. Patience is necessary to predict the stance of the hyena while feeding. Carcasses should be placed in a position that encourages the hyena to present a lateral profile. Use of a centrally located, secured carcass with a peripheral, spoke-wheeled scent trail improves chances for success. The strength of hyenas should not be underestimated. Adult hyenas have been observed carrying entire carcasses of freshly killed Cape fur seal pups (*Arctocephalus pusillus*) (Wiesel 2010), removing springbok (*Antidorcas marsupialis*), and large carrion away from dart sites. Carcasses must be secured with 1–2m posts driven deeply into the ground. Hyenas will carry carcasses to more secure locations if they can.

A combination of 3–4mg/kg of ketamine hydrochloride with 0.035–0.045mg/kg of medetomidine hydrochloride provides effect within 3 minutes and recumbency within 7 minutes on average. It is advisable to use either telemetry darts, and/or allow several minutes before attempting to locate the immobilized animal as brown hyenas are prone to running for extended distances if startled. The initial response is a sudden gallop from the dart site, followed by circling back to the general area as the drugs take effect. In most instances, the hyena can be located less than 50 yards from the initial site. On occasion, an anesthetized hyena may require 30–40mg of supplemental ketamine hydrochloride given intramuscularly to facilitate complete recumbency. This combination provides good muscle relaxation, stable heart rate and rhythm (although bradycardia is commonly encountered; heart rates average 40–60 beats/min), slight to moderate ptialism, and 40–50 minutes of stable anesthesia. Rectal body temperatures with this combination average 1000°F.

Atropine sulfate should not be utilized to control ptialism, as it counters the alpha adrenergic effects on peripheral vasoconstriction and can lead to complications. Initial hypoxia (<75% pulse oximetry) is routinely observed but improves over time. In most instances, brown hyenas achieve pulse oximetry readings of >90% after 20–30 minutes of anesthesia. Supplemental oxygen should be provided if available. Application of a bland ophthalmic ointment protects the eyes during times of blowing sand. Covering the eyes and placing plugs in the ear canal also lessens ocular and aural stimulation, which, in turn, provides consistent recumbency (Fig. 44.4). Reversal is achieved with atipamezole hydrochloride at five times the milligram dose of medetomidine induction. Atipamezole

Figure 44.4. A brown hyena (*Hyaena brunnea*) anesthetized with ketamine HCl and medetomidine HCl in Namibia. Note the aural plugs, pulse oximetry, and substrate barrier.

Figure 44.5. A brown hyena (*Hyaena brunnea*) shortly after reversal with atipamezole. Note the position of the head and cervical spine just prior to standing.

given intramuscularly produces smooth, reliable recovery within 5–10 minutes. Blepharospasm, followed by purposeful movement of the head and cervical spine, is a prelude to rapid recovery to standing within minutes (Fig. 44.5).

In general, the hyena stands then canters away with mild ataxia, which rapidly resolves to normal ambulation within an additional 3–5 minutes. It is advisable to remotely monitor the response to full recovery as black-backed jackals can antagonize and injure the hyena unless it is fully recovered (Fig. 44.6).

Use of ketamine/medetomidine produces, safe, reliable, and predictable results of the brown hyena in field situations and may be a suitable combination for captive anesthetic approaches.

Figure 44.6. An anesthetized brown hyena (*Hyaena brunnea*) immediately after reversal with atipamezole. Note the encroachment by a black-backed jackal (*Canis mesomelas*), which can injure recumbent hyenas.

Felids

Edward C. Ramsay

INTRODUCTION AND TAXONOMY

There are 38 species in the family Felidae and general agreement surrounding the taxonomy of the large felids, cheetah, and clouded leopard (Nowak 2005). The genus *Panthera* contains all the large cats: lions (*Panthera leo*), tigers (*Panthera tigris*), leopards (*Panthera pardus*), snow leopards (*Panthera uncia*), and jaguars (*Panthera onca*). The cheetah, *Acinonyx jubatus*, and the clouded leopard, *Neofelis nebulosa*, are the sole member of each respective genus. There is considerable controversy over the taxonomy of the smaller felids, but most small felids have been grouped, by some, in the genus *Felis*. *Felis* species range in size from the black-footed cat, *Felis nigripes* (body weight of 1.5–2.75 kg) to the cougar, *Felis concolor* (body weight of 36–103 kg). The large felids range in size from leopards (28–90 kg) to tigers (100–306 kg) (Nowak 2005).

Regardless of size or taxonomy, all adult members of the family Felidae require chemical restraint for performing a thorough physical examination and gathering samples. While some species and individuals can be trained to allow obtaining blood or other biological samples while awake (Fig. 45.1), chemical immobilization is the norm. Relatively little research has been done on small felids, but there are many reports on immobilization of the larger felids, particularly tigers, lions, leopards, and cheetahs. Additionally, the majority of the immobilization literature is based on studies of captive cats. As a result, the information in this chapter is heavily biased toward information on captive, large felids.

ANATOMY RELATED TO IMMOBILIZATION AND ANESTHESIA

The anatomy of nondomestic felids is very similar to domestic cat anatomy, such that virtually all routine

clinical procedures and techniques can be based on those used in domestic cats. Once immobilized, blood is most easily obtained from the jugular veins or the medial saphenous veins distal to the knee. These vessels are easily visualized after the overlying fur is clipped. These veins are also useful for intravenous injection and placement of intravenous catheters. Tail veins, located dorso-laterally at “10:00 and 2:00” on the tail, can be used to obtain blood samples or for administration of supplemental immobilization drugs. They can be difficult to visualize, even with the fur clipped. The femoral veins can also be used for blood collection, especially in animals where the hair cannot be clipped, but this vessel is not easily visualized and somewhat difficult to catheterize. The cephalic vein is accessible for blood collection and drug administration in some species, but it is difficult to visualize in large felids, even after clipping the hair. Dorsal pedal arteries or femoral arteries are most commonly used to obtain arterial blood samples.

PHYSICAL RESTRAINT

Some individuals of small felid species and young larger species (<10 kg) can be netted for injection by hand, but the safety of this method depends on the attitude of the individual cat, the skill of the netter, and the setup of the enclosure or room. It is preferable to transfer the animal to a small cage or squeeze cage for injection. Squeeze cages are useful for physical restraint of all felids, but even these cages do not allow much more than hand injection of drugs. As with any squeeze cage, the operator should not attempt to squeeze the cat until it is completely immobilized, as the possibility for injuring the animal increases as greater pressure is exerted. Ideally, a squeeze cage should be used to bring

Figure 45.1. Voluntary blood draw in a tiger. This tiger is trained to get into a small cage and lie down. The tail of the animal is pulled through the bars or a small opening in the cage and the veterinary technician is able to take a blood sample from the tail vein. The trainer is located at the front of the animal and rewards verbally and with food.

the animal into close enough proximity to permit safe hand injection.

TRANQUILIZATION OR PREMEDICATION

Benzodiazepines

Diazepam and midazolam are the two benzodiazepines most commonly used for tranquilization of nondomestic felids. Both drugs are also used to treat seizures and may be selected for use in cats prone to seizures while immobilized.

Diazepam is variably absorbed when given intramuscularly and thus should be given either orally or intravenously. Oral diazepam can be used as premedication, administered 1–3 hours before immobilization. Repeated dosing of diazepam has been reported to cause idiopathic hepatic toxicity in domestic cats (Center et al. 1996). This problem has not been observed in nondomestic cats, but most clinicians use oral diazepam for short periods (the day before and/or the day of immobilization) in nondomestic felids. Oral diazepam dosages of 0.15–0.46 mg/kg (20–60 mg/adult tiger or lion) have been used for premedication with good effect in large cats. Intravenous doses are typically 0.08–0.15 mg/kg (10–20 mg/adult tiger or lion).

Midazolam has largely replaced diazepam in clinical practice because of its more predictable intramuscular absorption. Although only available in the United States as an injectable agent, the injectable preparation can be given orally as a premedication or added to other agents in a dart. Typical dosages for premedication for a tiger are 0.08–0.14 mg/kg (15 mg/adult tiger or lion), PO or IM. A similar dosage is used during

induction protocols (Curro et al. 2004). In people, midazolam has amnesic properties and whether this is true in nondomestic felids is not known. If it does have some amnesic properties, this would be an added benefit of using midazolam in immobilization combinations.

OTHER TRANQUILIZATION AGENTS

Relatively few other tranquilizing agents are used in nondomestic felids. A trial of two long-acting tranquilizers, perphenazine enanthate and zuclopenthixol acetate, used separately and together, in cheetahs showed perphenazine enanthate (3.0-mg/kg deep IM) significantly reduced the cats' behavior for days 1–6 post injection (PI) (Huber et al. 2001). Perphenazine enanthate treated cheetahs returned to normal behavior patterns by day 14 PI. Zuclopenthixol acetate at 0.6 mg/kg produced profound adverse effects (inappetence, ataxia, extrapyramidal effects), and the authors felt it "should not be used in cheetahs" (Huber et al. 2001).

INDUCTION AND CHEMICAL IMMOBILIZATION

Safety

All nondomestic felids are capable of harming, potentially mortally, those working with the cat. Every cat should, following administration of immobilizing drugs, remain restrained, either in a cage, squeeze cage, or box, until it is ascertained that the animal is sufficiently obtunded. In the author's practice, cats are assessed for depth of anesthesia by monitoring an ear twitch reflex. Using a stick or similar item (pole syringe, rake handle, etc.), the hair inside the ears is brushed and ear movement noted. No cat that moves its ear following stimulation should be handled. Wait and/or administer supplemental drugs if the anticipated induction time has passed. Additionally, supplemental ketamine should always be carried with an immobilized nondomestic cat wherever it is outside of a cage or exhibit. If an animal begins to move or awaken, an immediate injection of 1- to 3-mg/kg ketamine, IM or IV, should be administered.

Ketamine Hydrochloride

Ketamine HCl is the most common immobilization agent used in nondomestic felids and has proven itself safe and effective in a wide variety of species (Table 45.1 and Table 45.2) (Armstrong et al. 1996; Deem et al. 1998; Grassman et al. 2004; Jalanka & Roeken 1990; Kolata 2002; McKenzie & Burroughs 1993; Tomizawa et al. 1997). In smaller species or small individuals, ketamine can be used alone for chemical immobilization. In larger species, complete and satisfactory immobilization with ketamine alone may not be possible due to the adverse effects seen with greater dosages, such

Table 45.1. Dosages for immobilization agents used in large nondomestic felids (*Panthera* spp.) and cheetahs (*Acinonyx jubatus*)

Species	Agents	Dosages (Reversal Agents and Dosages)	Reference	
Cheetah	Ketamine + medetomidine	2.5 mg/kg + 50–70 µg/kg (atipamezole 0.3 mg/kg [25% IV/75% SC])	Klein and Stover (1993)

as seizures (Taylor et al. 1998). For these animals, ketamine is typically combined with an alpha-2 adrenergic agonist, benzodiazepine, and/or an opioid.

Ketamine inductions are usually smooth and rapid but can be stormy if an inadequate initial dose is given, either due to poor dart placement or to partial dart discharge. Felids immobilized with ketamine alone, and with some ketamine combinations, will keep their eyes open, retain palpebral reflexes, and have poor muscle relaxation. Maintaining a low amount of environmental stimulation (i.e., darkening the room, decreasing noise) during induction, immobilization, and recovery, regardless of the agent or combination of agents given, will benefit the patient. Supplemental doses of ketamine (Table 45.2) can be given IM or IV to animals immobilized with ketamine alone and with most immobilization drug combinations (Curro et al. 2004; Epstein et al. 2002). There is no reversal agent for the effects of ketamine; however, ketamine immobilizations, in dosages typically used in felids, are generally short (20–45 minutes). Felids recovering from ketamine alone may be stormy, that is, display ataxia, falling, and hallucination-like behavior.

In the United States, ketamine is commercially available in a 100-mg/mL concentration. At this concentration, large volumes (>5 mL) may be required to immobilize a very large cat, such as a Siberian tiger. More concentrated ketamine (200 mg/mL) can be compounded, and many practitioners prefer this concentration as it permits smaller injection volumes. Limited

availability in the United States and issues with crystals forming in the vials, causing concern about actual concentration of preparation, have caused the author to rely on the 100 mg/mL product.

Ketamine plus an alpha-2 adrenergic agonist is the most commonly used drug combination for nondomestic felid immobilization (Table 45.1 and Table 45.2). A great advantage to the addition of an alpha-2 adrenergic agonist is their effects can be reversed with an alpha-2 antagonist (see discussion later), greatly shortening recovery times and improving the safety of the immobilization. While protocols vary, the author and others prefer to initially inject the cat with an alpha-2 agent, possibly in combination with or following premedication with midazolam. Once the animal is sedated, then ketamine is administered (Armstrong et al. 1996; Curro et al. 2004). The alpha-2 agents do not appear to cause intense irritation when injected, such as occurs with ketamine injections, and once the cat is sedated, it will frequently not respond to injection of the ketamine.

Ketamine/medetomidine combinations in felids are probably the most widely used induction “cocktails” in the past decade. A variety of dosages have been reported, with ketamine dosages ranging from 1 to 6 mg/kg and medetomidine dosages of 20–60 µg/kg (Table 45.1 and Table 45.2). The dosage of each tends to change inversely, that is, as dosages of medetomidine are increased, dosages of ketamine are decreased. Sumatran tigers may be more susceptible to effects of medetomi-

*Dosages for immobilization of wild felids.

dine than others (Table 45.1) (Forsyth et al. 1999). Ketamine/medetomidine inductions and recoveries tend to be more rapid than those in cats immobilized with ketamine/xylazine (Curro et al. 2004; Schumacher et al. 1999). Midazolam or butorphanol can be added to ketamine/medetomidine combinations to smooth inductions and recoveries, and prolonged sedative effects (Curro et al. 2004; Ketz-Riley et al. 2003; Langan et al. 2000).

Ketamine/medetomidine inductions are rapid (3–11 minutes) when the drugs are given together, and cats typically become deeply sedated. Vomiting during induction and transient apnea immediately following induction are the two most commonly observed adverse effects (Curro et al. 2004). Occasionally, decreased

respiratory rates persist during immobilization, especially at greater medetomidine dosages. Medetomidine effects can be reversed with atipamizole (see discussion later).

Medetomidine is a racemic mixture of dextro- and levo-medetomidine, with both enantiomers present in equal proportions. It was previously commercially available in the United States as Dormitor®, a 1-mg/mL product, but this has recently been withdrawn from the US market. More concentrated medetomidine preparations (10–40 mg/mL) remain available from compounding pharmacies in North America. Dexmedetomidine (Dexdormitor®, Pfizer, Inc., New York, NY) contains only the active dextro-enantiomer of the medetomidine and is now marketed in the United States for use

in dogs and cats. It is available as a 0.5-mg/mL solution, making the volume of Dexdormitor used in immobilization cocktails the same volume as that previously used for Dormitor. Recent work in cheetahs and the author's experience indicate that one can directly substitute the volume of Dexdormitor for the volume of Dormitor previously used in immobilization combinations (Gunkel & Lafortune 2007).

Ketamine/xylazine combinations have been used to immobilize a wide range of captive and wild felids for many years. Because xylazine is the oldest alpha-2 sedative, a considerable body of information has been accumulated on its use in nondomestic felids (Table 45.1 and Table 45.2) (Beltrán & Tewes 1995; Ferraras et al. 1994; Greer et al. 2003; Sabapara 1995). Similar to ketamine/medetomidine combinations, dosages for each agent vary widely, with very large ketamine dosages (up to >20 mg/kg) used effectively in wild, small cat species (Grassman et al. 2004). Because of xylazine's profound cardiovascular effects, it has largely been replaced in immobilization combinations with medetomidine or dexmedetomidine.

Some species-specific dosage sensitivities have been noted with the ketamine/xylazine combinations. Captive Sumatran tigers (*Panthera tigris sumatrae*) appear to have a profound sensitivity to xylazine at dosages greater than 0.2 mg/kg, when given in combination with ketamine. At greater xylazine dosages, a number of Sumatran tigers show profound respiratory depression (Armstrong et al. 1996). South Chinese tigers (*Panthera tigris amoyensis*) show a gender difference in their susceptibility to ketamine, with females requiring considerably greater dosages than males, when ketamine is administered with xylazine (Table 45.1) (Armstrong et al. 1996). A similar phenomenon has been observed in wild bobcats, with females requiring 50% more ketamine per kilogram than males (Beltrán & Tewes 1995). Seizures have been reported in several species immobilized with ketamine/xylazine combinations and seem most common in tigers (Armstrong et al. 1996; Ferraras et al. 1994; Grassman et al. 2004; Quigley et al. 2001; Seal et al. 1987). Vomiting is also commonly observed in cats receiving combinations containing xylazine (Armstrong et al. 1996).

Ketamine and detomidine combinations have been used rarely in nondomestic felids. Orally delivered detomidine in combination with ketamine has been used as premedication in domestic cats, servals, and lions (Grove & Ramsay 2000; Ramsay et al. 1999). Large dosages, 0.5 mg/kg, combined with ketamine (6.7–11.4 mg/kg) squirted into the cats' mouths, reliably produced sedation and sternal or lateral recumbency in domestic cats and servals. This combination was less reliable in producing recumbency in the lions evaluated. Oral detomidine alone (0.5 mg/kg) routinely produced sternal, but not lateral, recumbency when used as a premedication in tigers (Ramsay et al. 1999). The

most common adverse effects of orally delivered detomidine or detomidine/ketamine were vomiting, salivation, and sinus bradycardia.

Ketamine and diazepam combinations have been used for immobilization of a few nondomestic felids (Epstein et al. 2002; Ofri et al. 1998; Sabapara 1995; Taylor et al. 1998). Large dosages of ketamine (20 mg/kg) were required initially, before lions could be supplemented with additional ketamine (5 mg/kg) IV and diazepam (0.5 mg/kg) IV (Ofri et al. 1998). The large injection volumes required, coupled with the variable absorption of the diazepam, generally prevent people from using this combination.

Tiletamine/Zolazepam

The combination of tiletamine, a dissociative agent, and zolazepam, a benzodiazepine, has also been used in a wide variety of felid species (Bush et al. 1978; Grassman et al. 2004; McKenzie & Burroughs 1993; Meltzer 1999; Schumacher et al. 2003; Smeller & Bush 1997). As an investigational drug, this combination was called CI744. In North America, this combination is marketed as Telazol[®] (Fort Dodge Animal Health, Fort Dodge, IA) and in other areas of the world as Zoletil[®] (Virbac Laboratories, Carros, France). For convenience, all three of these products will be referred to as Telazol in this chapter.

Telazol is marketed as a powder and is intended to be reconstituted with sterile water to produce 50-mg tiletamine and 50-mg zolazepam/mL; in routine usage, its concentration is typically identified as 100 mg/mL. This preparation is fairly potent, when compared with 100-mg/mL ketamine, and allows for small injection volumes. As a result, Telazol has been favored by some field researchers (Grassman et al. 2004; McKenzie & Burroughs 1993; Rabinowitz 1990). Telazol can also be reconstituted with less water or with another agent(s) to produce a more potent preparation. For example, the reconstitution of a bottle of Telazol with 400-mg (4.0 mL) ketamine and 100-mg (1.0 mL) xylazine is a preparation which has been used for cheetah immobilization (Lewandowski et al. 2002).

Telazol can be used alone or in combination with alpha-2 adrenergic agonists. When used alone, Telazol has a slightly faster induction time than ketamine alone and a longer duration of effect. Immobilizations with Telazol typically result in better muscle relaxation than those where only ketamine is used, but recoveries can be prolonged and stormier than ketamine recoveries.

For many years, it has been a common practice to avoid Telazol in tigers, as early reports of adverse effects (neurological signs, behavior changes, death) developed into the dogma that Telazol is contraindicated in tigers (Armstrong et al. 1996; Wack 2003). A recent reexamination of the literature regarding use of Telazol in tigers suggests that, while adverse effects may occur,

the scientific literature does not support its contraindication in tigers (Kreeger & Armstrong 2010).

Telazol/medetomidine combinations have been used in a number of felids species, but recent reports on their use are rare (Deem et al. 1998; Roken 1997). Telazol combined with ketamine and xylazine or only ketamine for felid immobilization has also been reported (Lewandowski et al. 2002; Taylor et al. 1998). The latter combination was the preferred drug combination for field immobilization of Florida panthers (Taylor et al. 1998).

A FULLY REVERSIBLE INJECTABLE COMBINATION

A medetomidine-butorphanol-midazolam combination has been studied and found useful for short procedures (<40 minutes) in cheetahs (Lafortune et al. 2005). Sudden early arousals were observed in that study. The prime advantage of this combination is that each component has a reversal agent, and thus immobilization can be fully reversed. This could be an advantage for fieldwork, where quick recoveries times speed the release of an immobilized cat. Additionally, such a combination could be more easily used in range countries where dissociative agents may be difficult to obtain or import (D. Armstrong, pers. comm., 2009).

INTRAVENOUS INDUCTIONS

Few awake nondomestic felids will allow intravenous injections, and cheetahs appear to be the only species where this approach has been routinely used (Meltzer 1999). South African veterinarians and managers have developed a restraint cage that allows intravenous induction of cheetahs using Saffan[®], a combination of two steroidal anesthetic agents: alphaxolone and alphadolone. This preparation produces rapid immobilization and sufficient relaxation to permit electroejaculation (Meltzer 1999). Saffan was not available in North America and appears not to be manufactured anymore. A new product Alfaxan[®] (Jurox Pty. Ltd., Rutherford, NSW, Australia), containing only alphaxalone, has recently become available in Canada.

SUPPLEMENTATION OF INJECTABLE AGENTS

Ketamine and midazolam are the two injectable drugs most commonly used to supplement or extend immobilization in the author's practice. Ketamine, at doses of approximately 1 or 2–3 mg/kg, can be given IV or IM, respectively, to extend immobilization for brief periods. Similar doses can be given during inhalation anesthesia, should decreased blood pressure or respiratory depression occur and it is desirable not to decrease the amount of the inhalant agent. Midazolam at doses

of 0.08–0.14 mg/kg (15 mg/adult tiger or lion) IM or IV can also be used for prolonging immobilization, but its effects are not as profound as those of ketamine. Although administering additional Telazol has been recommended in one report (Roken 1997), the author avoids administering supplemental Telazol or giving additional alpha-2 agonists during immobilization.

Propofol has also been used to complete induction or prolong immobilization in a number of nondomestic cats induced with other agents (Burgos-Rodriguez et al. 2004; Epstein et al. 2002; Galloway et al. 2002). Most commonly, cats had been induced with ketamine and medetomidine, and propofol (1–2 mg/kg IV) was administered to facilitate endotracheal intubation or provide additional relaxation for a short procedure, such as a bandage change. Potential disadvantages of using propofol in large felids are apnea, cardiovascular effects, and the risk of rapid, full recovery of a dangerous animal.

INHALATION AGENTS

Isoflurane in oxygen is commonly used for inhalation anesthesia in nondomestic felids. Isoflurane can also be used for chamber anesthetic induction of small cats, in either a specially built induction chamber or by encasing a carrier or small cage in a plastic bag. Typically, 5% isoflurane with high oxygen flow rates are used for chamber inductions, and some cats take a considerable amount of time to become safe to handle. Following the cat's removal from the chamber, anesthesia can be continued with isoflurane administered via face mask or endotracheal tube.

For any long procedures, endotracheal intubation and maintenance on isoflurane in oxygen are preferred to repeated supplementation of injectable agents. The muzzle of cats is relatively short and the larynx is found at the base of the tongue, allowing for easy endotracheal intubation of most felids. Intubation rarely requires numbing of the larynx. In small felids, traditional small animal endotracheal tubes can be used. Adult lions' and tigers' tracheas are large in diameter and typically require large animal/equine endotracheal tubes (interior diameters of 18–24 mm). Intubation is greatly assisted by the use of a long laryngoscope blade and a rigid stylet, placed within the tube. Large animal endotracheal tubes are designed for animals with longer necks, so care must be taken to prevent endobronchial intubation.

ANTAGONIST OR REVERSAL AGENTS

Benzodiazepine Antagonists

Flumazenil is the only benzodiazepine antagonist widely used in zoological medicine. It can be used to reverse the effects of diazepam or midazolam, such as when rapid reversal in the field is desired. In captive

settings, however, many clinicians prefer not to reverse the benzodiazepines and retain their calming effects to “smooth” recoveries. Flumazenil can also be used to speed recovery of an animal immobilized with Telazol. One study of flumazenil (31 µg/kg IM) and sarmazenil (0.1 mg/kg IM), another benzodiazepine antagonist, in cheetahs showed administration of each decreased recovery times, and improved (smoothed) recoveries (Walzer & Huber 2002).

Alpha-2 Adrenergic Antagonists

Yohimbine and atipamizole (Antisedon[®], Pfizer, Inc., New York, NY) are used to reverse the effects of xylazine and medetomidine (or dexmedetomidine), respectively. A number of yohimbine dosages have been used, but most are in the range of 0.1–0.125 mg/kg. An even wider range of atipamizole, dosages have been reported, but all are based on the amount of medetomidine administered. Typically, atipamizole is administered at two to five times the medetomidine dosage, with the lower end of that range more commonly reported from Europe, and the upper limit of that range being that recommended by the US manufacturer. Following long procedures or anesthetics (>2 hours), some clinicians will not administer an alpha-2 antagonist or will administer only a portion of the dosages discussed earlier.

Many routes of administration have also been used, including combinations of IV and IM or SC (Deem et al. 1998; Jalanka & Roeken 1990; Klein & Stover 1993; Lafortune et al. 2005; Lewandowski et al. 2002; Schumacher et al. 1999). In the author’s practice, IM or SC administration of yohimbine and atipamizole is preferred. Occasionally, during ketamine-medetomidine-isoflurane immobilization/anesthesia of a lion or tiger, hypotension or hyperkalemia can occur. If this happens, the clinician may elect to give a portion of the atipamizole reversal dose. Typically 2.5- to 5.0-mg atipamizole is administered, either IV or IM. This should be done only when the animal is intubated and well controlled under inhalant anesthesia.

MONITORING

Routine monitoring of felid chemical restraint should include serial body temperature, pulse, and respiration measurements, and continuous hemoglobin saturation monitoring via pulse oximetry (Fig. 45.2). Long procedures or cool weather can result in a dramatic decrease in body temperature, and regular measurement of body temperature is especially required in these situations. Measuring body temperature just before allowing the animal to recover, or before immobilization drugs are reversed, is also important to allow for remedial efforts for a hypothermic animal. Hypothermia is a major reason for prolonged recoveries.

Figure 45.2. A tiger with an endotracheal tube in place and instrumented for monitoring during anesthesia. A catheter is in the left jugular vein, a pulse oximetry probe is placed on the tongue, and ECG leads are attached to the cat.

For short procedures, animals are not typically intubated, but if respiratory rates are very low (<6 breaths/min) or if hemoglobin saturation remains low (<85%), endotracheal intubation and ventilation may be required. It should be pointed out that pulse oximeters are calibrated for use in humans and, as a result, absolute accuracy of any given saturation value cannot be guaranteed. Pulse oximetry is useful, however, for monitoring trends and providing information about oxygenation, especially if hypoventilation or ventilation-perfusion mismatching are present.

Routine monitoring for surgical anesthesia includes the measurements stated earlier, serial blood pressure measurements, and continuous electrocardiography (ECG) and end-tidal CO₂ monitoring. Noninvasive oscillometric blood pressure (NIBP) measuring is routinely done, but values can be difficult to obtain on some cats. Use of human arm or thigh cuffs, placed around the foreleg just above the carpus, attached to an automated pressure monitor is the method commonly used in our practice. A study comparing direct blood pressure measurement, obtained via an arterial catheter, with NIBP with cuffs placed around the foreleg, above the elbow, showed that the latter method accurately reflected the systolic (SAP) and diastolic (DAP) pressures, but overestimated the mean arterial pressures (MAPs) (Howard et al. 2006). That same study also compared direct arterial pressure measurements to those obtained via NIBP with the cuff placed around the base of the tail. The tail cuff NIBP measurements also accurately reflected the SAP, but underestimated the MAP and DAP. The authors concluded that NIBP with cuffs placed at either site could reasonably be used to monitor blood pressure in anesthetized lions (Howard et al. 2006).

Progressive hyperkalemia has been observed in 20% of anesthetized tigers (Gunkel & Lafortune 2007); however, the condition remains poorly described and

mainly anecdotal. The pathophysiology of hyperkalemia in healthy large felids under general anesthesia is not known and several mechanisms may be responsible. Alpha-2 adrenoceptor agonists, such as xylazine, medetomidine, and dexmedetomidine may play a role in increasing the serum potassium concentration. A significant increase in plasma potassium during anesthesia with xylazine and ketamine has been reported in tigers (Seal et al. 1987) and dogs (Taluker & Hikasa 2009); however, in both reports, the potassium concentration did not exceed 5.5 mmol/L. In dogs and cats, medetomidine induces hyperglycemia and hypoinsulinemia (Burton et al. 1997; Kanda & Hikasa 2008a, 2008b; Taluker & Hikasa 2009). Hypoinsulinemia may play a role in increasing serum potassium concentration during sedation with these drugs. Hyperkalemia-induced cardiac arrhythmias and ECG changes depend on the concentration of potassium in the extracellular fluid. ECG changes can include bradycardia, increase in T-wave amplitude, ST segment depression, widening of P and QRS waves, and loss of P-waves (Carroll 2008). Although ECG monitoring is recommended as an indirect mean for monitoring plasma potassium, a study on hyperkalemic domestic cats and dogs showed that 59% of the ECGs were normal or revealed abnormalities not previously described in conjunction with hyperkalemia (Tag & Day 2008). Therefore, ECG examination as a sole technique for monitoring the plasma concentration of potassium cannot be recommended. Gunkel and Lafortune (Gunkel & Lafortune 2007) recommended monitoring plasma electrolytes and blood gases every 15–30 minutes during general anesthesia of large cats. Certainly, if the anesthesia extends longer than 1 hour, routine monitoring of electrolytes and glucose seems prudent.

In a pilot study in the author's practice, plasma potassium concentration increased consistently during general anesthesia in four large captive felids (three tigers and one liger). ECG changes (bradycardia, spiked T-waves, and wide QRS complexes) were observed in three of these animals and cardiac arrest occurred in two animals. Plasma or serum glucose also rose concomitantly with the increase in circulating potassium in all these cats. A more extensive study on the pathophysiology of hyperkalemia in large felids during general anesthesia is currently underway (R. Seddighi and S. Reilly, pers. comm., 2010).

LOCAL AND REGIONAL ANESTHESIA

There are very few reports on regional anesthesia in nondomestic cats. It is assumed that most anesthetic blocks used in domestic cats can be adapted and applied to nondomestic felids. A transverse abdominis plane block has been used for abdominal surgery in a Canadian lynx (*Lynx canadensis*) (Schroeder et al. 2010). Briefly, diluted bupivacaine (0.125%) was injected, with

the assistance of ultrasonography, between the facial planes of the internal oblique and transversus abdominis muscles, bilaterally. An estimated 6.25-mg bupivacaine was administered on each side, and the block affected the spinal nerves of T-10 to L1, but analgesia extended as far cranial as T-7 (Schroeder et al. 2010).

Lumbosacral epidermal analgesia has been employed in lions and tigers undergoing ovario-hysterectomy or other procedures (Gunkel & Lafortune 2007; McCain et al. 2009). In the author's practice, 10 mL (equivalent to 0.06–0.12 mg/kg) of morphine sulfate without preservative is aseptically placed in the epidural space of the caudal lumbar spinal region, immediately prior to surgery. No side effects of this block could be identified post surgery, although one cat which received >11 mL of the epidural morphine and also received a parenteral opioid postsurgery exhibited dysphoria, which responded to treatment with an opioid antagonist. Use of larger doses of morphine (0.1–0.3 mg/kg) and bupivacaine (0.3 mg/kg, not exceeding 6.0–9.0 mL total) for epidural analgesia in nondomestic felids has been used by others (Gunkel & Lafortune 2007).

ANALGESIA

Very few analgesic agents are approved for use in domestic felids, and some commonly used human products, such as acetaminophen, can be toxic to cats. These facts, coupled with the feline ability to mask or hide pain, has made selection of analgesics and evaluating their efficacy in nondomestic felids challenging.

A number of nonsteroidal anti-inflammatory drugs (NSAIDs) and analgesics have been reported in single case reports, case series, or proceedings abstracts. These include gabapentin (3.7 mg/kg PO q 24 hours long term) for arthritic and presumed intervertebral disc disease in a lion (Adkesson 2006), etodolac (5 mg/kg PO q 48 hours for five doses, then q 72 hours) in a tiger (Ball et al. 2001), buprenorphine (0.015 mg/kg IM after surgery, then 0.005 mg/kg IM q 8 hours for three doses) in a tiger undergoing abdominal surgery (Hart et al. 2000), butorphanol (0.1–0.2 mg/kg SC) for analgesia following surgeries in lions and tigers (Conrad et al. 2002; Kolata 2002), and meloxicam (0.1–0.2 mg/kg PO or SC, 0.1 mg/kg q 24 hours for 5 days for short-term pain, and then continuing 0.1 mg/kg q 48–72 hours for long-term pain relief) in several nondomestic felids (Whiteside & Black 2004).

Injectable meloxicam (Metacam®, Boehringer Ingelheim Vetmedica, Inc., St. Joseph, MO) is the only NSAID approved for use in domestic cats in the United States at this time and is approved only for short-term use. Recently, a warning was issued against its long-term use in domestic cats. Our experience indicates that adequate analgesia may be achieved in nondomestic felids with lower meloxicam doses and longer dosing intervals than those previously used in domestic cats

Table 45.3. Dosages for analgesic and NSAIDs used in nondomestic felids

Agent	Perioperative/Short-Term Treatment	Long-Term Treatment
Buprenorphine	0.01–0.02 mg/kg SC, b.i.d., or q.i.d.	May also be given IM or orally (transmucosally)
Butorphanol	0.1–0.4 mg/kg SC	0.4–1.0 mg/kg PO q 4–8 h
Tramadol	1.0–4.0 mg/kg PO b.i.d.	0.8–1.5 mg/kg PO b.i.d.
Meloxicam	0.1–0.3 mg/kg SC	Day 1: 0.1–0.2 mg/kg PO once Days 2–4: 0.05–0.1 mg/kg q 24 h Days 5 on: 0.025 mg/kg q 48–72 h
Piroxicam	0.3 mg/kg PO q 24 h for 4 days	Days 1–4: 0.3 mg/kg PO q 24 h Days 5 on: 0.3 mg/kg PO q 48 h

(Table 45.3) and nondomestic felids have been maintained on meloxicam for months without adverse clinical signs. Postmortem examination of the kidneys from a large series of nondomestic felids found renal papillary necrosis (RPN) was significantly associated with meloxicam treatment, but not all felids receiving meloxicam developed RPN (Newkirk et al. 2011). Piroxicam, another NSAID more commonly used in oncology, is also useful for treating chronic pain in some nondomestic felids. Domestic cats treated with piroxicam show a number of adverse effects, but these have not been observed in the author's practice.

Tramadol, a drug with opioid-like effects, is used for analgesia in domestic cats and has proved to be an effective oral analgesic in a number of nondomestic felid species. It can be used long term and very few, if any, adverse effects have been encountered. It can also be used safely in geriatric cats with renal disease or gastrointestinal problems.

For perioperative or short-term pain relief, meloxicam and tramadol are used in our practice (Table 45.3). Oral tramadol is given the night before surgery, the evening following surgery, and for 3–4 days post surgery. Meloxicam is administered SC during surgery and orally for 2–4 days thereafter. For very painful procedures, buprenorphine can be used intraoperatively, instead of postrecovery tramadol. The author has also used butorphanol 0.03–0.04 mg/kg SC (4.0- to 5.0-mg total dose) in subadult and adult lions and tigers following castration with satisfactory short-term effects. Butorphanol should be redosed at 2-hour intervals to maintain postoperative analgesia.

In domestic cats, fentanyl transdermal patches offer a method of providing long-term postsurgery analgesia, without the need to continually redose an animal. These patches require good contact between the patch and skin, and protection of the patch to prevent removal. In nondomestic felids, these requirements preclude the use of fentanyl patches in most individuals. Delivery of fentanyl, or other analgesic, via subcutaneously implanted osmotic pumps is a potential alternative method for delivery of pain relief drugs. Modeling of osmotic pump fentanyl delivery in domestic cats showed that the cats treated with pumps had shorter lag times to therapeutic serum concentrations

and faster fentanyl elimination following pump removal, as compared with cats treated with transdermal fentanyl patches (Sykes et al. 2009). The latter might be especially useful should an animal show adverse drug effects.

Large nondomestic felids appear to be more prone to osteoarthritis than has been recognized in domestic cats, and osteoarthritis can be a cause of chronic pain (Kolmstetter et al. 2000). Meloxicam, piroxicam, tramadol, and gabapentin are used in our practice for treatment of chronic pain in nondomestic felids. Meloxicam or piroxicam can be used alone, or either can be used in combination with either tramadol or gabapentin. In nondomestic felids with chronic pain, combined meloxicam and tramadol therapy is typically attempted before trying other agents or combinations.

ACKNOWLEDGMENTS

The author would like to thank Dr. Seddighi, Dr. Reilly, and Dr. Steeil for the critical review of this manuscript.

Phocid Seals

Michael Lynch and Kate Bodley

INTRODUCTION

Seals, sea lions, fur seals, and walruses make up a distinctive group of mammals: the order Pinnipedia. Most members of this group can be divided into two families: the Otariidae (eared seals) contains 14 species and the Phocidae (true seals) contains 18 species (Riedman 1990).

Phocid and otariid seals share many adaptive features that enable them to occupy both aquatic and terrestrial environments. However, there are significant anatomical, physiological, and behavioral variations between these groups and between species within each group. Some of these variations must be taken into account during the planning and management of immobilization and anesthesia procedures.

ANATOMY AND PHYSIOLOGY

Phocid seal species have numerous anatomical and physiological adaptations that must be considered as part of their anesthetic management. The maintenance of a core body temperature within a narrow range is essential for the survival of endothermic mammals. This is particularly challenging for species that move between terrestrial and aquatic environments, as water conducts heat 25 times more efficiently than air (Nadel 1984). To maintain a constant core body temperature, semiaquatic species generally need to reduce heat loss when in the water, and often, heat stress when on land. Phocid seals rely on a thick layer of blubber to insulate the body core (Harrison & King 1980). In addition to behavioral means of thermoregulation, heat is conserved or off-loaded by altering the blood flow through arteriovenous anastomoses in the trunk and flippers

(Bryden & Molyneux 1978; Mauck et al. 2003). Anesthesia removes the seal's ability to employ behavioral means of thermoregulation and may also interfere with physiological mechanisms. Therefore, a consideration of likely changes in the animal's body temperature during immobilization procedures and planned responses to their potential hypo or hyperthermia is necessary.

Phocid seals also have adaptations that relate to their ability to dive. In some species such as leopard and Weddell seals, there is very little cartilaginous support of the trachea, allowing its dorso-ventral collapse while diving (Boyd 1975; Gray et al. 2006; Kooyman 1989). Phocids also have a flexible rib cage, enabling the thorax to compress, and the smaller pulmonary airways are supported by muscle rather than cartilage (Ridgway 1972; Welsch et al. 1989). During anesthesia, relaxation of pharyngeal and palatine tissues, of the musculature of the rib cage, and of the pulmonary airways may contribute to airway obstruction. This means that phocid seals, particularly large individuals, are susceptible to ventilation-perfusion mismatch. In addition, these anatomical adaptations of the respiratory system can increase the difficulty of providing adequate ventilation to anesthetized animals when employing intermittent positive pressure ventilation (Pang et al. 2006).

Physiological adaptations that aid diving in pinnipeds include a series of cardiovascular changes that are collectively known as the dive response. The dive response is most pronounced during prolonged dives and most profoundly elicited in deep diving phocid species (Kooyman 1981). The dive response is characterized by a profound bradycardia, peripheral vasoconstriction, and the shunting of blood to essential and

hypoxia-sensitive tissues such as the heart and brain (Scheffer 1990). The pinniped dive response is primarily controlled by central mechanisms influencing respiratory drive. Input from pulmonary stretch receptors, arterial chemo- and baroreceptors, and trigeminal receptors result in a vagally mediated bradycardia (Angell James et al. 1981). The activity of the sympathetic nervous system also increases, resulting in splenic contraction, peripheral vasoconstriction, and constriction of the muscular vena cava sphincter. Consequently, there is an increased hematocrit and pooling of blood within the hepatic sinus during diving (Thornton et al. 2001).

Profound bradycardia and periods of prolonged apnea are sometimes observed in anesthetized seals and have been suggested to be a result of an inappropriate elicitation of the dive response (Gales & Burton 1988). It is not unreasonable to suggest that the dive response could be elicited by anesthetic agents, as they generally depress central respiratory and cardiovascular centers, and may induce periods of apnea. Anesthesia may be considered as providing two of the triggers, central and peripheral, for elicitation of a dive response. However, cardiac arrest and cessation of breathing may be elicited by hypoxia in any mammal. Therefore, a conclusion of a dive response episode in an anesthetized seal may only be made if the animal's ventilation is being appropriately monitored by pulse oximetry and capnography. Careful monitoring of the physiological status of anesthetized phocid seals, including the use of capnography, allows continuous assessment of respiratory function and reduces the risk of development of hypercapnea and hypoxemia.

CAPTURE AND PHYSICAL RESTRAINT

When planning an immobilization procedure, the objectives must be clearly defined. Setting objectives clarifies whether animal restraint is needed at all, and, if restraint is necessary, what degree of immobilization is required. For all animal restraint procedures, the method of immobilization must take into account the animal's size, its demeanor, and its proximity to water. In addition, the skill level of handlers is a very important consideration.

It is possible to herd many phocid seals into trailers or transport crates using baffle boards and funneling arrangements, and this technique finds most application in the captive environment. Crates used to transport seals should be able to be opened at either end, be well ventilated, and of a width and height that does not allow the animal to turn around and become trapped. In the field, baffle boards may be suitable for herding animals to desired locations. Baffle boards are most useful when managing species that are relatively tolerant of human disturbance, such as Weddell and southern elephant seals.

Procedures of short duration that are minimally invasive may be most simply and safely achieved using

physical restraint methods. Skilled and confident handlers are essential when manually restraining seals. Phocid seals up to ~100 kg can be caught using a hoop net and then manually restrained. Young pups may be captured by simply grasping the individual in front of the hind flippers and holding. Once caught in a hoop net, the animal can be restrained within the net by grasping its neck just behind the skull, and pushing it down to the ground while straddling the body. This allows a second operator to perform brief procedures such as collection of blood or delivery of anesthetic agents by face mask or injection. Small seals (<30 kg) can be removed from the net by grasping in front of the tail flippers and then restrained by straddling the body and pinning the animal's neck and head.

Larger phocid seals such as crab eater, leopard, and southern elephant seals can be physically restrained using a head bag (Harcourt et al 2010; McMahon et al. 2000; Stirling 1966). Once the head bag is in position, the animal can be manually restrained: one person straddling its shoulders and another its hindquarters (Fig. 46.1). A third handler can then perform minor procedures, such as blood collection and flipper tagging.

More elusive species may be difficult to approach on land. Harbor seals can be caught in narrow water canals using fine drift nets. Entangled animals are then hauled into a boat. Ringed seals have been captured at breathing holes in sea ice using nets (Kelly 1996). Seals that are surfacing to breathe will trigger the fall of a weight that causes the net to extend.

One advantage of physical restraint is that the animal can be immediately released on completion of the procedure without residual drug effects that might

Figure 46.1. A head bag may be used to facilitate physical restraint of larger phocid seals. Once the head bag is in position, the animal can be manually restrained: one person straddles its shoulders and another its hindquarters (illustration by Beth Croce).

impair its behavior. Physical restraint may be used to facilitate accurate delivery of chemical immobilization agents after the animal is caught. Southern elephant seals that received anesthetic agents intravenously after physical restraint had shorter induction and recovery times and less variable responses than those that were given the same agents by intramuscular injection (Slip & Woods 1996). Alternatively, animals may be sedated via intramuscular injection of chemical agents prior to physical restraint for intravenous access (Woods et al. 1994b).

The disadvantages of physical restraint include the increased risk for the handlers (i.e., bite wounds), increased animal stress, and the difficulty of monitoring the animal's physiological state adequately. Excessively vigorous restraint may compromise the animal's breathing via occlusion of the airway or constriction of the thoracic wall. This may be of particular importance in phocid seals due to their tracheal and rib cage anatomy. Prolonged physical restraint in warm ambient temperatures may also cause hyperthermia.

VASCULAR ACCESS

The extradural intravertebral vein is most frequently used for intravenous access in phocid seals. The vein is located dorsal to the spinal cord, in the epidural sinus (Fig. 46.2). The animal is restrained in sternal recumbency and the vein is located by determining the dorsal midline in the lower lumbar region. The spinous processes of lumbar vertebrae 3–4 are located by palpation, and the needle is inserted perpendicularly between these processes until blood is observed in the needle hub. A 20-gauge, 25 mm (1 in.) needle has been recommended for harbor seal pups, an 18-gauge, 76 mm (3 in.) spinal needle has been recommended for harbor

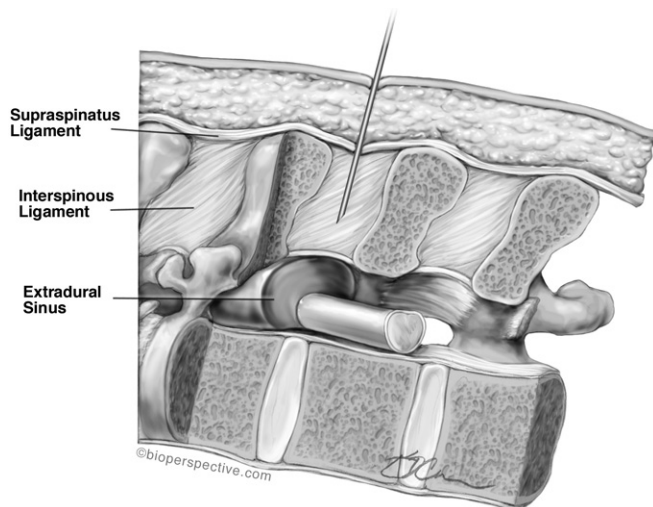

Figure 46.2. A schematic diagram of a sagittal section of the lower lumbar region of a phocid seal demonstrating the perpendicular placement of a needle to enter the extradural sinus (illustration by Beth Croce).

seal adults, and an 18-gauge, 90 mm (3.5 -in.) spinal needle has been recommended for southern elephant seal adults (Haulena & Heath 2001; McMahon et al. 2000). If extradural intravertebral venipuncture is performed without adequate skin preparation, there is potential for introduction of pathogens directly into a major vessel. Care must be taken when attempting intravenous access in a restrained seal: if the animal struggles, there is potential for vessel trauma. Inadvertent bone marrow contamination of blood samples has been reported during extradural intravertebral vein access in northern elephant seal pups (Goldstein et al. 1998).

The plantar interdigital veins of the hind flippers have also been used for intravenous access in phocid seals. A needle is inserted at the origin of the interdigital webbing, 10°–20° to the skin surface directly over the second digit or medial to the fourth digit (Gulland et al. 2001). Firm pressure must be applied to this site post venipuncture to prevent hematoma formation.

ENDOTRACHEAL INTUBATION

Intubation is strongly recommended in phocid seals to maintain the airway and provide the ability to ventilate the animal. Therefore, personnel performing chemical immobilization procedures should have the skills and capacity to intubate and ventilate animals. Intubation is required to ensure reliable maintenance of the airway during anesthesia. However, intubation may be difficult, particularly in larger animals, due to the presence of spongy peripharyngeal tissues and a flaccid soft palate that prevent visualization of the laryngeal opening. In some species such as Weddell seals, the laryngeal orifice is narrow (Hammond & Elsner 1977). This may result in difficulty of insertion of an endotracheal tube of a size suitable for the lumen of the trachea.

In larger phocid seals, intubation is most easily accomplished by manually palpating the laryngeal opening and then passing the tube. Laryngoscopes may be used for smaller species (up to around 100 kg), but often do not displace enough pharyngeal tissue to visualize the glottis opening. A spatula of 5- to 8-cm width will aid this process (Haulena & Heath 2001).

Manipulation of the glottis in apneic phocid seals will often stimulate respiration. However, apnea was associated with endotracheal tube placement in 24 of 31 previously breathing, lightly anesthetized southern elephant seals (Woods et al. 1996b). In most seals, the apnea was resolved by tube removal alone.

For assisted ventilation, intubated large seals require oxygen demand valves capable of delivering high flow rates. A modified Robert–Shaw demand and resuscitation valve (Ohmeda Pty Ltd), capable of delivering an oxygen flow of 140 L/min, has been used by the authors to ventilate phocid seals up to 300 kg body weight. Devices capable of delivering 300 L/min are used to

ventilate large terrestrial mammals and would be capable of ventilating the largest phocid seals (Horne et al. 2001).

PREANESTHETIC CONSIDERATIONS

Immobilization Location

There are many features in the captive environment that can be modified to achieve safe and effective chemical immobilization of phocid seals. For example, trained behaviors may allow venipuncture and administration of intravenous sedatives or anesthetics with minimal restraint. Facilities that allow rapid and safe animal restraint, restriction of access to water, and control of environmental factors, such as temperature and animal interactions, will simplify immobilization procedures and improve handler and animal safety.

Assessment of Physiological Status

An assessment of the current physiological status of an animal should be made prior to any immobilization procedure. Most captive animals will have a known medical history; many will have a previous anesthetic history and their current disease status can be readily assessed. It is often possible to weigh captive animals prior to immobilization and assess this in relation to their annual cycle of weight fluctuation. In free-living animals, preanesthetic assessment is usually limited to characteristics that can be easily observed (such as body condition), combined with an assessment of the likely physiological status of the animal.

Weight fluctuations in phocid seals are generally the result of deposition or utilization of blubber, and lean body mass varies much less dramatically. Blubber is less metabolically active than most other tissues; therefore, it is important that doses of anesthetic agents are used without total body mass being the sole guide to their calculation. A significant inverse relationship between body condition and duration of anesthesia has been demonstrated in southern elephant seals given a single intravenous dose of a combined 1:1 mixture of tiletamine and zolazepam (Field et al. 2002). The authors suggest that lipophilic drugs move out of the blood stream and into blubber more rapidly in fatter animals, and therefore duration of anesthesia is shorter than in thinner animals given the same dose (in mg/kg) of drug. However, there may be prolonged drug effects in fatter animals due to gradual passage from saturated sites (e.g., fat), where the drug is inactive, back into the plasma. The time to complete recovery (as opposed to the duration of effective chemical immobilization) might therefore be expected to be longer in fatter animals.

Delivery of Anesthetic Agents

The method of delivery of chemical immobilizing agents requires careful consideration in the planning stages of a procedure. In general, manually restraining

animals prior to delivery of anesthetic agents is not ideal, as they will be in a heightened state of excitement. However, the delivery of agents by remote means carries its own set of complicating factors, and the final decision about how to administer agents will depend on the demeanor of the species concerned, the individual's size, and whether or not the procedure is on free-ranging or captive animals. Immobilizing drugs may be safely administered by hand injection without full manual restraint in relatively tractable species such as Weddell seals (Phelan & Green 1992). Using a needle attached to extension tubing facilitates the ease of this technique (Ryding 1982). In addition, head bagging the seal prior to injection can provide for greater operator safety.

Remote injection of immobilizing agents by dart allows drugs to be delivered while minimizing animal disturbance and reduces the risk of the animal handler being bitten. Drug delivery by dart is useful for large and potentially dangerous species or for species that become agitated or flee when approached by humans. For free-ranging animals that are likely to flee, an assessment needs to be made of the likelihood that the individual will be stimulated to enter the water following darting. In most instances, this requires either stealthy approach to within the animal's flight distance or firing of darts from outside the flight distance. In most cases, flight distance will be altered depending on whether the approaching human is standing or crawling. Darting hauled out animals from a boat also often allows a much closer approach than if on land. Once the animal is chemically restrained, anesthesia can then be induced or maintained using intravenous administration of chemical agents or inhalant anesthesia.

One of the factors contributing to variability of response to any chemical immobilization agent is the site where the drug is deposited. Response to drug administration is less predictable following delivery by remote delivery systems such as darting than following accurate deposition of drug in an optimal site (e.g., into the extradural vein or directly into the lumbar musculature).

There are a number of advantages of using the inhalant anesthetics in phocid seals. Inhalation anesthesia techniques enable precise control of the animal's depth and give the anesthetist control over the animal's airway. Inhalant anesthesia is being used more frequently for field anesthesia of phocids because of the development of portable units that can be used for both large pinnipeds (Geschke & Chilvers 2009) and under a wide variety of climatic conditions (Bodley et al. 2005; Gales et al. 2005).

INDUCTION AND MAINTENANCE PROTOCOLS

Table 46.1 reviews drug regimens used in phocid seals.

Table 46.1. Some chemical immobilizing agents used in phocid seals 1990–2010

Species	Agent	Dose Rate	Route	Comments	Reference
<i>Halichoerus grypus</i> (gray seal)	Tiletamine and zolazepam	1 mg/kg	IM	Some animals became apneic, requiring ventilation. Tremors noted.	Baker et al. (1990)
	Tiletamine and zolazepam	0.5 mg/kg	IM	Additional doses given to maintain sedation; palpebral reflex maintained	Lawson et al. (1996)
	Medetomidine	50–100 µg/kg	IM	Note: adverse effects noted by other authors following use of medetomidine. Effects dependent on dose rate.	Barnett (1998)
	Ketamine, xylazine	2.2–5.9 mg/kg	IM	Muscle tremors, apnea, bradycardia, mortalities	Mitchell and Burton (1991)
<i>Hydrurga leptonyx</i> (leopard seal)	Tiletamine and zolazepam	2 mg/kg	IM	Apnea, bradycardia, mortalities	Mitchell and Burton (1991)
	Xylazine	0.8–2.8 mg/kg	IM	Variable plane of anesthesia with lower dose	Mitchell and Burton (1991)
	Midazolam, pethidine	0.18–0.27 mg/kg	IM	Unpredictable immobilization, poor airway maintenance.	Higgins et al. (2002)
	Tiletamine and zolazepam	1.0–1.5 mg/kg	IM	1.2–1.4 mg/kg IM gave most reliable response.	Higgins et al. (2002)
	Tiletamine and zolazepam	0.5–1.5 mg/kg	IM	Supplemented with midazolam (IV or IM) or ketamine (IV or IM) as required.	Vogelneist et al. (2009)
	Tiletamine and zolazepam	0.8–1.0 mg/kg	IM		Hurford et al. (1996)
<i>Leptonychotes weddellii</i> (Weddell seal)	Ketamine, halothane	0.15–0.25 mg/kg	IM		
		1–4%	IH		
	Tiletamine and zolazepam	0.3–1.1 mg/kg	IM	Plane of anesthesia varied with dosage, mortalities	Phelan and Green (1992)
	Midazolam, isoflurane	0.3–0.5 mg/kg	IM	Dose rate for midazolam based on estimated body mass only	Bodley et al. (2005)
<i>Lobodon carcinophagus</i> (crab-eater seal)	Ketamine, midazolam	2.5–5%	IH		
		1.6–2.4 mg/kg	IM	Dose rate per kilogram (animals were weighed).	Mellish et al. (2010)
		0.08–0.12 mg/kg	IV	Induction dose administered IM and additional doses given IV if required. Five animals were treated using intravenous flumazenil +/- doxapram	
	Ketamine, diazepam	2.0 mg/kg	IM	Dose rate per kilogram (animals were weighed). Described as “mild sedative.”	Harcourt et al. (2010)
	Ketamine, diazepam	0.01 mg/kg	IM	Some mortalities.	Shaughnessy (1991)
		2.9–7.7 mg/kg	IM		Tahmindjis et al. (2003)
<i>Mirounga angustirostris</i> (northern elephant seal)	Midazolam, pethidine	0.15–0.4 mg/kg	IM	Reversed using naloxone and flumazenil.	Gales et al. (2005)
		1–3 mg/kg	IM		
	Midazolam, isoflurane	0.26–0.85 mg/kg	IM	Purpose-built gas anesthetic machine for field use.	
		1–5%	IH		
	Medetomidine, ketamine	70–140 µg/kg	IM	Bradycardia, prolonged recovery, poor reversibility, variable plane of anesthesia	Haulena and Heath (2001)
<i>Mirounga leonina</i> (southern elephant seal)	Tiletamine and zolazepam	2.5 mg/kg	IM		
		0.8 mg/kg	IV	Atropine given routinely (0.02 mg/kg IV) at the time of induction. IV zoletil provides 15-minute anesthesia at a level sufficient for intubation. Can then supplement with isoflurane as required.	Dailey et al. (2002); M. Haulena personal communication
	Ketamine, diazepam	2.3–3.9 mg/kg	IM	Apnea, poor muscle relaxation	Woods et al. (1994a)
		0.02–0.35 mg/kg	IM		
	Ketamine, diazepam	4.4–8.6 mg/kg	IM	Apnea	Slip and Woods (1996)
		0.04–0.13 mg/kg	IM		
	Ketamine, xylazine	2.1–11.4 mg/kg	IM	Prolonged apnea	Mitchell and Burton (1991)
		0.2–0.5 mg/kg			

(Continued)

Species	Agent	Dose Rate	Route	Comments	Reference
<i>Phoca vitulina</i> (harbor seal)	Ketamine, xylazine	2.1–3.1 mg/kg	IM	Apnea, tremors	Woods et al. (1994a)
	Ketamine, xylazine	0.2–0.5 mg/kg	IM		Woods et al. (1996b)
	Ketamine, xylazine	2.5–3.4 mg/kg	IM	Apnea, responsive to doxapram 2 mg/kg	Woods et al. (1996a)
	Medetomidine	0.5–0.6 mg/kg	IM	Vomiting, hyperthermia, bradycardia	Woods et al. (1996a)
	Medetomidine, ketamine	13–27 µg/kg	IM	Hyperthermia, variable plane of anesthesia, poor reversibility, bradycardia	Woods et al. (1994b)
	Midazolam, pethidine	1.4–2.2 mg/kg	IM	Deeper sedation with higher doses of pethidine (2.7–6.7 mg/kg), faster recovery after naloxone or miltexone	Woods et al. (1994b)
	Midazolam, pethidine, thiopentone	0.02–0.07 mg/kg	IM	Good immobilization allowing intubation of 5-minute duration after thiopentone	Woods et al. (1994b)
	Midazolam, pethidine, ketamine	2.7–6.7 mg/kg	IM		Woods et al. (1994b)
		2.2–5.9 mg/kg	IV		Woods et al. (1994b)
		0.02–0.07 mg/kg	IM	Incremental doses of ketamine to maintain immobilization for 1 hour	Woods et al. (1994a)
		2.7–6.7 mg/kg	IM		Woods et al. (1994a)
		4.4–10 mg/kg	IV		Baker et al. (1990)
		2.1–3.7 mg/kg	IM	Deep sedation, apnea, prolonged recovery, hyperthermia, bradycardia	Mitchell and Burton (1991)
		0.02–0.03 mg/kg	IM	Some animals became apneic requiring ventilation	Woods et al. (1994a)
		1 mg/kg	IM	Prolonged apnea, muscle tremors, mortalities.	McMahon et al. (2000)
		1.6–2.4 mg/kg	IM	Apnea, tremors, possible hallucinations, prolonged recovery	Carlini et al. (2009)
		0.7–1.2 mg/kg	IM	Mean duration of immobilization 15.48 minutes. Immobilized such that stomach lavage and blood sampling were possible.	Gulland et al. (1999)
		0.46 mg/kg	IV	Addition of ketamine useful when initial level of sedation or duration of immobilization was unsatisfactory. Induction dose rate should be adjusted depending on stage of annual cycle (molting/breeding).	Gulland et al. (1999)
		0.5–0.7 mg/kg	IM	Optimum short-acting anesthesia at 5 mg/kg. Apnea.	Gulland et al. (1999)
		1.04 ± 0.66 mg/kg	IM	Easily intubated, apnea	Tuomi et al. (2000)
	2–6 mg/kg	IV	Decreased anxiety, relaxation sufficient for minor procedures (radiographic positioning, skin scrapes)	Tuomi et al. (2000)	
	3–5 mg/kg	IV	Immobilization sufficient for deep muscle biopsy, endoscopy	M. Haulena personal communication	
	2–5%	IH	Atropine given routinely (0.02 mg/kg IV) at the time of induction. Routine induction protocol for this species.	M. Haulena personal communication	
	0.4 mg/kg	IM	Atropine given routinely (0.02 mg/kg IV) at the time of induction.	Lapierre et al. (2007)	
	0.2 mg/kg	IV	Recommended as initial dose for sedation (then supplemented as required)		
	1.5–5.0%	IH			
	1.5–2.0 mg/kg	IV			

Source: Haulena M, Heath RB. 2001. Marine mammal anesthesia. In: *CRC Handbook of Marine Mammal Medicine* (LA Dieterauf, FMD Gulland, eds.), pp. 655–688. Boca Raton: CRC Press. IH, inhalational; IM, intramuscular injection; IV, intravenous injection.

Ketamine

Ketamine has been commonly used for chemical immobilization of phocid seals (Gales 1989), alone or in combination with other drugs. In phocids, ketamine has the advantage of causing minimal cardiopulmonary depression over a relatively wide dosage range. Northern elephant seals were immobilized using intramuscular doses of ketamine between 1.4 and 6.9 mg/kg (Briggs et al. 1975), and intravenous ketamine has been used successfully in young harp seals at doses between 0.5 and 7.5 mg/kg (Engelhardt 1977). Adverse effects of ketamine alone have included poor muscle relaxation and muscle tremors (Briggs et al. 1975). Therefore, it has been used most often in combination with other agents, such as benzodiazepines (e.g., diazepam or midazolam) or α_2 -agonists (e.g., xylazine, detomidine, or medetomidine).

Benzodiazepines

Benzodiazepines are very useful agents for phocid seal sedation because of their muscle relaxant properties, minimal cardiovascular effects, and reversibility with specific antagonists. They are often used as a premedication, delivered remotely to aid safe physical restraint in large phocids. Prior to the introduction of midazolam, mixtures of ketamine and diazepam were commonly used to immobilize many species of phocid seals. Midazolam has some advantages over diazepam: its unique solubility characteristics (water-soluble injection but lipid soluble at body pH) result in a very rapid onset of action following injection (Plumb 1999).

Diazepam at a mean dose of 0.32 mg/kg, administered intravenously to harbor seal pups, provided sufficient sedation to facilitate blood collection and muscle biopsy; however, mild-to-severe bradycardia was noted in some individuals (Lapierre et al. 2007). The authors suggested that a lower initial dose of diazepam (0.15–0.20 mg/kg IV), supplemented as required, would be effective and would not result in undesirable cardiac effects. A combination of ketamine and diazepam, given intramuscularly, has also been used to sedate male Weddell seals (Harcourt et al. 2010).

Midazolam given at dose rates of 0.15–0.2 mg/kg by intramuscular injection will produce moderate sedation, and dose rates of 0.4–0.5 mg/kg will produce heavy sedation. The higher dose rate is useful for the larger phocid species, where physical restraint in unsedated animals can be dangerous for handlers and stressful for the animal. Weddell seals have been immobilized using a preprepared 1:1 mix of ketamine 100 mg/mL and midazolam 5 mg/mL. Ongoing maintenance was then achieved using the same ketamine and midazolam mix, delivered intravenously as needed (Mellish et al. 2010). Midazolam dosages of 0.51 ± 0.19 mg/kg have been given intramuscularly to produce a moderate level of sedation in crab-eater seals (Gales et al. 2005). This level of sedation allowed restraint for

anesthetic induction using isoflurane. In contrast, premedication of harp seals, using midazolam given intramuscularly at 0.1 or 0.2 mg/kg, did not appear to improve quality of isoflurane anesthesia or ease of intubation (Pang et al. 2006). In addition, recovery from anesthesia was prolonged in some individuals.

Alpha-2 Adrenergic Agonists

Xylazine (alone and in combination with ketamine) has been used successfully in numerous phocid seals. The use of xylazine as a sole immobilization agent has been associated with hyperthermia, bradycardia, and high rates of mortality in leopard and southern elephant seals (Mitchell & Burton 1991). A medetomidine-ketamine combination used in southern elephant seals produced similar undesirable side effects (Woods et al. 1996a). Generally, the use of α_2 -agonists has resulted in undesirable cardiovascular side effects such as decreased cardiac output, bradycardia, and increased peripheral vascular resistance. Prolonged anesthetic recovery, bradycardia, and variable levels of anesthesia have been observed in harbor and northern elephant seals following administration of medetomidine (Haulena & Heath 2001). However, this drug has been routinely used by other authors to sedate harbor and gray seals, and when given in combination with ketamine, to induce anesthesia in these species (Barnett 1998). The α_2 -agonists offer the advantage of being reversible using antagonists such as yohimbine and atipamezole although the use of such agents is not well established in phocids.

Tiletamine and Zolazepam

A combination of tiletamine and zolazepam in a 1:1 ratio has been used in a wide range of phocids. As a combination of two drugs presented in a fixed ratio, it does not allow for fine adjustments in the dosage of either agent to suit a particular species. In general, intravenous administration of tiletamine and zolazepam produces more predictable immobilization with fewer adverse side effects (such as prolonged apnea and muscle tremors) when compared with intramuscular administration.

Tiletamine and zolazepam have been used in southern elephant seals both intramuscularly at a dose rate of 1 mg/kg (Woods et al. 1994a) and intravenously at a rate of 0.5 mg/kg (McMahon et al. 2000). Induction doses of 0.5–0.7 mg/kg given by intramuscular injection were also effective in this species although supplemental doses of ketamine were required to maintain an adequate plane of anesthesia in some animals (Carlini et al. 2009). Harbor seals have been anesthetized using 0.8–1.2 mg/kg tiletamine and zolazepam injected intravenously under physical restraint (Lander et al. 2005), and a similar regimen has been described in northern elephant seals (Dailey et al. 2002). An intramuscular dose of 1 mg/kg was also found to be effective in immo-

bilizing gray seals (Baker et al. 1990). Intramuscular administration of tiletamine and zolazepam to 30 Weddell seals produced variable planes of immobilization. Intramuscular administration of tiletamine and zolazepam to 30 Weddell seals produced variable planes of immobilization. Six animals displayed prolonged apnea, and three of these animals eventually died (Phelan and Green 1992). Variable responses were also obtained in leopard seals following intramuscular administration of tiletamine and zolazepam 1.2–1.4 mg/kg (Higgins et al. 2002); however, a lower dose rate (0.8–1.0 mg/kg) was found to provide reliable induction when used in another study (Vogelnest et al. 2009). In this later study, supplemental midazolam or ketamine (given IM or IV) was used to maintain anesthesia.

Opioids

Anesthetic regimens that include opioids have also been used to immobilize phocid seals. There are several advantages of using opioids: they can be reversed using naloxone or naltrexone, and they usually have relatively mild cardiovascular and respiratory side effects when used at low doses. A mixture of meperidine (pethidine) and midazolam has been used with good results in southern elephant seals, inducing a reliable deep sedation that allowed intravenous access for the administration of ketamine or thiopentone (Woods et al. 1994b). However, a meperidine and midazolam combination was considered unsatisfactory in leopard seals due to the variability in response produced, a loss of muscle tone that compromised patency of the airway and respiratory depression (Higgins et al. 2002). A combination of meperidine and midazolam has also been used to induce deep sedation and light anesthesia in crab-eater seals (Tahmindjis et al. 2003) although periods of prolonged apnea were noted. Meperidine, when given as the sole sedative agent, produced moderate restraint without respiratory depression in harbor and northern elephant seals (Joseph & Cornell 1988). Butorphanol tartrate (0.4 mg/kg IM) in harbor seals produced mild sedation and decreased anxiety during minor procedures (Tuomi et al. 2000). The addition of diazepam (0.2 mg/kg IV) allowed more invasive procedures (muscle biopsy, endoscopy) to be carried out. Potent opioids (i.e., etorphine and carfentanil) produced respiratory depression, hyperexcitability, and prolonged apnea in hooded and gray seals. Their only really advantage is small drug volume delivery (Baker & Gatesman 1985; Haigh & Stewart 1979).

Intravenous Anesthetics

Propofol (5 mg/kg IV) was evaluated in harbor seal pups, two northern elephant seal pups, and two harbor seal adults and produced short-duration general anesthesia, good muscle relaxation, and rapid recoveries (Gulland & Gage 1997; Gulland et al. 1999). The primary disadvantage of this agent is that large volumes

of the commercially available preparations (10 mg/mL) are required for animals over 40 kg.

Inhalation Anesthetics

Prolonged immobilization procedures or those requiring a surgical plane of anesthesia are most safely performed using inhalant techniques. Studies in gray seals have demonstrated an efficient exchange of large volumes of gases during surface breathing, in part, because the animals have a large tidal volume (Reed et al. 1994). This suggests that diving seals can achieve rapid and efficient uptake and distribution of inhalant anesthetic agents. The use of a precision vaporizer and anesthetic circuit allows the anesthetist to accurately deliver a known, clinically useful concentration of the anesthetic agent in oxygen. Intubation of the animal completes the anesthetic circuit and gives the anesthetist control over the animal's airway. Maintenance of a clear airway is particularly significant during anesthesia of phocid seals, as many of these species have reduced cartilaginous support of the trachea and so are prone to respiratory obstruction (Hammond & Elsner 1977; Higgins et al. 2002). In addition, many phocid species have a very fleshy pharyngeal region that may contribute to respiratory obstruction when muscular tone is reduced by sedation. The most frequently used inhalant anesthetic agents in pinnipeds are isoflurane and sevoflurane.

MONITORING

The plane of sedation or anesthesia in phocid seals can be assessed by basic means such as ability to move body, head and flipper movements, jaw tone, and palpebral reflex. Table 46.2 defines levels of chemical restraint observed in leopard seals according to Higgins et al. (2002).

The assessment of physiological parameters is essential for the safe management of any chemical immobilization procedure. The animal's heart rate should be continuously monitored so that bradycardia, whether resulting from hypoxemia or presumed dive response, is quickly detected and treatment instituted immediately. It is difficult to auscultate the heart through the thoracic wall and an esophageal stethoscope should be used for this purpose. Alternatively, the heart rate is counted by the visualization of movements of the thoracic wall. Monitoring devices with electrocardiographic capacity are useful for assessment of the rate and rhythm (Lapierre et al. 2007).

Prolonged apnea is common in chemically immobilized phocid seals (Haulena & Heath 2001). However, the respiratory pattern in sleeping phocid seals is also characterized by frequent periods of apnea (Castellini et al. 1994). Since anesthetic agents often produce changes in the cardiovascular and respiratory systems, direct time comparisons between these events should be interpreted with caution. The interpretation of what

Table 46.2. Classification of stages of immobilization in phocid seals

	Definition
Stage 0	No effect
Stage 1	Negligible sedation
Stage 2	Visibly sedated but mobile
Stage 3	Sedated. Sluggish movement in response to body or head touch. Locomotion may be elicited with repeated stimulus. Hand injection possible.
Stage 4	Small movements of head or eyes. Locomotion possible but sluggish. Stage of immobilization sufficient if not adjacent to water.
Stage 5	No body movement. Muscle tone variable, dependent on drug used. Eye may follow passing objects.
Stage 6	No response to vigorous shaking of the tail, body, or head. Very little muscle tone. Sluggish palpebral response.
Stage 7	As for stage 6 but slightly deeper, with some respiratory depression and negligible muscle tone. Negligible palpebral response.
Stage 8	Deep anesthesia. Cardiac or respiratory depression. Complete loss of muscle tone. No palpebral response.

Source: With permission from Higgins DP, Rogers TL, Irvine AD, Hall-Aspland SA. 2002. Use of midazolam/pethidine and tiletamine/zolazepam combinations for the chemical restraint of Leopard seals (*Hydrurga leptonyx*). *Marine Mammal Science* 18(2):483–499.

constitutes a life-threatening duration of apnea is species dependent and related to their aerobic dive capacity (Slip & Woods 1996). The aerobic dive limit (ADL) is defined as the time beyond which an animal must rely on anaerobic metabolism to prolong the dive (Kooyman 1989). Species that are capable of deep and prolonged dives (e.g., southern elephant and Weddell seals) have a greater ADL and would be expected to tolerate longer periods of apnea under anesthesia compared with shallow diving species. Ultimately, respiratory rates and periods of apnea in anesthetized phocid seals should be interpreted in light of the other physiological variables that reflect ventilation and perfusion.

Hypoventilation is a significant problem during phocid anesthesia. It is essential that both respiratory rate and tidal volume be continuously monitored. The anesthetist must be prepared to assist ventilation if hypoventilation becomes apparent (i.e., reduced thoracic excursions during breathing, increasing end-tidal CO₂ [ETCO₂] values).

In addition to visualization of mucous membrane color, determination of hemoglobin saturation with pulse oximetry is a valuable aid when assessing ventilation and perfusion. Probe placement sites include the vulva, lip, and tongue (Fig. 46.3). Capnography is also an extremely useful tool in anesthetized phocid seals for assessing adequacy of ventilation. Respiratory obstruction is very likely to occur in anesthetized leopard seals and is likely the major contributor to the high mortality associated with chemical immobilization procedures in this species (Higgins et al. 2002). To obtain accurate ETCO₂ readings, the animal must be intubated. There are no published normal values for this variable in anesthetized phocid seals, but it is the authors' belief that assisted ventilation is indicated when ETCO₂ exceeds 55 mmHg. This figure is based, in part, on the authors' observations of ETCO₂ values during the initial period of anesthetic procedures on both otariid seals and phocid seals and, in part, on experimental studies. Parkos and Wahrenbrock (1987)

Figure 46.3. Monitoring end-tidal carbon dioxide levels and hemoglobin saturation with a capnometer and pulse oximeter, respectively, in an intubated, anesthetized leopard seal. The pulse oximeter probe is placed on the tongue, and the capnometer is attached to the end of the endotracheal tube.

found that the ventilatory response to hypercapnia in unanesthetized Weddell seals did not differ from that of terrestrial mammals. Reed et al. (1994) measured ETCO₂ values in freely diving gray seals and found they ranged between 28 and 35 mmHg, a range not dissimilar to that seen in terrestrial mammals.

Noninvasive blood pressure monitoring would provide additional information to aid the anesthetic management of phocid seals. However, it is generally not applicable to phocids because of their lack of readily accessible peripheral arteries.

Anesthetic agents disrupt the ability of phocid seals to thermoregulate. Seals in cold environments given vasodilatory agents may become hypothermic (Hammond & Elsner 1977), probably due to disruption of their countercurrent heat exchange mechanisms. Behavioral thermoregulation will also be affected by immobilization and may result in hyperthermia. In temperate or warmer climates, seals recovering from

sedation or anesthesia should be kept wet and/or in the shade. Accurate measurement of the body temperature in larger phocid seals requires rectal temperature probes of at least 30 cm in length.

SUPPLEMENTAL DRUGS USED DURING ANESTHESIA

Doxapram

Doxapram increased the depth and frequency of respiration and stimulated breathing in apneic southern elephant seals (Woods et al. 1996b). It failed to stimulate breathing when delivered into the extradural sinus, but direct intratracheal administration (via an endotracheal tube) stimulated breathing in four of six apneic animals. The lack of efficacy of IV doxapram was probably due to low pressures and flows in this vessel during breath holding. There have been no reported studies to determine whether the doxapram administration to hypoventilating phocid seals improves respiration and/or oxygen delivery to the tissues. Doxapram (5.0 mg/kg) was a nonspecific antagonist for ketamine-diazepam sedation in southern elephant seals, but often caused shaking and hyper-responsiveness in animals, prompting a recommendation to use a lower dosage (Woods et al. 1995).

Atropine

Atropine has been used at a wide variety of dose rates in the anesthesia of phocid seals (Gales & Burton 1988; Mitchell & Burton 1991). It has been included in some anesthetic regimens in an attempt to block some of the physiologic effects of the dive response. Doses that are standard for terrestrial carnivores (0.02–0.04 mg/kg) were used in unsedated harbor seals to eliminate the reflex bradycardia that occurs during diving (Galantsev et al. 1984), and it is likely that doses of this order would be efficacious in most pinniped species. However, it would be expected that atropinization would not affect the vasoconstriction and venous pooling seen with this physiological mechanism. While atropine, historically, was often included in anesthetic drug protocols for phocid seals, a number of authors describe protocols that do not routinely include atropine, without apparent adverse effects (Bodley et al. 2005; Gales et al. 2005; McMahon et al. 2000). Increased salivation was noted following intravenous administration of diazepam to harbor seal pups (Lapierre et al. 2007) and, therefore, atropine may have a role in management of excessive salivation and upper respiratory tract secretion during anesthesia.

RECOVERY

Adequate management of the recovery of phocids following anesthetic procedures is essential. For captive animals, access to water should be denied until the

individual is fully recovered. The potential for hyperthermia must be managed by wetting the animal or keeping it shaded. Conversely, individuals at risk of hypothermia can be insulated using blankets or thermal devices until they have reached a light plane of anesthesia. Timing of extubation is a key decision during recovery. Premature removal of the endotracheal tube increases the risk of respiratory obstruction, while delayed intubation increases risk to handlers. Animals that have been induced and maintained on gaseous anesthesia may recover suddenly and become startled by the close presence of the anesthetist. In the field situation, this may lead to the animal fleeing while not fully coordinated, thereby increasing its chances of injury.

Antagonists

Antagonists potentially improve safety of chemical immobilization of pinnipeds: they may be used during emergency resuscitation and to reduce recovery times.

Yohimbine and Atipamezole Yohimbine (0.5 mg/kg IM) hastened recovery from ketamine-xylazine-diazepam sedation in Weddell seals (Bornemann & Plotz 1993) and has also been used (0.06 mg/kg IV) to hasten recovery in southern elephant seals under ketamine-xylazine sedation (Woods et al. 1995). Low dose atipamezole (median dosage of 0.04 mg/kg IV) failed to arouse southern elephant seals from ketamine-medetomidine anesthesia (Woods et al. 1996a).

Flumazenil Flumazenil appears to be a useful adjunct to anesthetic management of phocid seals immobilized with benzodiazepine combinations. In crab-eater seals (250–300 kg), a combination of meperidine (1.29–2.2 mg/kg IM) and midazolam (0.29–0.37 mg/kg IM) was partially antagonized by naloxone (1.2–4 mg IV) and flumazenil (0.1–0.5) (M. Lynch, unpublished data 1997). While the time to recovery was greatly shortened, reversal of drug effects was not complete and larger doses may be indicated. Flumazenil (1 mg per 20–25 mg benzodiazepine IM) has also been used to reverse the zolazepam in southern elephant seals immobilized with tiletamine-zolazepam (Karesh et al. 1997). Mellish et al. (2010) administered flumazenil intravenously, at a dose rate of 0.002 mg/kg, to Weddell seals that had been immobilized using midazolam and ketamine; however, the authors commented that its effect was questionable.

FIELD ANESTHESIA

Free-ranging phocid seals occupy a variety of habitats, and many of these are difficult to access as well as presenting challenging environmental conditions to operate within. The grouping of sexes and age groups for each species and the physiological status of the

animals may vary depending on the time of the year, as do the nature of interactions between animals and their reactions to the presence of humans. The value of the outcome gained from immobilizing an animal must always be balanced against the detrimental impacts that the intervention produces. Where possible, procedures should be conducted at times of the year when the expected impact upon animals is lowest. For example, if a procedure on a lactating female decreases the likelihood of survival of her pup, then the procedure should be delayed if possible.

A major consideration in most immobilization procedures conducted on free-ranging phocid seals is the assessment of the likelihood of the animal fleeing to the water. This is particularly important when the chemical agent is being delivered by remote injection, as sedated animals are at risk of drowning. In this situation, it is important to understand the animal's response to human interference, and carefully approach the animal to a distance where the dart can be placed as accurately as possible. Ideally, the seal should not be aware of the approach of the operator. Regardless of whether this can be achieved, the aim is that the animal remains calm to reduce the likelihood of it fleeing to the water when darted.

Optimal techniques for anesthesia, monitoring and recovery management can often be difficult to apply in a field procedure. For example, inhalant anesthetic techniques may be logistically difficult during field procedures conducted in extremely cold environments. Precision vaporizers function efficiently within a limited temperature range and must be housed in insulated containers when environmental temperatures are low (Gales et al. 2005). Effective insulation may be difficult to maintain for prolonged procedures, and the use of injectable anesthetic agents may be more practically useful in such circumstances (Mellish et al. 2010).

Optimal management of the recovery period is extremely important. As previously discussed (see Recovery section), the timing of extubation is of particular significance for phocid seals as they are prone to respiratory obstruction. It is also worthwhile to consider the potential effect of immobilization technique on physiological parameters. For example, male Weddell seals show a clear, prolonged elevation in cortisol levels in response to physical restraint (Harcourt et al. 2010). This effect may impact upon biological parameters being measured during field experiments.

ANALGESIA

Phocid seals may require analgesia during periods of illness or following trauma or surgery. Use of both opioids and nonsteroidal anti-inflammatory drugs (NSAIDs) has been reported. Nutter et al. (Nutter et al. 1998) described pharmacokinetics of single-dose butorphanol in northern elephant seals and determined that

a dose rate of 55 µg/kg IM resulted in detectable plasma levels for up to 5 hours post injection, and produced a degree of sedation for up to 3 hours. The NSAID flunixin meglumine has been used to treat ocular inflammation in southern elephant seals (Vogelnest et al. 1996) and musculoskeletal disorders in gray and harbor seals (Barnett 1998). Anorexia has been reported in southern elephant seals treated with flunixin meglumine for more than 72 hours, possibly the result of gastric inflammation/ulceration (Barnett 1998; Vogelnest et al. 1996). The NSAIDs carprofen and meloxicam have been administered to phocid seals both orally and intramuscularly at canine dose rates without adverse effects (Barnett 1998; Lucas et al. 1999).

47 Otariid Seals

Martin Haulena

INTRODUCTION

The chemical immobilization of otariid and other marine mammal species has historically been considered to be of relatively high risk and associated with high mortality (Gage 1993). Recent advances in monitoring and support, improved preanesthetic risk assessment, and the use of newer and safer immobilization agents have, however, greatly increased successful outcomes from anesthetic procedures in these species (Stringer et al. 2012).

The family Otariidae (sea lions and fur seals) within the order Pinnipedia is composed of 14 species. Otariids bear weight on all four flippers, climb, locomote quickly, and are more adept on land than phocid seals. However, their aquatic adaptations are less developed, and they generally do not dive as deep or for as long as phocids. Anatomic and physiologic adaptations for diving (i.e., large venous sinuses and a dive response) are, therefore, not as extreme (Elsner 1999; Pabst et al. 1999). Some of these differences make otariids more difficult to physically or mechanically restrain than phocids of similar mass.

CAPTURE AND PHYSICAL RESTRAINT

Many otariid species are easily trained to follow trainers and voluntarily enter different housing units or transport cages. Training of animals maintained at public display institutions is essential for enrichment, minimizing stress, and facilitating medical procedures. Animals in care for only short periods of time, as in a wildlife rehabilitation center or research facility, require the use of protective equipment by handlers. Depending on size and species, animals can be safely moved with herding boards, chutes, and mobile fencing. They

can be herded into cages or transport containers for longer travel. Depending on the local topography, moving healthy adult otariids is very challenging and requires well-trained, experienced personnel.

Physical Restraint

Physical restraint is primarily limited by the animal's size and the experience of personnel. Training captive animals for a variety of behaviors minimizes the requirement for physical restraint. Towels, protective gloves, or sedative drugs may facilitate restraint of smaller individuals. Multiple personnel are required to restrain animals ≥ 20 kg. Mechanically or chemically assisted restraint is strongly recommended for healthy untrained animals ≥ 90 kg. Larger debilitated animals, such as those encountered at rehabilitation centers, may be restrained using only physical methods. The limitations of physical restraint in otariids include minimal duration of procedures, poor accessibility to various parts of the animal, lack of analgesia, risk of injury to personnel, and undue stress to the animal as a result of prolonged struggling.

Otariids are quick, agile, and strong and will use their large carnivorous teeth in defense. Controlling the head is essential. Sea lions have tremendous power in their forelimb muscles. If they gain a purchase and are able to lift their thorax off the ground, they will easily throw off a person. Care is taken to control the front flippers, raising them slightly and holding them against the side of the animal. This is particularly important in animals ≥ 20 kg. Animal safety concerns include ensuring airway integrity and that the head is not turned at an awkward angle or held over an edge that may collapse the trachea. Too much weight on the thorax will inhibit ventilation. Musculoskeletal problems arise from excessive restraint on the extremities.

Figure 47.1. (a and b) Nets with reinforced, small conical openings are useful for restraining small otariid seals. They can also be used for restraint for inhalant anesthesia induction with a mask. Care must be taken to prevent obstruction of the nares.

Care must be taken to avoid soft tissue injuries, including abrasions and scrapes, if restraint is on a rough substrate.

Mechanically Assisted Restraint

There are several commercially available large carnivore squeeze cages that have been used successfully in a variety of otariid species. Although many designs exist, squeeze cages that entrap the animal's neck in a vise or noose will put pressure on the trachea and should be avoided. The otariid trachea easily collapses due to incomplete tracheal rings. When using squeeze cages, it is important to closely monitor the respiratory excursions and mucous membrane color of the animal. Care is taken to avoid pinching extremities, especially as the cage begins to squeeze. Animals will bite at the bars potentially resulting in tooth fracture. The cage bars may be padded to avoid soft tissue injury and minimize dental injuries. Animals maintained in zoos or aquaria can be trained to enter a cage and be lightly squeezed for sample collection (e.g., for venipuncture). Some animals have been trained to accept delivery of an anesthetic gas through a mask without further restraint. As with physical restraint, sedative agents may decrease the degree of struggling and facilitate restraint.

Nets

There are a variety of commercially available nets custom-designed for use in otariids. Nets aid in capturing animals, can be used for restraint, and allow the administration of chemical immobilization drugs. Well-designed nets are somewhat tubular to keep the pectoral limbs against the side and prevent the animal from lifting itself up. Nets should be wide enough to easily capture the animal, but taper to a point so the head can be easily controlled. In the field, care must be

taken to monitor an animal in a net for hyperthermia and exhaustion after capture. Animals have overheated in tightly fitting nets left in the sun while other animals were being sampled or processed. Some nets have small openings at the tip that allow exposure of the nares and rostrum but are tight enough to prevent the animal from biting personnel (Fig. 47.1a,b). These openings aid in masking an animal with an inhalant anesthetic after capture.

Although most methods of mechanical restraint enhance safety for personnel, training and experience are required to ensure adequate and safe restraint. Most mechanical devices, including nets, limit access to the animal for some procedures.

VASCULAR ACCESS

Vascular access for placement of catheters for fluid and emergency drug administration is difficult in small animals, hypothermic individuals, or otariids anesthetized with certain drugs (e.g., alpha-2 agonists). Some species have readily accessible interdigital veins in the pelvic limbs. However, these are not accessible in some species (e.g., California sea lion). Other accessible veins for catheterization include the cephalic, jugular, subclavian, and vessels running along the digits of the hind flipper. Ultrasound-guided placement is recommended if available. An indwelling catheter was maintained by the author for 4 days in a juvenile California sea lion using the common jugular vein. Arterial access has also been achieved through a variety of vessels including the median artery.

ENDOTRACHEAL INTUBATION

Endotracheal intubation is strongly recommended for any prolonged procedure that requires a surgical plane

of anesthesia (Sedgwick 1999; Work et al. 1993). Otariid intubation is easier than in phocids, resembling intubation of terrestrial carnivores. In general, endotracheal tubes are of similar diameter to those that would be used on terrestrial carnivores of the equivalent mass. Care is taken to ensure that endotracheal tubes do not extend past the prethoracic bifurcation of the trachea resulting in unilateral lung intubation (McGrath et al. 1981). The mouth is opened with soft nylon straps or rope. The head and neck are held straight and in a slightly hyperextended (opisthotonic) position. Ensure table edges or other equipment does not compress the trachea and interfere with passage of the endotracheal tube (Lynch et al. 1999). Gentle manipulation is used to prevent trauma to the larynx. Standard laryngoscopes facilitate visualization of the airway (Haulena et al. 2000; Heard & Beusse 1993). Very large adults can be intubated by manual palpation of the epiglottis (Heath et al. 1996). Cuffed endotracheal tubes are used to prevent aspiration. It is important not to cause tracheal injury by overinflating the cuff. Endotracheal tubes can be secured over the maxilla or mandibles using rolled gauze, rope, or tape passed caudal to the canine teeth.

PREANESTHETIC CONSIDERATIONS

Preanesthetic assessment is important for selection of the optimal method of immobilization and to decrease the incidence of adverse side effects. It is often very difficult to obtain a complete medical history for an individual animal, particularly for free-living animals or those undergoing rehabilitation. A medical history for zoo and aquarium animals may be available. However, even for these animals, the purpose of the immobilization procedure may be to gather information and samples to diagnose an unknown condition. A recent study (Stringer et al. 2012) confirmed that health status is an excellent predictor of a successful immobilization. It is important, therefore, to try to select animals that are in good body condition and of known health status for elective procedures or for field studies. In addition, it is important to have some knowledge of the common medical conditions that affect both captive and free-living animals to facilitate preprocedure planning.

Some problems are specific to species, sex, age, season, or geographic location. For example, most stranded animals entering a rehabilitation program are dehydrated, malnourished, and may have infectious disease conditions that should be stabilized prior to an anesthetic procedure. Particular attention to these potential problems will lead to better intraprocedure physiologic support. Free-living animals, particularly juveniles, may have high parasite loads. Parasitic pneumonia caused by *Parafilaroides decorus* in species such as the California sea lion (*Zalophus californianus*) (Gage

et al. 1993) may exacerbate ventilation problems encountered during an anesthetic procedure. Young animals such as northern fur seals (*Callorhinus ursinus*) may be affected by hookworm (*Uncinaria* spp.) which can cause anemia (Lyons et al. 2000). These animals are prone to hypoxemia and vascular compromise. Dehydrated juvenile and subadult California sea lions stranding during the late summer and early fall are often affected by leptospirosis, which may cause renal failure (Gulland et al. 1996). Poor renal function can significantly alter the excretion of some parenteral anesthetics. Animals with clinical leptospirosis are poor anesthetic candidates. Animals housed in zoos and aquaria may live longer than free-living animals and may be prone to developing progressive organ failure similar to domestic species.

Atropine (0.02 mg/kg IM) has been recommended 10 minutes prior to immobilization to prevent bradycardia associated with the dive reflex in anesthetized otariids (Gage 1993; Heath et al. 1996). Atropine has also been administered after injection of sedatives to control airway and oral secretion and prevent bradycardia (Spelman 2004). However, alpha-2 agonists such as medetomidine will cause bradycardia. Use of atropine with medetomidine is contraindicated in terrestrial mammals (Cullen 1996). There is currently a debate over the use of atropine in otariids, especially those anesthetized with alpha-2 agonists, with some studies indicating that the use of atropine is associated with increased mortality (Stringer et al. 2012).

INDUCTION/MAINTENANCE PROTOCOLS

Intravenous sites for injection of immobilizing agents are poorly accessible in many otariid species. This is particularly true for difficult to restrain animals and under field conditions (Work et al. 1993). Most anesthetic drugs evaluated for use have, therefore, been limited to those that can be administered IM (Bester 1988; Heard & Beusse 1993; Heath et al. 1996; Loughlin & Spraker 1989; Melin et al. 2013) and inhalant anesthetics (Heath et al. 1997; Work et al. 1993; Yamaya et al. 2006).

Intramuscular drugs are injected into the large muscle masses overlying the lower lumbar spine (Bester 1988; Loughlin & Spraker 1989), tibia, and hips (Haulena et al. 2000; Heard & Beusse 1993; Loughlin & Spraker 1989; Sepulveda et al. 1994) as well as the shoulders (Loughlin & Spraker 1989). Immobilizing IM agents have been hand injected or delivered by dart. Physical or mechanical restraint may facilitate accurate hand injection of anesthetic agents.

Inhalation anesthetics (e.g., isoflurane) appear to be the safest method for anesthetizing otariids because of the ability to titrate the level of drug to effect. The main limitation is the availability and portability of equipment to safely and reliably deliver the anesthetic in the

field. In addition, delivery of a gas for a sufficient period of time to induce anesthesia may be difficult in a fractious, unrestrained animal. Most public display facilities, rehabilitation centers, and research facilities are equipped for delivery of inhalant anesthetics. A recent publication describes the use of an induction chamber for delivery of inhalant anesthesia to sea lions (Yamaya et al. 2006). The development of safe, portable gas anesthesia machines for field work has greatly increased the use of gas anesthesia in free-living species. A comprehensive animal training program, adequate physical or mechanical restraint, or the use of chemical sedative and immobilizing agents (Haulena & Gulland 2001; Haulena et al. 2000; Heard & Beusse 1993; Heath et al. 1996) facilitates the use of inhalation anesthesia.

Although chemical immobilization is the safest method of restraint for personnel and allows complete access to the entire animal, there is some risk to the animal being anesthetized. This risk is minimized by adequate preparation and preanesthetic evaluation of the patient, use of experienced anesthetists, use of safe and efficacious immobilization agents, careful monitoring, and physiologic support of the animal.

Sedation

The use of a variety of IM sedative drugs may facilitate physical or mechanical restraint and aid induction with other drugs (e.g., isoflurane) (Gales 1989). Diazepam (0.1–0.2 mg/kg PO) prior to transport aids physical restraint of some animals. More reliable sedation is achieved with midazolam in California sea lions (0.15–0.2 mg/kg IM) and fur seals (0.25–0.35 mg/kg IM) (Lynch et al. 1999). Benzodiazepines can be reversed with flumazenil (Karesh et al. 1997). Butorphanol (0.05–0.2 mg/kg IM) has been used for mild sedation and analgesia. Combination of midazolam and butorphanol results in an increased level of sedation. Medetomidine (70 µg/kg IM) is recommended for sedation of sea lions for electroencephalography because of its apparent lack of interference with brain wave patterns in contrast to a combination of medetomidine and butorphanol (0.1–0.2 mg/kg IM) (Dennison et al. 2008). Although sedation was variable, placement of multiple percutaneous leads for recordings was accomplished for greater than 30 minutes.

Chemical Immobilization

Drugs commonly used to immobilize otariids are discussed in the following section. Table 47.1 summarizes drug dosages from recent studies. Several reviews have been written and should be referred to for a complete list of pinniped immobilization methods (Gales 1989; Haulena & Heath 2001; Lynch et al. 1999; Williams et al. 1990).

Zolazepam/Tiletamine The advantages of this combination include small injection volume, low cost, and

Table 47.1. Blood gas variables from the caudal gluteal vein in 10 physically restrained California sea lions (*Zalophus californianus*)

Variable	Mean ± SD	Range
Na	149 ± 3	146–152
K	4.3 ± 0.5	3.6–5.3
TCO ₂	23 ± 5	17–29
iCa (mmol/L)	1.20 ± 0.07	1.07–1.31
Hct (%)	45 ± 5	37–51
Hb (g/dL)	16 ± 2	13–17
pH	7.31 ± 0.05	7.22–7.38
PCO ₂ (mmHg)	43.9 ± 4.9	38.4–53.8
PO ₂ (mmHg)	74 ± 21	45–103
HCO ₃ (mmol/L)	22 ± 4	16–27
BE	–4 ± 5	–11–2
SO ₂ (%)	91 ± 7	77–97

dependable deep sedation and immobilization. However, some studies report significant mortality, prolonged recovery, and a narrow margin of safety (Dabin et al. 2002; Heath et al. 1996). Zolazepam/tiletamine (1.7 mg/kg IM) in California sea lions is administered 10 minutes after atropine (0.02 mg/kg IM) (Gage 1993). A slightly lower dosage (0.9–1.3 mg/kg IM) is recommended in subantarctic fur seals (*Arctocephalus tropicalis*). Additional “top-up” doses to increase anesthetic depth have been associated with increased mortality (Heath et al. 1996). However, additional ketamine has been used successfully without mortality (Karesh et al. 1997). The combination is partially reversed with flumazenil (Karesh et al. 1997).

Medetomidine/Ketamine In California sea lions, the combination of medetomidine (140 µg/kg IM) and ketamine (2.5 mg/kg IM) provides effective and safe immobilization that is reversed by atipamezole (0.2 mg/kg IM). Animals were premedicated with atropine (0.02 mg/kg IM). Disadvantages of this combination in sea lions include moderately variable anesthetic depth, large injection volume when commercially available products are used, and high cost (Haulena et al. 2000).

Medetomidine/Zolazepam/Tiletamine The combination of medetomidine (70 µg/kg IM) and zolazepam/tiletamine (1 mg/kg IM) produced reversible (atipamezole 0.2 mg/kg IM), reliable anesthesia (Haulena & Gulland 2001). Injection volume and cost were much less than for medetomidine/ketamine. Adverse effects observed during recovery included tremors, ataxia, and disorientation. These were less than with zolazepam/tiletamine alone, but occur more often than with medetomidine/ketamine. Animals were premedicated with atropine (0.02 mg/kg IM). One mortality did occur in the study. Consequently, a lower medetomidine dosage (40 µg/kg) in combination with zolazepam/tiletamine is recommended.

Medetomidine/Butorphanol/Midazolam A combination of medetomidine (10–13 µg/kg), midazolam (0.2–0.26 mg/kg), and butorphanol (0.2–0.4 mg/kg) IM was evaluated in California sea lions (Spelman 2004) maintained at a zoo. The combination is completely reversible using atipamezole (0.05–0.06 mg/kg IM), flumazenil (0.0002–0.002 mg/kg IM), and naltrexone (0.1 mg/kg IM), respectively. The combination produced safe, light anesthesia in animals that was supplemented with isoflurane for deeper planes of anesthesia. Atropine (0.02 mg/kg IM) was given immediately after injection of the immobilizing agents. This combination was further evaluated in free-ranging adult male California sea lions at a dosage of 0.03 mg/kg medetomidine, 0.15 mg/kg midazolam, and 0.1 mg/kg butorphanol, where it was found to have much superior immobilization characteristics in comparison with medetomidine/zolazepam/tiletamine and with medetomidine/midazolam (Melin et al. 2013).

Inhalant Anesthetics Inhalant anesthetics including isoflurane (Gales & Mattlin 1998; Haulena et al. 2000; Heard & Beusse 1993; Heath et al. 1996, 1997), sevoflurane, and halothane (Work et al. 1993) have all been used in otariids. The safest anesthesia with the best recovery characteristics has been obtained with isoflurane and sevoflurane. Otariids uptake anesthetic gases very rapidly and efficiently and are readily induced with a mask. Controlled studies on the efficacy of mask induction and maintenance of anesthesia with an inhalant are few for marine mammals. However, California sea lions, New Zealand fur seal (*Arctocephalus forsteri*) bulls, and adult female New Zealand sea lions (*Phocartos hookeri*) appear to be more rapidly masked to anesthetic depths in comparison with terrestrial species (Gales & Mattlin 1998; Heath et al. 1997). The use of inhalant anesthetic agents alone appears to be a reliable and safe method of anesthesia in otariids if it is possible to accomplish restraint and masking (Fig. 47.2). Premedication and induction with intramuscular drugs facilitate masking and maintenance of anesthesia with an inhalant agent if the animals cannot be masked voluntarily or with physical restraint (Haulena & Gulland 2001; Haulena et al. 2000; Heard & Beusse 1993; Heath et al. 1996). Once anesthesia has been attained, reversible induction agents may be antagonized.

Immobilization Location

As with phocid seals, otariid immobilization success is greatly enhanced by good planning, proper equipment, experienced staff, and a well-prepared space. The ability to safely handle, restrain, and deliver anesthetic agents to the animal is essential. A surgery or procedure area that includes an accessible immobilization and recovery pen for monitoring or emergencies is recommended. The ability to control temperature, noise, and light will

Figure 47.2. Training a Steller sea lion (*Eumetopias jubatus*) for voluntary acceptance of a mask for induction with isoflurane at the Vancouver Aquarium (photo courtesy of the University of British Columbia Marine Mammal Research Unit).

help induction and physiologic support of the patient. Immobilization of larger animals may require procedures be carried out in the animal's pen due to space and transport limitations. Adequate preprocedure planning and availability of emergency equipment are essential for a safe procedure.

MONITORING

An anesthetic plan is developed based on available history, knowledge of the species, and any available laboratory data. Monitoring physiologic variables (especially cardiopulmonary) should begin as soon as possible after induction and throughout the procedure. Most commonly used monitors can be adapted for use in the otariid (Chapter 3). Variables that are commonly measured include heart and respiratory rates, capillary perfusion, response to painful stimuli, body temperature, hemoglobin saturation (relative SpO₂), end-tidal carbon dioxide (EtCO₂), blood pressure, and blood gas levels. For otariids, the trends in the measured variables are more important than the point measurements.

Heart rate is one of the most important variables to monitor. It is determined by either palpation or observation of thoracic wall movement over the heart, just caudal to the axilla. Chest auscultation can be used, but thoracic noise is muffled compared with terrestrial mammals (Lynch et al. 1999). Heart rate can also be determined using electrocardiogram (ECG) leads placed externally (Heard & Beusse 1993) or attached within an esophageal probe (Haulena & Heath 2001). Pulse oximeters also generate a pulse wave that can be used to calculate heart rate. However, the pulse wave does not reflect adequacy of tissue perfusion (Chapter 3). The pulse oximeter probes can be clipped to the tongue

(Haulena et al. 2000; Heard & Beusse 1993; Heath et al. 1996, 1997), but the clips tend to slip off the short, thick tongue. Probes are placed on the nasal septum of larger animals. Reflectance probes can be placed rectally, vaginally, or along the buccal or gingival mucosa (Heath et al. 1996). Sudden or progressive bradycardia may be an early indication of initiation of the dive reflex. Some drugs, particularly the alpha-2 agonists, also cause bradycardia.

Respiratory rate is measured by observing thoracic movement, opening of the nares, or by chest auscultation. Capnography and respiratory monitors can be used to electronically calculate respiratory rate. Apnea is common in anesthetized otariids (Sedgwick 1999) and may be due to excessive anesthetic, the immobilizing drug used, or the dive reflex.

Anesthetic depth is assessed using response to various stimuli such as noise and deep pain (interdigital web pinch, ear pinch, and surgical stimulation), presence or absence of the palpebral and pupillary reflexes, respiratory rate rhythm, tidal volume, and jaw tone (Heath et al. 1996, 1997; Work et al. 1993).

Peripheral body temperature measurement does not accurately reflect core because of the thick layers of insulating blubber. Flexible temperature probes are inserted at least 10 cm into the rectum of the animal (Bester 1988; Ferreira & Bester 1999; Loughlin & Spraker 1989). Alternatively, esophageal probes inserted to the level of the heart (Heath et al. 1997) may give accurate core temperature readings.

Body temperature fluctuations resulting in either hypo- or hyperthermia can occur in anesthetized otariids. It is particularly important to monitor temperature in field conditions where control of the environment is more difficult. Temperature changes are influenced by the drugs used, species, size, geographic location, and physiologic status of the animal. For example, larger animals have a greater tendency to hyperthermia than smaller animals (Work et al. 1993). Some drugs (e.g., ketamine) may cause hyperthermia (Sepulveda et al. 1994), while others (e.g., isoflurane) cause vasodilation that promotes hypothermia (Loughlin & Spraker 1989; Work et al. 1993). Profound hyperthermia was seen in a late-term pregnant California sea lion that was anesthetized using medetomidine and ketamine. Shelter from rain, wind, and sun, while maintaining adequate ventilation, is recommended to prevent temperature irregularities. A variety of commercially available heating blankets, heated surgical tables, hot water bottles, wraps, and insulating pads can be used to prevent hypothermia (Heath et al. 1997; Sepulveda et al. 1994; Work et al. 1993). Ice or cold water applied to extremities is used to treat hyperthermia.

Mucosal membranes (oral, rectal, and vaginal) are used for monitoring color and capillary refill time as indicators of perfusion and oxygenation (Heath et al. 1997; Work et al. 1993). Capnometer probes are

attached to the endotracheal tube via filter line (Haulena & Gulland 2001; Heard & Beusse 1993). Elevations or sudden decreases in EtCO₂ levels may indicate ventilation and perfusion problems.

Noninvasive, oscillometric blood pressure monitoring is performed by attaching cuffs to the proximal portion of the limbs or to the base of the tail. Venous blood gas samples are collected from the caudal gluteal, interdigital, or common jugular veins. Blood gas values obtained from 10 healthy California sea lions under physical restraint (Table 47.1) indicate that arterial blood is sometimes obtained from the area of the caudal gluteal vein (Haulena et al. 2001). Direct blood pressure and arterial blood gases have been collected from a variety of sites including the median artery.

Low SpO₂ values (<85%) have been reported in sea lions immobilized with zolazepam/tiletamine (Heath et al. 1996) and with medetomidine/ketamine (Haulena et al. 2000). This effect is greater in animals not intubated and provided with supplemental oxygen. Conversely, sea lion pups maintained with isoflurane in oxygen maintained higher SpO₂ values (Heath et al. 1997). This may be due to the drugs used, anesthetic depth, or to the animal's physiology. Low SpO₂ levels indicate that the anesthetist should be prepared to intubate, provide oxygen therapy, and assist ventilation.

High EtCO₂ (>70 mmHg) levels (Haulena & Gulland 2001; Heard & Beusse 1993) associated with acidemia (pH < 7.15) in anesthetized California sea lions support the need for assisted mechanical ventilation in some animals (Haulena et al. 2001). Some drugs are more commonly associated with hypoventilation and hypercapnia. Animals anesthetized for prolonged periods, maintained at deep anesthetic planes, and positioned in a manner that interferes with normal thoracic expansion are particularly prone to developing hypercapnia. Conversely, hyperventilation of California sea lions has resulted in alkalemia (pH > 7.5).

In anesthetized otariids, mechanical ventilation is recommended at a starting tidal volume of 15 mL/kg and a rate of 8–10 breaths/min (Haulena et al. 2001). Capnometry is essential with mechanically assisted ventilation to adjust tidal volume and rate to maintain normocapnia. Blood gas monitoring is recommended to prevent alkalosis. Venous blood gas values for California sea lions are listed in Table 47.2.

FIELD IMMOBILIZATION (WILD CAPTURE)

Many of the physical and mechanical restraint methods described earlier can be modified for use in field conditions. Immobilization of animals in the field presents significant challenges. However, portable gas anesthesia machines, battery-operated monitoring equipment, and emergency equipment are all available (Gales & Mattlin 1998). If injectable chemical immobilization is required prior to adequate physical or mechanical

restraint, it is essential that animals selected for capture are as far as possible from water or other hazards (Fig. 47.3 and Fig. 47.4). It is also important to choose animals that are relatively calm and have the least risk of escaping into the water or to inaccessible areas (Heath et al. 1996). This will help minimize the risk of drowning or falling from large heights.

Young animals such as pups can be herded on suitable haul-out sites into temporary pens where individual animals can then be isolated for further handling (Merrick et al. 1995). For procedures requiring immobilization, the use of portable anesthetic machines for delivery of inhalant anesthesia is preferred (Heath et al. 1997).

Large adult animals have been trapped on artificial haul outs and then funneled through chutes and into squeeze cages to facilitate sample collection and handling (Melin et al. 2013). These animals can then be

masked with inhalant anesthetics for more invasive sampling procedures.

Recently, a method of capturing free-ranging Steller sea lions (*Eumetopias jubatus*) in the water was developed using a team of divers, baited nooses attached to floats, and a surface capture team in boats (Raum-Suryan et al. 2004). This capture method requires a tremendous amount of training and planning and should only be carried out by highly experienced staff.

Delivery of immobilizing agents by dart has been used in animals undergoing rehabilitation (Haulena et al. 2000) as well as in the field (Geschke & Chilvers 2009; Heath et al. 1996; McKenzie et al. 2012). In free-living animals, delivery by dart poses some risk to animals that may escape to the water or to an inaccessible area as the anesthetic drug begins to take effect prior to complete immobilization (Heath et al. 1996). The remotely delivered use of zolazepam-tiletamine has been associated with a high degree of risk in some species such as Steller sea lions (Heath et al. 1996), while other studies report much lower risk in New Zealand fur seals and sea lions (Geschke & Chilvers 2009; McKenzie et al. 2012). Some authors report a decrease in the reliability of anesthesia when darts are employed in comparison with hand injection (Haulena et al. 2000).

More recently, the reversible combination of medetomidine, midazolam, and butorphanol (Melin et al. 2013; Spelman 2004) has been evaluated for remotely delivered use in adult female Steller sea lions (Haulena et al. 2011) (Fig. 47.2 and Fig. 47.3). Medetomidine (0.04–0.06 mg/kg), midazolam (0.20–0.22 mg/kg), and butorphanol (0.13–0.15 mg/kg) reliably and safely immobilized animals for sampling and attachment of telemetry instruments (Fig. 47.5 and Fig. 47.6a,b). The sea lions were maintained with isoflurane and reversed with atipamezole (0.25 mg/kg IM) and naltrexone (0.15 mg/kg IM). Animals that went

into the water after darting were either darted with the reversal agents, and observed fully recovered, or monitored until they spontaneously recovered. No mortalities occurred. Advantages included a smooth induction and full recovery prior to entering the water after the procedure.

It is apparent that careful selection of individuals is very important for successful darting. Animals should be very calm and preferably sleeping. Steller sea lions darted in an undisturbed group appear to be less likely to move and enter the water after they are darted. Animals that spot darting team members after being darted are more likely to move and enter the water. Animals react more to brightly colored dart stabilizers and darkening the stabilizers with a black permanent marker is recommended. Animals also react more to darts that remain embedded, and nonbarbed and non-collared needles should be used that allow the dart to fall out as soon as possible after delivery.

ANALGESIA

There are very few studies evaluating the use of analgesics in otariids. Use and dosage of analgesic agents have been based on extrapolation from other species and personal experience. Analgesics that have been used with good clinical response in otariids include opiates, nonsteroidal anti-inflammatory drugs (NSAIDs), and alpha-2 agonists. The most commonly used opioid is butorphanol (0.05–0.2 mg/kg PO, IM, or IV q 6 h). Buprenorphine (0.01 mg/kg SC, IM, or IV BID) has been used as well as tramadol (0.5–2.0 mg/kg PO BID). NSAIDs used by the author include flunixin meglumine (1 mg/kg IM q 24 h) for up to 3 days, ketoprofen (1 mg/kg IM q 24 h) for up to 5 days, buffered acetylsalicylic acid (5 mg/kg PO q 24 h) for up to 5 days, carprofen (2–4 mg/kg PO q 24 h) for up to 14 days (Dold et al. 2004), meloxicam (0.1–0.2 mg/kg PO, SC, or IM SID), and piroxicam (0.2–0.3 mg/kg PO SID). For additional analgesia, butorphanol has been combined with an NSAID. Medetomidine (10–40 µg/kg) has also been used to provide analgesia.

ACKNOWLEDGMENTS

Sincere thanks go to the staff and volunteers of The Marine Mammal Center, the Vancouver Aquarium, the North Pacific Universities Marine Mammal Research Consortium, the National Marine Mammal Laboratory, and the University of British Columbia Marine Mammal Research Unit. Funding for research involving mechanically assisted ventilation was provided by the California Oiled Wildlife Care Network. Special thanks go to Dr. David Huff for his thoughtful review.

Walrus

David B. Brunson

SPECIES-SPECIFIC PHYSIOLOGY

Walruses are one of the most difficult marine animals to anesthetize. The large size, limited vascular access, and propensity for sudden physiological changes during chemical restraint have led to their reputation of high anesthetic risk. High mortality rates have been reported with both opioids and dissociative anesthetics but are most likely due to severe respiratory and circulatory compromise when the animals are anesthetized out of the water. Respiratory arrest is commonly reported during immobilization with potent opioids. Additionally, walruses have died during chemical immobilization; they have developed circulatory failure despite effective ventilatory support.

There are two subspecies of walruses; the Atlantic walrus, *Odobenus rosmarus rosmarus*, and the Pacific walrus, *O. rosmarus divergens*. A third subspecies, the Laptev sea walrus, *O. rosmarus laptevi*, has been proposed but this is not commonly recognized. The walrus is a large and powerful pinniped. The skin is typically a cinnamon-brown color which is covered by short course hair. As the animal ages, the skin becomes lighter. The name *rosmarus* comes from the reddened color due to cutaneous vasodilatation when warmed by the sun while the animal is out of the water. Walruses have enlarged upper canine teeth commonly referred to as tusks. The Atlantic subspecies, the males measure 300 cm and weigh 1200 kg. Females measure 250 cm and weigh 750 kg. At birth, pups are 140 cm long and weigh 50 kg. The Pacific walrus is slightly larger with males being up to 360-cm long and weighing up to 1600 kg; Pacific walrus females are 260-cm long and weigh approximately 1250 kg. Young Pacific walrus pups measure 140 cm and weigh 60 kg (Garlich-Miller & Stewart 1999).

Problems with chemical immobilization of marine mammals and, in particular, walruses have been associated with elicitation of the dive reflex. Clinical signs during chemical immobilization appear similar to this classic physiological reflex. Since walruses can submerge for extended time periods for foraging at the sea bottom, they are capable of prolonged breath holding. Additionally, the simultaneous occurrence of low heart rates with breath holding has close similarities to the classic "dive reflex." However, the ability to dive for long periods of time is not the same as the adverse reactions seen by marine mammals to anesthetic or immobilization drugs. Unlike the normal diving physiology, apnea and bradycardias during chemical immobilization are associated with high mortality. Normal dive responses are not associated with lasting metabolic derangements or cardiac failure. It appears that during chemical immobilization or general anesthesia, the physiological dive mechanisms do not function normally. A necropsy finding of a captive walrus showed disseminated myocardial fibrosis and atherosclerosis which was attributed as the cause of death. Underlying myocardial disease would increase the risk of anesthesia (Gruber et al. 2002).

The upper airway of walruses is characterized by small nostrils with large muscles to close the openings during submersion. The nasal passages are small and the nasal turbinates are such that the nasal passages lack a large meatus. This adaptation prevents water from passing through the nose into the pharynx and trachea. The oral cavity is large and characterized by a high arched hard palate. The walruses tongue is large and thick. Because the tongue lacks thin edges, standard veterinary pulse oximetry probes are not easily placed on the tongue. The lower jaw moves between the large upper canine teeth (tusks). Even in very large

individuals, the rostral opening to the mouth is no more than 10–12 cm in width and height. Because of the limited size of the opening, smaller walrus are difficult to manually direct an endotracheal tube into the larynx as is done in cattle.

Walrus have a unique pharyngeal pouch that can be inflated to provide buoyancy while resting on the ocean surface. Although this adaptation seems to be more highly developed in wild free-ranging walrus, it may also present a potential problem for airway management in captive raised walrus (Fay 1969). During tracheal intubation, it is important to direct the tube through the larynx and not into the pharyngeal pouch.

PHYSICAL CAPTURE AND RESTRAINT

Physical restraint of untrained wild adult walrus is impractical. Captive walrus can be conditioned to enable physical examination including oral examination and thoracic auscultation. Cargo nets are used for young animals but have limited effectiveness in animals greater than 100–150 kg of body weight.

CHEMICAL RESTRAINT AND ANESTHESIA

Vascular Access

The heavy subcutaneous fat layer and the thickness of walrus skin prevent identification and access to veins in the cervical region or the appendages. Venous access can be obtained through the dorsal extradural intravertebral vein (EIV) and the gluteal vein. Placement of a catheter into the dorsal EIV has been described (Stetter et al. 1997). The epidural IV access can be used for fluid administration, emergency drugs, and for intravenous anesthetic administration.

Needle placement for intravenous access into the epidural venous sinus is identical to placement of epidural needles or catheters via the lumbo-sacral space in other species. Palpate the wings of the ilea on each side of the spinal column and the midline of the walrus back to identify the approximate location of the last lumbar vertebra. In the author's experience, it is easiest to find these landmarks with the animal in sternal recumbency. Even in animals with normal body fat and in healthy condition, these landmarks for needle placement can be found. If an epidural catheter is being used for IV access, a tuohy needle is recommended to assist in directing the catheter cranially into the vein. The needle will be placed on the midline approximately 3–5 cm behind a line transecting the midline from the cranial aspects of each ileum. This should be approximately at the third to fourth lumbar vertebra (L3–L4). The landmarks for the proper access site are the same as those used for epidural anesthesia in the dog or cat. In adult walrus, a 16- or 17-gauge 8.9-cm-long needle is necessary to access the EIV. Advance the needle into the animal at a perpendicular angle to the skin. A

syringe can be placed on the needle and gentle aspiration used to determine entrance into the vein.

Vascular access from the flippers has been described in phocid seals but not walrus. Attempts to obtain blood samples following the landmarks described for seals would be as follows. At the level of the proximal edge of the interdigital webbing of the second and third digits, insert a 37-mm (1 1/1 in) 19-gauge needle at a 10°–20° angle until the blood is aspirated into the syringe. Blood obtained will most often be of mixed arterial and venous origin (Geraci 1978).

An alternative vascular access location is the caudal gluteal vein. A needle is inserted lateral to the sacral vertebra approximately 1/3 of the distance from the femoral trochanter to the base of the tail. In adult walrus, a 12.5-cm-long needle is necessary to reach the vessel. The needle should be held perpendicular to the skin and advanced slowly until blood can be aspirated into a syringe.

Endotracheal Intubation

Intubation of walrus is relatively easy to perform. Intubation is easier if the neck is extended to straighten the oral-laryngeal axis of the head and neck. This is facilitated by positioning the walrus in sternal recumbency. If the animal has large tusks, they can be used to prop up the head and extend the neck. Small ropes or towels placed in the mouth facilitate positioning for intubation. Because of the highly arched hard palate, using a separate rope or towel around each tusk allows better access to the oral cavity than a single one rope passed across the oral cavity. Palpation of the larynx with one hand while directing the endotracheal tube into the trachea with the other hand is recommended. Because of the small size of the oral cavity of even large walrus, it may be difficult to pass a large endotracheal tube while palpating the larynx. In these cases, the use of a small diameter stylet is recommended. The stylet must be at least twice as long as the endotracheal tube. Palpate the larynx as described earlier and pass the stylet through the larynx and into the trachea. The endotracheal tube is then fed over the stylet and into the trachea. Blind intubation is not recommended because of the difficulty in correct placement and the potential for the endotracheal tube to enter the esophagus or pharyngeal pouch.

Tracheal intubation is facilitated by muscle relaxation during immobilization and anesthetic induction. Opioids and dissociative immobilization techniques are frequently associated with extensive muscle rigidity. Small dosages of propofol (40–60 mg) via the EIV will produce muscle relaxation and facilitate endotracheal intubation.

Preanesthetic Concerns

Because of the large size and physical power of walrus, most procedures are performed with the animal

immobilized with drugs or general anesthetics. If the animal is well trained and will allow handling while awake, surgical procedures can be performed using local anesthetics. The thick skin and heavy layer of insulating fat present mechanical challenges for effective regional nerve blocks. However, infiltration of the skin can be performed to provide effective local anesthesia. Both lidocaine HCl and bupivacaine HCl are effective for blocking pain.

Opioid analgesics have been used for capture and immobilization in walruses (DeMaster et al. 1981; Gales 1989; Griffiths et al. 1993; Lynch et al. 1999). As with other marine mammals, analgesia in addition to immobilization is assumed. Of the opioids analgesics, meperidine and butorphanol have been used with benzodiazepines or alpha-2 agonists. Assessment of the analgesic effects of opioids has been limited to the responses observed during immobilization.

Drug Delivery

The walrus, like seals and sea lions, have relatively small pelvic limbs. The pelvis, femur, and tibia are short and the associated muscles are small in relations to the size of the animal. The femur of an adult 1500-kg pacific walrus is approximately ~12–14 in. in length. In addition, the upper pelvic limb is not well demarcated, resulting in injections often occurring at or below the knee joint. The muscles of the hind limbs and pelvis can be used for IM injections but are relatively smaller than the epaxial muscles.

The best sites for intramuscular injections are the large muscles of the back. The epaxial muscles are large and well developed. The areas caudal to the last rib and cranial to the pelvis on both sides of the vertebral column provide a large target area for remote drug injection. The muscles of the front limbs can also be used for IM drug administration. Caution should be used to ensure that injections do not occur into the large cervical blood vessels which are located cranial to the front legs.

During immobilization and anesthesia, injections can be made into the base of the tongue. Sublingual injections have the advantage of rapid absorption due to the high blood flow to the tissue. In emergencies, sublingual injections provide a readily available route for cardiac and respiratory support drugs. Alternatively, emergency drugs can be administered by flushing the drugs into the lungs via the endotracheal tube. A long semirigid piece of plastic tubing can be passed through the ET tube and the medications flushed into the airway. Dilution of the drugs or flushing the tubing with sterile water is recommended to ensure that the entire drug dosage has been administered. Antagonists for immobilization drugs may also be given by these routes when the end of the immobilization has been reached.

MONITORING ANESTHESIA AND SUPPORTIVE CARE

Baseline heart rate and respiratory rates should be taken prior to drug administration. Changes associated with the onset of the effects of immobilization drug can be used to determine the time to approach and to intervene.

Respiratory Function

Apnea is a common sequel to anesthetic or immobilization drugs. Ventilatory support is essential when working with these animals. End tidal gas monitoring is recommended to assess both the efficacy of ventilation and to determine the relative anesthetic concentrations in the animal. Spontaneous ventilation is likely to be inadequate and methods for assisting ventilation should be available. In contrast to the conscious animal's ability to breath hold for long time periods, apnea during immobilization and anesthesia are associated with respiratory and metabolic acidosis, arrhythmias, and poor anesthetic delivery. For this reason, controlled ventilation coupled with expired gas monitoring is important for immobilization or anesthesia. Ventilation rate is essential to monitor during all phases of handling. Adequacy of ventilation is best determined by measurement of end tidal carbon dioxide (EtCO₂) or by blood gas measurements. CO₂ can be monitored with battery operated side-stream style monitors with a catheter placed into the animal's airway or from an endotracheal tube in the intubated animal. Blood gases can be measured on blood samples taken from any vessel including the epidural intervertebral sinus.

Monitoring the Cardiovascular System

Captive walruses are usually immobilized with a combination of midazolam (0.1 mg/kg) and meperidine (2.2 mg/kg) (Klein et al. 2002). Atropine (0.04 mg/kg) is also recommended to prevent vagal induced bradycardia. Intramuscular injections into the hip or epaxial muscles are the recommended injections sites. A long needle (3–4 in.) is necessary to ensure effective drug injection into muscle and rapid absorption.

Heart rate during the onset of immobilization and anesthesia is usually between 80 and 100 beats/min. As anesthesia deepens, the heart rate slows to around 60 beats/min. Heart rate can be determined by observation of movement of the animal's chest wall. Once at the animal's side, auscultation of the heart with a stethoscope or use of an electrocardiograph (ECG) to determine the rate and rhythm of the heart is essential to detect early changes in cardiac function. The use of a pulse oximeter has proven difficult because of the lack of places to position the sensing probes. The author has found that a reflectance style pulse oximeter probe placed against the oral mucosa or rectum has worked intermittently.

PHARMACOLOGICAL CONSIDERATIONS

Whether immobilizing a walrus in captivity or in the wild, the attendant problems are similar. The drugs must be administered via intramuscular injection and from a distance. For this reason, drug volumes must be small and choices are restricted to alpha-2 agonists, benzodiazepines, opioids, and dissociative classes of drugs. All of these drug groups have been used successfully; however, mortalities have also been associated with all drug groups. The reversibility of alpha-2 agonists, benzodiazepines, and opioids has made them the preferred drugs.

Meperidine

Based on early studies within marine mammals, meperidine was shown to be an effective sedative and immobilization drug in a variety of species (Joseph & Cornell 1988). Meperidine was administered by hand injection to 10 walruses at a dosage of 0.23 and 0.45 mg/kg. Sedation/restraint was moderate without apparent detrimental effects. If used as an analgesic, meperidine was associated with obvious sedation (Cornell 1978). As a result of clinical experience, a higher dose of meperidine (2.2 mg/kg) is frequently used to immobilize captive walruses when combined with midazolam (0.1 mg/kg). It is recommended, because of the high incidence of bradycardia during sedation, that atropine (0.04 mg/kg) IM, SQ, or IV be included in the immobilization technique (Klein et al. 2002). A long needle (3–4 in.) is necessary for effective drug injection to ensure rapid complete absorption.

Potent Opioids +/- Alpha-2 Agonists

The use of highly potent opioid analgesics for immobilization of walruses has proven to be less than ideal. Complications include apnea, muscle spasms, rigidity, and death. Adult male Atlantic walruses on a land haul out were effectively immobilized with carfentanil with an intramuscular dose of 2.7–3.0 mg. Muscle spasms were associated with the onset of immobilization. All of the animals had extended periods of apnea; tracheal intubation was not possible due to muscle rigidity (Lanthier & Stewart 2002; Lanthier et al. 1999). The estimated effective dosage range was 4–5 µg/kg.

Many factors make accurate drug dosing difficult in field situations, the body weight can only be estimated prior to drug administration, dart placement, and vascularity of the injection site all affect the ultimate success of remote drug delivery. Pacific walruses injected with similar carfentanil dosages were not adequately immobilized despite the presence of apnea and muscle spasms.

A field study was preformed to test combinations of the alpha-2 agonist medetomidine with opioids carfentanil in adult Pacific walruses. Medetomidine was selected because of the presence of an effective antago-

nist (atipamezole) and availability of a concentrated formulation which minimized dart size and injection volume. The addition of medetomidine with carfentanil would likely decrease the opioid dose and improve muscle relaxation (Mulcahy et al. 2003). A medetomidine dose of 30 mg was combined with carfentanil doses that varied from 0.06 to 3.0 mg per animal. At the 0.06-mg carfentanil dose, immobilization was inadequate, while a dose at the 3.0 mg caused severe respiratory and circulatory depression that was judged to be life threatening. Carfentanil doses of 0.15 and 0.3 mg with 30 mg of medetomidine enabled approach and handling, but apnea occurred and immediate reversal of both drugs was administered. Due to the low numbers of animals, it was not possible to further evaluate this combination. It should be noted that the addition of medetomidine did markedly decrease the carfentanil needed for immobilization although respiratory depression was still severe. Dexmedetomidine is now available and is a purified form of medetomidine. The dosage is 1/2 of the medetomidine dose due to the elimination of the "left handed" isomer levomedetomidine. Thus it would be appropriate to use 1/2 of the milligram medetomidine dosage if using dexmedetomidine. Atipamezole is an effective and recommended reversal agent for dexmedetomidine.

Seventeen walruses were immobilized with carfentanil alone with immediate reversal with naltrexone. Carfentanil (2.4- to 2.7-mg total dose) was administered via dart to the muscular area of the rump. Sedation occurred in 7–21 minutes. Muscle twitching of the muzzle was noted with full body tremors lasting a few seconds, leading to muscle rigidity and immobilization (Tuomi et al. 2002). Naltrexone at 175- to 350-mg total dose was administered into the muscular area of the lip as soon as the walrus was safe to approach. Reversal occurred between 10 and 20 minutes after administration. One animal had a rapid reversal in approximately 5 minutes following injection. An additional dose of naltrexone (175–350 mg) was administered to each animal at the completion of the desired work time to ensure complete reversal of the carfentanil. Use of gas anesthesia provided additional anesthesia when needed (Tuomi et al. 2002).

Field immobilizations with etorphine HCl have had similar effects. Dosages between 4.0 and 15.5 mg/adult male based on estimated body weight were used in field immobilizations of Pacific walruses, with or without reversal with either diprenorphine or naloxone. A dose of 7 mg/adult male was used for the standard dose. Overall mortality rates varied but were in the range of 15–20% (Griffiths et al. 1993; Hills 1992).

Because of the rapid onset of severe respiratory depression associated with potent opioid administration in walruses, an opioid antagonist should be available. Naltrexone is recommended because the antagonism will last beyond the expected effects of

opioid antagonist. A naltrexone dose of 0.1 mg/kg of the estimated body weight has been used in field immobilization situations with complete reversal occurring in less than 5 minutes. If the immobilization technique includes the use of an alpha-2 agonist such as medetomidine, atipamezole should be administered if full immediate recovery is desired. A 5:1 ratio of atipamezole to medetomidine is recommended for complete reversal.

Dissociative Anesthetics

Tiletamine and ketamine have been used to immobilize free-ranging walrus. The principal problem associated with dissociative chemical restraint is the long duration of effect and the lack of a reversal agent. Since walrus are often immobilized near water, it is imperative that conditions prevent the partially anesthetized animal from entering water.

Tiletamine and zolazepam (Telazol or Zolatil) at a dose of 1.4- to 2.2-mg/kg IM have been studied for chemical restraint of walrus. Induction time ranged from 14 to 29 minutes, and the duration of immobilization lasted from as short as 75 minutes to as long as 220 minutes. The induction and recoveries were reported to be smooth. Apnea was not reported although one of the three animals died during recovery (Griffiths et al. 1993).

Atlantic walrus have also been immobilized with a combination of Telazol and medetomidine. A total dose of Telazol and 100 mg of medetomidine (approximately 3.3 mg/kg Telazol and 17 µg/kg medetomidine) were administered by dart to two animals. The respiration rate varied between 10 and 12 breaths/min throughout the procedure. Despite oxygen supplementation via a nasal cannula, pulse oximetry showed relatively low oxygen concentration (37–79%) (Lanthier & Stewart 2002). Atipamezole was used to antagonize medetomidine. Three additional walrus (one male and two female) were injected with a total dose of 2 gm of ketamine and 90 mg of medetomidine (approximately 2.5–4.0 mg/kg of ketamine and 11–18 µg/kg of medetomidine). In each case, the respiration rate appeared to be normal (rate and depth). Immobilization occurred in 15 minutes. None of the walrus showed muscle spasms. Procedure length varied between 16 and 40 minutes. Atipamezole was injected intravenously and intramuscularly 50/50 as the antagonist (approximately 9.5–19.0 µg/kg). Recoveries were smooth and rapid (6–23 minutes) (Lanthier & Stewart 2002).

Propofol

The author has used small boluses of propofol (40–60 mg) via the EIV sinus to provide unconsciousness, muscle relaxation, and to facilitate endotracheal intubation. The use of propofol decreased the need for higher doses of the immobilization drugs and the asso-

ciated muscle relaxation appears to facilitate spontaneous ventilation. Similarly, ultrashort-acting barbiturates (thiamylal sodium) have been successfully used to produce general anesthesia in walrus. Dosages of 3.3–4.8 mg/kg with 1/2 of the calculated dose administered initially and the additional drug given to effect as needed (Walsh et al. 1990).

Volatile Anesthetics

Isflurane has been used to maintain general anesthesia in walrus. However, because of the low blood:gas solubility of sevoflurane, both uptake and elimination will be faster and may improve the ability to reach surgical anesthesia and have shorter recovery times than with isoflurane. Since the cardiovascular and respiratory depressive effects of isoflurane and sevoflurane are similar, the lower solubility of sevoflurane would be of significant advantage in walrus. Oxygen flow rates and vaporizer settings will be similar to equine anesthesia. Oxygen should be set at >4 L/min to ensure delivery of anesthetic and oxygen for metabolic needs. Initial vaporizer settings will likely be between 3.0 and 4.5%; however, vaporizer settings should be reduced in anticipation of equilibration of the animal with the anesthetic machine. Maintenance levels of 2.0–2.5% isoflurane and 2.5–3.0 sevoflurane are expected.

ANALGESIA

Analgesic methods used in other marine mammals should be considered to decrease stress associated with painful procedures or conditions. As previously discussed, local anesthetics are effective if injected around the surgical site or on sensory nerves to a region. As with other species, total local anesthetic dosages should be kept below 4 mg/kg to avoid potential local anesthetic toxicity. Opioid analgesics have been used as a part of chemical immobilization techniques are believed to provide reduction in pain perception, modulation, and transduction. Chronic pain management has not been addressed in walrus and no recommendations can be made for the use of anti-inflammatory drugs at this time.

Cetaceans

Christopher Dold and Sam Ridgway

INTRODUCTION

Cetaceans (whales, dolphins, and porpoises) are mammals whose ancestors developed on land. Around 55 million years ago, these ancestors went back to the water (Gingerich et al. 1983) and evolved anatomically, physiologically, and behaviorally for a completely aquatic existence. Most clinical experience has been with the bottlenose dolphin (*Tursiops truncatus*, *Tursiops truncatus gilli*, and *Tursiops truncatus aduncus*) since it is the species most commonly found in display, research, and rehabilitation facilities. Other odontocete species, including the killer whale (*Orcinus orca*), the beluga or white whale (*Delphinapterus leucas*), the Pacific white-sided dolphin (*Lagenorhynchus obliquidens*), and the false killer whale (*Pseudorca crassidens*), have been successfully managed in zoos and aquaria for many years. A growing amount of clinical experience with these species has led to increasingly frequent need for sedation and, in certain instances, general anesthesia.

DOLPHIN SLEEP

Bottlenose dolphins, like all cetaceans, have an apneustic style of breathing. Even when resting at the water surface, dolphins ordinarily take 1–3 breaths/min. Each breath is a deep one, rapidly filling the lung to 80 or 90% capacity (Ridgway et al. 1969). Expiratory flow rates are very rapid and empty the lung almost completely (Kooyman & Cornell 1981). Thus the effort of breathing, even at rest, appears much more pronounced than that of humans and other terrestrial mammals.

Given their need to swim and breathe air with these deep breaths, it is not surprising that many biologists

and veterinarians have wondered how dolphins sleep in the water. In the early 1960s, John Lilly (1962a) suggested that bottlenose dolphins slept with one eye closed and utilized one brain hemisphere at a time. However, he produced no electroencephalograms (EEGs) to support this hypothesis. Serafetinides et al. (1970) reported the first EEG evidence of unihemispheric sleep using subcutaneous (SC) needle electrodes during a one-night recording from a pilot whale (*Globicephala scammoni*). Mukhametov et al. (1977) and Mukhametov (1984) recorded many 24-hour periods, from multiple dolphins using screw electrodes inserted through the skull in a multichannel array with a low-noise wire system that allowed some animal movement around a shallow pool. They demonstrated overwhelming evidence that the vast majority of dolphin slow waves were unihemispheric and appeared first in one hemisphere and then the other. Remarkably, each hemisphere appears to accumulate a separate sleep debt. When one hemisphere was deprived of slow wave sleep for several days, only that hemisphere showed the typical sleep rebound; the nondeprived hemisphere continued to alternate its slow wave sleep in the usual amount (Oleksenko et al. 1992). Since slow waves appeared only very rarely and then very briefly in both hemispheres simultaneously, Mukhametov (1984) and Mukhametov et al. (1977) suggested that slow waves in both hemispheres are not compatible with respiration.

Using a small implantable telemetry unit, Ridgway (2002) replicated the earlier unihemispheric EEG findings and also recorded symmetrical EEG in both hemispheres during pentothal/halothane anesthesia. There were short periods of EEG slow waves in both hemispheres during the unanesthetized state, but slow waves in both hemispheres were not seen during breaths.

From behavioral observations, Lilly (1962b) stated "In regard to lateralization of the sleep pattern, these animals sleep with one eye closed at a time. The eye closures are 180° out of phase; it is rare to have both eyes closed at once. The accumulated sleep in each eye runs 120–140 minutes per day. The sleep occurs in brief periods between each respiration running from 20 to 40 seconds per eye closure. A dolphin wakes up to take each breath." Extensive behavioral observations were conducted by McCormick (1969), who was able to observe bottlenose dolphins through large underwater viewing windows. He observed dolphins resting at the water surface, virtually immobile, with both eyes closed and breathing in an "automatic fashion" for periods of ≥ 1 hour.

McCormick (1969) also observed, unlike the bottlenose dolphin, the Dall porpoise (*Phocoenoides dalli*) swam continuously without ever stopping to rest or become immobile. Azov porpoises (*Phocoena phocoena*), in the same family as Dall porpoises, were observed to swim continuously as well (Mukhametov & Polyakova 1981). From these observations, it would be easy to conclude that Dall porpoises and Azov porpoises never sleep. Mukhametov and Polyakova (1981) fitted three of the Azov porpoises with their EEG recording equipment. The animals swam continuously around their pool. Unihemispheric slow waves alternated between the hemispheres while the porpoises continued to swim (Mukhametov & Polyakova 1981). Therefore, stopping to rest, or becoming immobile, is not an absolute requirement for sleep. Although bottlenose dolphins and the largest member of the dolphin family, the killer whale, often rest at the surface, as described by McCormick (1969), both mother and calf swim constantly for several weeks after the birth (Lyamin et al. 2005). Thus if mother and calf are sleeping, it must occur while they are continuously swimming.

HISTORY OF DOLPHIN GENERAL ANESTHESIA

The physiology of anesthesia is different from sleep, especially in cetaceans. The superficial appearances of these two physiologic states, however, gives rise to the common comparison of administering general anesthesia with inducing sleep. Although there are many differences, unconsciousness in these two different physiologic states is considered somewhat similar to humans and other land mammals. However, the phenomenon of unihemispheric sleep in cetaceans makes the comparison between sleep and anesthesia not as applicable in these species. Moreover, in all mammals, arousal from sleep by noxious stimuli has a relatively low threshold, whereas arousal from anesthesia is possible only after recovery.

The first attempt to put a dolphin "to sleep" or to give general anesthesia was made by Langworthy

(1932), who administered ether by a cone held over the blowhole. The dolphin stopped breathing and died. After a number of attempts to employ intraperitoneal barbiturate anesthesia resulted in dolphin deaths (Lilly 1962a; Nagel et al. 1964), the latter group successfully developed endotracheal intubation methods and induced anesthesia with 70% nitrous oxide (Nagel et al. 1964). Although nitrous oxide was safe, it was inadequate for major surgery. Ridgway and McCormick (1967, 1971) used halothane, and later IV thiopental, for induction and halothane for anesthesia maintenance. Other early work in dolphin anesthesia has been reviewed in French by Lecuyer (1983).

More recently, propofol has been the choice for induction followed by intubation and isoflurane maintenance (Linnehan & MacMillan 1991). When general anesthesia is achieved, dolphins do not breathe and slow waves appear on the EEG of both brain hemispheres (Howard et al. 2006; Ridgway 2002). All successful general anesthetics have required intubation and the use of a respirator. A Bird Mark 9 large animal respirator fitted with an apneustic control device has been employed to mimic the normal respiration of the animal (Nagel et al. 1964; Ridgway & McCormick 1967, 1971).

ANATOMY AND PHYSIOLOGY RELEVANT TO ANESTHESIA

Specific anatomic and physiologic adaptations of the respiratory and cardiovascular systems, although beneficial for a purely aquatic existence, pose challenges to the clinician for sedation and general anesthesia of the cetacean patient. Much of the physiological and anatomical knowledge discussed here was gained from work on bottlenose dolphins. Fortunately for the clinician, most of the adaptations are well conserved among the other odontocete species commonly encountered in zoos and aquaria.

The most obvious adaptation of the respiratory system is the blowhole, the external nasal opening of cetaceans (Fig. 49.1). It is positioned on top of the head rather than at the front of the face as it is in all other mammals. Immediately, ventral and lateral to the blowhole are right and left lateral vestibular sacs. One can readily palpate these sacs by placing a finger through the blowhole directed to the left or to the right. The right sac is larger. Paired internal nares can be seen below the nasal plug when it opens. The paired nasal cavities, separated by the nasal septum, extend from the nares ventrally along the cranial aspect of the calvarium to the naso-pharynx just above the larynx, which is beak-shaped structure frequently referred to as a "goosebeak" because of its semblance in shape (Fig. 49.1). The goosebeak is an elongation of epiglottal and cricoarytenoid cartilages supported laterally by arytenoepiglottal muscles (Green et al. 1980). It is held in

Figure 49.1. The laryngeal “goosebeak” rises from the center of the oropharynx (from Green et al. 1980, U.S. Navy photograph).

Figure 49.2. Left lateral view of excised dolphin lung, trachea, and larynx (U.S. Navy photograph).

its dorsally oriented position by the nasopharyngeal sphincter muscle along the dorsal oropharynx. Foods, usually swallowed whole, course laterally around the larynx. The larynx is not permanently affixed in this position. It can be displaced voluntarily by the animal or when swallowing large food items, and by the clinician manually when intubating the animal. The larynx leads to a short trachea (Fig. 49.3). Preceding the carina is a right-sided accessory bronchus (Green 1972), which is an important consideration when intubating these species because the separate right bronchus is required for inflation of a portion of the right lung.

Compared with terrestrial mammals, cetaceans have more extensive pulmonary support structures including complete tracheal and bronchial cartilagenous rings that extend beyond the mainstem bronchi into deep bronchioles, and plates and rings of cartilage that extend all the way to the junctions of aveoli. Smooth-muscle sphincter-like narrowings occur at the terminal bronchioles (Simpson & Gardner 1972). The lungs contain a great amount of elastic tissue. A dense elastic visceral pleura 1 mm or so in thickness covers each nonseptate, nonsegmented lung (Fig. 49.2). Since ceta-

ceans must be intubated and put on a respirator for general anesthesia, the anatomy relative to the endotracheal intubation process is especially important.

As previously mentioned, cetaceans have a specialized respiratory cycle with short, rapid exchange phases followed by long inspiratory apneustic plateaus. They take fewer and deeper breathes than their terrestrial counterparts. Bottlenose dolphins breathe an average of 2–3 times/min and have a tidal volume of 5–10L, which may represent 80% or more of their total lung capacity (Ridgway 1972).

Anatomic adaptations of the cardiovascular system to support deep diving, long breath holds, and temperature conservation in the cold ocean include large, distensible veins, venous sinuses, venous valves in the lungs, portal triads of the liver, and a venous sphincter in the common hepatic vein at the junction of the inferior vena cava below the diaphragm. A rete mirabile, a highly developed meshwork of arteries and veins between the thoracic vertebral bodies, and periarterial venous rete represent temperature countercurrent exchange systems that allow cetaceans to peripherally vasoconstrict and still perfuse the brain with warm, oxygenated blood even under the great pressure and temperature extremes experienced at depth (McFarland et al. 1979). Finally, cetaceans have a profound respiratory sinus arrhythmia that is normal—the heart rate speeds up with each breath and slows between breaths (Fig. 49.3).

PHYSICAL RESTRAINT

Physical restraint of small cetaceans is a common practice, but requires multiple personnel. Even then it can still result in injury to both people and patient due to the substantial size and strength of most small cetaceans. It is recommended, therefore, that physical restraint be performed under the supervision of trained, experienced personnel. However, because experience

Figure 49.4. A dolphin is lifted from its pool in a fitted sling (U.S. Navy photograph).

with cetacean sedation and anesthesia is still relatively limited, most, if not all, clinically relevant procedures can be, and have been, performed under physical restraint alone.

Animals requiring care can be separated from pool mates either under voluntary control or with the use of nets or stranding devices. Care must be taken when introducing a net into the water. If animals do become entangled, they must be quickly assisted to the surface so that they can breathe. Many facilities have medical pools designed to strand animals out of the water for clinical procedures without the need for nets, slings, or stretchers. Clinical procedures have been performed on dolphins and other odontocetes with animals out of the water suspended in fitted slings (Fig. 49.4), suspended in water tight boxes, or most commonly out of the water supported on a soft foam rubber pad on the ground or on large animal surgical tables. When not suspended in stretchers or slings, animals are commonly positioned onto closed-cell foam padding. Personnel are positioned on both sides of the animal; one or two people restrain the animal's tail flukes, and one or two people are positioned near the animal's head. For animals that are relaxed out of the water, simple support by only one or two people may be all that is required. For more fractious animals, multiple people may be needed to provide adequate restraint.

Due to the challenges associated with physical and chemical restraints in these animals, operant conditioning and training have resulted in many small cetaceans being conditioned to voluntarily participate in clinical procedures (blood sampling, ultrasound, radiographs, and endoscopy).

Whenever the cetacean is out of water, its skin must be kept moist for temperature control and prevention of drying. Special attention should be paid to the eyes to prevent injury or drying. During anesthesia, it is best

Figure 49.5. Prior to induction of anesthesia, a dolphin rests on a special table held loosely by seat belt straps (U.S. Navy photograph).

Figure 49.6. The dolphin is anesthetized and ventilated with a Bird respirator through an oral endotracheal tube. White rubber suction cups hold surface electrodes for monitoring the electrocardiogram (ECG). The suction cups provide insulation for the electrodes to allow for recording ECG while the animal is immersed. The dolphin will be supported by the warm water and padded straps in the adjacent tank during the surgical procedure. IV fluid is given through the caudal vascular bundle. Blood transfusions, if needed, may be given through the same site or via the PAVR. For long procedures, a nebulizer is placed in the line for humidification of respiratory gas (U.S. Navy photograph).

to apply a lubricating ophthalmic ointment to prevent drying of the eyes. Special tables (Fig. 49.5) or tanks (Fig. 49.6) have been constructed to maintain the dolphin patient in proper position for monitoring and surgery.

VASCULAR ACCESS

There are several peripheral sites from which blood may be collected. The arteriovenous nature of the peripheral vasculature, however, means very few of these sites allow rapid drug or fluid administration. Consequently, central venous access is desirable and has become increasingly attainable as imaging and vascular access technologies improve. Both peripheral and central access sites are described.

Dorsal and Ventral Fluke Periarterial Vascular Rete (PAVR)

The ventral fluke PAVR is most commonly used for routine venipuncture in odontocetes species (Ridgway 1965). In dolphin collections, animals are often trained to allow venipuncture in the site under voluntary stimulus control. Blood can be collected with 19- to 23-gauge and 2- to 4-cm (3/4- to 1 1/2-in) needles, depending on animal size and species. Intravenous (IV) antibiotics and fluids can be administered into this site, but the size and microanatomy of the vessel, the accuracy of the needle stick, and the dynamic nature of the peripheral blood vessels in this species can limit the success of administration. Blood collected from this site (Fig. 49.7) is most commonly venous or an arterial-venous admixture, and rarely purely arterial.

Peduncle PAVR

This venipuncture site is located on the ventral aspect of the terminal vertebral bodies. The landmarks for injection are the ventral peduncle ridge, immediately proximal to the confluence of the right and left fluke PAVR. Venipuncture at this site is best performed with needles longer and larger than those used for fluke vessel venipuncture in the same animal: 18- to 21-gauge, 2- to 4-cm (1.5- to 2-in) needles and larger may be required. The site may be accessed from voluntary fluke presentations or in animals out of the water for exams and procedures (Fig. 49.8). The larger diameter of the artery at this site allows rapid collection of large volumes of arterial and arterial-venous admixed blood. This site has been successfully used for repeated phlebotomy to treat iron overload in bottlenose dolphins (Johnson et al. 2009). The larger vessels also make the site appropriate for IV injection. Assuming appropriate positioning, and if necessary, restraint of the flukes, the needle may be left indwelling in this site during longer procedures for constant rate infusion of fluids, as well as repeat blood samples for arterial blood gases. Arterial blood pressure has been measured at this site (Ridgway et al. 1974); however, needle placement and movement must be carefully monitored because shifts may lead to values not necessarily reflective of the patients' status.

Figure 49.7. A 20 gauge butterfly needle is used to collect a blood sample from the fluke blade (U.S. Navy photograph).

Figure 49.8. Blood is collected from the peduncle PAVR employing a 20 gauge needle and vacutainer tube. The peduncle PAVR is the best peripheral site for collecting arterial samples (U.S. Navy photograph).

Dorsal Fin PAVR

Although a challenging site for venipuncture in smaller cetaceans, this location is useful for killer whales (Fig. 49.9). For dolphins, it is usually reserved for fractious animals that will not allow access to the flukes or peduncle. It is also used as a second site for blood collection during anesthetic or sedative procedure. The dorsal fin PAVR has all of the same anatomic challenges as the fluke PAVR. When considering IV drug administration, it is important to note the blood draining from this site travels directly to a rete around animal's gonads. The authors usually access this site with needles similar to those used for fluke PAVR venipuncture.

Figure 49.9. Accessing the dorsal fin PAVR is much easier in larger animals such as the killer whale (U.S. Navy photograph).

Hemal Arch/Caudal Vascular Bundle

The caudal vascular bundle runs longitudinally along the ventral midline of the caudal vertebral bodies within an arch formed by the chevron bones. In an adult bottlenose dolphin, a 9-cm (3.5 in.) spinal needle is advanced transversely into the ventral intervertebral space, ventral and parallel to the lateral processes of the caudal vertebral bodies in the mid- to caudal peduncle region. The caudal vascular bundle is a low pressure, mostly venous system. This site can be catheterized (Van Bonn et al. 1996) and, when accessed, it is appropriate for IV fluid and drug administration. Given the venous rete at this site, however, rates of absorption of drugs and fluid may be more variable and delayed compared with administration into other sites.

Common Brachiocephalic Vein (CBV)

The CBV (Fig. 49.10) is not part of a PAVR. It is, therefore, an appropriate site to collect purely venous blood samples and to measure venous blood pressure. It is also large enough to allow catheterization, and indwelling catheters in this site have improved anesthesia monitoring and support capabilities in these species. Drugs and fluids given into the CBV may have more predictable and rapid absorption and effect than when injected intravenously into other peripheral sites that are part of PAVRs. Accessing the brachiocephalic vein is a challenge. In bottlenose dolphins, it lies 10- to 12-cm deep under skin, blubber, and muscle, and runs in a transverse plane. The actual site for access is large: 2- to 3-cm wide and 2-cm thick. Slight misdirection at the skin, however, can translate into significant misdirection of the long needles at the level of the vessel. The transverse orientation of the vessel also makes catheterization difficult.

The authors have had the greatest success accessing the vein using ultrasound guidance. As such, the procedure benefits from two people working together; one

Figure 49.10. Drawing from a dissection of the ventral neck of a bottlenose dolphin. H, hyoid; TC, thyroid cartilage; CTM, cricothyroid muscle; ECA, external carotid artery; TG, thyroid gland; CBV, common brachiocephalic vein; S, sternum. Note that the ECA is covered by a meshwork of veins. Drawing by Barbara Stolen Irvine from Ridgway and Patton (1971).

person guides the probe and holds the image steady, while the other person performs venipuncture. For catheterization, we pass a 14-gauge, 16-cm needle into the vein and then feed a 60-cm polyurethane catheter through it to a depth of approximately 25 cm. For short term access (IV drugs, bolus fluids), we use a needle and no catheter. The stylet from an equine 16g, 14-cm (5.5 in) radio-opaque (Abbocath®) catheter is the sharpest, disposable needle to use. The animal is placed in lateral recumbency for the procedure. We have recent evidence that placing the animal in right lateral recumbency is more anatomically appropriate for catheterization. Right lateral recumbency, along with the natural tendency of the phlebotomist to orient the needle tip toward the floor, encourages the catheter to feed toward the heart (with left to right flow in the vessel). In left lateral recumbency, the catheter tends to feed toward the venous return from the rete (against flow). Successful catheterization, however, can also be performed with the animal in left lateral recumbency.

Hepatic Vein

Recent collaborations with interventional radiologists have enabled the development of a safe, percutaneous, transhepatic approach to the hepatic vein. Using local anesthesia and ultrasound guidance, Johnson et al. (2010) were able to reliably and repeatedly pass a 6Fr peripherally inserted central catheter (PICC) into the hepatic vein and advance the catheter into the caudal vena cava. Catheter placement can be achieved from

both the right and left sides of the animal. In addition to offering the same advantages of the brachiocephalic vein (medication and fluid administration), this site carries the added advantage of a lateral approach reducing risk of displacement. Retention times of up to 6 hours (out of water) were reported. While considered to be generally safe, the approach does carry the added risk of hepatic bleeding. The authors recommend placement of embolized Gelfoam™ during removal of the catheter (Houser et al. 2010; Johnson et al. 2010).

ENDOTRACHEAL INTUBATION

Endotracheal intubation of adult bottlenose dolphins and larger odontocete species is usually performed by an oral approach to the larynx (Fig. 49.1). This can be accomplished when the animal is either awake (in an emergency situation) or following sedation or anesthetic induction. Large animal endotracheal tubes with inflatable cuffs (size of 16- to 30-mm internal diameter) are appropriate for most adult bottlenose dolphins. Intubation usually requires multiple personnel; one person to hold the mouth open with soft rolled towels and another to pass the endotracheal tube. The oral approach to the larynx is done blind. Intubation requires manual removal of the larynx (goosebeak) from the nasopharyngeal sphincter to orient it in a rostral direction. Once the laryngeal tip is positioned rostral, two fingers can be placed into the glottis (Fig. 49.1) and the endotracheal tube guided through the glottis into the short trachea. The trachea is very short in most odontocetes (Fig. 49.2), and there is a right-sided accessory bronchus (Green 1972) that precedes the carina. Care must be taken not to advance the endotracheal tube too far and block the right bronchus.

The oral approach to intubation may not be possible in smaller odontocetes due to their small mouths and oropharynx. Intubation in these animals can be accomplished with a small tube placed through the blowhole (Fig. 49.11). This approach is more complicated than the oral due to redundant tissue and muscular folds used for vocalization and echolocation between the goosebeak and the blowhole. The tube must be inserted through either the right or left nasal cavities. This limits the size of tube that can be used. Intubation is greatly facilitated by the use of a bronchoscope for visualization of the goosebeak and a stylet to advance the endotracheal tube through the glottis. A possible adverse effect of prolonged intubation is abnormal with blowhole function when the animal is returned to the water. To our knowledge, prolonged blowhole intubation has not previously been performed.

Blowhole intubation was used in small dolphins (*Stenella styx* and *Delphinus delphis*) under experimental conditions at sea (Rieu & Gautheron 1968). Xylocaine

Figure 49.11. Dolphin open blowhole. Anterior is down in this photograph. The nasal septum divides the nares so that only a small tube can be inserted down one nostril through the nasal cavity to reach the glottis sitting below the opening of the distal nares (also see Fig. 49.1 and Fig. 49.2) (U.S. Navy photograph).

(2%) was injected through the tube to produce laryngeal anesthesia and analgesia.

ANESTHESIA SUPPORT AND MONITORING

Anesthesia monitoring and support is just as critical in cetaceans as in terrestrial mammals, if not more so. Since normal spontaneous ventilation, circulation, and perfusion in cetaceans are typically performed with the animals' bodyweight supported by the buoyancy forces exerted by the water column, simply removing the animals from the water for a clinical procedure may place them at a cardiopulmonary disadvantage. A collapsible thorax, gravity, and the animals' mass combine to increase respiratory effort and compress muscles and vessels. Changes in temperature and pressure may cause hyper- or hypothermia, abnormal vasoconstriction, or vasodilation with resultant blood shunts. This can happen even before any respiratory, cardiovascular, or central nervous system depressing drugs are given.

A comprehensive approach to monitoring and support should be applied to the cetacean patient and, since reported drug protocols are frequently limited to experience with only a few individual animals, the anesthetist should always be on alert for the possibility of profound and unexpected drug reactions. Applying anesthesia monitoring equipment to patients out of the water and without sedation is as important as applying it to the fully anesthetized patient, if for no

other reason than it can help to build the clinician's familiarity with individual animal's normal heart and respiratory rates, core temperatures, and reflexes.

Respiratory support in sedated animals that are still spontaneously ventilating is not necessary. Many marine mammal clinicians, however, will still provide supplemental oxygen to dolphins and whales that are out of the water or sedated. For general anesthesia in dolphins, successful mechanical ventilation has been performed with use of a Bird Mark 9 respirator with an apneustic plateau modification to allow for prolonged inspiratory hold in the ventilation cycle. A respiratory rate of 2–4 breaths/min (Ridgway & McCormick 1967, 1971; Ridgway et al. 1974) is generally employed. Early experiences suggested that general anesthesia lasting longer than 4 hours without this modification resulted in reduced lung expansion and alveolar inflation, and associated respiratory acidemia, and cardiovascular depression (Ridgway & McCormick 1971). One recent report suggests that the apneustic plateau ventilatory cycle may not be necessary for shorter procedures (Reidarson 2003). Recently, one animal (*Tursiops*) maintained under isoflurane anesthesia for 2 hours by the authors and ventilated with and without the apneustic plateau pattern showed lower end-tidal CO₂ (EtCO₂) levels (45–50 mmHg) that more closely approximated the animal's nonanesthetized expiratory CO₂ when ventilated without the apneustic plateau pattern.

Monitoring EtCO₂ as an indicator of adequate ventilation and perfusion is recommended for dolphins under general anesthesia, and may be helpful even with dolphins under sedation (not intubated). For sedated animals, the sampling probe can be held in the blow stream above the blowhole. EtCO₂ measurements should always be checked against the patient's pCO₂ before determining just how representative the measured EtCO₂ is of true alveolar CO₂.

Blood gases can be measured as in other animals, and normal ranges appear similar to other mammals. Due to cetacean vascular anatomy, collecting a purely arterial or purely venous sample is possible, but less likely than collecting an arteriovenous admixture when sampling from peripheral sites. A truly venous sample can be collected from the brachiocephalic vein, as described earlier. In the authors experience, the best peripheral site for a purely arterial sample is the peduncle PAVR.

Heart rate can be monitored with electrocardiogram leads as in other species. The authors recommend placing the leads before the animal has received any drugs to establish baseline readings. Normal, stable animals should have a profound resting sinus arrhythmia (Fig. 49.11). Some animals that are anxious or stressed, however, will override the arrhythmia and maintain a steady, mildly tachycardic rate (100–120 beats/min). Additionally, general anesthesia results in abolition of the sinus arrhythmia (Ridgway 1972;

Ridgway et al. 1974). Published reports suggest that a heart rate of less than 60 beats/min may be a cause for concern in anesthetized dolphins (Ridgway & McCormick 1971).

Perfusion can be measured with a pulse-oximeter impedance probe placed on the tongue of anesthetized patients (Linnehan & MacMillan 1991). In sedated animals, the authors have attempted to place reflectance probes rectally and within the genital slit of some patients with little success in obtaining readings.

Mean arterial blood pressure (MAP) has been monitored and reported in bottlenose dolphins and pacific white-sided dolphins (Ridgway & McCormick 1971; Ridgway et al. 1974). These measurements were recorded from an indwelling needle within the ventral peduncle PAVR. The authors have also successfully measured central venous pressure (CVP) in several bottlenose dolphins through an indwelling IV catheter placed in the CBV. CVP can also be measured by the PICC line placed via the hepatic vein into the caudal vena cava under ultrasound guidance (Johnson et al. 2010).

Body temperature has been monitored with a flexible thermometer probe placed rectally (Fig. 49.12) to a depth of 15- to 25-cm depending on animal size (Nagel et al. 1964; Ridgway 1965; Ridgway & McCormick 1967; Ridgway et al. 1974). Clinicians should be aware that countercurrent heat exchange systems for internal gonads may interfere with thermometer readings if the probe is placed too deep or too shallow, and lead to misinterpretations of core body temperature readings (Rommel et al. 1992, 1993).

Depth of anesthesia can be determined through assessment of reflexes as in other mammals. Palpebral and corneal responses, response to manipulation of the blowhole, jaw tone, and swallow reflexes are all appropriate. Ridgway and McCormick (1967) reported that loss of swimming motion in the tail flukes may be the

Figure 49.12. A flexible probe from an electronic thermometer is inserted 15–25 cm into the rectum, depending on the animal size, to measure temperature (U.S. Navy photograph).

most reliable indicator that a surgical plane of anesthesia has been reached. Future advances in assessing anesthetic depth may be achieved through application of entropy measuring programs and EEG monitoring, as described earlier.

FIELD TECHNIQUES AND STRATEGIES

Due to limited experience and serious potential complications associated with the use of sedatives in small cetaceans, most field work is accomplished with animals physically, rather than chemically, restrained. There appear to be no peer-reviewed publications describing data for sedation of odontocetes in a field setting. Sedation of entangled North Atlantic right whales (*Eubalaena glacialis*) has been attempted by Moore et al. (2010). Midazolam, meperidine, and butorphanol were given alone and in combination by cantilevered pole syringe and ballistic dart to two whales. The goal was to achieve a deep enough level of sedation to permit safe removal of the whales entangled in fishing gear, and still allow for the animals to protect their blowholes, ventilate, and maintain awareness and position in the water column. The authors conclude that these first attempts were conservative, and while the levels of sedation achieved were light and signs not obvious, the sedation did allow for enhanced disentanglement.

BODY WEIGHT RANGES OF SOME CETACEAN SPECIES

Body weights range with age class, sex, and species, as in other mammals. Adult weight ranges of the commonly encountered cetacean species are listed in Table 49.1. Cetaceans are relatively large, with large body mass, and therefore might require a large drug dose.

For many pharmaceuticals, a direct extrapolation of mg/kg dosing may be appropriate, however, in the specific instance of sedative and anesthetic drugs; consideration of dose scaling and basal metabolic rate must be made. In the author's experience, larger cetacean species may require smaller dosages of drug (on a mg/kg basis) than smaller species to achieve the same level of sedation. As mentioned previously, most anesthetic and sedative drug use in cetaceans is limited to a very small sample size: in most instances, only one or a few individuals. As such, the potential for unpredictable drug reactions, even from published dosages, may exist.

ANALGESIA

If there is little published data on anesthetic drugs used in cetaceans, there is even less for analgesics. The greatest challenges to cetacean pain management are presented by the difficulty in effective assessment of pain, in measuring response to therapy, and in assessment of potential drug reactions. Several marine mammal clinicians have encountered acute, negative side effects after the use of nonsteroidal anti-inflammatory drugs in cetaceans (J. McBain, pers. comm., 2005). With that caveat, Table 49.2 lists several

Table 49.1. Common juvenile and adult weight ranges for selected species of cetaceans housed in oceanaria and aquaria

Species	Weight Range (kg)
<i>Lagenorhynchus obliquidens</i>	60–160
<i>Tursiops truncatus</i>	90–315
<i>Orcinus orca</i>	500–5600
<i>Delphinapterus leucas</i>	300–1600
<i>Pseudorca crassidens</i>	430–800

Table 49.2. Analgesic drugs used in cetaceans

Category	Drug Name	Species	Dosage	Route	Comments	Reference
NSAIDs	Flunixin meglumine (Banamine)	<i>Tursiops truncatus</i> , <i>Orcinus orca</i>	0.25–0.5 mg/kg SID	IM	Caution with use in cetaceans as gastric ulcers are common	J. McBain, pers. comm., (2005)
	Carprofen	<i>T. truncatus</i>	0.5 mg/kg SID	PO	Gastric ulceration seen	T. Schmitt, personal comm., (2006)
	Acetaminophen	<i>T. truncatus</i> , <i>O. orca</i>	3–5 mg/kg SID	PO	Monitor transaminases	M. Walsh, pers. comm., (2005)
Opioids	Butorphanol	<i>T. truncatus</i> , <i>O. orca</i>	0.05–0.13 mg/kg	IM	Possible excitatory response seen in one dolphin	Chittick et al. (2006)
	Tramadol	Multiple (bottlenose dolphin, common dolphin, rough tooth dolphin, spinner dolphin, spotted dolphin, and pygmy and dwarf sperm whales)	0.1–0.4 mg/kg BID	PO	Titrate up to least effective dose. Produces good analgesia without change in appetite. Drowsiness seen at 0.73 mg/kg (can be used IM or IV as well)	C. Manire, pers. comm., (2006)

analgesic and anti-inflammatory agents that have been used in cetaceans.

ANESTHETIC AND SEDATIVE DRUGS

Drugs that have been reported or used by the authors for sedation and local or general anesthesia of several

cetacean species are presented in Table 49.2 and Table 49.3. The authors wish to caution, in most instances, that the number of animals exposed to these drugs is small and the potential for unpredictable or as yet unrevealed drug reactions is not insignificant. Also, to give perspective, we estimate that general anesthesia in cetaceans has been performed less than 100 times.

Table 49.3. Chemical sedative and anesthetic agents used in bottlenose dolphins (*Tursiops truncatus*)

Category	Drug Name	Dosage	Route	Comments	Reference	
Premedication	Atropine	0.02 mg/kg	IM		Ridgway and McCormick (1971)	
Sedatives	Diazepam	0.1–0.2 mg/kg	IM	Larger doses reserved for research or for animals that may have become refractory to smaller oral doses of diazepam. Keep flumazenil available for reversal.	Reidarson (2003)	
		0.25–1.0 mg/kg	PO		S. Ridgway, pers. obs.; Ridgway et al. (2006)	
	Midazolam	0.26–0.36 mg/kg	PO		Provides good plane of sedation lasting about 45–60 minutes. Caution when using in spp. other than <i>T. truncatus</i>	Schroeder et al. (1986)
		0.05–0.15 mg/kg	IM			J. McBain and M. Walsh, pers. comm. (2005); S. Ridgway and C. Dold, pers. obs.
	Flumazenil	0.005 mg/kg	IM, PO, IV, sublingual		Can be given at equal volume of midazolam when midazolam is 5 mg/mL and flumazenil is 0.5 mg/mL. Usually titrate dose to effect.	J. McBain and M. Walsh, pers. comm.; S. Ridgway and C. Dold, pers. obs.
	Butorphanol	0.05–0.15 mg/kg	IM		Provides sedation adequate for bronchoscopy and other minor procedures. Possible drug reactions seen when combined with bronchodilators.	Chittick et al. (2006)
	Meperidine	0.1–2.0 mg/kg	IM		Given in combination with midazolam can produce deep level of sedation that is reversible.	Joseph and Cornell (1988); Reidarson (2003); Ridgway (1965)
Tramadol	0.15–0.2 mg/kg	PO	Given in combination with diazepam (0.15 mg/kg) provides sedation adequate for tooth extraction.	T. Schmitt, pers. comm., (2005)		
Induction agents	[Naloxone]	5–10 mg/kg	IM/IV	Butorphanol and meperidine reversal	Reidarson (2003)	
	[Naltrexone]	0.005 mg/kg	IM/IV	Opioid reversal	Chittick et al. (2006)	
	Ketamine	1.75 mg/kg	IM	Single case only	Reidarson (2003)	
	Medetomidine	10–40 mg/kg	IM/IV	Abolishes sinus arrhythmia and causes respiratory depression, decreased CVP	Reidarson (2003); S. Ridgway and C. Dold, pers. obs.	
	[Atipamezole]	50–200 mg/kg	IM/IV	Equal volume of medetomidine for reversal; medetomidine is 1 mg/mL and atipamezole is 5 mg/mL	S. Ridgway and C. Dold, pers. obs.	
	Thiopental	10–15 mg/kg	IM	Requires additional inhalant anesthesia for full induction	Ridgway and McCormick (1971)	
	Propofol	0.5–3.5 mg/kg	IV	Onset and duration of effect injection site dependent	Linnehan and MacMillan (1991); S. Ridgway and C. Dold, pers. obs.; W. Van Bonn, pers. comm., (2005)	
Inhalational agents	Isoflurane	0.5–2.0%	IH	Higher dose for induction, lower maintenance dose	Dover et al. (1999); Linnehan and MacMillan (1991); S. Ridgway and W. Van Bonn, pers. obs., (1991–2005)	
	Nitrous oxide	70%	IH	Light anesthesia	Nagel et al. (1964)	

Figure 49.13. A trained dolphin remains still for a PET scan following 0.55–0.60 mg/kg of oral diazepam. The animal is kept moist with sponges and spray bottles during the 35- to 45-minute procedure (Ridgway et al. 2006) (U.S. Navy photograph).

Cetaceans have, however, been safely and, in some instances, repeatedly sedated or anesthetized with the listed drugs. Benzodiazepines and opioids are most commonly used for sedation in cetacean patients.

Benzodiazepines

Diazepam and midazolam are frequently employed for light sedation as an oral and a parenterally administered drug, respectively. Diazepam (0.55- to 0.60-mg/kg PO) has been used to help trained dolphins remain still for 35- to 45-minute functional scans such as positron emission tomography (Fig. 49.13). Diazepam (0.5-mg/kg PO) combined with tramadol (0.5-mg/kg PO) results in an enhanced sedation, as well as providing some analgesia. This combination has been used successfully for tooth extractions (with regional lidocaine) in white whales (T. Schmitt, pers. comm., 2011). Midazolam (0.05–0.1 mg/kg IM or IV) is effective and generally safe in Atlantic bottlenose dolphins (*T. truncatus*). Extreme caution, however, is indicated in species other than Atlantic bottlenose dolphins as profound sedation resulting in respiratory and cardiac depression has been witnessed in Pacific bottlenose dolphins (*T. truncatus gilli*) and Atlantic/Pacific hybrids (C. Smith, pers. comm., 2005). In the case of overdose, flumazenil may be given orally (Votey et al. 1991) or intravenously depending on the urgency (Geller et al. 1988; White et al. 1989).

Opioids

Meperidine (Demerol) is not infrequently used, but for some clinicians may be supplanted by butorphanol.

Several marine mammal clinicians are developing a growing comfort level with butorphanol (Chittick et al. 2006) as a sedative that provides analgesia, safe light sedation, and is easily reversible (Naloxone/Naltrexone).

Parenteral Anesthetics

Thiopental, pentothal, and propofol have been used for induction to general anesthesia. Reidarson (2003) reported the use of ketamine and medetomidine for the successful intubation and maintenance of anesthesia in one animal. The authors have limited experience with medetomidine, and experience with ketamine in only one patient (SR). In the author's experience, medetomidine alone produces significant respiratory and CVP depression, in addition to light sedation. The effects are reversed with atipamazole administration.

Inhalant Anesthetics

Anesthesia has been maintained with the inhalant anesthetics halothane (Ridgway 1965; Ridgway & McCormick 1967, 1971; Medway et al, 1970) and isoflurane (Dover et al. 1999; Haulena & Heath 2001; Linnehan & MacMillan 1991) in oxygen. Isoflurane is currently the inhalational anesthetic of choice (SR), although sevoflurane deserves consideration since, following induction of anesthesia with propofol, awakening from sevoflurane is faster (in people) compared with isoflurane.

RECOVERY

Perhaps greater than the challenges posed by induction and maintenance of general anesthesia in cetaceans are those encountered upon recovery. Due in part to the difficulty in observing depth of anesthesia, and also the replacement of the goosebeak as a necessary step for voluntary ventilation, great care must be taken as one attempts to recover the animal and get it breathing on its own.

LOCAL ANESTHESIA

Two percent xylocaine (Lidocaine HCl) has frequently been used for subcutaneous infiltration for surface surgical procedures. Blocking the infra-alveolar nerve, a branch of mandibular nerve, with xylocaine infiltration, has been effectively employed for dental procedures (Ridgway et al. 1975).

DISEASE ISSUES AFFECTING ANESTHESIA

Cetaceans, given their anatomy and physiology, are particularly susceptible to lung disease, and pneumonia is the most commonly diagnosed cause of severe disease in these species. Consequently, since these animals are also known to mask disease (Geraci & Sweeney 1986), a high index of suspicion should be maintained for

animals showing that evidence of disease may have some loss of normal pulmonary function and, accordingly, the potential for hypoxemia.

50 Sirenians (Manatees and Dugongs)

Elizabeth C. Nolan and Michael T. Walsh

INTRODUCTION

Distributed throughout fresh, brackish, and marine tropical waters of North and South America and Africa, three species of manatees (Trichechidae) and one species of dugong (Dugongidae) comprise the family Sirenia (Table 50.1) (Domning & Hayek 1986; Reynolds & Odell 1991). Genetically related to elephants (Proboscidae) and hyrax (Hyracoidea), these hind gut fermenters are the sole obligate herbivores of the marine mammal world. Manatees are considered “weakly” social species, establishing no long term bonds other than mother–calf pairs and forming only temporary congregations of individuals during winter months at warm water sites or when breeding (Hartman 1979; Odell 2003; Reynolds 1981; Wells et al. 1999). Calves generally stay with their mothers for 1–2 years, and reach sexual maturity between 2 and 5 years of age (Odell 2003; U.S. Fish and Wildlife Service 2001) although this may be influenced as much by achieving biological size versus chronological age. In comparison, dugongs take approximately 9–10 years to reach sexual maturity and are often found in large herds with “amorphous” social organization, the only close identifiable social bonds being those between mother and calf (Odell 2002; Wells et al. 1999).

Due to habitat loss or degradation, human interaction problems, and natural disease in their home ranges, sirenians are currently listed under the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES) Appendix I or II and the International Union for the Conservation of Nature (IUCN) Red List (Baillie et al. 2004; Reynolds & Odell 1991). The United States Endangered Species Act categorizes West Indian and Amazonian manatees and dugongs as endangered and the West African manatee

as threatened (U.S. Fish and Wildlife Service 2001). Mortality associated with human interaction either due to hunting, watercraft interaction, or habitat loss is believed to have had significant impacts on sirenian populations, in general (Odell 2003; Reynolds & Odell 1991). Severe cold stress periods in 2010 and 2011 in Florida resulted in increased mortality for manatee populations with inadequate natural warm water refuges. Current conservation efforts for sirenians include worldwide public education campaigns, local and national legal protection, enhancement of warm water sites, and rescue and rehabilitation programs.

Medical advancements in the care of rescued sirenians have improved survivability and potential for reintroduction to the wild. The use of sedative agents was first applied in Florida manatees in the late 1980s and general anesthesia was first attempted in 1990 (Walsh et al. 1997). Anesthesia of manatees and dugongs is still an emerging field, but much has been recently learned to effectively sedate, anesthetize, and treat these species. The information presented in this chapter focuses predominately on the West Indian manatee, but likely has applications across the Sirenia family.

ANATOMY AND PHYSIOLOGY

Sirenians have a somewhat tubular body shape and a wide dorsoventrally flattened fluke that is paddle shaped in manatees and bilobed resembling a dolphin tail in dugongs. Whereas manatees tend to have more dorsoventrally flattened bodies, dugongs are more laterally compressed, particularly caudally. Sirenian skeletons are comprised of dense pachyostotic bone (Fawcett 1942a). They have relatively short but mobile pectoral flippers and lack hind limbs. Flippers of male

manatees are longer in length than those of females, and have more roughened epithelium medially, which likely aids in holding a female during copulation. Male manatees also tend to weigh less than females and have more lean body composition.

The skin of manatees is generally thick, tough, and sparsely haired, with the exception of the Amazonian manatee which has smooth skin (Domning & Hayek 1986; Reynolds & Odell 1991). Nill et al. (1999) found that the increased collagen network of the manatee dermis is roughly 2.5 times denser than that of terrestrial mammals. This unique skin density, along with their pachyostotic bones, helps counterbalance the positive buoyancy effects of the air-filled lungs and intraluminal gas of the gastrointestinal tract in these animals (Kipps et al. 2002; Nill et al. 1999).

Unique sirenian facial features include small eyes which close by a sphincter rather than upper and lower eyelids, a flexible upper lip and an oral disk covered with modified vibrissae for use when foraging, and nostrils with valves that close between breaths. Dentition varies between manatees and dugongs. While manatees horizontally replace their molars throughout life, dugongs do not. In addition, manatees lack functional incisors and premolars, whereas dugongs have both premolars and small tusk-like maxillary incisors (Reynolds & Odell 1991). In place of incisors, manatees have a dorsal dental pad which articulates with the lower jaw just caudal to a firm gingival ridge overlying the symphysis of the mandible. Due to manatees' relatively small mouth, laterally narrowed oral cavity, thick short tongue, and elongated soft palate, oral visualization of the glottis is very difficult. Even with maximal distension of the jaws in adult manatees, the glottis cannot usually be seen.

The manatee trachea is relatively short and bifurcates at the thoracic inlet into two separate pleural cavities or hemithorax. The specialized diaphragm of sirenians has a transverse septum separating the heart from the lungs and other organs, as well as two hemidiaphragms that horizontally extend the length of the body and divide the pleural spaces from the abdominal cavity (Rommel & Reynolds 2000). Unlike other marine mammals, manatee and dugong respiratory tracts comprise the dorsal third of their body cavity, extending from the shoulders to the pelvis and remaining dorsal to the heart (Fig. 50.1) (Rommel & Reynolds 2000). Due to this position of the lungs, IM injections are placed in the gluteal muscles to avoid injury to organs under more cranial epaxial musculature. Alternatively, IM injections can be administered in the caudal neck musculature, cranial to the shoulder. Another consideration with regards to the respiratory system of sirenians is the position of the gastrointestinal tract, which lies ventral to the thorax and can comprise 23% of an animal's weight (Reynolds & Rommel 1996). As hindgut fermenters, manatees have a distinct round cecum with

two ovoid diverticulae and an enlarged colon which aid with digestion of vegetation. In well-nourished animals, the cecum and large intestine together comprise approximately 10% of the body weight in dugongs and 14% in manatees (Marsh et al. 1977; Reynolds & Rommel 1996). The nutritional status of the animal and the amount of ingesta present in the intestinal tract can influence the respiratory capacity in the awake and sedated animal. When animals are removed from water for anesthetic procedures, pulmonary compression can occur from these internal organs and ventilatory variables must be closely monitored.

Respiratory adaptations for diving in sirenians are similar to those of other marine mammals. The terminal bronchioles of manatees are reinforced with cartilage (Pabst et al. 1999). Inspiration is closely paired with and follows forceful expiration, allowing animals to dive with replenished oxygen stores. Sirenians also have long interbreath intervals, which generally last 2–3 minutes in Florida manatees, but can extend as long as 24 minutes in "bottom resting" individuals (Reynolds 1981). In studies evaluating the response of Amazonian manatees to hypoxemia and hypercapnia in relation to respiratory drive, carbon dioxide rather than oxygen was concluded to be the "primary controller of ventilation and dive time" (Gallivan 1980). Similar to other marine mammal dive responses, dugongs and manatees develop bradycardia; however, it is generally characterized as "sluggish and modest" compared with that of cetaceans and pinnipeds (Elsner 1999; Scholander & Irving 1941).

The sirenian heart lies cranioventral to the lungs and anterior to the abdominal organs between the pectoral flippers. The heart rate can often be assessed by evaluating the skin pulse over this area when an animal is in ventrodorsal recumbency.

Unlike other marine mammals, West Indian manatee metabolic rates are 25–30% of predicted values and result in their unique warm water thermoregulatory requirements and relative cold intolerance (Irvine 1983; Worthy 2001). Amazonian manatees also have relatively low metabolic rates and limited capacity for thermogenesis (Gallivan et al. 1983). Depending on the season, Florida manatees are found in water ranging from 22°C (72°F) to over 32°C (90°F). While manatees may reside in water cooler than 21°C (70°F) during winter months, they have been observed to shiver at these temperatures and develop skin damage in temperatures $\leq 16^\circ\text{C}$ (61°F). The degree of damage is dependent on length of cold water exposure, and the animal's nutritional state and size. Manatees ≤ 300 kg are physiologically less adaptable to cold stress than larger manatees; juveniles seem unable to increase their metabolic rates to compensate for cold temperatures $\leq 16^\circ\text{C}$ (61°F) (Worthy 2001). For long term rehabilitation of manatees, water temperatures are generally maintained $\geq 24.5^\circ\text{C}$ (76°F), although often raised to 27–29°C (80–

84°F) for neonates, cold stressed, or thin individuals. The recommended ambient air temperature for animals removed from the water for procedures is 22–26°C (72–79°F) (Bossart 2001). If ambient temperatures drop $\leq 20^{\circ}\text{C}$ (68°F), time for out-of-water procedures is minimized to reduce exposure to cooler air. Water is often used to cool animals maintained out of water in warm ambient temperatures or in direct sunlight. In addition to thermoregulatory impacts, it has been suggested that the lower metabolic rate of sirenians has implications for drug metabolism, distribution, and elimination (Murphy 2003).

CAPTURE AND PHYSICAL RESTRAINT

To minimize injury to an animal or handlers, it is preferred that manatees are removed from the water for medical and surgical procedures. Acquisition of sick or

injured wild manatees usually involves setting long nets to encircle, then “bag” an animal before pulling it onshore or into a boat. When working with nets in bodies of water, particular care is taken to avoid net entanglement of the animal(s) or personnel that lead to injury or drowning. Hoop netting has limited success with dugongs, and where regulatory and equipment constraints exist for handling this species, a “rodeo method” of capture in shallow open water has been described (Lanyon et al. 2006). Care is taken to minimize injury to animal handlers, as well as reduce dugong chase and handling time, and the potential development of fatal capture stress or myopathy (Marsh & Anderson 1983). The authors do not recommend this capture method for manatees.

In captive environments, physical restraint is accomplished using nets, dry docking with pool water drops, raising a medical pool floor above the water level, or

Table 50.1. Family Sirenia

Genus and Species	Common Name	Length ^{a,b}	Mass ^b	Distribution
<i>Dugong dugon</i>	Dugong	Adults: 2.7 m average, up to 3.3 m Calves: 1–1.3 m	Adults: 250–300 kg average, up to 400 kg Calves: 20–35 kg	Coastal waters of Indo-Pacific
<i>Trichechus senegalensis</i>	West African manatee	Adults: 3–4 m	Adults: <500 kg	Coastal waters, rivers, and lakes of West-Central Africa
<i>Trichechus inunguis</i>	Amazonian manatee	Adults: 2.8–3 m Calves: 0.8–1 m	Adults: 450–480 kg Calves: 10–15 kg	Freshwater rivers and lakes of Amazonian basin
<i>Trichechus manatus</i>	West Indian manatee (two subspecies)			
<i>Trichechus manatus manatus</i>	Antillean manatee	Adults: 1.85–2.7 m, up to 3.5 m	Adults: max 1000 kg	West Indies, Caribbean, coastal waters and rivers of Mexico, Central America, Northeastern South America
<i>Trichechus manatuslatirostris</i>	Florida manatee	Adults: 2.7–4 m, average 3 m Calves: 1.2–1.4 m	Adults: 400–1775 kg, avg 400–600 kg males, max 1600 kg females Calves: 18–45 kg, average 30 kg	Coastal waters and rivers of Southeastern United States

placing an animal within a stretcher. Whether in captivity or the wild, care is taken during any “catch-up” as these animals may actively avoid capture and restraint. The strong thrust of sirenian tails and often large body size (Table 50.1) make injury a possibility to both handlers and animals. Only trained personnel participate in the capture and restraint of sirenians.

While these animals spend their entire lives in water, they are capable of being sustained outside of the aquatic environment for a number of hours. Intermittently spraying with water throughout a procedure will help prevent skin desiccation and overheating, although their skin is much more resistant to drying than cetaceans. When “stranded” for diagnostics or therapeutics, animals are generally placed on closed or open cell foam to cushion their body mass and reduce pressure on internal organs. Animal position is adjusted with stretchers, boat sling straps (placed around the animal’s body), cranes, and in smaller animals, manually. When animals are in sternal recumbency, a sheet of closed cell foam is placed over the dorsal aspect of the fluke for handlers to sit on and restrain the tail (Fig. 50.2). Handlers also position themselves on either side of the animal to prevent lateral movement. It is not uncommon for manatees to lie quietly either sternally or dorsoventrally during transport or nonpainful procedures. Care must be taken around the head and tail areas. Manatees can explosively resist restraint and are capable of touching the tips of their tails to their snouts and/or rolling quickly. Particularly fractious animals are secured to restraint boards or administered sedatives if necessary. In cases of thoracic trauma, where rib fractures exist, manatees may be sedated or strapped to

Figure 50.2. Restraint of a Florida manatee (*Trichechus manatus latirostris*).

a board to minimize further damage to the chest during diagnostic or treatment procedures.

VASCULAR ACCESS

One of the few available vascular access sites in manatees includes a brachial vascular bundle comprised of a rete of veins and arteries in the interosseous space between the radius and ulna (Fawcett 1942b). This site is accessed from the medial or lateral sides of the pectoral flippers (Fig. 50.3a,b). A cephalic vessel has been accessed in one anesthetized Florida manatee (J. Bailey, pers. comm., 2011), and, historically, blood has been collected from the distal humeral region although this has not been investigated further. A caudal tail ventral

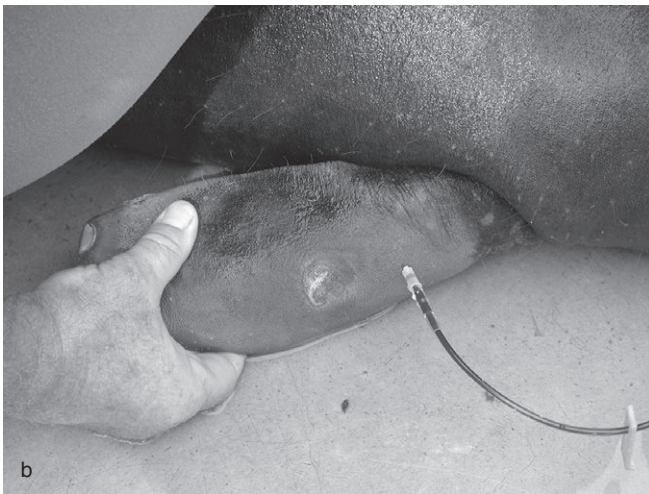

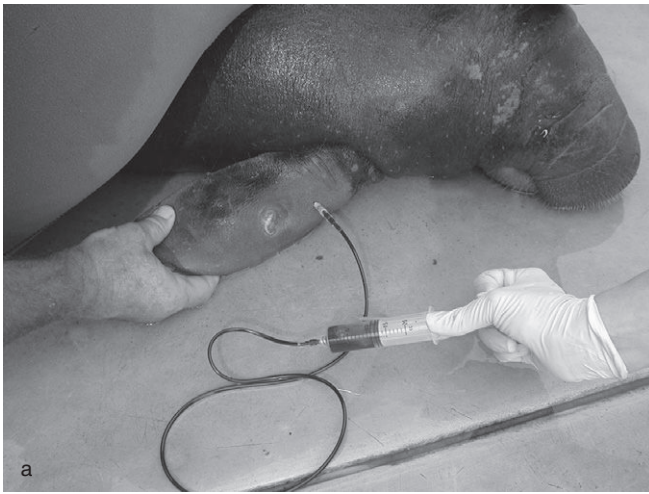

Figure 50.3. (a and b) Brachial vascular bundle venipuncture site in a Florida manatee calf (*Trichechus manatus latirostris*).

vertebral arch vascular bundle is also available for venipuncture, particularly in younger animals where pectoral vessels are small (Fig. 50.4). Care is taken when using this caudal tail site for IV access in unanesthetized animals, since forward thrust of the fluke could injure the phlebotomist. Due to the potential danger from the fluke, this site is generally not used in awake individuals except for compromised neonates.

Spinal needles may be used to obtain IV access for drug and fluid administration in anesthetized adult manatees in the caudal tail vascular bundle. This site is accessed by elevating the tail to visualize its ventral aspect or placing the animal in lateral or dorsoventral recumbency. Tissue glue may be used to secure needles in place. Calves that are easily restrained due to size or illness are catheterized awake in the caudal tail site with 20- or 21-gauge 3.75- to 5-cm (1.5–2 in) needles. The brachial vascular bundle is difficult to catheterize due to needle placement perpendicular to the arteriovenous plexus. It is accomplished with 18-gauge 5-cm

Figure 50.4. Caudal tail vascular bundle venipuncture site of the Florida manatee calf (*Trichechus manatus latirostris*).

(2 in) needles in adults and 20-gauge 3.75-cm (1.5 in) needles in juveniles (Murphy 2003). Although the pectoral flippers can be catheterized either medially or laterally, contact between the body wall and a medially placed catheter may displace it. Perivascular leakage of drugs can occur, potentially resulting in local tissue inflammation or necrosis. To reduce the likelihood of catheter displacement, venous access is best attempted after sedative administration, tracheal intubation, and/or final patient positioning for a medical or surgical procedure. During fluid administration, closely monitoring flow rates and observing vascular access sites for swelling are recommended.

ENDOTRACHEAL INTUBATION

Manatees can occasionally be intubated under midazolam or midazolam/butorphanol sedation at higher dosages, but others may require anesthetic induction with an inhalant administered by mask prior to endotracheal tube passage. Mask administration is usually done with a modified 20-L (5 gal) clear plastic water jug with the bottom removed. The edges are padded for a tighter fit over the animal's head (Walsh & Bossart 1999). A large mask allows adequate tidal volume exchange with less resistance to rapid inspiration. Even in sedated manatees, breath holding during mask induction can occur. The manatee patient may require stimulation, such as rocking side to side, to facilitate additional respirations during mask induction. Animals inadequately sedated for intubation will often respond to sound, open their eyes partially, or retract their head when stimulated.

For intubation, a manatee's trachea can be accessed, at least theoretically, from both the oral or nasal cavities. Initial attempts at oral intubation in manatees

were historically unsuccessful. Given the poor visualization of the caudal pharynx and larynx due to the curved angle of the tongue, the narrow width of the buccal cavity, and the long soft palate, nasal intubation is preferred. Nasogastric tubes can be passed blindly in manatees, but dependable tracheal intubation is best accomplished with rhinoscopic assistance. Wild sirenians commonly have mild to heavy loads of nasopharyngeal trematodes, and in some cases, heavy parasitic infestations cause severe rhinitis or tracheitis and complicate intubation (Beck & Forrester 1988; Bossart 2001). In Florida manatees, it is recommended to use cuffed elongated foal endotracheal tubes (8- to 14-mm internal diameter, based on the size of the animal) for intubation. Stylets may be used to assist passage of the tube into the laryngeal opening (Murphy 2003; Walsh & Bossart 1999). Due to the short length of the manatee trachea, however, intubation of a single bronchus can occur. Preplacing the endotracheal tube over the end of a bronchoscope and using the bronchoscope to guide the tube past the loose palatopharyngeal tissues into the trachea allow visual confirmation of proper positioning. An additional benefit of the bronchoscope's small diameter is that it can be gently passed into the trachea even when the glottis is closed, allowing quick and minimally traumatic intubation. Breath holding and the periodic, brief opening of the glottis in a sedated manatee can result in multiple attempts for successful intubation using other methods. Regardless of the method used to intubate manatees, bronchoscopic confirmation of endotracheal tube placement cranial to the carina is recommended. The endotracheal tube is secured to the muzzle with white waterproof tape strips secured to white tape encircling the muzzle caudal to the oral disk (Fig. 50.5). Periodic suctioning of endotracheal tubes is required to remove mucous that accumulates in the tube (Walsh & Bossart 1999). Once intubated, sirenians can be maintained

Figure 50.5. Endotracheal tube securing on muzzle of a Florida manatee (*Trichechus manatus latirostris*).

with isoflurane levels similar to those used in domestic animals (Table 50.2).

PREANESTHETIC CONSIDERATIONS

Similar to other mammals, sirenians are physically examined and their bloodwork is evaluated prior to anesthesia to identify any health conditions that would pose risks. Florida manatees present to rescue and rehabilitation programs with a variety of injuries and illnesses secondary to both natural and human causes, as have been described in previous mortality studies (Ackerman et al. 1995; Bossart et al. 2004; O'Shea et al. 1985; U.S. Fish and Wildlife Service 2001; Walsh & Bossart 1999). Two of the more commonly seen naturally occurring conditions in Florida manatees are cold stress and brevetoxicosis. Traumatic injuries from crab trap, monofilament line entanglement, and boat strike are also common presentations to rescue and rehabilitation programs. Understanding the extent of illness or injury is critical to assessing the anesthetic risk to a manatee patient.

Prior to anesthesia, sirenians are ideally fasted for 24 hours to reduce the likelihood of regurgitation. However, these species have a slow gut transit time (4–7 days in the Florida and 5–9 days in the Amazonian manatee), so complete emptying of the gastrointestinal tract (GIT) in 24 hours does not occur (Gallivan & Best 1986; Walsh & Bossart 1999).

Respiratory rates are monitored prior to sedation and through the induction procedure. In sirenians, respirations are counted over 5 minutes to determine a rate because they are usually ≤ 1 breath/min. If a manatee in the water shows signs of depression or incoordination after sedatives are administered, it is removed prior to the usual 20–25 minutes before handling. In animals with pulmonary compromise, oxygen supplementation with a portable oxygen tank and Hudson or Elder demand valve is often provided during short sedative procedures or prior to administration of general anesthesia.

INDUCTION/MAINTENANCE PROTOCOLS

Reported anesthetic drugs and dosages are listed in Table 50.2. It has been suggested that the relatively low metabolic rate of sirenians may contribute to their apparent sensitivity to sedative and opioid drugs compared with terrestrial mammals (Murphy 2003) but further work has shown that manatees can be successfully sedated with similar dosages of some drugs. Diazepam and midazolam have been used extensively for both mild and preoperative sedation. Meperidine has also been used in conjunction with benzodiazepines for more fractious individuals or for procedures that may result in surgical discomfort. In captive environments, after administration of these sedatives, animals are often placed back in

Table 50.2. Analgesic, anesthetic, and reversal agents for the Florida manatee (*Trichechus manatus latirostris*)

Agent	Use	Dosage	Comments	Reference
Atipamezole	Reversal	1 mg/20 mg of xylazine IV	For xylazine reversal	Murphy (2003)
		1 mg/2 mg of detomidine IV	For detomidine reversal	Murphy (2003)
Butorphanol	Sedative, analgesic	5 mg/1 mg of detomidine IM	For detomidine reversal	Murphy (2003)
		0.01–0.025 mg/kg IV	In combination with diazepam for mild painful procedures, anesthetic induction, give butorphanol 10 minutes prior to diazepam	Murphy (2003)
		0.005–0.01 mg/kg IV	In combination with detomidine for minor surgical procedures or anesthetic induction	Murphy (2003)
		0.0086 mg/kg IM	In combination with detomidine for heavier sedation, +/- intubation	M.T. Walsh and A.D. Bukowski, pers. comm., 2010
		0.04–0.06 mg/kg IM	With midazolam 0.1 mg/kg IM for anesthesia induction or for short procedures involving fractious individuals	M.T. Walsh et al., pers. comm., 2010b
Detomidine	Sedative	0.1 mg/kg IM	With midazolam 0.1 mg/kg IM for anesthesia induction in severely fractious individuals, results in very deep sedation, use with caution	Murphy (2003)
		0.005–0.01 mg/kg IV	Moderate sedation, beware of narrow therapeutic index, cardiac and blood pressure effects not noted	Murphy (2003)
		0.025–0.005 mg/kg IV	In combination with butorphanol, excellent analgesia and muscle relaxation, beware of narrow therapeutic index	Murphy (2003)
Diazepam	Sedative	0.0086 mg/kg IM	In combination with butorphanol for heavier sedation, +/- intubation	Murphy (2003)
		0.02–0.035 mg/kg IV	For nonpainful diagnostics	Murphy (2003)
		0.01–0.025 mg/kg IV	In combination with butorphanol for mild to moderate painful procedures	Murphy (2003)
Flumazenil	Reversal	0.066 mg/kg IM	For tranquilization, lasts 60–90 minutes	Bossart (2001)
		1 mg/10–20 mg of midazolam or diazepam IV	Reversal for midazolam or diazepam	Murphy (2003)
Isoflurane	Anesthetic	Equal volume as midazolam IM	Reversal for midazolam may require redosing after long procedure	Walsh and Bossart (1999)
		0.5–5%	Reversal for diazepam	Bossart (2001)
Ketoprofen	Analgesic	Similar settings as in domestic animals	Similar settings as in domestic animals	Walsh and Bossart (1999)
Lidocaine 2%	Analgesic	1–2 mg/kg IM	Analgesia for severe abdominal pain. Authors' note: caution in dehydrated animals, side effects not well documented in this species	R. Ball, pers. comm., 2011
Meperidine	Sedative, analgesic	Local infusion to effect	Local analgesia	
		Up to 1 mg/kg IM	In combination with midazolam for more painful procedures or anesthetic induction	Walsh and Bossart (1999)
Midazolam	Sedative	0.5–1 mg/kg IM	Sedation/analgesia for minor surgical procedures	Bossart (2001)
		0.02–0.05 mg/kg IM	Mild to moderate sedation	Murphy (2003)
		0.045 mg/kg IM	Sedation for 60–90 minutes can also use in conjunction with meperidine for more painful procedures or anesthetic induction	Walsh and Bossart (1999)
		0.05–0.072 mg/kg IM	Sedation for 20–30 minutes at peak effect for endoscopy, freeze branding, or noninvasive procedures	R. Ball, pers. comm., 2011
		0.08 mg/kg IM	Anesthetic induction, intubation	Walsh and Bossart (1999)
Naltrexone	Reversal	0.1 mg/kg IM	Anesthetic induction, in combination with butorphanol	M.T. Walsh et al., pers. comm., 2010a
		1–2 mg/1 mg of butorphanol IV, IM	Reversal for butorphanol	Murphy (2003)
Xylazine	Sedative	Equal volume dose as meperidine IM	Reversal for meperidine	Murphy (2003)
Xylocaine 1%	Epidural anesthetic	0.05–0.1 mg/kg IM	Moderate sedation, beware of narrow therapeutic index	Murphy (2003)
		Dose not noted, epidural	Used in one case for vertebral fracture surgery	Bossart (2001)
Yohimbine	Reversal	1 mg/5–10 mg of xylazine IV	Reversal for xylazine	Murphy (2003)
		2–3 mg/1 mg of detomidine IV	Reversal for detomidine	Murphy (2003)
		IM at the above dosages	Reversal for xylazine, detomidine	

IM, intramuscular; IV, intravenous.

shallow water pools to allow the agent to take effect and minimize the effects of restraint overriding the sedative, in particular, the benzodiazepines. Sirenians are monitored closely with higher sedative dosages for evidence of hypoventilation or reduced ability to surface to breathe. A combination of detomidine (0.017 mg/kg IM) and butorphanol (0.017 mg/kg IM) resulted in marked respiratory depression in a 700-kg female Florida manatee (D. Neiffer and A. Stamper, pers. comm., 2006). Intravenous administration of yohimbine/naltrexone/supplemental atipamezole reversed the respiratory effects. Manatees have subsequently been sedated with lower dosages of detomidine (0.0085 mg/kg IM) and butorphanol (0.0085 mg/kg IM) without adverse side effects (D. Neiffer and A. Stamper, pers. comm., 2006). In one instance of a manatee sedated with this detomidine/butorphanol combination, an additional 0.017-mg/kg midazolam IV was administered to achieve adequate sedation for intubation.

Local infusion of 2% lidocaine at a surgical site is effective, in conjunction with sedation, for analgesia in minor procedures. Epidural administration of 1% lidocaine has been reported once in a manatee undergoing spinal surgery for a vertebral fracture (Bossart 2001). Other analgesic agents used in sirenians include non-steroidal anti-inflammatory drugs, but care is taken to avoid gastrointestinal upset with these drugs by minimizing dosage and frequency of use. Intramuscular flunixin meglumine is not used for more than a few days in succession to avoid gastrointestinal or renal compromise. Butorphanol has also been administered for analgesia either intra or post operatively in West Indian manatees.

Sedative or analgesic drugs are administered IM or IV. Onset of drug effects after IM injection is approximately 15–20 minutes (Bossart 2001), although maximum effect may not occur until 25 minutes in some individuals. Due to the thickness of the skin and subcutaneous blubber, needles are advanced perpendicularly and forcefully to reach the deep layers of the lumbar epaxial musculature for injection of sedatives. For adult Florida manatees, 18-gauge 8.75-cm (3.5 in.) spinal needles are used to administer drugs IM, whereas 20- or 21-gauge 3.75- to 5-cm (1.5–2 in.) needles are used in calves. When administering IM injections in the caudal neck region, 18-gauge 3.75-cm (1.5 in.) or 21-gauge 5-cm (2 in.) are used on adult manatees. The individual administering the drug keeps pressure on the syringe plunger to avoid reflux of sedative back into the syringe. Digital pressure is applied to the injection site to avoid drug leakage after removal of the needle.

Mechanically assisted ventilation is preferred over manually assisted ventilation during general anesthesia to maintain adequate gas exchange and oxygenation. For shorter sedative procedures without inhalant anesthesia, oxygen supplementation is accomplished with an oxygen demand valve. When mechanically ventilat-

ing a manatee, some unique anatomical and physiological traits need be considered. Mechanical ventilation does not mimic the sirenian respiratory cycle of inspiration closely following expiration. Rather, it reverses the cycle with expiration closely following inspiration. Higher respiratory rates on mechanical ventilators shorten time of lung inflation in a breath-holding species and leads to hypoventilation and hypercapnia. In the authors' experience, a slow inspiratory flow rate improves oxygenation while decreasing carbon dioxide accumulation.

In manatees, pulmonary resistance is increased from other organs when they are removed from the water. In dorsoventral recumbency, the ventilator must counter the weight and pressure of abdominal organs and ingesta on the lungs. In sternal recumbency, the ventilator must also provide enough pressure to inflate the lungs despite limited lateral mobility of the pachyostotic ribs and ventral pressure from abdominal organs. Pulmonary resistance is further increased by loss of lung function from concurrent respiratory disease (e.g., severe pyothorax, pneumothorax, or pulmonary fibrosis or adhesions secondary to thoracic trauma). In these cases, it may be difficult to alleviate hypercapnia or hypoxemia due to loss of functional tissue. In some cases, whether due to disease or patient positioning, the peak inspiratory pressure of the ventilator must be adjusted above 20 mmHg to achieve lung expansion, oxygenation, and carbon dioxide exchange. Close monitoring of physiological variables will determine the most appropriate ventilatory settings. Ventilations are initially set at 6 breaths/min (Murphy 2003). Doxapram (IV, IM) has been administered to improve respiration in sedated and anesthetized manatees although this approach should not be considered a substitute for proper ventilation management.

MONITORING

Manatees are closely monitored during sedation and anesthesia using standard techniques or modalities used in domestic animals (Chapter 3). Anesthetic depth is determined by assessing blink response, jaw tone, and resistance to limb movement. Eye position is often difficult to assess due to recession of the globe into the orbit during anesthesia.

Physiological variables of the Florida manatee are listed in Table 50.3. Heart rates are calculated by listening to the heart with a stethoscope, placing a Doppler on the skin near the heart, or observing the pulsation of the skin overlying the heart when animals are positioned in dorsoventral recumbency. Electrocardiography, either by esophageal probe or pad/needle placement of leads on skin, is used for assessment of cardiac rate and rhythm (Siegal-Willott et al. 2006). If esophageal probes are inserted orally, care is taken to prevent the probe inadvertently being advanced into

Table 50.3. Physiological parameters for the Florida manatee (*Trichechus manatus latirostris*)

Parameter	Range
Respiratory rate	Variable, average 2–4 breaths/5 min in water, 3–15 breaths/5 min out of water
Heart rate	40–60 beats/min (can be as low as 30 with diving)
Body temperature	35.5–36°C ^a
Tidal volume	2.9% of body weight ^b
Lung volume	Approximately 5% of total body weight

^aOral temperatures. Note that body temperatures are dependent on environmental water temperatures as well as site of thermometer placement.

^bBased on Scholander and Irving's work, $N = 2$.

Sources: Murphy (2003); Pabst et al. (1999); Scholander and Irving (1941); Walsh and Bossart (1999).

the trachea instead of the esophagus. It may be prudent to verify placement with a bronchoscope. Placement of a pulse oximetry probe on the tongue is difficult because of the short, thick shape and reduced mobility of sirenian tongues and their firm attachment to the lower jaw (Levin & Pfeiffer 2002; Yamasaki et al. 1980). Pulse oximetry readings are occasionally collected from the nasal septum, buccal mucosa, or rostral gingival ridge of the lower jaw. Rectal reflectance pulse oximetry probes are placed in the nostril to obtain saturation readings. Gingival capillary refill time is generally ≤ 2 seconds in manatees.

Body temperature is measured with a rectal, oral, or nasal probe. Flexible rectal thermometers are difficult to place due to high sphincter tone and the fibrous consistency of feces obstructing advancement into the colon. Rectal temperatures may read lower than core temperatures for these reasons (Irvine 1983). Nasal passage of flexible probes is relatively easy; however, inhalation can result in spurious results due to mixture with ambient air. Oral placement of thermometers alongside the caudal buccal mucosa appears to give fairly accurate results although also lower than core body temperature. Equipment damage from the molars or accidental advancement into the trachea must be avoided.

End tidal carbon dioxide (ETCO₂) levels follow those of other mammals', yet no scientific study has been reported, to the authors' knowledge, to correlate results with arterial blood gases. Samples for blood gas analysis have been collected from manatees, but the arteriovenous plexus in the pectoral flipper makes interpretation difficult. Venous or mixed samples are still diagnostically valuable when the animal is used as its own control during the procedure.

RECOVERY CONSIDERATIONS

Following recovery from anesthesia, manatees are not placed in water until they are appropriately responding

to stimuli and breathing voluntarily. If possible, animals are placed in shallow water (≤ 1 m) so they are able to surface to breathe by pushing off the pool floor with their pectoral flippers.

The unique anatomy, physiology, and aquatic environment of sirenians make sedation and anesthesia challenging. Continued efforts to develop knowledge of sirenian anesthesia are important to advance conservation efforts and improve our ability to treat sick and injured animals.

ACKNOWLEDGMENTS

The authors would like to thank Dr. Dan Odell and Dr. Sentinel Rommel for their help in manuscript preparation, and Carol Swain for her photographic assistance. We would also like to thank the staff members of the SeaWorld Orlando Veterinary and Animal Care Departments for their photographic contributions and their help and support in the development of Florida manatee anesthesia techniques. Additional thanks to the Disney Department of Animal Health and the Seas Marine Mammal Department for their help and support with advancing our knowledge of Florida manatee anesthesia.

Elephants

William A. Horne and Michael R. Loomis

Elephants belong to the order Proboscidae, family Elephantidae. There are two surviving genera: *Loxodonta*, the African elephant, and *Elephas*, the Asian elephant. The genus *Elephas* consists of a single species with three subspecies: *Elephas maximus indicus*, the Indian elephant; *Elephas maximus maximus*, the Sri Lankan elephant; and *Elephas maximus sumatranus*, the Sumatran elephant. A fourth subspecies, *Elephas maximus borneensis*, has recently been proposed based on genetic studies (Fernando et al. 2003).

The genus *Loxodonta* is generally considered to be divided into two species: *Loxodonta africana*, the savanna or bush elephant, and *Loxodonta cyclotis*, the forest elephant (Roca et al. 2001). A third species (or possibly a subspecies), the West African elephant, has been proposed based on recent genetic studies (Eggert et al. 2002). Table 51.1 gives geographic ranges, heights, and weights of the different elephant taxa.

As of August 2011, 606 Asian elephants and 382 African elephants were registered with the International Species Information System (ISIS). Recent estimates for numbers of free-ranging elephants are 400,000–500,000 African elephants (Blanc et al. 2007) and 35,000–50,000 Asian elephants (Focus 2005). These numbers indicate that the captive elephant population has nearly doubled in the last 15 years, and that estimates of wild elephant populations have declined by 30% (compared with Kock et al. 1993). Both captive and free-ranging elephants require sedation and anesthesia for a variety of reasons (Table 51.2). In captivity, elephants are sedated or anesthetized predominately for medical reasons (though operant conditioning has allowed many minor procedures to be performed without anesthesia or sedation). These reasons are numerous and include a range of activities from dental work on tusks to caesarian section.

Captive elephants also require long-term analgesia. In the coming decade, more than 50% of all captive elephants will be 40 years old or older; osteomyelitis in the bones of the feet has been a significant cause of morbidity, often leading to euthanasia, in elephants of this age group.

By far, however, the vast majority of anesthetic episodes occur in free-ranging populations. These episodes generally involve translocations, various types of research, disease surveillance, and tracking-collar deployment for monitoring movement and land use patterns (Fig. 51.1). Occasionally, free-ranging elephants are anesthetized for medical procedures, such as removing a snare from a foot.

GENERAL CONSIDERATIONS FOR ELEPHANT SEDATION AND ANESTHESIA

Herd and Reproductive Behavior

Social structure and reproductive behavior must be considered in planning for anesthetic procedures both in field and captive settings. Elephants are long-lived (up to 65 years in the wild, 50 years in captivity), highly social animals that live in matrilineal family groups. The family group is lead by a matriarch, who is generally the oldest and tallest female in the group. The group (Fig. 51.2, *top*) consists of the matriarch and her descendants, her sisters and their daughters and their offspring. Males are driven from the family group before reaching sexual maturity (12–15 years) and live alone or in small dynamic groups.

With age, females acquire social knowledge that benefits the entire group. For example, groups with older matriarchs have higher per capita reproductive success (McComb et al. 2001). Moreover, matriarchs retain geographical memories that define the home

Table 51.1. Geographic distribution, height, and weight of officially recognized elephant taxa

Taxonomic Designation	Common Name	Geographic Range	Weight (kg)	Height (m)
<i>Elephas maximus indicus</i>	Mainland or Indian elephant	Indian Subcontinent, Southeast Asia, Peninsular Malaysia	2000–5000	2.5–3.5
<i>Elephas maximus maximus</i>	Sri Lankan elephant	Island of Sri Lanka	2000–5500	2.5–3.5
<i>Elephas maximus sumatranus</i>	Sumatran elephant	Island of Sumatra, Indonesia	2000–4000	2.5–3.2
<i>Loxodonta africana</i> ^a	Savanna or bush elephant	East and South Africa	4000–7000	3.0–4.0
<i>Loxodonta cyclotis</i> ^a	Forest elephant	Central and West Africa	2000–4500	2–3

^aRanges may overlap somewhat.

Table 51.2. Procedures requiring elephant sedation or anesthesia

Procedure(s)	Drug Protocol	Reference
Captive elephants: standing sedation		
Transport (juveniles)	Xylazine and ketamine	Heard et al. (1988) ^a
Abscess treatment, venipuncture, TB testing, manual ejaculation	Azaperone with local anesthetics	Ramsay (2000) ^a
Aggressive abscess debridement	Azaperone and butorphanol	Ramsay (2000) ^a

Deployment of satellite and/or radio tracking collars	Etorphine	Elkan et al. (1998) ^b ; Horne et al. (2001) ^a ; Kock et al. (1993) ^a ; Osofsky (1997) ^a ; Tchamba et al. (1995) ^a
	Etorphine and acepromazine	Dangolla et al. (2004) ^c ; Elkan et al. (1998) ^b
	Carfentanil	Elkan et al. (1998) ^b

Notes: All elephants were adults unless otherwise indicated.

Species of elephant sedated or anesthetized in the selected references:

^a*Loxodonta africana*, the African savanna or bush elephant.

^b*Loxodonta cyclotis*, the African forest elephant.

^c*Elephas maximus*, the Asian elephant.

range and corridors of seasonal herd migration patterns. For this reason, herd matriarchs are often selected for deployment of radio/satellite tracking collars (“tagging”), which requires 30–60 minutes of field anesthesia. The ecological success of the herd is thus very dependent on the successful outcome of the anesthetic procedure. As a result, the authors are strong advocates of providing 100% oxygen, intermittent positive pressure ventilation, and cardiopulmonary monitoring (discussed later), even in very remote locations.

Females reach sexual maturity at approximately 10 years; gestation lasts 22 months. Calves are weaned at 2–3 years, and the calving interval is 4–6 years. Over her lifetime, a cow may produce seven offspring; in the field, it is not unusual to observe a cow with an infant and two older offspring. The presence of multiple offspring can complicate anesthetic procedures enormously (Fig. 51.2, *middle*). Although the oldest siblings typically follow the herd and separate from an anesthetized female when provoked by gunfire, the younger

Figure 51.1. Adult free-ranging female African elephant with satellite tracking collar deployed. The transmitter can be seen dorsally between the ears. The photograph was taken 3 minutes after intravenous injection of the etorphine reversal agent, naltrexone.

ones often do not (Fig. 51.2, *bottom*). Infants weighing 100–200lb can often be managed by physical restraint; older, more aggressive offspring may require anesthesia to protect team personnel.

Physical Restraint

Free-ranging wild elephants must be adequately anesthetized in order to ensure the safety of all those involved in an anesthetic procedure. Physical restraint is impractical and dangerous. Elephants in captivity, however, can be trained to accept some forms of handling. There are two distinct handling approaches currently in use: free contact and protected contact. The former involves direct contact between the keeper and the elephant, and often includes the use of an ankus to control the elephant. The legs are often chained for control (Fowler 1995). Negative reinforcement is sometimes employed. The elephant is essentially placed in a subservient position to the keeper.

Free contact is potentially more dangerous than protected contact for the handler. Many zoological institutions feel that protected contact is a more preferable way to manage captive elephants. The other, more acceptable approach is protected contact. Here, the keeper is separated from the elephant by a protective barrier, often with access ports to access various body parts, especially the feet or ears. The elephant, through operant conditioning, is taught to present body parts

Figure 51.2. Free-ranging African elephants (*Loxodonta africana*) are highly social animals that live in matrilineal family groups. (Top) A small family group of adult females and their offspring. The activity of cattle egrets around herds is especially helpful in spotting elephants from a distance. (Middle) A single adult female may stray away from the herd and bring a number of offspring with her. (Bottom) Very young offspring are difficult to separate from their anesthetized mothers. Note the dart in the left hindquarter of the adult female. In this case, it was possible to physically restrain the infant while procedures were performed.

for inspection for minor procedures, such as foot trimming or venipuncture. The elephant is positively rewarded for performing the desired behavior, and can choose whether or not to perform the behavior (Desmond & Laule 1991).

In either approach, an elephant restraint device (ERD) may be used as an adjunct to restraint to perform more invasive procedures, such as reproductive evaluations (Fig. 51.3). An ERD should allow safe access to all four feet, trunk, tusks, ears, face, both sides, hindquarters, and back by moving parts of the ERD or the

Figure 51.3. Captive elephants can be trained to stand in an elephant restraint device for minimally invasive procedures.

elephant (Schmidt 2003). Most ERDs are hydraulically operated and are large enough for an elephant to stand in comfortably for the duration of the procedure. The ERD should be constructed so that it can be quickly and easily opened in case an elephant falls down in the device.

Allometric Scaling

The energy cost of living (kJ/day) varies over a range of five orders of magnitude across species (Nagy et al. 1999). And though there is no consensus as to whether energy cost scales as the 2/3 (surface area) or 3/4 (volume) power of mass, it is widely accepted that the physiological processes that underlie metabolic scaling are the same as those that regulate uptake, distribution, and elimination of drugs. Given that the elephant is the largest of all land mammals, it is important to consider allometric scaling when calculating dosages of drugs used for anesthetic procedures. When the energy cost (kJ/d) of a variety of mammalian species is plotted against the log of their individual masses (kg), the graph that results is a straight line with a slope of approximately 0.75. This indicates that metabolic rate (MR) varies according to the following simple relationship, MR is proportional to $(\text{Mass})^{0.75}$. This fits with the general observation that smaller mammals have higher metabolic rates than larger ones. Accordingly, this relationship can be used to extrapolate drug dosages to be used in elephants from known dosage regimens worked out for other placental mammals. (The relationship can also be applied across energy groups by introducing a taxa specific allometric constant [MR is proportional to $K(\text{Mass})^{0.75}$; see Sedgwick 1993]).

The species most commonly used for comparison to elephants is the horse (Mikota and Plumb, *Elephant Formulary*, available at <http://www.elephantcare.org/drugdex.htm>, last accessed January 29, 2014). Assume, for example, that we want to give an average-sized

African elephant (weighing 3000 kg) atropine as a pre-anesthetic agent. Though not used often in the horse, a published dosage for a 500-kg animal is approximately 0.05 mg/kg (Plumb VDH). To adjust the elephant's dose by taking the different metabolic rate into account, the following relationship applies:

$$\begin{aligned} (\text{horse dosage})(\text{horse metabolic rate}) &= \\ (\text{elephant dosage})(\text{elephant metabolic rate}), \text{ or} \\ (0.05 \text{ mg/kg})(500 \text{ kg}^{0.75}) &= (\text{elephant dosage}) \\ & \quad (3000 \text{ kg}^{0.75}). \end{aligned}$$

Rearranging to solve for elephant dosage and solving for body mass raised to the 0.75 power,

$$\begin{aligned} \text{elephant dosage} &= (0.05 \text{ mg/kg})(106)/(405) \\ &= (0.05)(0.26) = 0.013, \end{aligned}$$

we see that the elephant dosage should be reduced by 74%. If this is a 6000-kg male elephant, a 84% reduction would be required (substitute $6000^{0.75} = 682$ into the equation above). Thus, giving the published horse dose would result in a dramatic overdose. This may explain why a 28-year-old Asian elephant developed immediate CNS signs (central excitation leading to restlessness, irritability, disorientation, and ataxia) of atropine toxicity after receiving 0.05 mg/kg atropine IV (Gross et al. 1994). The process of scaling down dosages has been applied to a variety of drugs used in elephant sedation and anesthesia.

Tracheal Anatomy and Intubation

To maximize the safety of any anesthetic procedure in any species, it is very important to have access to, and control of, the patient's airway. This is especially true in the case of elephants, as etorphine, the drug used most commonly for induction and maintenance of anesthesia/immobilization, is a very potent respiratory depressant. In addition, as the animal goes down in either sternal or lateral recumbency, there is significant pressure on the diaphragm from abdominal contents. The combination of these two factors can result in severe hypoxemia and hypercapnea. Even though 70% of inhaled air is taken through the elephant's trunk, attempts of positive pressure ventilation through the nares would prove futile as most of the forced air or oxygen would escape through the mouth. Complete control of the elephant's airway requires endotracheal intubation. Elephants are relatively easy to intubate; however, success of intubation requires an understanding of the unique feature of the elephant's larynx (Fig. 51.4).

Intubation is done blindly, with the greatest success coming with hand-guided insertion of the tip of the endotracheal tube into the dorsal opening of the glottis. It is imperative that the mouth be opened wide enough

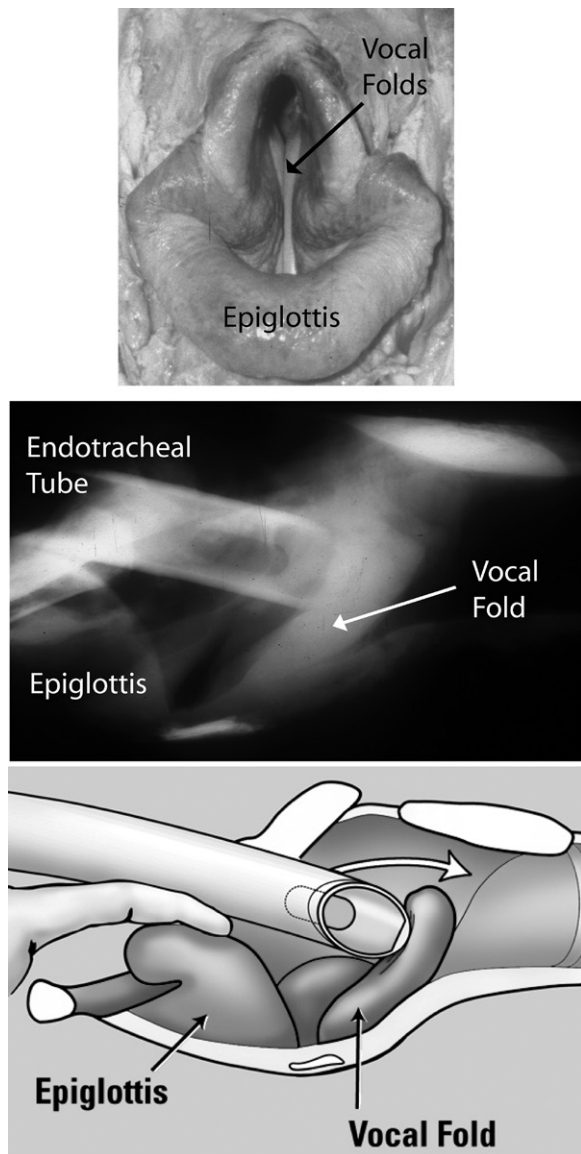

Figure 51.4. Anatomy of the elephant larynx. (Top) Elephants have a large fleshy epiglottis and extremely thick vocal folds. (Middle) The thickness of the elephant's vocal fold can be appreciated in this lateral radiograph of a dissected larynx. The curvature of the endotracheal tube makes intubation difficult. It is hard to get the end of the tube past the vocal folds. (Bottom) Intubation can be achieved by manually guiding the end of the tracheal tube to the dorsal aspect of the glottis.

to allow insertion of the arm, as elephants have large molars and a very narrow intermandibular space. The *top panel* of Figure 51.4 shows the larynx as it would be palpated when approaching from the oral cavity.

Elephants have a very large, fleshy epiglottis that is free of cartilage. It allows for a very tight seal to be formed between the trachea and the openings to the nares on the roof of the pharyngeal cavity. (The trunk and pleural adhesions that are unique to elephants are thought to have evolved for snorkeling [West 2002].) The epiglottis is very pliable and can readily be pulled

forward to allow access to the glottis. Elephants have very thick vocal folds that, at rest, largely occlude the entrance to the trachea. Difficulty in intubation, as shown radiographically in the *middle panel* of Figure 51.4, arises in part as the result of the curvature of the endotracheal tube causing its end to press up against the vocal folds. The solution to this problem is to, in coordination with breathing, manually guide the end of the tracheal tube to the dorsal aspect of the glottis where the vocal folds are much thinner and therefore more easily separated (Fig. 51.4, *lower panel*).

Physiology

Allometric scaling predicts that a 3000-kg elephant standing at rest would have a heart rate of 33 beats/min ($241 \times M^{-0.25}$), respiratory rate of 7 breaths/min ($53.5 \times M^{-0.26}$), and tidal volume of 20L ($6.2 \times M^{1.01}$). Though there are few references to substantiate these predictions in awake elephants, the numbers are in close agreement with what has been compiled to date (Mikota 2003, at <http://www.elephantcare.org>, accessed January 29, 2014): heart rate, 25–30 beats/min, and respiratory rate, 4–6 breaths/min. Interestingly, the heart rate more than doubles in awake elephants lying in lateral recumbency (Honeyman et al. 1992). These physiologic variables differ somewhat in anesthetized animals, as will be discussed in later sections.

Elephants have an average rectal temperature of 36–37°C. Their packed cell volumes are comparable to other mammals (40–45%); however, elephant red blood cells are large (MCV = 130 fl vs. 50 fl for horses) and fewer in number compared with other mammals ($3\text{--}4 \times 10^6/\mu\text{l}$ vs. $8\text{--}12 \times 10^6/\mu\text{l}$). Overall the oxygen carrying capacity of elephant blood is comparable to other mammals (20–21 mL O₂/100 mL). However, elephant hemoglobin binds oxygen with somewhat higher affinity than other species [$P_{50} = 23\text{--}24$ mmHg vs. 23–27 mmHg for the horse, and 29–31 mmHg for the dog (Cambier et al. 2004, 2005; Dhindsa et al. 1972)].

It is also of interest to point out some physiological variables important to anesthesia that do not scale allometrically. These include mean arterial blood pressure (about 100 mmHg in all species), maximum functional capillary diameter, and fractional airway dead space (constant at about 25–30% in large species). Plasma protein concentrations vary little with size or species.

Cardiopulmonary Monitoring in Remote Locations

Regardless of procedure location, it is very important to continuously monitor the oxygenation and ventilation status, blood pressure, heart rate and rhythm, respiratory rate, and temperature of anesthetized elephants. Monitoring anesthetized animals in remote geographic locations with no electrical power can be accomplished with the use of commercially available equipment or with modifications of available equipment.

Figure 51.5. Cardiopulmonary monitoring in remote locations. A portable solar panel (a) is used to recharge batteries. Adequacy of oxygenation and ventilation can be assessed with a portable pulse oximeter (b), blood gas analyzer (c), and capnograph (d). Adequacy of cardiovascular function can be assessed with a battery-operated ECG monitor (e), and a blood pressure monitor (f) that can be charged directly from the solar panel through a voltage regulator (g).

Portable solar panels that recharge batteries can ensure adequate power to operate most equipment. Equipment for monitoring oxygenation, ventilation, cardiac rhythm and rate, blood pressure, and core temperature have been successfully used in areas without an electrical grid or electrical generators (Fig. 51.5).

Size, weight, power requirements, durability, and dependability in harsh environmental conditions should be considered when choosing monitoring equipment for field use. Of concern are power requirements and the source of the power, particularly in areas where there is no power grid or generator available. There are a number of types of rechargeable batteries on the market.

We use nickel metal hydride batteries (NiMH) in monitoring equipment in our studies (MAHA Powerx 2100mAh, Thomas Distributing, Paris, IL). NiMH batteries have several features that make them attractive for remote use. They can be recharged 500–1000 times, have no memory, have a fairly steady discharge curve, and have a minimal negative environmental impact when disposed of. One disadvantage of NiMH batteries is that they have a self-discharge rate of 2–3% per day when not in use. AA-size NiMH batteries produce 1.2V. Battery energy output is measured in milliamp hours (mAh), with higher mAh ratings implying greater

battery output. A battery rated at 1700mAh will produce 1700mA for 1 hour. Different manufacturers produce batteries with different power outputs. AA-size NiMH batteries are rated at up to 2400mAh.

Batteries are charged using fast, smart chargers attached to portable solar panels (iPowerUS fast smart charger, iPower Corporation, El Monte, CA). A fast charger delivers the amount of current necessary to recharge the battery in 1 hour or less. In general, however, a slower charge rate will extend the overall life of the battery. To overcome the deleterious effects of rapidly charging a battery, a smart charger has a current-limiter built into it that reduces the current as the battery is charged, thereby limiting deterioration. The fast smart charger is attached to a portable solar panel (Sun Catcher Expedition solar charger, PowerQwest, Inc., Duluth, GA) via a 12-V “cigarette lighter” type plug. The panel (Fig. 51.5a) produces 25W of power, which is more than enough power to charge 8 AA-size NiMH batteries at a time. Monitoring equipment that uses AA- or AAA-size batteries is preferred so that a large number of different-sized rechargeable batteries are not required in the field.

There are a number of commercially available cardiopulmonary monitors that can be adapted for use in the field. Oxygenation status is assessed continuously with a pulse oximeter and intermittently by arterial blood gas determination using a portable clinical analyzer. Several brands of pulse oximeters have been successfully used and recharged in the field. An Invacare model 3402NV (Sims BCI, Inc., Waukesha, WI) is relatively small, lightweight, and operates on 6 AA-size batteries (Fig. 51.5b). This pulse oximeter is durable and operates well on rechargeable AA-size NiMH batteries. An I-Stat portable clinical analyzer (Heska Corp., Loveland, CO) has been successfully used in the field using rechargeable 9-V NiMH batteries (Fig. 51.5c). A challenge of using the I-Stat in the field is the analyzer’s normal operating temperature of 16–30°C (61–86°F), which is often exceeded in typical elephant habitat. The I-Stat can be maintained at the proper operating temperature range by placing it in a 12-V thermoelectric cooler (Coleman, Spirit Lake, IA). The thermoelectric cooler can be powered directly off the solar panel.

Ventilation status is measured continuously by capnography (end-tidal CO₂ measurement) and intermittently by arterial blood gas determination. The criteria for choosing a capnograph include availability of a waveform display, mainstream and side-stream capabilities, and power requirements. The Novamatrix Tidal Wave model 615 (Novamatrix Medical Systems, Inc., Wallingford, CT) meets these criteria (Fig. 51.5d). The Tidal Wave comes standard with a rechargeable computer-type battery, but can be ordered with a battery tray which holds seven AA-size batteries. This instrument is durable and operates well on rechargeable batteries. The side-stream capability allows a large-

gauge needle to be placed in the lumen of a large endotracheal tube or respirator for sampling.

Cardiac rate and rhythm are monitored by use of an electrocardiograph (ECG). A compact ECG unit (Heska Vet/ECG 2000, Heska Corp., Fort Collins, CO), which operates on 3 AAA-size rechargeable NiMH batteries, is durable and dependable in the field (Fig. 51.5e).

Blood pressure can be measured using a direct arterial line or by indirect methods. Of the indirect methods, automated oscillometry has been successfully used in the field. We have not identified an automated blood pressure machine that runs on replaceable batteries. We have, however, modified a compact, durable instrument, Oscillomate 9300 (CAS Medical Systems, Inc., Branford, CT) for field use (Fig. 51.5f). We manufactured a voltage regulator (Fig. 51.5g), which is inserted between the internal battery of the blood pressure monitor and the solar panel. This allows the internal battery of the blood pressure monitor to be recharged directly from the solar panel.

All monitoring equipment, battery chargers, and rechargeable NiMH batteries can be transported into the field in a backpack that is designed for photographic equipment (Lowepro Supertrecker AW II, Lowepro USA, Santa Rosa, CA). All of the earlier equipment has been dependably used to monitor immobilized elephants in a variety of remote habitats in Cameroon, including forest savannah (hot and dry) and rainforest (hot and humid) locations.

IMMOBILIZATION OF FREE-RANGING ELEPHANTS

Etorphine

Etorphine is a nonselective opiate agonist that binds to μ , κ , and δ opiate receptors; consistent with the ability of the drug to activate G-proteins, its effects occur at very low fractional receptor occupancy (Perry et al. 1982). Etorphine has been used safely for elephant restraint and anesthesia for nearly 40 years (Wallach & Anderson 1968). The first in-depth report of the use of etorphine for prolonged maintenance of an elephant in lateral recumbency for a surgical procedure was published by Fowler and Hart in 1973. Etorphine was used as the sole anesthetic agent on two separate occasions for castration of a subadult Asian elephant. Several important guiding anesthetic principles emerged from this report. First, it demonstrates that by using incremental dosing or constant rate infusion of etorphine, elephants can be maintained in lateral recumbency for up to 3 hours and 40 minutes without adverse effects. Of particular importance is the fact that even in the absence of fluid administration, the elephant under study did not develop postanesthetic myopathy or nerve paralysis, conditions that are common in other large mammals subjected to prolonged recumbency.

Second, the report shows that it is possible to maintain adequate ventilation and oxygenation throughout the procedure. The authors went to great lengths to maintain a patent airway, provide a supplemental source of 100% oxygen, and maintain a surgical plane of anesthesia that did not compromise ventilation. Most importantly, they monitored for adequacy of oxygenation and ventilation by performing serial blood gas analysis.

Third, reversal of etorphine with diprenorphine was rapid and complete regardless of procedure time. The elephant stood within 8 minutes following each procedure and was immediately able to eat, drink, and urinate. The option of immediate reversal added considerably to the safety of the anesthetic procedure.

A few other points from this report are worth noting. Given that the elephant was confined, the authors were able to induce anesthesia with a relatively low intramuscular dose (5–6 mg) of etorphine. Ataxia was noticeable within 6 minutes; an additional 5–10 minutes was required for the animal to lie down on its side. Maintenance of anesthesia for 1 hour required a total of approximately 10 mg of etorphine. As is a general property of opiates in all species, etorphine had minimal effects on cardiovascular function in this study. Neither anticholinergic agents nor sympathomimetics were required to maintain hemodynamic stability. Although blood pressure was not monitored, there was no evidence of hypotension (acidosis associated with poor perfusion, tachycardia) or hypertension (pulmonary hemorrhage). The elephant had minimal postoperative complications and was considered safe for elephant rides five months after surgery.

Lessons learned from this report have for the most part been carried into the field for larger-scale immobilization projects (Horne et al. 2001; Osofsky 1997; Raath 1993; Still et al. 1996). Larger initial doses of etorphine have been recommended for free-ranging elephants, often in combination with either acepromazine or azaperone. Carfentanil (Jacobsen et al. 1988; Kreeger et al. 2002) and thiofentanyl (Kreeger et al. 2002) have been used instead of etorphine; naltrexone has been used in the place of diprenorphine as a reversal agent. Hyaluronidase has been used by some with the intent of improving uptake of the drug at intramuscular injection sites. Table 51.3 gives the doses of the

Table 51.3. Doses of opiate agonists used in elephant anesthesia

Drug	Taxa	Dose (mg/kg)
Carfentanil citrate	<i>Loxodonta</i>	0.0021
Etorphine hydrochloride	<i>Loxodonta</i>	0.003
Thiafentanil oxalate	<i>Loxodonta</i>	0.003
Etorphine hydrochloride	<i>Elaphus</i>	0.003

most commonly used opiate agonists used in elephant anesthesia.

Drug Delivery

Delivering anesthetic agents to free-ranging elephants can be very challenging. Terrain, equipment and infrastructure vary greatly across elephant range countries. Raath (1993) describes the use of helicopters or vehicles to approach elephants. In areas with limited infrastructure and no access to helicopters, approach on foot is necessary. Great care must be taken when approaching an elephant or a herd of elephants this way. An armed game guard and an experienced tracker should be part of the approach team. As elephants have excellent senses of smell and hearing, the approach should be from downwind and as quiet as possible. In areas where there is access to cover, the approach should be from one area of cover to the next.

Perhaps most importantly, a long-range remote delivery system (RDS) should be used. (For a thorough review of RDSs, see Kreeger et al. 2002). Both CO₂ and powder-charge rifles are available, as are polyamide and aluminum syringes. Regardless of the RDS, 50- to 65-mm needles should be used in order to ensure an intramuscular injection. The hind leg, back, and shoulder are preferred darting sites (Raath 1993). If darting in the shoulder, care must be taken to avoid darting the ear. The dart impact should be perpendicular to the target site to ensure that the drug is delivered intramuscularly.

Elephants have relatively poor eyesight. The elephant will have limited ability to see the darter at distances greater than 40ft. It is extremely important to know the position of all of the individuals in a herd so that the approach does not place the team within the perimeter of the herd. The shot should be taken from cover if possible. Although most elephants will run away from the darter, an elephant may occasionally charge the darter. Also, elephants may initially run in random directions after a herd mate is darted; this places the approach team in jeopardy. A human cannot outrun an elephant, but can run around a tree faster than an elephant can. Finding a tree that an elephant can not easily push over, and not leaving the tree until the charging elephant is at a safe distance, is a good practice. In forests, it may be necessary to dart an elephant from a distance of 10m or less due to the thickness of the surrounding vegetation. In such situations, it is extremely important to dart from behind cover. Once the elephant is darted, the tracker(s) should follow at a safe distance.

A “Typical” Etorphine Field Immobilization Procedure

All of our immobilization procedures have been initiated either from a vehicle (savannah regions) or on foot (forest-savannah or rainforest). What follows also

applies to helicopter-assisted immobilizations, except that physiological parameters measured in these elephants often reflect significant sympathetic stimulation. Adult, free-ranging female African elephants weighing 3000–3500kg are typically administered a single intramuscular 10–12mg dose of etorphine delivered by dart to a region high on the hind limb. (Large males may require up to 20mg.) At this dose, elephants show first effects in 3–5 minutes, but are capable of running at high speed over a long distance during this time. Within 10–15 minutes, the elephant will often sit down into sternal recumbency. Though some elephants will roll spontaneously into lateral recumbency, many remain in this sternal position. It is important to locate the elephant as soon as possible, as it is widely believed that elephants do not ventilate adequately while sternal. (Drug effects on breathing often cause the elephants to make a loud rumbling sound that can be heard over long distances.) While approaching the darted elephant, the remaining members of the herd, including offspring, must be frightened off with rifle fire.

An elephant found in sternal position must be rolled onto her side, which may require 6–10 people depending on the size of the elephant and the terrain. While rolling the elephant, great care should be taken to protect the airway by extending the trunk. Heart rate, pulse pressure, respiratory rate, and arterial blood gases (blood drawn from auricular artery) should be evaluated immediately. Table 51.3 lists some of the published values for physiological parameters that have been recorded under similar field conditions. The elephant should have a very strong pulse as assessed by palpating an auricular artery. The table indicates that an etorphine immobilized adult female elephant, regardless of species, typically has a heart rate of 50 beats/min and a respiratory rate of 5–7 breaths per minute. Any deviation from these values, whether higher or lower, should alert the anesthetist to the possibility of hypoxemia. This would be confirmed by arterial blood gas measurements. As is the case with most mammals, elephant hemoglobin begins to desaturate very quickly below an oxygen partial pressure of 60mmHg (SpO₂ = 93%).

A number of elephant immobilization studies, including our own, have determined that etorphine-immobilized elephants are at-risk for developing severe hypoxemia (PaO₂ = 40–60mmHg). Though the actual number of hypoxemic elephants we have encountered is small (approximately 1 in 10), the importance of the matriarchal female to the social structure of the herd dictates that every effort be made to provide oxygen to immobilized elephants, even in remote locations. We have developed a simple and effective respirator device to provide oxygen and intermittent positive pressure ventilation to immobilized elephants in the field (Fig. 51.6, see Horne et al. 2001). The respirator can be

Figure 51.6. A portable respirator can be constructed with readily available parts (for details, see Horne et al. 2001). Oxygen is delivered through two high flow (160L/min) demand valves connected to an oxygen cylinder (not shown).

driven off a single MM oxygen cylinder (aluminum cylinders weigh 45lb) which holds 3500L of oxygen, enough for at least 45 minutes of continuous use. High partial pressures of oxygen (>400mmHg) can be achieved when the oxygen is delivered in synchrony with the elephant's breathing pattern through a 35-mm endotracheal tube with an inflatable cuff.

Placement of the endotracheal tube requires a team approach. The process is easy if the elephant has been properly dosed. Higher doses of etorphine tend to cause rigidity of the muscles of the jaw, making it difficult to access the pharyngeal cavity. With one person holding the tusk and pulling dorsally, and another pulling the lower jaw ventrally (a rope is helpful), the person inserting the tube lies on the ground and reaches between the jaws with the lower arm to locate the epiglottis. In large females, this is typically a full arm's length reach. Once the epiglottis is located (see Tracheal Anatomy and Intubation), the tube is passed alongside the arm and guided into the dorsal aspect of the glottis. The arm is removed, and the endotracheal tube cuff is inflated with a large syringe. The "Y" piece of the respirator is then connected by way of a standard

Figure 51.7. Continuous pulmonary monitoring using a pulse oximeter and capnograph while providing intermittent positive pressure ventilation. For pulse oximetry, a large C-probe is placed on the tip of the elephant's tongue. The sidestream capnograph draws expired air through a needle inserted into the expiration port of the respirator.

endotracheal tube adapter, and oxygen is delivered through one side of the "Y" (inspiration port) by two demand valves connected in parallel. A large rubber stopper is used to plug the opposite side of the "Y" (expiration port) during inspiration and then removed during expiration. The respirator can deliver oxygen at a rate of 5L/s; delivery over 4–5 seconds (elephant inspiration time) generates an adequate 20- to 25-L tidal volume with noticeable expansion of the chest wall.

Indirect methods of cardiopulmonary monitoring work well with immobilized elephants. Heart rate and SpO₂ can be monitored continuously via pulse oximetry with a large C-probe positioned on the tip of the tongue. End-tidal CO₂ can be monitored using a sidestream capnograph drawing from a needle inserted into the endotracheal tube (Fig. 51.7). Blood pressure can be monitored oscillometrically with a small adult human cuff (12 × 30cm) positioned at the base of the tail (Fig. 51.8). As summarized in Table 51.4, three separate studies report SpO₂ values less than 93%, which is indicative of hypoxemia. Note also that end-tidal CO₂ values may under represent actual PaCO₂ values by up to 25%, due to the presence of physiologic dead space. Mean arterial pressures measure in the range of 80–120mmHg, indicating that the 10mg dose provides an adequate plane of anesthesia, at least for the placement of radio/satellite tracking collars.

Our experience has been that 10–12 mg of etorphine provides a full hour of immobilization without any signs of awakening; however, a typical collar deployment requires less than 45 minutes. We have not had to redose any cases in which it was clear that the drug delivery was complete with the first dart.

Pink Foam Syndrome

Opioids have been implicated as the cause of hypertension in elephants (Raath 1993), with pulmonary hemorrhage being a common sequela. The pulmonary

edema and bleeding is manifest as “pink foam” bubbling from the elephant’s trunk. Surprisingly, we have not observed this effect of opioids in nearly 50 immobilizations. This is probably because the procedures we perform require that we approach elephants on foot, rather than by helicopter, as is common in South Africa where pink foam syndrome has been reported. Approach on foot causes significantly less stress to the elephant. Second, the dose of etorphine that we use may be more appropriate for our procedures compared to previous reports of documented hypertension. Hattingh et al. reported mean arterial pressures > 185 mmHg in 5000 kg bull elephants that had received only 8 mg etorphine; the pressure increased to >260 mmHg during electroejaculation. The elephants were obviously not fully anesthetized. Azaperone and acepromazine have been recommended for use in elephants because of their vasodilatory effects, and because of their potential to reduce the probability of pulmonary hypertension. We have not found them to be necessary and believe that hypertension in elephants is not a direct result of opiate administration.

Recovery

Several drugs have proven to be effective in reversing opiates in elephants, including diprenorphine, nalmefene, and naltrexone. Because of the potential for renarcotization resulting from the reversal agent wearing off too soon, we routinely reverse with naltrexone at 100 times the etorphine dose (1–1.2 g) given intravenously or 25% of the dose given intravenously and the remaining 75% given intramuscularly. First signs of recovery—movement of the trunk and ears—generally occur within two minutes, and recovery is often complete within 10 minutes. Figure 51.9 shows the first stages of

Figure 51.8. Blood pressure can be monitored continuously with a portable oscillotonometer and a small adult human cuff positioned near the base of the tail.

a typical recovery. Elephants roll into sternal, throw their heads backward, and stand on their front legs first. They then stand on their hind legs, balance in a saw-horse position for a short time as the reversal becomes complete, and then amble off to find their herd mates. Given the promptness of recovery, it is essential that all equipment, vehicles, and personnel be a safe distance away prior to administration of the reversal agent.

CAPTIVE ELEPHANT PROCEDURES

Drug Delivery

Anesthetics and sedatives can be delivered to captive elephants by most acceptable means. Hand intramuscular or intravenous injections can be given to conditioned elephants in captivity with or without the use of an ERD. For less tractable elephants, pole syringes or a variety of RDS may be required.

Standing Sedation

Standing sedation is useful in situations where a degree of sedation is required to perform a procedure that does

not require general anesthesia. Procedures performed under sedation include treatment of abscesses, tuberculin testing, trunk washes for acid fast culture, venipuncture, reproductive evaluations, manual stimulation of ejaculation, radiology, loading for transport and transport (Ramsay 2000). Sedation is often performed in conjunction with an ERD. Azaperone is preferred to α -2 agonists for reproductive procedures (Schmitt et al. 1996). But there are anecdotal reports of azaperone causing excitement in elephants. Azaperone has been reported to cause paradoxical excitement in the horse (Dodam & Waterman 1979). Xylazine/butorphanol provides a greater level of sedation than does azaperone (Ramsay 2000). Xylazine can be reversed with the intramuscular administration of yohimbine (0.5 mg per mg xylazine used), tolazoline (2mg per mg of xylazine used) (Kock et al. 1993), or atipamizole (0.1 mg per mg xylazine used) (Kreeger et al. 2002). Table 51.5 lists drugs and dosages commonly used for standing sedation of elephants.

Etorphine Induction and General Anesthesia

A variety of anesthetic protocols have been used in captive elephants. A summary of published cardiopulmonary values obtained during these procedures are listed by protocol in Table 51.6. As mentioned earlier, the striking difference between published free-ranging and captive elephant procedures is the method of administering etorphine as an induction agent. For example, rather than a single dose of 10–12mg etorphine IM, Dunlop et al. have reported that, in two out of three attempts, 6-mg etorphine administered by pole syringe was sufficient to allow an elephant to be positioned into sternal recumbency. An additional 2mg of etorphine administered IV permitted positioning in lateral recumbency. In a third attempt, the elephant appeared to be apprehensive and stressed and required an additional 7mg of etorphine and a 210-mg dose of azaperone.

Maintenance of a surgical plane of anesthesia for prolonged periods can be achieved by repeated 1- to -2-mg doses of etorphine (Allen et al. 1984; Fowler & Hart 1973) or with inhalation anesthetics (Dunlop et al. 1994; Heard et al. 1988; Stegmann 1999; Tamas & Geiser 1983). Inhalation anesthetics have also been used following induction with carfentanil (Jacobsen et al. 1988) and xylazine-ketamine (Abou-Madi et al. 2004). As with any species, recoveries from inhalation anesthetic procedures may be prolonged. Opiates should be reversed, even if it has been several hours since they were administered.

ANALGESIA

Nonsteroidal Anti-Inflammatory Agents

Although nonsteroidal anti-inflammatory agents (NSAIDs) are used extensively in elephants, very little

pharmacokinetic data are available. Ketoprofen was studied by Hunter et al. (2002). Dosage recommendations resulting from their study are 1–2 mg/kg every 24–48 hours, IV or PO. Table 51.7 lists NSAIDs commonly used in elephants. Care should be used in treating elephants with other NSAIDs. Extrapolation of elephant dosages from equine pharmacokinetic parameters is inappropriate (Hunter et al. 2002). Metabolic scaling dosages and treatment intervals for elephants may correlate with pharmacokinetic data (Hunter et al. 2002; Mortenson 2001).

SUMMARY

Despite their very large size, elephants can be readily anesthetized and stably maintained for hours under both free-ranging and captive conditions. Fortunately, they respond very predictably to the potent opiate agonists, etorphine and carfentanil. Whether the opiates are used alone or in combination with inhalation anesthetics, it is possible to maintain hemodynamic and respiratory stability for many hours without pharmacological intervention. Quite amazingly, a number of multiple-hour anesthetic procedures have been performed without any postanesthetic complications, such as nerve paralysis or myopathy.

As with any anesthetic procedure, it is important to monitor cardiopulmonary function and temperature continuously in elephants. Monitors developed for companion animal species are readily adapted to the elephant, even in remote locations. Of all the potential complications that might be expected during anesthesia, elephants are most at risk of developing hypoxemia. We and others have shown, however, that hypoxemia is readily corrected by simple oxygen supplementation. We recommend that, whether by continuous insufflation or by intermittent positive pressure ventilation, some means of oxygen supplementation be readily available for use when anesthetizing ele-

phants. This is especially true in field situations, where severe hypoxemia is most likely to occur.

Nondomestic Equids

Chris Walzer

INTRODUCTION AND TAXONOMY

The Equidae family encompasses the zebras, asses, and horses. These descended some 50 million years ago from the “dawn horse” (*Hyracotherium*), with the *equus* emerging in the Pleistocene, about 1.5 million years ago. The taxonomy of the nondomestic equidae is controversial; the International Species Information System (ISIS) lists eight wild species with several subspecies, three zebras and one wild ass in Africa, and three wild asses and the Przewalski’s horse in Asia (Table 52.1). They are distributed solely throughout the Old World, from the deserts of Namibia across the plains of eastern Africa to the high altitude semi-deserts of central Asia. In addition to the wild equidae, feral horses and donkeys (or burros) exist on all continents except Antarctica. Generally, the present-day equids exploit the semiarid grasslands, where they play a key role in the functioning of natural grazing systems. Within their natural range, many equids are subjected to extreme weather conditions. For example, temperatures range from -45°C in the winter to 40°C in the summer, with diurnal temperature ranges in excess of 35°C at the reintroduction site for Przewalski’s horses in the Dzungarian Gobi in Mongolia. The equidae utilize a great range of altitudes within their present-day distribution, 60 m b.s.l. (Danakil: Somali wild ass) and 5000 m a.s.l. (Tibet: Kiang) (Strauss 1995). For further information concerning the status and geographical distribution of the various subspecies, the reader is referred to the IUCN/SSC Equid specialist group publications (Moehlman 2002). Of particular importance in the captive and medical management of the wild equids is an understanding of their two distinct social systems (Moehlman 2002). In the equids of the arid habitats, some males defend territories—preferably near water sources, which confer mating

rights over females when they enter the territory. Asses and Grevy’s zebra form loose groups, and the only long-term relationship occurs between mother and offspring for a period of 2 years. Asses in central Asia may aggregate to loose groups in excess of several 100 individuals. The other equid species form permanent family groups, so-called harem groups. In this system, lifelong relationships between adult individuals are formed. Young males form bachelor groups. The various social systems must be considered when managing these species in general, but especially the removal of individual animals from a harem group during anesthesia must be critically evaluated.

ANATOMY AND PHYSIOLOGY

The anatomy and physiology of the wild equids is similar to that of their domesticated counterparts (Table 52.2). The mountain zebras (*Equus zebra hartmannae* and *Equus zebra zebra*) are distinguished from other zebra species by a “grid iron” pattern formed by stripes on the rump and a small dewlap on the throat (Duncan 1992). The Grevy’s zebra (*Equus grevyi*) is the largest wild equid. They are easily recognizable on the one hand due to their size, and on the other due to the large ears and distinct fine stripe pattern. The plains zebras (*Equus burchelli* spp.) are one of the most abundant ungulate species in Africa. Subspecies can be distinguished by the variations in their stripe patterns. The classification and number of the subspecies is controversial. The African wild asses are sympatric throughout their range with the domestic African donkeys, and it is probable that the genomes of the wild and domestic asses are extensively mixed. Unlike the Przewalski’s horse and the domestic horse, the wild asses and donkeys have the same number of chromosomes and

appear similar. Differences persist in leg colors, counter shading, and shoulder crosses. The Asian wild asses (*Equus onager*, *Equus kiang*, and *Equus hemionus*) vary little in size, but skeletal and color differences allow the various subspecies to be distinguished. The Przewalski's horse (*Equus ferus przewalskii*) is closely related to the domestic horse; though they are distinct in the number of chromosomes (Przewalski's horse $2n = 66$; domestic horse $2n = 64$) their hybrids are fertile (Ryder et al. 1978). The Przewalski's horse has an erect mane, and the proximal aspect of the tail has short guard hairs. Most Przewalski's horses have a dark stripe along the back and distinct horizontal stripping of the palmar aspects of the front legs. Latest genetic research has shown that the Przewalski's horse is most probably not the direct ancestor of the present domestic horses, but more likely a sister taxa (Wallner et al. 2003).

VASCULAR ACCESS SITES AND MONITORING

Vascular access is easily performed in the various equid species. As a routine measure, an IV catheter should be

placed during all equid anesthesia procedures, as this provides constant venous access if an emergency should arise or additional drugs must be provided. The jugular veins provide an excellent venous access site for standard "over the needle" catheters. Large bore catheters should be used to provide adequate fluid flow rates. At least 14 standard wire gauge (swg) should be used (Taylor & Clarke 2007). These can be placed either with the flow or against the flow. Placing catheters against the flow (towards the head) is often easier and reduces the risk of air entrainment (Taylor & Clarke 2007). Alternative venous access sites are the distal branches of the saphenous vein and the external thoracic vein. Arterial access and catheter placement is most easily achieved in the facial and transverse facial artery. These sites can be used to determine the pulse rate, collect arterial blood samples for blood gas analysis, and direct blood pressure monitoring. The handling and storage of arterial blood samples may affect blood gas values (Klein et al. 2005).

In general, anesthesia monitoring in the wild equid species is analogous to the domestic horse. Anesthesia monitoring should be implemented as soon as the animal is fixed. Sequential rectal temperature measurements, thorax excursion to determine breaths per minute, and auscultation for heart rate are the absolute minimum in anesthesia monitoring. Relative percent oxyhemoglobin saturation measured with a battery-powered pulse oximeter (e.g., Nellcor NP-20, Nellcor Incorporated, Pleasanton, CA) is useful to determine arterial oxygenation and gives a good insight into respiratory function. Pulse oximeter probes can be affixed to the tongue, nasal septum, and the plucked ear (Fig. 52.1). Several excellent reviews have been previously published and the reader is referred to these (Saint John 1992; Taylor & Clarke 2007).

INTUBATION

Endotracheal intubation is easily achieved in the equid species. For intubation, the head is extended. When using the almost straight silicone endotracheal tubes (ET), these can be advanced directly into the trachea. When using the older curved red-rubber type ET, the

Figure 52.1. Portable pulse oximeter probe affixed to the tongue of an Asiatic wild ass.

Figure 52.2. Nonchemical capture of the zoo-born horses. Individual horses are fed in large crates over a period of several weeks. These crates are subsequently closed using a cable controlled remote drop-door system.

ET is initially advanced with the concave curve dorsally until the soft palate is dislodged from the epiglottis and then rotated 90° and passed on down the trachea (Taylor & Clarke 2007).

NONCHEMICAL CAPTURE OF EQUIDS

Though physical restraint cannot be recommended for any wild equid, except possibly newborn foals, nonchemical capture methods have been employed in the zoo-born Przewalski's horse. In the course of the various reintroduction projects to Mongolia, specific techniques and methods have been developed in order to facilitate loading. For the first time in 2002, nonchemical capture and crating was possible for the majority of the zoo-born horses. The system was based on training each individual horse to feed in large crates over a period of several weeks. These crates are subsequently be closed using a remote system and the horses moved into the smaller transport crates (Fig. 52.2) (Walzer

Figure 52.3. Head and neck movement in transport crates is restricted with padding in order to reduce the risk of a horse turning onto its back at take off during air transport.

et al. 2004). In 2005, a similar simplified system was also used successfully in Takhin Tal, Mongolia, to move eight horses into the west of the Gobi B Strictly Protected Area (Schönplflug and Walzer, unpubl. data, 2005).

Individual transport crates for equids are based on the IATA recommendations but have been adapted over the years for this specific airfreight transport scenario but are most probably beneficial for all equid transports (IATA 2006). Head and neck movement in the crate has been limited in order to reduce the risk of a horse turning onto its back while inside the crate at take off during air transport (Fig. 52.3). The headroom of the crates is additionally lined with high density foam mats to limit abrasions and trauma due to head—rubbing. Alternatively and for land transport, equids can be mass crated (Openshaw 1993).

CHEMICAL RESTRAINT AND CAPTURE

Oral Sedation

Varying degrees of sedation can be achieved using acepromazine as granules (Vetranquil 1%, Albrecht, Germany) or as a paste (Sedalin, Chassot, Switzerland) at a dosage of 0.5–1.5 mg/kg PO. The granules are mixed into moistened pelleted feed, and alternatively the paste is placed in apples both of which are then readily consumed by the animal. Though this is not sufficient for subsequent physical restraint, it has proven valuable as a transport and preimmobilization sedation (Wiesner 1993).

Parenteral Sedation

Various drugs, especially alpha2-agonists and acepromazine (Vetranquil 1%, Albrecht, Germany), have been used to sedate wild equids. Detomidine (Domosedan, SmithKline Beecham Animal Health) at 20–80 µg/kg IM has been used successfully in some wild equids (Morris

1992; Vitaud 1993). In contrast to the experiences gained with detomidine, these authors warn against using the alpha2 agonist medetomidine (Dormitor, SmithKline Beecham Animal Health) alone as a pre-anesthetic due to the occurrence of significant ataxia (Morris 1992). Similarly romifidine (Sedivet, Boehringer, Germany) has been shown to cause ataxia (Wiesner & von Hegel 1990). Acepromazine is used at a dosage of 0.15–0.25 mg/kg IM. Furthermore, Azaperone at a dosage of 200 mg has been suggested for the sedation of zebras (Burroughs 1993b). Several other drugs would potentially be useful in sedating equids but are impracticable in their use due to the large volumes necessary.

Long-Acting Neuroleptics

When long-term sedation is required, as during a transport process, this is best achieved using one of the long-acting neuroleptics (LAN). This group of drugs can be used to reduce anxiety and stress during long-distance translocation, and for reintroduction into novel enclosures and habitats. As a result of the delayed absorption of the neuroleptics, it is prudent to combine a long-acting tranquillizer with a short-acting analog (Ebedes 1992). Haloperidol belongs to the butyrophenone group of neuroleptics with a longer duration of activity. It is available in Europe as a 5-mg/mL injectable solution (Haldol, Janssen-Cilag, Vienna, Austria) that can be applied intramuscularly (IM) and IV. Furthermore, 1- and 10-mg tablet forms (Haldol, Janssen-Cilag) for oral application are also available. It is important to note that in Europe, haloperidol is also available as a decanoate ester (Haloperidol decanoate, Janssen-Cilag), an oily form that results in a long-term deposit. Haloperidol decanoate results in a prolonged sedation of up to 25 days and its effects are generally unsatisfactory due to adverse side effects, such as inappetence and central nervous system symptoms (Swan 1993). Zuclopenthixol acetate is a thioxanthene similar to the phenothiazine group of tranquillizers. Through esterification with the acetate and dissolution in a vegetable oil, absorption and duration has been extended. It is available as 50 mg/mL injectable solution (Ciatyl-Z-Accuphase, Bayer, Leverkusen, Germany). Similar to haloperidol, zuclopenthixol is also available in some countries as a decanoate ester; again, the duration is extended, but once again the effect seems inadequate

(Swan 1993). Perphenazine is a phenothiazine derivate with a piperazine side chain. It is available as a 100 mg/mL injectable solution in the enanthate ester form, dissolved in a sesame oil (Decentan Depot, Merck KgaA, Darmstadt, Germany). When compared with haloperidol and zuclopenthixol, perphenazine has a markedly prolonged duration of action that can subsist for 10 days. These neuroleptics have been used successfully in various zebra species (Swan 1993) and in the Przewalski's horse (Atkinson & Blumer 1997; Walzer et al. 2000). Extrapyramidal symptoms (EPS), a neurological side effect, causes a variety of symptoms, for example, involuntary movements, tremors, changes in breathing and heart rate, and inapetenz have been recorded as the most important side effects of LAN. The EPS can be treated with biperidine (Akineton, Knoll, South Africa) and diazepam (Valium, Roche, Switzerland). The use of long-acting neuroleptics has greatly facilitated the in-crate phase during flight (36 hours) and reloading of Przewalski's horses. This author presently recommends treatment with a combination of 0.2–0.3 mg/kg haloperidol (Haldol, Janssen-Cilag) and 150–200 mg/adult equid perphenazine (Decentan-Depot, Merck KgaA, Darmstadt, Germany). It is important to carry out this treatment at least 12–24 hours prior to transport or anticipated stressor influence (Table 52.3).

Anesthesia

Applying drugs over a greater distance requires specific remote delivery systems. For an excellent review of the various available systems, the reader is referred to Kreeger et al. (2002) and the previous chapter by Isaza in this book. The author recommends the use of a CO₂ propelled dart gun, such as the Daninject JM model (Daninject JM™, Wildlife Pharmaceuticals, Fort Collins, CO). Previous authors have warned against using high velocity gun systems (e.g., Cap-Chur® system) in zebras due to their thin skin (Burroughs 1993a). When working in the wild, this author prefers to use new 3-mL darts discharged by expanding compressed air (Daninject, Wildlife Pharmaceuticals). Old darts are not used, as these are never as accurate. By shortening the dart stabilizers to 3 cm, the effective range is 80 m under ideal conditions (Lengger et al. 2002). However, this distance is significantly reduced in the windy conditions. A sufficiently long dart needle of 55 mm is required to efficiently dart an Asian wild equid in good

Table 52.3. Suggested dosages for long-acting neuroleptics in selected wild equids

Drug	Burchell's Zebra	Hartmann's Zebra	Przewalski's Horse	Onset of Sedation	Duration
Haloperidol	0.3 mg/kg	0.28–0.35 mg/kg	0.2–0.3 mg/kg	5–10 minutes	8–18 hours
Zuclopenthixol	50–100 mg/adult	50–100 mg/adult	50–100 mg/adult	1 hour	3–4 days
Perphenazine	100–200 mg/adult	200 mg/adult	150–200 mg/adult	12–16 hours	10 days

Figure 52.4. The head of a horse should be fixated at all times during an immobilization procedure. The knee is best placed laterally on the maxilla.

condition during the late summer and fall, due to significant layers of fat in the rump region. For zebras, a needle length of 25–30 mm has previously been recommended (Burroughs 1993a). In captive zebras, this is most probably too short, and the use of 55 mm should be considered. The use of wire barbs or collars on the needle to securely retain the dart in the animal is recommended in order to enable complete drug expulsion. Once an animal is successfully darted, one should attempt to keep it in sight. However, it is very important at this stage to not disturb the animal any further by chasing it or approaching before the drugs have taken full effect. Once the animal has become recumbent, an approach on foot from behind and immediate fixation of the head is recommended (Fig. 52.4). Be aware that in the first few minutes of recumbency, the animal may become aroused by voices or loud noises and attempt to rise and flee further. Anesthesia monitoring should be implemented as soon as the animal is fixed.

The agent of choice for wild equid immobilization and anesthesia is the potent opiate ethorphine. The opiates interact in the central nervous system (CNS) with stereo-specific and saturable receptors (Kreeger et al. 2002). Various receptors have been identified. These are classified as κ , δ , σ , and μ receptors. A major advantage in the use of the opiates is the specific opiate antagonists that allow for the complete reversal of the anesthetic effects. Whereas some agents can be classed as sole antagonists (e.g., naltrexone), others have agonist–antagonist properties (e.g., diprenorphine). The opiate ethorphine is an analog of thebaine and is in humans 500 times more potent than morphine (Jasinski et al. 1975; Kreeger et al. 2002). Ethorphine at 2.45 mg/mL is available in Europe and many other parts of the world in combination with acepromazine 10 mg/mL (Large Animal Immobilon, C-Vet Veterinary Products, Leyland, UK). Furthermore, ethorphine is

available as a mono substance at 4.9 mg/mL and 9.8 mg/mL (M99, Vericore Ltd., Dundee, Scotland). All products are supplied in a container together with the antidote diprenorphine or M5050 in the respective adequate dosages. The use of diprenorphine to antagonize ethorphine in nondomestic equids may increase the likelihood of renarcotizations. In North America, due to difficulty in obtaining ethorphine, a similar, more potent opiate, carfentanil (Wildlife Pharmaceuticals) has been used extensively in equids (Allen 1992, 1994, 1997; Klein & Citino 1995). However, the effects of carfentanil cannot be equated with those of ethorphine as the procedure is markedly rougher with significant muscle contractions (Morris 1992). In the past years, several additional nonnarcotic immobilization protocols have been developed and used more or less successfully in wild equids (Matthews et al. 1995; Morris 1992; Vitaud 1993). For prolonged surgical procedures, intubation and inhalation anesthesia with isoflurane or halothane is recommended.

For wild equid anesthesia, this author presently recommends a combination of the opiate ethorphine (M99, C-Vet Veterinary Products, Lancashire, UK), the sedative α_2 agonist detomidine-HCl (Domosedan, Orion Corp. Farnos, Turku, Finland), and the mixed antagonist-agonist opioid butorphanol (Torbugesic, Fort Dodge Animal Health, Fort Dodge, IA). Detomidine acts on the α_2 -adrenergic receptors, where it inhibits the release of norepinephrine. Butorphanol is a μ -opioid receptor antagonist that alleviates the marked respiratory depression induced by the ethorphine at the μ receptor and potentiates the sedative effect at the kappa and sigma receptors. Furthermore, this combination has significantly limited the ethorphine specific pacing, which greatly reduces the distance an equid travels after darting. This is particularly important in open steppe habitats, where equids darted without the addition of butorphanol can cover several kilometers before becoming recumbent. However, the combination still allows for “walk-in” crate loading. Ethorphine is reversed with the opioid antagonist naltrexone at a rate of 20:1 (Trexonil, Wildlife Laboratories Inc., Fort Collins, CO). Naltrexone has a longer half-life than the antagonist-agonist diprenorphine (Revivon, C-Vet Veterinary Products) and eliminates in- and posttransport renarcotization. Renarcotization is an effect that occurs when using opioids. Several hours after antagonist application, the animals once again come under the influence of the opioid agonist (Kreeger et al. 2002). Especially in equids captured in the wild, this effect could be fatal as it potentially makes an individual more prone to predation and injury. However, it is important to note that due to the long half-life, a subsequent anesthesia induction with ethorphine (or any other opioid), in case of emergency, would not be possible, and an alternative method (e.g., the α_2 -agonist medetomidine and ketamine) needs to be considered (Table 52.4).

Table 52.4. Selected anesthetic protocols for wild equids

Species	Drug 1	Drug 2	Additional Drugs	Antagonist	Comments	Literature

Chemical Capture of Equids in the Wild

Przewalski's Horses Due to the general lack of cover in the Gobi area wild Przewalski's horses are extremely difficult to approach in the field. During the past years, we have employed various methods to get within shooting range, such as approaching on a motorcycle and horseback or waiting at water points. Using a combination of 2.5- to 3.0-mg ethorphine, 10-mg detomidine, and 10-mg butorphanol, 14 horses have been successfully captured in the wild (and 35 procedures in the very large adaptation enclosures—20–30 ha) in Mongolia (Walzer et al. 2006). Initial effects were noticed after 3–5 minutes when the animal exhibited a stiff, high stepping gait and became ataxic. Induction to lateral recumbency occurred within 5–10 minutes. Procedures lasted on average 35 minutes. Following IV antagonist application anesthesia was smoothly reversed without any signs of excitement, and the animals were back on their feet within 2 minutes. It is important to note that the head of all equids should be fixed to the ground as long as possible following antagonist application to prevent premature uncoordinated attempts at getting up, as these could result in injury (Walzer et al. 2006) (Fig. 52.5).

Asiatic Wild Ass In Mongolia, the wild ass is extremely skittish—most probably due to poaching activities—and in some areas, flees human presence at several kilometers' distance (e.g., in Great Gobi B SPA). We have employed three distinct techniques to capture this species in the wild. In the summers of 2002 and 2005, we used a modified high pressure CO₂ dart gun (Daninject JM, Wildlife Pharmaceuticals) from a pre-placed hide, 60–80 m distant from water points. This method was especially useful in the south Gobi as the

Figure 52.5. The head of all equids should be fixed to the ground as long as possible following antagonist application to prevent premature uncoordinated attempts at getting up, as these could result in injury.

khulan are readily approached in the area. Some water points additionally offer good cover that allows for a shooting distance of 40–55 m. If possible, it is a distinct advantage to take a position high above the animal (e.g., cliff face), as they are unwary of danger from above. As open water is lacking in large parts of the distribution range in the south Gobi, the wild ass must dig to a depth of approximately 45 cm to access ground water. At this time, it is very difficult for animal to see movements in its vicinity. Furthermore, the use of ground water increases the amount of time the animals have to remain stationary, which additionally greatly facilitates darting.

In 2003 and 2005, we also employed a chase method where the khulan was darted from a moving jeep. This method had previously been used to collar a wild Bactrian camel (*Camelus bactrianus ferus*) and is traditionally employed by wild ass poachers with 12-gauge shotguns (Blumer et al. 2002). When using the local UAZ jeeps it is important to remove the window from the passenger side and to provide seatbelts for the driver and shooter. If using the Daninject JM CO₂ dart gun, a short 4-cm barrel can be used instead of the standard barrel as this greatly facilitates movement in the jeep. Once an animal is identified, it is chased until the jeep is able to approach within approximately 10–15 m on a parallel track (see Fig. 52.6). It is then easily darted in the rump musculature using standard pressure settings. It is essential to define a chase cut off time before the procedure is started. Our experience has shown that a cut off time of 15 minutes is adequate for the Asiatic wild ass. To date, we have captured six animals with this very time-efficient method. The shortest chase time was 2 minutes and the longest 13 minutes. In all cases, induction was extremely rapid

Figure 52.6. An Asiatic wild ass being darted in the rump musculature from a moving jeep (60 km/h) at a distance of approximately 10–15 m on a parallel track.

and smooth (4–8 minutes), and body temperature was below 40°C. A severe limitation to this method is that one is only able to capture males or juveniles without foals. A chase of a female with a foal would result in (permanent) separation of the young from the mare and is therefore unacceptable.

Finally, we have used a video-enabled remote controlled CO₂ gun (Walzer & Boegel 2003) at several water points in attempts to capture khulan in 2003 and 2005. To date, this method has not been successful for wild ass mainly due to the abundance of water in the areas it was employed. In the authors' view, this method has great potential in areas with small waterholes that the animals have to visit.

In all wild ass procedures, anesthesia was induced with a single 3-mL dart containing a combination of 4.4-mg etorphine (M99, C-Vet Veterinary Products, Lancashire, UK), 10-mg Detomidine-HCl (Domosedan, Orion Corp. Farmos) and 10-mg Butorphanol (Torbugesic, Fort Dodge Animal Health). Anesthesia was initially reversed with an IV combination of 200-mg naltrexone (Trexonil Wildlife Laboratories Inc.) and the alpha₂-antagonist 20mg Atipamezole (Antisedan, Orion Corp. Farmos). Reversal was rapid and generally smooth, but some signs of excitation related to radio collar placement—head shaking—were noted. Subsequently, the opioid antagonist-agonist diprenorphine (Revivon, C-Vet Veterinary Products) was used. This eliminated head shaking and provided a smoother reversal. All animals were standing and alert approximately 2 minutes following administration of the antagonists.

Zebras The chemical capture of zebras has been described previously (Burroughs 1993a). Similar to the Asiatic wild equids, zebras are very difficult to approach in the wild. The techniques employed are similar to the ones described earlier. When available, darting from a helicopter is recommended (Burroughs 1993a).

Surgical Field Anesthesia For some procedures, it can be necessary to extend and deepen the anesthesia as the chemical capture drug combinations at the doses provided, do not offer the necessary depth of anesthesia for surgical procedures as significant muscle contractions and uncontrollable movements can occur. Following recumbency, an IV catheter is placed, and an IV infusion of guaifenesin-ketamine-xylazine (1 L of 5% guaifenesin) (Myolaxin, Vétquinol UK Ltd., Buckingham, UK), 1000 mg ketamine (Ketamidol, Richter Pharma, Wels, Austria), and 500 mg xylazine (Rompun, Bayer Austria Ges.m.b.H, Vienna, Austria) is started. Nasal oxygen at a flow rate of 10 L/min is provided. An adult Przewalski's horse received on average 733 mL of the triple drip at an average rate of 12.6 mL/min. Despite oxygen supplementation, most equids will

become hypoxic and slightly hypercapnic throughout the procedure.

Approximately 10 minutes before the surgical procedure is finished, the IV infusion should be stopped. Subsequently, the opiate anesthesia components from the capture event are reversed with 150 mg IV naltrexone. This multidrug procedure is well adapted for surgical anesthesia in Przewalski's horses and most likely for other wild equids in a field setting. However, it is strongly recommended that adequate anesthesia monitoring is available for the early recognition of critical respiratory and metabolic problems (Walzer et al. 2009) (Fig. 52.1 and Fig. 52.7).

Figure 52.8 shows a horse post antagonism getting up.

Figure 52.7. Field anesthesia and surgery setting in the Hortobágy National Park, Hungary. Following induction with etorphine-detomidine-butorphanol, surgical-depth anesthesia is maintained with a so-called triple-drip IV consisting of guaifenesin-ketamine-xylazine.

Figure 52.8. A radio-collared Przewalski's horse rising following the reversal of the opiate anesthesia components with 150-mg naltrexone.

Chemical Capture of Captive Nondomestic Equids

Carfentanil has been extensively studied as an immobilizing agent for nondomestic equids (Allen 1990, 1992, 1994, 1997; Klein & Citino 1995). Ethorphine was not available to zoo and wildlife veterinarians working in the United States for several years, so carfentanil was used as a primary immobilizing agent for nondomestic equids (Allen 1992, 1994, 1997). There are several disadvantages of using carfentanil versus ethorphine as an immobilizing agent for nondomestic equids. Oftentimes, nondomestic equids immobilized with carfentanil have to be assisted into recumbency or be given supplemental anesthetic induction agents to achieve complete immobilization (Allen 1992, 1994; Klein & Citino 1995). Supplemental anesthetic agents are given IV after the animal partially immobilized by carfentanil. Ketamine, glyceryl guaiacolate, or propofol is often used to get adequate muscle relaxation and complete immobilization (Zuba & Burns 1998). The delivery of carfentanil by dart into the muscles of the neck or shoulder will result in faster induction times and less morbidity (Allen 1992, 1994, 1997). Significant respiratory depression is commonly seen with carfentanil immobilizations (Allen 1992, 1994). This can often be successfully treated with IV administration of doxapram and the delivery of intranasal oxygen (Allen 1992, 1994, 1997). Most nondomestic equids immobilized with carfentanil alone experience a significant tachycardia, which may be due the stress of the procedure and inadequate immobilization (Allen 1992, 1994). Additionally, renarcotization may occur in nondomestic equids immobilized with carfentanil.

Renarcotization seems to be more common in the Somali wild ass (*Equus onager*) when immobilized with carfentanil alone (Allen 1997). Carfentanil, when used alone, was not adequate for the immobilization of Grevy's zebra (*Equus grevyi*) unless unacceptably high doses were used (Allen 1997).

Grevy's zebra (*Equus grevyi*) can be immobilized with carfentanil in combination with other drugs in a staged immobilization protocol (Klein & Citino 1995). First, detomidine (0.1–0.15 mg/kg) is given IM. Then approximately 20 minutes later, carfentanil (0.098 mg/kg) in combination with ketamine (2 mg/kg) is given IM. In one study, this combination was compared to medetomidine and ketamine in combination. Both study groups experienced significant hypertension with these combinations (Klein & Citino 1995). The preferred method for immobilizing captive Grevy's zebra is using ethorphine in combination with detomidine or detomidine and acepromazine (see Table 52.4).

Although carfentanil can be used to immobilize captive nondomestic equids, ethorphine is the preferred primary immobilizing agent. Diprenorphine, in most cases, will adequately antagonize the effects of ethorphine. But in one comprehensive review of renar-

cotization in nondomestic equids, renarcotization was relatively common in zebra and onager when using diprenorphine to antagonize ethorphine (Allen 1990). The use of naltrexone to antagonize ethorphine typically does not result in any episodes of renarcotization in nondomestic equids.

53 Tapirs

Sonia M. Hernandez, James Bailey, and Luis R. Padilla

INTRODUCTION, TAXONOMY, AND NATURAL HISTORY

Tapirs belong to the family Tapiridae, within the order Perissodactyla, which are distinguished from the Artiodactyla by their foot morphology and digestive system. Their closest relatives are rhinoceroses and horses. The small family of Tapiridae has only four species within the single genus *Tapirus*. There are three New World species (*Tapirus terrestris*, *Tapirus bardi*, and *Tapirus pinchaque*) and a single Old World species (*Tapirus indicus*). Tapirs are typically solitary (except mother and offspring pairs), largely nocturnal, tropical forest herbivores. In the wild, tapirs spend most days sleeping in dense areas and forage at night. They often inhabit aquatic habitats, spending large amounts of time in or near water (Klingel & Thenius 1990; Nowak 1991). Further, they are found to frequently urinate and defecate in water. These are all proposed as passive, stealth defense mechanism for survival. Despite their size, they can travel very quietly in the forest, are extremely agile, can run fast, and if threatened or protecting offspring, will charge (S. Hernandez-Diver, pers. obs., 2000).

All species, except the mountain tapir (*T. pinchaque*) are commonly exhibited in zoological institutions. To date, both captive and free-ranging individuals of all four species have been physically and chemically immobilized; however, the protocol used, and its success, varies with capture situation. Therefore, no one anesthetic protocol is recommended for all situations.

CLINICAL ANATOMY AND PHYSIOLOGY

A variety of sources have reviewed the anatomic peculiarities of tapirs (Janssen 2003); therefore, details pro-

vided here are limited to those relevant to physical or chemical restraint. Table 53.1 summarizes the body weight and sizes for each species of Tapiridae. As with any animal of that size and weight, rough induction or recoveries can lead to severe, often untreatable, traumatic injuries and safety concern for personnel. Unlike horses, tapirs rarely kick, but can inflict severe injury by biting, stomping, bucking, and charging. The dental formula for tapirs is $2 \times (I-3/3, C-1/1, P-4/3, M-3/3)$. The upper third incisor is large, and separated from the canine by a narrow diastema which allows the manipulation of the tongue in the anesthetized animal. The glottis of the tapir is similar to the horse. Therefore, blind or laryngoscope-assisted intubation is possible (Fig. 53.1). Pulmonary atelectasis, ventilation-perfusion mismatch, or neuropathies associated with prolonged recumbency can complicate anesthetic procedures. The anesthetists are encouraged to review principles of large animal anesthesia when planning an immobilization procedure to minimize these risks as much as possible (Muir & Hubbell 1991; Steffey et al. 1990a,b). Supplemental oxygen, assisted ventilation, and appropriate padding should be considered even in field captures. Tapirs, like horses, are unable to vomit; however, regurgitation is still possible. Tapirs are hindgut fermenters, with small stomachs and large cecae and colons. Much like horses, tapirs can be at risk for gastrointestinal disease following chemical immobilization. Tapirs have a highly mobile proboscis which acts as a tactile and prehensile organ. The proboscis is a fleshy organ lacking any internal osseocartilaginous support, constructed of connective tissue and muscle (Witmer et al. 1999). This organ is highly sensitive and care should be taken not to restrict its movement during immobilization or cause it injury during anesthesia.

Table 53.1. Typical body weight and size for members of Tapiridae

Species	Body Weight (kg)	Body Length (cm)	Height at Shoulder (cm)
<i>Tapirus bairdii</i> (Baird's tapir)	150–300	198–202	Up to 120
<i>Tapirus terrestris</i> (lowland tapir)	250–300	180–250	77–108
<i>Tapirus pinchaque</i> (mountain tapir)	225–250	180	75–80
<i>Tapirus indicus</i> (Malayan tapir)	200–375	185–240	90–105

Physical Capture and Immobilization

Despite their large size, tapirs have had a reputation of being docile in captive environments and extremely elusive as free-ranging animals. In free-ranging situations, tapirs are adept at hiding, are extremely quiet when moving even in dense habitats, and generally stay out of sight. Reports of tapir captures for ecological studies include attracting the animal to bait stations, pitfall traps, box traps, capture pens, and using dogs for locating and chasing an individual animal (Foerster et al. 2000; Hernandez-Divers & Foerster 2001; Mangini & Velastin 2001; Mangini et al. 2001; Medici et al. 2001). All capture techniques reported were followed by chemical immobilization.

As opposed to similarly sized mammals maintained in captivity, many tapirs have traditionally been managed through “direct contact.” Reports of severe biting, crushing, mutilating and possibly lethal injuries inflicted on caretakers should caution tapir handlers of the safety implications when attempting physical immobilization and the individual temperament of the animal should be taken into account. When provoked, even free-ranging tapirs can inflict fatal injuries, and at least one report exists of a tapir that killed a farmer that stabbed the animal because it was eating his crops (Haddad et al. 2005). Current standards of the Association of Zoos and Aquariums (AZA) allow for tapirs to be worked in an unprotected or protected contact setting, where caretakers enter or do not enter the same space as an animal, respectively, but the individual's temperament and institutional policies must be taken into account (AZA Tapir TAG 2013). Physical immobilization is possible with training and conditioning by using a large animal chute (Janssen 2003).

Tapirs are amenable to training using positive reinforcement techniques. Additionally, they can be “scratched down,” a technique that involves using a horse brush or outdoor broom to stroke the animal's dorsum, neck, lateral, and abdominal walls (Janssen 2003). This appears to induce a pleasurable state in which the animal first sits, and then lays down in lateral recumbency. Although tapirs apparently enjoy this interaction, the level of immobilization induced

Figure 53.1. How to intubate a tapir. In a fashion similar to a horse, intubation is performed in the tapir—with ease—blindly. Optimally, the tapir's mouth is flushed with water to remove debris prior to anesthesia. In the field, the only opportunity to remove debris may be after anesthetic induction by a brief finger sweep of the buccal surfaces and examination of the oropharynx. After induction of anesthesia, the tapir is moved to lateral recumbency. The optional mouth speculum (PVC pipe segment) may be placed between the upper and lower incisors and the head extended to create a linear oral-laryngeal-pharyngeal axis. The endotracheal tube is then passed through the mouth speculum, over the base of the tongue into the pharynx. The tube may pass immediately into the larynx and trachea. More frequently, it is necessary to hold the head in extension, retract the endotracheal tube 10–15 cm, rotate the tube on its axis 45–90° and advance to the larynx once more. Multiple gentle rapid advancements and retractions, lightly tapping on the laryngeal opening will usually lead to intubation. Changing the degree of extension of the head while advancing the endotracheal tube may be of assistance. In the event blind intubation fails, a long bladed laryngoscope may be used for direct laryngoscopic examination to intubation. Anticipate endotracheal tubes from 16- to 20-mm inside diameter (cuffed) will be appropriate for adult tapirs (illustration courtesy of MGS Studio).

should not be overemphasized. This technique, alone or combined with desensitization training and operant conditioning techniques, have been used for physical examination and even repeated blood collection (e.g., Kusuda et al. 2007), and can be utilized to administer injections. Positive reinforcement has also been used to move animals from one area to another, to enter crates,

Table 53.2. Criteria that should be considered when designing an anesthetic protocol for tapirs

Criteria	Free-ranging	Captive
Anesthetic onset	Rapid induction (avoid predation, trauma, and drowning)	Not as crucial, as animal is typically confined
Reversible anesthetic	Fully reversible	Not as crucial, as animal is typically confined
Anesthetic safety	Wide margin of safety (precapture body weight may not be available)	Wide margin of safety (disease is a more common indication for anesthesia in captivity)
Cost	Relatively inexpensive	Expense concerns vary
Volume	Volume should be minimized for remote delivery	Volume not as crucial, as dart distance is typically short

to present body parts for examination and to stand still for biological sample collection and intravenous catheterization.

Chemical Immobilization

The refinement in techniques using alpha-2 adrenergic agonists alone or in combination with other drugs has made them the basis of most modern, balanced anesthetic protocols used in tapirs. These drugs have largely replaced the need for ultrapotent opioids, such as etorphine or carfentanil, which had been historically associated with poor ventilation, poor oxygen saturation (Janssen 2003), hypoxemia, and personnel safety risk. The anesthetic protocol preferred may depend on whether the animal is captive or free-ranging, the facilities available, and the experience of the available personnel. Table 53.2 summarizes the major concerns in captive or free ranging scenarios.

PREANESTHETIC CONSIDERATIONS

As with any animal, individual tapirs that are calm are better candidates for anesthesia. The physiologic effects of excitement and endogenous release of catecholamines may delay or prevent anesthetic induction or muscle relaxation. In fact, the success of some anesthetic protocols utilized for free-ranging tapirs depend on the animal's degree of relaxation (Foerster et al. 2000; Hernandez-Divers & Foerster 2001). In all cases, it is important to create a quiet environment while working with these animals. If the animals cannot remain stress-free (i.e., transport, trauma, or disease), preanesthetic medication is highly recommended. Tapirs are often maintained in enclosures with bodies of water, and when threatened, they often retreat into the water. This must be taken into consideration when planning an anesthetic procedure. In free-ranging situ-

ations, capture protocols are designed to specifically avoid drowning by either anesthetizing animals that are contained, or are at least 200 m away from a body of water (Foerster et al. 2000; Hernandez-Divers & Foerster 2001). To maximize safety, capture techniques should be designed to minimize the probability an animal will walk or run after anesthesia has been administered. Although vomiting is generally not a consideration, fasting for 24 hours prior to anesthetic procedures is recommended. This will decrease the amount of food within the oral cavity and esophagus; minimize the probability of regurgitation, and minimize the pressure on the diaphragm related to the gastrointestinal tract distention secondary to fermentation of food material during the anesthetic period (Andersen et al. 2006). Tapirs are tropical animals; therefore, in regions with cold climate, they should be maintained in an indoor area that can be heated prior to the anesthetic period. In warmer climates, hyperthermia is a concern, and procedures should be planned for early morning or times when ambient temperatures are more favorable. In addition, methods to prevent and decrease excessive body temperatures should be available. Regardless of temperature concerns, tapirs should not be anesthetized in full sun, as their skin is sensitive to sunburn. If previous training allows, the length of the anesthetic period may be minimized by collecting samples or placing intravenous catheters ahead of time, although this must be judiciously balanced with any stress that these procedures can cause. Whenever possible, it is important to obtain a resting heart, respiratory rate, and body temperature on each individual to use as baseline for comparison during anesthetic monitoring.

PREANESTHETIC MEDICATION AND INDUCTION

Although the administration of preanesthetic medication is not always feasible in tapirs, in horses, it is considered a standard practice of care (Martinez et al. 2006; Muir & Hubbell 1991). Preanesthetic agents provide tranquilization, reduce the amount of induction and maintenance anesthetic agents required, balance the anesthetic technique to limit negative side effects, and may improve the quality of recovery. The common equine preanesthetic agents, xylazine and butorphanol, have been applied successfully in tapirs (Foerster et al. 2000; Hernandez-Divers & Foerster 2001). An estimated dosage of 0.15–0.25 mg/kg butorphanol combined with 0.3–0.5 mg/kg xylazine delivered IM produced immobilization of tapirs. Similarly, the use of a 0.06 mg/kg detomidine, an alpha-2 agonist related to xylazine, has been used in captive Baird's tapirs in combination with 0.15–0.2 mg/kg butorphanol to induce immobilization and recumbency (Pukazhenthil et al. 2011) These dosages would likely provide

Figure 53.2. One method of immobilizing free-ranging tapirs. Bananas are placed in the center of a bait station. Additional bananas are thrown from a chosen location—such as this tree platform—into the forest and hung from nearby trees to disperse the odor of bananas for several days. Once evidence of tapir visitation is noted (tracks), captors sit at the proven bait station, starting at dusk (Foerster REF). Tapir movements are often not detected until the animal is with 20 m of the captors. Once an animal's footsteps were heard, a low power flashlight or a night-vision telescope is utilized to scan the area and confirm that the animal is a tapir. Immobilization drugs are then prepared while additional bananas are dropped every 10–20 seconds to bring the animal closer to the captors. This feeding technique distracts the tapir while the dart is being loaded and entices the tapir to move to an area for an advantageous dart shot. The tapir's reaction to thrown bananas is also used to evaluate its demeanor and level of nervousness. When the dart is loaded and the tapir is in an acceptable location for darting, a final decision is made regarding behavior and likely reaction to dart impact. A low power flashlight may be used to transiently illuminate the tapir (if night vision is unavailable) and the tapir is darted (illustration courtesy of MGS Studio).

sedation in the domestic horse, but are not likely to cause recumbency. For comparison, routine mild to moderate sedation of a horse would require xylazine 0.3–0.5 mg/kg and butorphanol 0.01–0.02 mg/kg IV. Intramuscular dosages of up to 2 mg/kg xylazine, with and without butorphanol, have been used for moderate to profound sedation of horses (Muir & Hubbell 1991). The apparent greater sensitivity of the tapir to these common equine preanesthetic agents suggests a lower dosage could be used if only mild sedation is desired. In fact, sedation (although unclear to what degree) was achieved in an ill Malayan tapir with 5-mg detomidine hydrochloride and 10-mg butorphanol administered by hand injection (Peters et al. 2012), although the animal was likely debilitated. Standing sedation, using xylazine or other alpha-2 agonist combinations, should be considered for short procedures that require little

manipulation (i.e., skin biopsy, blood collection, and portable radiography). Standing sedation using azaperone (1 mg/kg IM) has also been reported (Janssen et al. 1996).

Induction of anesthesia is typically achieved by intramuscular injections delivered by remote injection systems (free-ranging and captive), (Fig. 53.2) or by intravenous injections (captive). Despite their thick skin, a variety of peripheral vessels can be used in tapirs for administration of intravenous agents. Based on the author's experience and previous reports, the marginal auricular vein, carpal, cephalic, and saphenous veins can be used for either blood collection or short-term catheterization (Janssen 2003) (Fig. 53.3). A sedated or conditioned tapir may tolerate intravenous injection of propofol or ketamine into the saphenous, cephalic, or medial carpal vein to induce recumbency. The use of a

Figure 53.3. Intravenous access site in a Baird's tapir. The medial aspect of the forelimb of a tapir provides easy vascular access for short-term catheterization or administration of intravenous agents. In this image, a butterfly catheter has been placed in anesthetized tapir to provide propofol to maintain a desired plane of anesthesia (photo courtesy of Dr. Budhan S. Pukazhenth, Smithsonian Conservation Biology Institute, Front Royal, VA).

Figure 53.4. Intravenous anesthetic induction of anesthesia in a sedated Baird's tapir. An intravenous butterfly catheter has been placed in the medial aspect of the forelimb in a sedated tapir and propofol is being administered slowly to effect to induce recumbency and anesthesia (photo courtesy of Dr. Budhan S. Pukazhenth, Smithsonian Conservation Biology Institute, Front Royal, VA).

butterfly catheter is a safe and practical way to reach the medial aspect of a forelimb for vascular access. (Fig. 53.4).

When anesthesia is induced in tapirs, they behave similarly to the horse, with some minor differences.

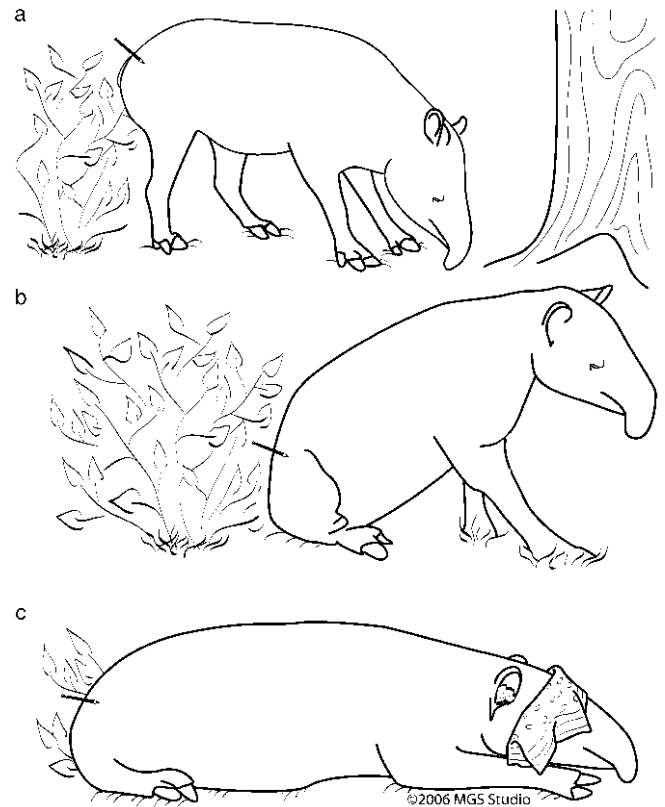

Figure 53.5. Typical induction behavior of a tapir. (a) The tapir getting drowsy; head-down with a basewide (sawhorse) stance, leaning back slightly and proboscis extended; (b) down to a sitting position with forelimbs extended; and (c) down in sternal recumbency (on its stomach), now with a blindfold applied over its eyes and gauze sponges placed in its ears (to reduce ambient sound stimulus) (illustration courtesy of MGS Studio).

Initially, they stand still, often in a saw-horse position, with limbs further apart than normal and drop their head. Tapirs may drool and lose control of their proboscis. From this position, they often sit, in a dog-like position, and then move to sternal recumbency (Fig. 53.5). In some cases, they remain standing and may need some light pressure on the hindquarters to encourage sitting. Rarely, a tapir may elevate the head from the sitting position and fall onto lateral recumbency. Table 53.3 reviews reported protocols for immobilization of free-ranging tapirs.

A wide range of drug combinations have been reported for use in captive tapirs. Table 53.4 summarizes the protocols used in captivity.

Despite their thick skin, a variety of peripheral vessels can be used in tapirs for administration of intravenous agents. Based on the author's experience and previous reports, the marginal auricular vein, carpal and medial saphenous veins can be used for both blood collection and short-term catheterization (Janssen 2003). Intravenous induction is rarely utilized, but can be accomplished in trained or sedated individuals using

Table 53.3. Summary of protocols utilized to immobilize free-ranging tapirs

Geographic Location	Species	Capture Method	Anesthetics	Comments
Costa Rica	<i>Tapirus bairdii</i>	Attracted animals to bait stations	Etorphine 1.88- and 7.7-mg acepromazine IM per animal; reversal: Diprenorphine hydrochloride at 3 × the etorphine used	Administered to animals from a tree blind via a dart. The animals had been habituated to come to bait (ripe bananas) for several days and thus were relatively calm when darted (Parás et al. 1996)
Costa Rica	<i>Tapirus bairdii</i>	Attracted animals to bait stations	Total dosage for a 200- to 300-kg animal: 40–50 mg of butorphanol and 100 mg of xylazine in the same dart. Additional ketamine (187 ± 40.86 mg/animal) or constant rate infusion of propofol (50–200 µg/kg/min), administered IV. Reversal: Naltrexone 50 mg IM with 1200 mg of tolazoline in the same syringe IM; no sooner than 30 minutes from last administration of ketamine.	The animals had been habituated to come to bait (ripe bananas) for several days and thus were relatively calm when darted. Animals weight estimated between 200 and 300 kg. Average time to sternal recumbency: 11 minutes. Average return to standing after reversal: 12 minutes (Foerster et al. 2000; Hernandez-Divers et al. 2005).
Venezuela	<i>Tapirus terrestris</i>	Immobilized animals were captive, semi-captive, or wild tapirs	Ketamine (3.5–4 mg/kg) and xylazine (2–2.2 mg/kg) IM supplemented with ketamine (1.4 mg/kg) IM; reversal: tolazoline 4 mg/kg	Administered using darts projected by a blowpipe, or IV using syringe (Blanco Márquez & Blanco Márquez 2004).
Venezuela	<i>Tapirus terrestris</i>	Immobilized animals were captive, semi-captive, or wild tapirs	Telazol (2.5–2.8 mg/kg) supplemented with ketamine (1.2–1.5 mg/kg) IM; reversal: tolazoline 4 mg/kg	Administered using darts projected by a blowpipe, or IV using syringe (Blanco Márquez & Blanco Márquez 2004).
Mexico	<i>Tapirus bairdii</i>		Total dosage for a 200- to 250-kg animal: 1.96-mg etorphine hydrochloride and 5.90 mg of acepromazine maleate, in the same dart; Reversal: Diprenorphine hydrochloride 5.88 mg	This protocol was designed for specific environmental conditions (slopes of more than 60°) of the Sierra Madre. Induction times minimized to avoid fatalities. (I.L. Torres, pers. comm., 2006, modified from Kreeger 1997; Parás et al. 1996)
Brazil	<i>Tapirus terrestris</i>	Captured in pens or pitfalls	Butorphanol tartrate (0.15 mg/kg) with medetomidine (0.03 mg/kg) IM, in same dart; reversal: atipamezole (0.06 mg/kg) with naltrexone (0.6 mg/kg) in same syringe, IV	Adequate chemical restraint for radio collaring, and biological sampling. Average induction time: 10 minutes (Velaslin et al. 2004)
Brazil	<i>Tapirus terrestris</i> and <i>Tapirus pinchaque</i>	Captured in pens or pitfalls, or immobilized by dart	Dosages were calculated using allometric scaling: ketamine (0.62 to 0.41 mg/kg) and atropine (0.025 to 0.04 mg/kg), and tiletamine-zolazepam (1.25 to 0.83 mg/kg), and romifidine (0.05 to 0.03 mg/kg) OR detomidine (0.06 to 0.04 mg/kg) OR medetomidine (0.006 to 0.004 mg/kg) in the same dart; reversal: atipamezole 0.06 mg/kg.	Average induction time: 5 minutes. Medetomidine produced best results obtaining good muscular relaxation and more stable cardiopulmonary parameters. Authors state that the use of atropine should be at the discretion of the veterinarian in charge (Mangini & Velastin 2001; Mangini et al. 2001).

Table 53.4. Anesthetic protocols used in captive tapirs

Type of Facility	Species	Anesthetic Protocol Used	Comments
Zoological institution	<i>Tapirus pichanque</i>	Carfentanil (5.4 ug/kg), ketamine (0.26 mg/kg) and xylazine (0.13 mg/kg) IM; reversal: yohimbine (0.2 mg/kg IV) and naltrexone (100–200 mg/kg, half IV, half SC)	Six immobilizations of tapirs (1 female, 3 males; 1 juvenile male immobilized 3 times) for footwork, gastrointestinal endoscopy, and reproductive surgery (Miller-Edge & Amsel 1994).
Zoological institution	<i>Tapirus indicus</i>	Butorphanol (0.15 mg/kg) and detomidine (0.05 mg/kg) OR xylazine (0.3 mg/kg) all IM; use ketamine if needed (0.5 mg/kg IV); reversal: naloxone and yohimbine (0.2–0.3 mg/kg IV)	Nineteen immobilizations of Malayan and mountain tapirs (Janssen et al. 1996).
Zoological institution	<i>Tapirus bairdii</i>	Butorphanol (0.15–0.2 mg/kg) and detomidine (0.06 mg/kg); ketamine (1–2 mg/kg) was used to reach or maintain recumbency and light anesthesia. Boluses of propofol (0.2–2.0 mg/kg per bolus) were used to effect as needed.	Report of 11 males anesthetized for semen collection by electroejaculation in three captive institutions in Panama (Pukazhenthii et al. 2011), but one of the authors (Padilla) has also used in females with the same effects, and anesthesia was antagonized with naltrexone and yohimbine.
Zoological institution	<i>Tapirus bairdii</i>	Acepromazine (7.7 mg/animal), butorphanol (0.13–0.2 mg/kg), detomidine (0.065–0.13 mg/kg) and ketamine (2.2 mg/kg) IM; no reversal	Trim et al. (1998)
Zoological institution	<i>Tapirus indicus</i>	Etorphine 2.45 mg and acepromazine 10 mg total IM, then guaifenesin IV until intubation was possible; then isoflurane maintenance	Eighteen-month-old female; estimated to weigh 265 kg; immobilized for diagnosis and surgical management of abdominal abscess (Lambeth et al. 1998).
Zoological institution	<i>Tapirus indicus</i>	Butorphanol (80 mg IM) and Xylazine (120 mg total IM) OR detomidine (12 mg total IM); reversal: naltrexone (200 mg total IM), tolazoline (1400 mg total IM)	Estimated body weight 340 kg; repeated immobilizations of light anesthesia for diagnosis and treatment of oral squamous cell carcinoma (Miller et al. 2000).
Teaching hospital	<i>Tapirus terrestris</i>	Detomidine (0.03 mg/kg PO), 20 minutes later, carfentanil (1.85 µg/kg PO)	One animal repeatedly immobilized for wound management; variety of combinations of alpha-2 agonist/etorphine or carfentanil were used, but eight immobilizations with detomidine/carfentanil PO were most useful (Pollock & Ramsay 2003).

propofol or ketamine. Standing sedation, using xylazine or other alpha-2 agonist combinations, should be considered for short procedures that require little manipulation (i.e., skin biopsy, blood collection, and portable radiography). Standing sedation using azaperone (1 mg/kg IM) has also been reported (Janssen et al. 1996).

MAINTENANCE ANESTHESIA

Typically, general anesthesia is maintained in horses by inhalation anesthetics or total intravenous anesthesia (TIVA). Isoflurane, and sevoflurane and halothane are all commonly used inhalation anesthetic agents for horses (Martinez et al. 2006; Muir & Hubbell 1991). To date, isoflurane is the most common inhalant used in for maintenance of anesthesia of tapirs, but the use of sevoflurane in the future is anticipated. Mixtures of injectable anesthetic agents, such as the classic xyla-

zine, ketamine, and guaifenesin (also known as triple-drip), may be used to maintain general anesthesia for relatively short procedures in horses, but no published reports exist in tapirs (Aubin & Mama 2002). Intravenous guaifenesin in a dextrose solution has been safely used in a small number of Baird's tapirs by one of the authors (LRP) to increase relaxation, depth, and duration of anesthesia after anesthetic induction with other agents using empirical rates similar to those used in domestic horses. The effects were similar to those seen in equids, with dose and rate dependent respiratory depression. Two tapirs showed increased nasal secretions and salivation during recovery after guaifenesin usage, although a cause-effect relationship could not be established. Since guaifenesin susceptibility varies between equid species (Matthews et al. 1997), its usage in tapirs should be done with extreme caution until objective documentation of its effects has been reported. Propofol, though not routinely used in large animals,

is an acceptable TIVA method for horses. Constant rate infusions of propofol have been reported in tapirs (Hernandez-Divers & Foerster 2001), and small boluses have been used as supplements to maintain or reach deeper planes of anesthesia. Horses anesthetized with either isoflurane or propofol experience cardiopulmonary depression in a dose-dependent fashion. Propofol is more likely to lead to apnea than isoflurane (Mama et al. 1995, 1996; Reid et al. 1997).

MONITORING AND ANESTHETIC SUPPORT

Once anesthetized, tapirs can be maintained in sternal or lateral recumbency. However, sternal recumbency (Fig. 53.6) allows for better ventilation in large animals (Steffey et al. 1990a, 1990b). If lateral recumbency is necessary, proper padding and vigilance of pressure points on the recumbent side is essential, to minimize the likelihood of myositis or neuropathies, especially during prolonged anesthetic procedures. While on lateral recumbency, the “up” leg should be elevated to improve flow through major arteries, while the “down” leg should be pulled forward to minimize physical pressure on the brachial (axillary) plexus. A blindfold should be applied to protect the corneas from physical damage and minimize visual stimulus. Corneal edema, presumptively associated with prolonged exposure to ultraviolet radiation, has been reported in tapirs (Janssen 2003). Gauze or cotton should be inserted into the ears, to decrease auditory stimulus. Premature arousal can occur with excessive noise, particularly when using alpha-2 agonist and/or opioid combina-

tions. Minimally, heart rate, peripheral pulse strength, respiratory rate, and body temperature should be monitored as with any other large animal.

Pulse oximetry is best accomplished by applying the probe to the tongue, cheek, or ear, or by direct contact with the rectal, preputial, or vaginal mucosa. Although the oxygen-hemoglobin disassociation curve has not been determined for tapirs, the curve for horses ($p50 = 25$ mmHg) indicates that a 90% saturation reading on the pulse oximeter is approximately equal to an arterial partial pressure of oxygen of 60 mmHg, which is distinctly hypoxemic (Clerbaux et al. 1993). Therefore, saturation levels as measured by a pulse oximeter should be maintained well above 90% (i.e., 95–100%). The use of a capnograph is recommended, and with the advent of portable units, it is a useful monitoring device even in field situations. When intubation is impractical or not feasible, the capnograph can be attached to a tightly fitting rubber hose or endotracheal tube placed nasally to monitor respiratory trends, even if the absolute values are not reliable.

Blood gases can be monitored by sampling the facial, auricular, or medial saphenous arteries (Fig. 53.4). In one of the authors' experience, anesthesia induced with a butorphanol, and detomidine protocol in Baird's tapirs results in a time-dependent elevation in $PaCO_2$ and decrease in PaO_2 , which is consistent with the effects seen during sedation with these drugs in the domestic horse (Nyman et al. 2009). Even in healthy animals, heavy sedation and general anesthesia frequently lead to a fall in the arterial partial pressure of oxygen (PaO_2). This is particularly true of larger animals, but only in part due to hypoventilation. Importantly, ventilation to perfusion mismatching increases dramatically in anesthetized large animals (Muir & Hubbell 1991). To compensate for hypoxemia, the use of nasal oxygen (10–15 L/min) or intubation and assisted ventilation should be considered.

As blind intubation of the tapir is accomplished with relative ease (adult tapir: 16- to 20-mm internal diameter endotracheal tube), intubation with tracheal insufflation of oxygen, or positive pressure ventilation (20–30 cm H_2O) are reasonable solutions. Improved oxygen saturation and ventilation may be accomplished in the field using a demand valve driven by 100% oxygen, or a manual resuscitator bag with supplemental oxygen attachment (Ambu A/S, Ballerup, Denmark, <http://www.ambu.com>). Only one report of the aforementioned protocols assessed the cardiopulmonary effects in detail (Foerster et al. 2000). In that report, hypoxemia was noted and supplemental oxygen was recommended.

Blood pressure can be measured indirectly, through the use of blood pressure cuffs on the limbs. Direct blood pressure measurements can be achieved most readily with the use of a 22-gauge catheter placed in the readily accessible auricular artery. A study that com-

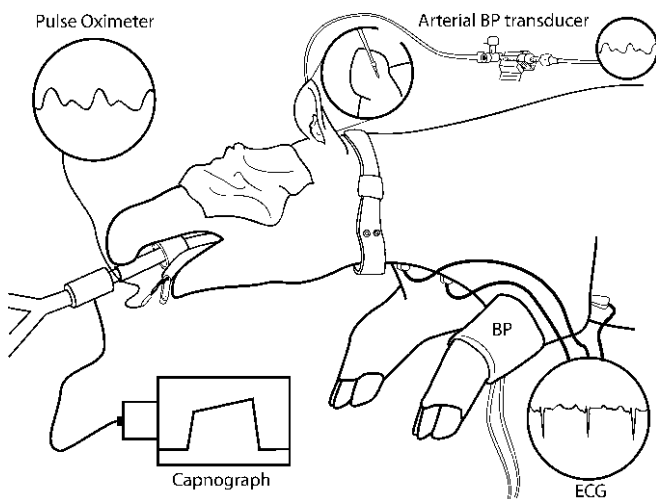

Figure 53.6. Vigilance monitoring of the tapir. Seen here: lingual transmittance pulse oximeter and associated plethysmographic waveform; side-stream (diverting) capnography and capnogram; noninvasive, oscillometric arterial blood pressure monitoring (BP cuff); invasive (direct) arterial blood pressure monitoring through a blood pressure transducer with associated arterial waveform; base-apex lead electrocardiogram (illustration courtesy of MGS Studio).

pared the usefulness and accuracy of indirect versus direct blood pressure monitoring methods in tapirs found that indirect blood pressure measurements using an oscillometer blood pressure monitor correlated with direct readings, indicating that this is a valid method to measure blood pressure in tapirs (Bailey et al. 2000) as measured within the limits of pressure ranges examined (field conditions).

Base-apex lead electrocardiograph application simply requires a positive lead caudal to the heart apex and a negative lead cranial to the heart base. Those unaccustomed to the base-apex lead are often perplexed by its classic description. A less confusing base-apex lead places the left leg lead caudal to the heart apex (left sternal boarder), the right arm and left arm leads cranial to the heart base on the neck in the right jugular furrow, with the ECG monitor set for lead II (often the default setting). This produces a base-apex lead electrocardiogram similar in appearance to the standard lead II. Species with a diffuse Purkinje fiber network produce a unique mean electrical axis. A simple rule of thumb states that if the animal is small or its ancestors were small, it is likely to have a type I heart with a less diffuse Purkinje network, caudally oriented mean electrical axis, and primarily positive wave form in lead II, such as seen in dogs and cats. If the animal is large or its ancestors were large, it is likely to have a type II heart with a diffuse Purkinje network, cranially oriented mean electrical axis, and primarily negative wave form in lead II, such as seen in the horse and the tapir (Fig. 53.6) (Muir & Hubbell 1991).

Temperature is typically monitored through a rectal thermometer. The depth of anesthesia can be monitored subjectively much as in a horses. Ideally, at a moderate plane of anesthesia, muscles should be relaxed even when stimulation is applied, the animal should breath in a regular manner with chest excursions that approximate a conscious animal, the position of the eye should be central, and there may be a very slight palpebral reflex. The corneal reflex should remain until very deep planes of anesthesia.

The use of atropine has been advocated by some veterinarians as an adjunct to anesthesia induced with alpha-2 agonists in tapirs to counteract bradycardia and reduce respiratory and salivary secretions. Atropine should be used judiciously at the clinician's discretion, as systemic usage in domestic equids has been associated with decreased gastrointestinal motility (Ducharme & Fubini 1983), and this effect would be difficult to document in free-ranging animals. In addition, the use of atropine could be contraindicated in hypertensive animals.

RECOVERY

To avoid rough recoveries and to minimize the cardiopulmonary effects of anesthetic agents, protocols that

allow for their antagonism are preferred. Protocols that include alpha-2 adrenergic agonists are typically antagonized well and lead to smooth, uneventful recoveries. If supplemental ketamine (or related drugs) is used, it is recommended that the reversal agent not be administered until at least 30 minutes have elapsed, to allow for redistribution of the drug. In free-ranging situations, maintaining containment of the tapir (in trap, or pit fall) can allow the animal to fully recover before release. In cases where this was not possible, authors reported following the recovered animals for a period of time to monitor signs of ataxia, depression, or renarcotization (Foerster et al. 2000). In captivity, animals should be maintained in a quiet, dark, enclosed area until fully recovered and away from water sources if the facilities allow it. Individual captive tapirs habituated to their caretakers can be enticed to remain adjacent to keepers by showing them food or other positive rewards (scratching) until fully recovered. Attempts at physical restraint by humans are not recommended once a tapir is standing, as even a partially sedated tapir can be extremely dangerous and capable of biting when cornered or aggravated. Aggressive individuals may try to fight or even chase humans during recovery.

In all cases, tapirs should be allowed to recover in the shade. The low surface area to body mass ratio of tapirs may predispose them to overheat if recovering in direct sunlight. Tapirs that are recovering from anesthesia typically begin by twitching their ears, moving the tongue in and out of the mouth, which is followed by return to sternal recumbency. From sternal recumbency, they may first sit on the hindquarters, or fully stand. Many tapirs begin walking in reverse as they gradually regain orientation to their environment. Horses recovering from inhalation anesthetics often experience dysphoria and are prone to self-inflicted trauma; therefore, additional sedatives or tranquilizers are often administered prior to recovery to buy time for inhalation anesthetic washout (Martinez et al. 2006; Muir & Hubbell 1991). Tapirs undergoing prolonged surgical procedures (beyond metabolism of injectable induction agents) may need similar treatment. If sedatives are administered, horses, as with tapirs, tend to roll to sternal recumbency and sit in a controlled pause for several minutes prior to standing directly. Ideally, the horse stands steady or walks with intent with limited ataxia. Ataxia has been reported in tapirs recovering from anesthetic protocols that included ketamine, emphasizing the need for containment and monitoring. Occasional reports of tapirs returning to a deeper plane of sedation hours after antagonism of alpha-2 agonist protocols using medetomidine or detomidine suggest that these alpha-2 agonists may be longer lived in tapirs than the agents used to antagonize them (atipamezole or yohimbine). A recent study supports the occurrence of similar effects in domestic horses

following antagonism of sublingual detomidine (Knych & Stanley 2011).

Rhinoceroses

Robin W. Radcliffe and Peter vdB. Morkel

THE RHINOCEROTIDAE

Introduction

Like the fabricated creature in Albrecht Durer's famous lithograph, the rhinoceros has long been a source of mystery, myth, and intrigue. Part unicorn and part armored beast, the current knowledge of rhinoceros anesthesia likewise represents a melding of pure art and hard science. Today, rhinoceros anesthesia is relatively commonplace, yet no less demanding in practice.

The Rhinocerotidae are truly living fossils—a remnant and archaic mammalian family represented by only five extant species in four genera restricted to Africa and Asia. The relic survivors belie a one-time place of dominance among vertebrate organisms, with over 150 fossil rhinoceros species discovered by paleontology across four continents (Prothero 2005). Today, however, four of the five rhinoceroses are critically endangered from poaching and loss of habitat (Emslie & Brooks 1999; Foose & van Strien 1997).

Field anesthesia made possible the rhinoceros conservation success stories of the twentieth century (Hart-horn & Lock 1960; Meadows 1996; Player 1972) and remains a critical tool for proactive rhinoceros management programs incorporating translocation, ear-notching, radiotelemetry, microchip implantation, and other techniques designed to secure the conservation of both African and Asian species (Dinerstein 2003; Dinerstein et al. 1990; Kock et al. 1990, 1995). Historical and current rhinoceros anesthesia protocols are based on highly effective reversible opioid combinations, yet new anesthesia techniques continue to improve efficacy and safety for both animals and human personnel (Bush et al. 2005, 2011).

Taxonomy and Evolutionary History

The odd-toed ungulates of the order Perissodactyla include three living families: the rhinoceroses, horses,

and tapirs. As the order name denotes, all Perissodactylids bear weight on one (equids) or three (rhinoceroses and tapirs) digits. Rhinoceroses and tapirs are among the most primitive of the world's large mammals and are further grouped into the suborder, Ceratomorpha, based upon a similar ancient body plan. The stout body of the rhinoceros is graviportal or designed for weight bearing with limb modifications to support large mass rather than the long angular limbs of equids in the suborder, Hippomorpha, specialized for speed.

The Perissodactyla enjoyed a period of extraordinary diversity in the Eocene epoch 34 to 55 million years ago before climate change presumably limited specie radiation, culminating in extinction of 10 of the 14 perissodactyl families by the end of the Oligocene (Radinsky 1969). Prehistoric rhinoceroses in particular, as interpreted from fossil evidence, represented a far expanded group of organisms than exist today and included both horned and hornless forms. In fact, rhinoceroses were once the most common large herbivore in North America for most of the last 50 million years (Prothero & Schoch 2002). An extinct hornless rhinoceros, named *Paraceratherium* (also called *Indricotherium*), is known to science as the largest land mammal that ever lived, measuring over 6 meters at the shoulder and weighing an estimated 20 tons (Prothero 2005; Prothero & Schoch 2002).

Biology and Morphology

The Rhinocerotidae are large terrestrial herbivores that have evolved either a browsing (black, Sumatran, and Javan) or grazing (white and greater one-horned) strategy in order to process large quantities of fibrous feeds or simple grasses, respectively. As such, they share bulky elongated skulls, dental patterns largely devoid of canines and incisors (retained to various degree in the Asian species), and prehensile or wide, flat lips in

the browsers and grazers, respectively. Like the equids, fermentation takes place in the cecum and colon. The rhinoceros gut is less efficient than that of ruminants since the microfloral protein formed in the hindgut is largely unavailable to the animal. As a result, rhinoceros must eat more, have a relatively fast passage of gut contents, and possess limited time to reabsorb water from the feces. Therefore, rhinoceros must drink every day or every second day, making it a water-dependent species rarely found more than 15 km from a water source.

Despite their often conspicuous absence in many fossil rhinoceros, the single horn (*Rhinoceros* sp.) or pair of horns (*Ceratotherium*, *Diceros*, and *Dicerorhinus* sp.) is certainly the most distinguishing feature of the living Rhinocerotidae, giving name to the group literally as the *nose-horned beasts* (Prothero & Schoch 2002). Rhinoceros horns differ from true horns of the Artiodactyla by having no central core of bone. Instead, the tubular hair-like keratin filaments are compressed in a linear fashion and set upon a bony protuberance of the skull. Underneath the horns, the skull incorporates extensive nasal bones and sinuses—structures inordinately prone to complications from trauma during capture and translocation.

Rhinoceros skin is thick (several centimeters of primarily collagenous dermis; Cave & Allbrook 1958; Shadwick et al. 1992), with the Asian species sporting subdermal plates and heavy skin folds, making skin anatomy an important consideration for remote drug delivery in the rhinoceros. The greater one-horned rhinoceros of Asia is perhaps best known for the exaggerated armor-like plates or folds first popularized in the famous Durer woodcutting of the Middle Ages. The epidermis, however, is very thin (1 mm) and heavily keratinized, incorporating extensive vasculature, which may predispose the rhinoceros to pressure necrosis, particularly in calves (Cave & Allbrook 1958; Gandolf et al. 2006). Significant body hair is an antiquated trait retained in but one living species, the Sumatran or “hairy rhinoceros,” so-called for its shaggy coat of hair (Fig. 54.1). Wild *Dicerorhinus* have shorter more bristly coats than their captive relatives, a trait providing protection for the skin from the numerous biting insects that share its environment. Hair, a primordial trait of many fossil rhinoceros including the woolly rhinoceros *Coleodonta* and massive one-horned hairy *Elasmotherium*, eloquently links the Sumatran rhinoceros with its long and prosperous past.

RHINOCEROS IMMOBILIZATION AND CAPTURE

Rhinoceros Capture Beginnings

Before widespread application of chemical capture techniques, early African rhinoceros capture operations utilized ropes and a chase vehicle (made famous in the

Figure 54.1. The distinctive hair coat of a Sumatran rhinoceros—a feature linking the primitive *Dicerorhinus* genus with its prehistoric past (image courtesy of Mohd Khan bin Momin Khan, Malaysia Department of Wildlife and National Parks).

film *Hatari* starring John Wayne and Hardy Kruger). Although dangerous to the operator and stressful to the animal, some teams in East Africa became remarkably proficient at this form of capture. Chemical capture of rhinoceros was first attempted with the dissociative anesthetic, phencyclidine, and the curariform muscle relaxant, gallamine triethiodide. In 1960, during Operation Noah, many black rhinoceros (*Diceros bicornis*) were saved from the rising waters of the newly constructed Lake Kariba, bordering Zambia and Zimbabwe, using these novel techniques (Child & Fothergill 1962; Condy 1964; Harthoorn & Lock 1960; Meadows 1996). Phencyclidine and gallamine were succeeded by the easily reversible opioids, first morphine and diethylthiambutene, followed quickly by the more potent opioids, including etorphine HCl (M99) (Keep et al. 1969; King 1969; King & Carter 1965). Over the past 50 years, etorphine has become the standard opioid for capture of the African and Asian rhinoceros, with fentanyl citrate (Sublimaze), carfentanil citrate (Wildnil) and thiafentanil oxalate (A3080) proving useful alternatives. Pioneering investigation by early practitioners, such as Toni Harthoorn, Eddie Young, Ian Hofmeyr, Ian Player, and many others, provided the foundation upon which future rhinoceros chemical capture methods including the present work are based (Harthoorn 1976; Player 1972; Young 1973).

Remote Drug Delivery: Equipment and Darting Techniques

An assortment of remote drug delivery equipment is available for rhinoceros capture, including new developments, yet some of the early systems are still in common practice today, attesting to their simple and durable design. In captive and boma situations, all darting systems can be utilized, but nylon darts (Daninject or Telinject with 60 × 2-mm smooth needles) are

preferred, as they are quiet and relatively atraumatic. The authors prefer to hand-inject (using appropriate human protective safety measures) or pole-syringe captive rhinoceroses including animals held in bomas to eliminate the excitement phase associated with projectile darting.

For field capture of rhinoceros on the ground or from a helicopter a robust and reliable darting method, such as the Cap-Chur system, is preferable. Dart barrels made of aluminum or stainless steel are the most reliable for field use, especially since power settings and impact energy are high, wind or down drafts from the helicopter can be significant, and the operator is often forced to shoot through vegetation. The dart needle should be 5- to 6-cm long for adult rhinoceros. Rhinoceros skin can plug the lumen of a dart needle unless the needle has a relatively thick wall and narrow lumen (Cap-Chur NCL needles) or the tip is bent over (Fauncap dart needles) or the point is sealed and side ports are provided. The needle must have a bead, low barb, or small collar about 25 mm from the base to hold the dart in the thick skin. A novel spiral-threaded needle was developed by Deon Joubert specifically for use on thick-skinned pachyderms; the dart needle can be easily removed by screwing it out of the animal, thereby reducing skin and tissue trauma (Fig. 54.2; Joubert

Figure 54.2. Robust dart needles for the capture of free-ranging rhinoceroses demonstrating the various design configurations of needle tip and barb. The spiral-threaded needles on the right are less traumatic and can be screwed back out of thick rhinoceros skin (photo courtesy of Joubert Capture Equipment, South Africa).

Capture Equipment, Hadison Park, Kimberley, South Africa).

Proper dart placement is essential to ensure good drug deposition. The dart should be placed perpendicular to the skin for deep intramuscular injection (the thick skin of a rhinoceros often makes an angled shot ineffective). When darting from the helicopter, the muscles of the rump or the upper part of the hind leg offer the best target. In the boma or on foot, any large muscle mass can be used for dart placement although the neck and shoulder are preferable.

Recumbency and Positioning

Recumbency and positioning are critical considerations for safe anesthesia of rhinoceros whether in a zoological setting or in the wild. Prior to induction in captivity, thick padding or heavy mats should be utilized to protect recumbent animals from the concrete floors common in these environments. Myositis and neuropathy are serious potential complications. Traditionally, rhinoceroses immobilized in the field are maintained in or moved into sternal recumbency; however, irreversible muscle damage has developed in this position (especially if the rhinoceros goes down on a slope facing upwards with the full weight on its hind legs) as a result of occlusion of the blood supply to the limbs. Although uncommon, problems even occur with careful “placement” of the legs in an apparently natural position. With the rhinoceros on its side, blood flow to the limbs is improved and circulation to the muscles allows delivery of oxygen and dissipation of carbon dioxide and heat generated while running. With the animal in lateral recumbency, the legs should be physically “pumped” up and down by hand every 20 minutes to aid circulation. The weight must be taken off the lower legs to “pump” them effectively; this is accomplished by two or more people lifting the upper legs and rolling the animal partially onto its back about 45 degrees from horizontal. We recommend that all black rhinoceros that have undergone any degree of exertion be placed in lateral recumbency for at least a few minutes.

The decision to move white rhinoceroses onto their sides should be based on several factors, including the degree of exertion, presence of muscle tremors, and duration of recumbency. White rhinoceroses often experience significant muscle rigidity, paddling, and even convulsions under opioid anesthesia; these effects are exacerbated by lateral positioning but tend to resolve with time. Therefore, white rhinoceroses should be positioned initially in sternal recumbency until complete relaxation is achieved (Kock et al. 1995).

The position in which a rhinoceros is placed during recumbency is also an important consideration for respiratory function. It has been observed that oxygen saturation of the blood is higher in sternal than lateral posture. Consistent with observations in domestic

animals and humans, the black rhinoceros has greater dead space in lateral compared with sternal posture as indicated by a lower end-tidal carbon dioxide and higher dead space ratios and volumes in lateral (Morkel et al. 2010). The most appropriate posture for rhinoceroses during anesthesia must be based on the circumstances of each capture and should strike a balance between maintaining respiratory function while providing optimal circulation to the limbs.

Eyes and Ears

The eyes of the recumbent rhinoceros must be shielded with a large towel or appropriate-sized blindfold to prevent retinal damage from direct sunlight, dirt accumulation and corneal abrasion from the environment. For black rhinoceroses undergoing translocation, the use of a muslin cloth wrapped tightly around the face several times and secured to the horn with cable ties is preferred to a simple blindfold (Fig. 54.3). This technique serves to fix the eyes in a closed position and quiets the rhinoceros during crate transport. Before blindfolding, foreign material should be washed from the eyes using physiologic saline. The ear canals are plugged with cotton wool or a cloth while the rhinoceros is anesthetized, leaving tabs for quick removal. Alternatively, when a large number of rhinoceroses are to be immobilized, two cloth-covered cotton wool plugs can be joined with cord so they remain together. If the rhinoceros is being transported, its ears should remain blocked for the entire trip. Caution should be used upon removal of the earplugs as the sudden auditory stimulation can result in excitement or aggression.

Figure 54.3. Attachment of the “mutton cloth” blindfold to aid in crate transport of the black rhinoceros (*Diceros bicornis*). Note the use of cable ties in front of the caudal horn to secure the blindfold over both eyes.

Anesthesia Monitoring

A thorough clinical examination with monitoring of vital functions (respiration, temperature, heart rate, capillary refill time) must be conducted regularly for the duration of anesthesia. The focus should be on respiration and blood oxygenation while temperature and heart rate are usually of lesser importance. These functions are very much dependent on the degree of exertion and excitement before and during induction and must be kept in mind during your evaluation. Careful monitoring is especially important in old, debilitated, very young, and heavily pregnant animals. Any residual dart contents should be checked to see if they were injected, especially if more than one dart was used, as the success of drug delivery may dictate protocols for anesthetic monitoring and antidote administration.

Pulse oximetry (SpO_2) provides an indirect measure of oxygen saturation of hemoglobin (SaO_2) and is a valuable aid to help monitor blood oxygenation and pulse in anesthetized rhinoceros. However, it should not be a replacement for thorough patient monitoring. Without simultaneous correlation with arterial blood gases, pulse oximetry is a tool best used to monitor trends in oxygen saturation. SpO_2 values often fluctuate so the pulse oximeter should be observed for at least 1 minute; if the SpO_2 does not consistently read above 80% or is declining, an intervention is warranted. Based on lower oxygen affinity of white rhinoceros hemoglobin, it has been suggested that SaO_2 levels (ranging from lows of 40% up to 98%; Atkinson et al. 2002; Kock et al. 1995) in rhinoceros underestimate true oxygen saturation of hemoglobin when calculations are made using human formulae (Bush et al. 2004). The sensor clip is attached to the pinnae of the ear after careful scraping with a sharp blade to remove the epidermis or on mucosal folds of the penis, vulva, or rectum. A cloth is placed over the sensor as ambient light can affect the reading. In animals with excessive muscle rigidity or tremors, as is common in immobilized white rhinoceroses, the sensor may fail to obtain an accurate reading. A reflectance probe held against the nasal mucosa works well (applied beyond the pigmented area) and has also been used with varying success on the inner surface of the lips, against the gums and in the rectum or vagina.

Respiratory Gases: Oxygen and Carbon Dioxide Respiratory depression is perhaps the most significant life-threatening complication encountered during routine anesthesia of the rhinoceros (Atkinson et al. 2002; Bush et al. 2004, 2005; Fahlman et al. 2004; Heard et al. 1992; Kock et al. 1995). Large recumbent animals experience cardiopulmonary depression and perfusion-ventilation inequalities because of large size and abdominal organs pressing upon the diaphragm. Severe respiratory compromise with hypoxemia, hypercapnia

and acidosis is more common with long captive procedures or under field conditions where higher doses of opioids are used to shorten induction times (Heard et al. 1992; Kock et al. 1995). Among the African species, these physiologic changes are more prevalent in the white than black rhinoceros (Bush et al. 2004, 2005).

Respiration is the first and most critical function to be monitored in rhinoceros under anesthesia. In the field situation, it is valuable to have a reliable person who does nothing but watch the respirations, noting rate and depth. Be sure there is a free flow of air in and out of both nostrils and that the blindfold does not restrict airflow. The lower nostril, in particular, should remain clear of obstruction so passive regurgitation of stomach contents is free to drain. A cloth sack can be placed under the head to limit inhalation of dust or other debris. Respiratory rate and depth are noted by observing chest movement. When monitoring breaths on a bouncing vehicle as with immobilized rhinoceros transported on a sledge where it is difficult to watch chest movement, a finger can be hooked in the nostril or a hand held close to the nares to feel for the warm exhaled air. Breathing should be deep and regular. Respiratory rate is approximately 10–15 breaths per minute on induction, going down to 4–8 bpm about 10 minutes post induction when using potent opioids. Respiration must be monitored for at least 30–60 seconds to obtain an accurate picture of ventilatory pattern as immobilized rhinoceroses often give two or three quick breaths followed by a period of apnea. Rhinoceroses often develop apnea when moved into a different position. Animals should be rolled slowly and watched for breathing. A painful stimulus often incites the apneic rhinoceros to take a breath. Observation of venous blood color during venipuncture provides a reliable early indicator of blood oxygenation. Dark red, almost black blood indicates poor oxygenation, while a lighter red color is normal and correlates well with mucous membrane color.

If breathing is slow, the rhino develops apnea or blood oxygenation is poor (SpO_2 consistently less than 80%); partial reversal with nalorphine HBr (Nalline), nalbuphine (Nubain), or butorphanol (Torbugesic) or complete reversal with naltrexone HCl [Trexonil] or diprenorphine are indicated. Nalorphine given intravenously produces a marked and sustained improvement in the quality of respiration (Table 54.2 and Table 54.3). Its use has been associated with an approximate 20% increase in the hemoglobin saturation of oxygen (SaO_2) based on pulse oximetry (Kock et al. 1995). Although widely reported to improve oxygenation (Rogers 1993a, 1993b), recent investigation suggests nalorphine produces negligible change to oxygen partial pressures (PaO_2) in the anesthetized rhinoceros (Bush et al. 2004; Fahlman et al. 2004). Since black rhinoceros stand up readily with very small volumes of nalorphine, we recommend dosing at 5-mg nalorphine for adult black

rhinoceros and 25–30 mg for white rhinoceros under field conditions. It is very safe to use nalorphine in white rhinoceros, as this species rarely rises without stimulation and even if arousal does occur adult animals are relatively harmless in a semi-narcotized state. Intravenous doxapram HCl (Dopram; black rhinoceros 200 mg, white rhinoceros 400 mg) provides a smaller, transient improvement in respiratory rate and depth. Doxapram must be used with caution in white rhinoceroses, as it causes central nervous system excitation and exacerbates muscle tremors; effects are best noted if used in conjunction with nalorphine and supplemental oxygen.

Nasal or tracheal insufflation of oxygen (O_2 ; 15–30 L/min) can produce a rapid and significant increase in blood oxygen saturation in immobilized rhinoceros. Although it did not correct systemic acidosis or hypercapnia, O_2 insufflation did substantially improve oxygenation and anesthetic safety (Bush et al. 2004; Fahlman et al. 2004). A variety of factors influence pulmonary blood gas exchange, including dose of anesthetic drug, position of the rhinoceros during immobilization, body temperature, oxygen delivery, and size of the animal. Oxygen supplementation at the flow rates commonly used for rhinoceros appears to produce a more profound improvement of patient oxygenation (PaO_2 108–194 mmHg) in subadult African rhinoceroses compared with adults, perhaps indicating greater ventilation-perfusion mismatch with larger body size (Fahlman et al. 2004).

A control valve and flow meter are attached to the O_2 bottle, and oxygen is administered via a flexible silicon or rubber nasogastric tube (edges rounded to prevent damage to nasal mucosa), measuring 2-m long and 9- to 14-mm inside diameter (Fig. 54.4). Concurrent monitoring of the respiratory rate and depth, and

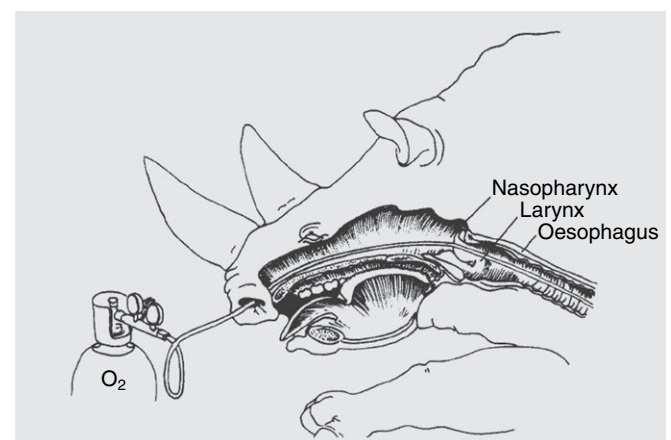

Figure 54.4. Illustration of the nasogastric tube tracheal insufflation technique for oxygen delivery in a recumbent white rhinoceros (*Ceratotherium simum*) under field conditions (adapted from Bush et al. 2004; illustration courtesy of the South African Veterinary Association).

blood oxygenation remains essential. Administration of a partial antagonist (nalorphine, nalbuphine, or butorphanol) will increase the rate and depth of respiration and improve the efficacy of oxygen delivery. Oxygen supplementation is a practical solution to enhance pulmonary gas exchange in immobilized rhinoceros and if used wisely one bottle is sufficient for many animals. Therefore, we recommend immediate intranasal or tracheal insufflation of oxygen at a high flow rate in all recumbent rhinoceroses. Within a few minutes, vital statistics will provide information about respiratory function, and in most situations, all physiologic parameters are satisfactory and the flow can be reduced or discontinued. A small percentage of animals, however, will develop a physiologic crisis where continued oxygen supplementation is critical. Aluminum oxygen bottles are now available that are small and lightweight, making them convenient for helicopter use.

Capnography offers a useful adjunct to monitoring with pulse oximetry, and many portable devices combine measurement of end-tidal carbon dioxide with oxygen saturation of hemoglobin. Capnography is common practice in human anesthesia as an aid to confirm placement of endotracheal tubes and for early warning of hypoventilation. In expired respiratory gases, capnography provides a direct measure of CO₂ eliminated from the lungs. It also gives an indirect measure of CO₂ production in the tissues and circulatory transport of CO₂ to the lungs. Capnography is a rapid noninvasive technique that offers reliable information about tissue CO₂ production, circulation, pulmonary perfusion, and alveolar ventilation and respiratory patterns. For rhinoceros capture, capnography is gaining acceptance by practitioners as a tool to help enhance anesthetic safety by offering a quick method to detect ventilatory or circulatory failure (Morkel et al. 2010).

Body Temperature Body temperature is an important parameter and the best indicator of the degree of exertion endured by the rhinoceros before induction. For every 1° increase in body temperature above normal, there is approximately a 10% increase in oxygen consumption. A rhinoceros's body temperature varies slightly during the day as the ambient temperature changes. Black rhinoceros immobilized without excessive exertion have a rectal temperature of between 36.5 and 38.5°C, and anything over 38.5°C should be liberally doused with cool water. Young rhinoceros tend to have a higher body temperature than adult rhinoceros after running a comparable distance. Although drenching with water is important, it will not have a dramatic effect in lowering the core body temperature, as there is considerable thermal inertia in such a large mammal. It helps to fan the rhinoceros with branches or a portable leaf blower after the animal has been wetted with

water. Holding leafy branches over the rhinoceros to provide shade can help lower the temperature, but it is important that people do not crowd around an immobilized rhinoceros and prevent air movement. A beach umbrella is the most efficient way to make shade—it is cheap, light, and easy to transport and can be folded to fit in the helicopter. A rhinoceros with a body temperature over 39°C must be processed quickly, while a temperature greater than 41°C mandates immediate delivery of the antidote.

The rhinoceros, like other large mammals, is prone to hyperthermia during capture and translocation. The black rhinoceros appears to suffer a greater level of hyperthermia-related morbidity and mortality in the peri-capture period than the white rhinoceros. The goal of the capture team should be to minimize exertion and speed induction. The rise in body temperature can be documented while the animal is in recumbency following excessive exertion; however, a second phase apparently unrelated to the level of exertion appears to occur upon crating. The mechanism of this hyperthermic response observed at variable periods after the rhinoceros enters the crate is not well understood, but could result from postreversal agitation and muscle activity, a physiologic stress response, inadequate airflow inside the crate, or a combination of factors or mechanisms. Simultaneous comparison of rectal and muscle temperatures in recumbent rhinoceroses demonstrates a 1°F (0.5°C) higher temperature in the muscle (Morkel et al. 2012). Since equilibration between rectal and muscle temperatures occurs slowly with time, a deep muscle thermistor can be a useful aid to measuring core body temperature. The probe is readily inserted into the dart site; however, caution must be taken to avoid exposure to dangerous immobilizing drugs.

Additional options for temperature measurement in the rhinoceros include use of a handheld infrared thermometer (Fluke Hart Scientific Inc.) in the ear canal. In a recent pilot study, deep infrared ear temperatures were comparable with deep muscle temperatures, giving a reliable and rapid assessment of core body temperature. Surprisingly, the use of cotton or wool earplugs resulted in ear canal temperature above deep muscle temperature and suggests that the inner ear in the rhinoceros may be an important site for cooling. In animals predisposed to hyperthermia (prolonged capture, high environmental temperature, etc.), rhinoceroses may benefit from removal of the earplugs and perhaps even application of some cooling mechanism to this site, such as a cold pack (Morkel et al. 2010, 2012). Another tool that has been adopted to enhance temperature monitoring in rhinoceroses is the temperature microchip (LifeChip Inc.). After reaching equilibrium when implanted under the skin or into a muscle, chip temperatures were slightly lower than rectal temperatures.

Pulse and Blood Pressure Heart rate is best obtained using a stethoscope while the pulse is readily palpable on the inside of the ear (medial auricular artery) or under the base of the tail (caudal artery). Pulse quality should be evaluated subjectively and compared with the pulse oximeter reading. It is often quite easy to visualize heart compressions by watching the chest wall or by feel with a hand placed over the cardiac window. The heart rate is usually 55–80 beats per minute, although it will be higher in rhinoceros that have undergone marked exertion, especially in young animals (up to 140bpm). Cardiovascular function and peripheral perfusion are assessed by capillary refill time (CRT) and is measured by blanching the rhinoceros's gum for several seconds and then releasing. The observed delay or refill time should not exceed 2 seconds.

Hypertension is prevalent under etorphine anesthesia in black and white rhinoceros (Hattingh et al. 1994; Heard et al. 1992; LeBlanc et al. 1987). One report in white rhinoceros anesthetized under field conditions noted an apparent reduction in blood pressures when azaperone tartrate (Stresnil) replaced fentanyl in etorphine-based combinations, an effect observed despite the higher dose of etorphine used in the cocktails containing azaperone (Hattingh et al. 1994). These conclusions are questionable since fentanyl itself is a potent opioid with prominent hypertensive effects; possessing an activity approximately 1/15 that of etorphine, fentanyl was likely a confounding factor in the study. Although no definitive mechanism has been identified, increased sympathetic nervous system action, peripheral vasoconstriction, and hypoxemia are purported factors in etorphine-induced hypertension in both rhinoceroses and equids (Daniel & Ling 1972; Heard et al. 1992). Opioid-related hypoxemia may induce sympathetic system stimulation and hypertension. Elevated heart rate is a good indicator of hypoxia; once hypoxia resolves, the sympathetic response and associated hypertension disappear.

RHINOCEROS ANESTHESIA IN CAPTIVITY

Guidelines for Anesthesia of Captive Rhinoceroses

The large size of the rhinoceros belies an unexpected sensitivity to the opioid class of pharmacologic agents (Raath 1999). Surprisingly, the same dose of carfentanil citrate used to immobilize a 20-kg blackbuck (*Antelope cervicapra*) would also fully immobilize a 2200-kg white rhinoceros (*Ceratotherium simum*) making the rhinoceros over 100 times more opioid sensitive per unit mass than the average artiodactylid. This inordinate sensitivity of the rhinoceros family to the opioid class—while responsible for the undesirable changes observed in cardiopulmonary function—also makes it possible to adapt less potent mixed agonist-antagonist opioid

agents into anesthetic protocols for both captive and wild rhinoceroses (Bush et al. 2005; Radcliffe et al. 2000a; Walzer et al. 2000).

Planning for anesthetic events should include preparation of the subject and environment where these variables can be controlled. Depending on the purpose for anesthesia, it is generally desirable to fast the animal for 12–48 hours prior to anesthesia (Radcliffe et al. 2000b). However, fasting is certainly not essential as evidenced by the many successful field operations where capture of wild rhinoceroses is conducted in the absence of preanesthetic fasting. Water access should be denied for at least 12 hours, and all water sources removed from the environment prior to drug delivery as regurgitation has been noted in white rhinoceros (Raath 1999). Both passive and active regurgitation of stomach contents are known, with the latter being very rare but quite spectacular. Passive regurgitation is common in immobilized rhinoceroses, presumably secondary to drug or hypoxemia-induced relaxation of the cardiac sphincter (Fig. 54.5). Because of the risks of regurgitation and inhalation pneumonia, great care must be taken with positioning of the head and nostrils, especially with animals in lateral recumbency.

Habitual patterns of behavior are important aspects of captive rhinoceros husbandry, facilitating close medical management. Anesthesia techniques should be adapted as part of these conditioning protocols. Regular visits by animal health staff to rhinoceros barns or bomas for acclimatization to the sights, sounds, and smells of the veterinary profession will help limit the stress of such procedures. In boma situations, it is helpful to learn the nature of each animal, including its likes and dislikes, while also listening carefully to the keeper in charge of caring for the animal.

Figure 54.5. Passive regurgitation from the nares of a black rhinoceros (*Diceros bicornis*) forcefully expelled at expiration. The rhino is positioned in sternal recumbency to help the reflux drain away from the airway.

African Rhinoceros Captive Anesthetic Regimens

White Rhinoceros (*Ceratotherium simum*) The adult white rhinoceros is large and generally placid in captivity. Anesthesia with potent opioids is often associated with marked hypermetria, muscle rigidity, trembling, head shaking, and limb paddling (Fig. 54.6). These effects are undesirable and can be prevented by pre-anesthetic administration of the sedative or tranquilizer component of the cocktail. In captive animals, initial dosing with intramuscular azaperone or detomidine 20–30 minutes prior to induction with etorphine helps preclude muscle spasms and rigidity. With wild rhinoceroses, positioning in sternal recumbency until complete relaxation is achieved was deemed important in field practice (Kock et al. 1995).

Mixtures of etorphine or carfentanil combined with a sedative are standard agents for anesthesia of the captive white rhinoceros (Table 54.1). Doses ranging from 0.8 mg up to 3 mg of etorphine and 1.2 mg carfentanil are common, with supplemental opioids given IM or IV to extend anesthesia (Heard et al. 1992; Walzer et al. 2000). Following immobilizing doses of etorphine or carfentanil, other agents provide additional muscle relaxation and a deeper plane of anesthesia, including intravenous alpha-2 agents, propofol, guaifenesin, ketamine, and midazolam (Klein et al. 1997; Kock et al. 2006; Walzer et al. 2000; Zuba & Burns 1998). Muscle relaxation is critical for deep ventilation and to counteract the associated risk of oxygen depletion from muscle tremors and hyperthermia inherent with use of potent opioids. Lower opioid doses are indicated in zoo-conditioned animals, yet the potent opioids are still associated with significant cardiopulmonary changes, especially as procedure length increases (Heard et al. 1992). One captive white rhinoceros immobilized with etorphine remained hypoxemic despite maintenance of inhalation anesthesia using intermittent partial positive pressure ventilation (Cornick-Seahorn et al. 1995). Hypertension is common, while hypoventilation, pulmonary shunting, and atelectasis induce hypoxia and hypercapnia (Bush et al. 2004; Heard et al. 1992).

Butorphanol combinations are replacing use of more potent opioids for rhinoceros anesthesia in many zoological settings, as safe and reliable anesthetic planes can be achieved for most procedures including surgery (Radcliffe et al. 2000a, 2000b, 2000c). While not appropriate for all applications (i.e., fractious, nonconditioned animals or those with access to large areas), butorphanol combinations are highly effective. The author has used a mixture of butorphanol and azaperone for standing sedation and recumbent anesthesia in all four rhinoceros species maintained in captivity (white, black, greater one-horned, and Sumatran) with safe, predictable results (Radcliffe & Morkel 2007; Radcliffe et al. 2000a, 2000c). Butorphanol doses for white rhinoceros range from 50 to 120 mg for an adult and

10 to 20 mg for a calf or juvenile animal, while azaperone doses range from 100 to 160 mg for an adult with supplemental doses given up to a maximum of 300 mg (Table 54.1 and Table 54.4). Intravenous butorphanol supplementation is effective at inducing recumbency in white rhinoceroses after initial drug delivery, if needed and desirable. Intravenous dosing of azaperone without prior sedation has been associated with adverse extrapyramidal reactions in the horse and white rhinoceros and should be avoided (Radcliffe et al. 2000a).

Inhalation anesthesia is possible in captive rhinoceroses where more invasive procedures requiring surgery or longer anesthesia times are indicated. Intubation in the rhinoceros is accomplished by hand or with an endoscope to guide placement of the endotracheal tube or a guide catheter into the airway. Unlike the horse, rhinoceroses have a unique, blind diverticulum in the dorsocaudal pharynx above the glottis. The anesthetist must be careful not to pass the tube into the diverticulum during intubation (Radcliffe et al. 1998).

A white rhinoceros was safely anesthetized to treat a surgical colic by sedation with butorphanol (80 mg) and detomidine (50 mg), followed by IV glyceryl guaicolate (50 g) and three boluses of ketamine (200 mg per bolus) for induction (Valverde et al. 2010). Anesthesia was maintained for an additional 6 hours using isoflurane in oxygen delivered at 1–2% using a circle breathing system. Positioning for surgery and recovery were challenging, but made possible through use of inflatable mats and expertise of the local fire department. Although the rhino eviscerated 3 days post surgery, the anesthesia and recovery were considered a success. Inhalation anesthesia together with a sling system facilitated laparoscopic-assisted transvaginal oocyte recovery in a black rhinoceros (Portas et al. 2006). Abdominal laparoscopy with insufflation of the abdomen is possible in rhinoceroses without general anesthesia by using a standing approach (Radcliffe et al. 2000b).

Black Rhinoceros (*Diceros bicornis*) Black rhinoceros appear predisposed to excitation during induction with etorphine, especially with remote drug delivery in zoological environments (Portas 2004). Using appropriate human safety practices, the stress of darting can be avoided by hand-injection, thereby alleviating much of the undesirable excitatory phase black rhinoceroses experience while also significantly reducing the total dose of opioid agents required (Radcliffe & Morkel 2007; Table 54.1). In bomas, to limit the “undesirable excitatory phase,” great care should be taken to minimize the number of people and unusual objects close to the boma. Noise and movement should be avoided and, once recumbent, the rhinoceros’s eyes should be covered and ears blocked as soon as possible. Significant induction risks include lacerations, limb and foot

Table 54.1. Suggested doses for chemical restraint of adult *capitive* rhinoceroses producing anesthetic planes from sedation to recumbency

Rhino Species	Standing Sedation			Recumbency		
	Protocol	Reversal	Reference and Comments	Protocol	Reversal	Reference and Comments
White rhinoceros	50- to 70-mg butorphanol (BT) + 100-mg azaperone IM hand-injection plus constant rate infusion (CRI)	Naltrexone at 2.5 mg per mg BT IM or IV	Radcliffe et al. (2000a, 2000b); use CRI in long procedures	70- to 120-mg butorphanol + 100- to 160-mg azaperone IM hand-injection	Naltrexone at 2.5 mg per mg BT IM or IV	Radcliffe et al. (2000a); supplemental IV dosing or CRI
	120- to 150-mg butorphanol + 5- to 7-mg medetomidine (MED) IM dart (Give 1- to 2-mg nalorphine IV to keep standing)	Naltrexone at 1 mg per mg BT Atipamezole at 5 mg per mg MED	Citino (2008)	120- to 150-mg butorphanol + 5- to 7-mg medetomidine (IM dart; recumbency ~20 minutes)	Naltrexone at 1 mg per mg BT Atipamezole at 5 mg per mg MED	S. Citino, unpubl. data; improved analgesia for surgery
	0.8- to 1.5-mg etorphine (M99) IM dart	Naltrexone at 40 mg per mg M99	Portas (2004)	2- to 3-mg etorphine + 20- to 40-mg azaperone IM dart	Naltrexone at 40 mg per mg M99	Portas (2004)
Black rhinoceros	25- to 50-mg butorphanol IV or IM hand-injection	Naltrexone at 2.5 mg per mg BT IM or IV	Radcliffe et al. (2000c) and unpubl. data; use for subadults and crating	1.2-mg carfentanil IM dart	Naltrexone at 100 mg per mg M99	Portas (2004)
	1.5- to 2-mg etorphine + 2- to 3-mg medetomidine (Give 1- to 2-mg nalorphine IV to keep standing) IM dart	Naltrexone at 30 mg per mg M99 Atipamezole at 5 mg per mg MED	Citino (2008)	1- to 1.5-mg etorphine + 100-mg azaperone IM hand-injection	Naltrexone at 50 mg per mg M99 1/2IV 1/2IM	R. injuries, head trauma, damage to nasal sinuses, horn avulsion, and even death. With careful animal conditioning and procedure planning, the risks of induction excitation are easily minimized. Likewise, antagonism of narcotic anesthesia in the black rhinoceros is characterized by rapid and powerful recoveries mandating extra care; never stand in front of a narcotized rhinoceros as arousal is often sudden and unpredictable (Kock et al. 2006).

As in the other rhinoceros species, potent opioids (primarily etorphine) have historically been used for anesthesia of captive black rhinoceros with predictable results (Portas 2004). Zoo-conditioned animals require much lower doses of etorphine (1–1.5 mg) than their wild counterparts, especially when administered by hand-injection or pole-syringe (Table 54.1). Butorphanol alone or in combination with azaperone or detomidine HCl (Dormosedan) has also been used in the black rhinoceros, although its use is primarily limited to subadult animals, crating and translocation procedures, or well-conditioned animals since black rhinoceros are easily excitable and may override drug effects (Radcliffe et al. 2000c). In addition to reversing the respiratory depressant effects at the μ receptors, butorphanol also antagonizes the powerful μ sedative effects, thereby greatly lightening anesthesia. For butorphanol use in the black rhinoceros, expect light planes of anesthesia and the need for frequent redosing. A more thorough discussion of mixed agonist-antagonist opioid cocktails and newer alpha-2 agents for use in both captive and field immobilization protocols for the African rhinoceroses can be found in the New Techniques section of this chapter and Table 54.1 and Table 54.2.

Asian Rhinoceros Captive Anesthetic Regimens

Indian or Greater One-Horned Rhinoceros (*Rhinoceros unicornis*) Despite the common occurrence of Indian rhinoceroses in zoological parks and a propensity for foot problems necessitating chronic care, few published accounts of anesthesia in captive greater one-horned rhinoceros exist (Atkinson et al. 2002; Portas 2004). One report combined injectable and inhalation anesthesia in a female *Rhinoceros unicornis* for ovariohysterectomy using etorphine and isoflurane in oxygen. The 7-hour long anesthesia (much of it in dorsal recumbency) was considered effective despite the animal succumbing to postsurgical complications (Klein et al. 1997). The most complete summary of captive anesthesia in this species, however, describes serial opioid-based anesthesia to facilitate long-term medical foot care in one animal. A combination of etorphine-detomidine (3–3.6 and 10–14 mg IM, respectively) was given by projectile dart or etorphine-detomidine-ketamine (3.5–3.8, 14, and 400 mg IM, respectively) administered by pole-syringe (Atkinson

et al. 2002). Use of the pole-syringe for drug delivery was preferred because darting was limited by a small target area among the peculiar anatomic neck folds and by drug selection for small dart volumes. While both drug combinations proved efficacious, subjective assessment suggested that the etorphine-detomidine-ketamine protocol produced more rapid induction, lowered the need for supplemental ketamine, and shortened reversal times (Atkinson et al. 2002).

The author has used butorphanol and azaperone (100 mg of each drug mixed in a syringe and given by hand-injection) to induce standing sedation in the Indian rhinoceros (R. Radcliffe and N. Lung, unpubl. data., 2004). A combination of butorphanol and detomidine (120 and 80 mg, respectively) produced sternal recumbency for surgical repair of a rectal prolapse (Bertelsen et al. 2004). As in the white rhinoceros, these protocols provide adequate muscle relaxation, sedation, and analgesia while being completely reversible with the pure opioid antagonists naltrexone or naloxone hydrochloride (Narcan). Naltrexone is preferred unless short immobilization intervals are anticipated since renarcotization is common using naloxone alone; naloxone provides complete reversal for a short duration (approximately 30–60 minutes) and is only suggested if repeat procedures are planned for the same day (Bertelsen et al. 2004; Gandolf et al. 2000; Portas 2004; Radcliffe et al. 2000a).

Javan or Lesser One-Horned Rhinoceros (*Rhinoceros sondaicus*) *Rhinoceros sondaicus* is the only rhinoceros not presently represented by captive specimens and was only extraordinarily displayed in zoological gardens during the seventeenth, eighteenth, and nineteenth centuries (Rookmaaker 1998). Although historical records indicate that at least 22 Javan rhinoceros were captured between 1647 and 1939, only four survived long enough to reach zoo exhibits in Adelaide, Calcutta, and London (Rookmaaker 1998). The entire surviving wild population of Javan rhinoceros can be found in Ujung Kulon National Park in West Java ($n \sim 40$) and Cat Tien National Park in Vietnam ($n \sim 3?$). No accounts of Javan rhinoceros anesthesia exist, but techniques presumably would be analogous to approaches used for the Sumatran rhinoceros (*Dicerorhinus sumatrensis*) or greater Asian one-horned rhinoceros (*Rhinoceros unicornis*) with size difference being a notable exception.

Sumatran Rhinoceros (*Dicerorhinus sumatrensis*) Few reports of Sumatran rhinoceros anesthesia exist since captive specimens are rare. Etorphine (0.98–1.23 mg or 1 mg) combined with acepromazine (PromAce; 4–5 mg) or azaperone (60 mg) has been used to anesthetize captive Sumatran rhinoceroses (Portas 2004; Radcliffe & Morkel 2007). One adult male was immobilized on two occasions using a two-stage darting protocol. The

Table 54.2. Suggested doses for chemical restraint of adult *wild* rhinoceroses including supplemental agents used for respiratory support

		Respiratory Support			
		Immobilization			
Rhino Species	Protocol	Reversal	Reference and Comments	Protocol	Reference and Comments
White rhinoceros	2- to 3.5-mg etorphine (M99) + 40- to 90-mg butorphanol (BT) + 25- to 50-mg midazolam (MDZ) IM dart. Detomidine, medetomidine, midazolam, or azaperone can be added to this mix: (a) for better muscle relaxation and often better blood oxygenation—DMM; (b) to speed induction—DMMA.	Naltrexone at 40 mg per mg M99 IV (full reversal) OR 2- to 2.5-mg diprenorphine (M50:50) per mg M99 IV (reverses M99, but not BT)	Bush et al. (2005, 2011); reduces respiratory depression, hypoxia, tachycardia, muscle rigidity, and tremors, but with slower induction and an animal that may stay on its feet. Avoid butorphanol in combination with etorphine in rough terrain where a quick induction is safer.	<ul style="list-style-type: none"> • Produces immobile rhino in ~10 minutes and crating <i>without</i> partial opioid reversal • In case of inadvertent overdose or cardiopulmonary suppression, give diprenorphine to reverse the M99 while preserving the sedative effects of the BT 	Bush et al. (2005, 2011) and unpubl. data; reverse part or all of opioid effects based on desired outcome
	3- to 4.5-mg etorphine + 40- to 60-mg azaperone (replace azaperone with 10- to 20-mg detomidine if no transport) IM dart Consider 5- to 20-mg midazolam slowly IV for muscle relaxation	For crate reversal: 2.4-mg M50:50 per 1-mg M99 plus 1- to 2-mg naltrexone IV if pushing. NTX will be a relatively "lively" wake up and one must be adequately prepared (i.e., animal close to crate, rope properly attached to head, and well-organized team) For field/boma reversal: naltrexone at 40 mg per mg M99 IV (full reversal)	Kock et al. (1995, 2006) Rogers (1993a); still considered standard translocation protocol P. Morkel, unpubl. data Kock et al. (1995)	<ul style="list-style-type: none"> All white rhino: • 20-mg butorphanol per mg M99 (20X M99 considered minimum dose for white rhinoceros, reduce to 10X or 15X if light) OR • 20- to 30-mg nalorphine IV OR • 20- to 40-mg nalbuphine IV AND/OR • 1-mg M50:50 	Kock et al. (1995, 2006) M. Hofmeyr and P. Morkel, unpubl. data; Butorphanol is being used with greater frequency for its partial agonist properties in white rhinoceros across Africa

Black rhinoceros	4-mg etorphine + 40- to 60-mg azaperone (Replace azaperone with 100-mg xylazine or 10-mg detomidine) + 5000IU hyaluronidase IM dart. Azaperone can be increased to 200 mg for a quicker induction if no transport. Can also combine azaperone with alpha-2 agonists. 2- to 2.5-mg thiafentanil (A3080) + 2- to 2.5-mg etorphine IM dart. Can also use thiafentanil alone at etorphine doses (i.e., up to 5 mg) but watch the respirations 2- to 2.5-mg etorphine + 10-mg acepromazine IM dart OR 0.7-mg carfentanil (CF) 2-mg etorphine + 80-mg azaperone + 5000IU hyaluronidase IM dart OR Use M99:BT:MDZ 80-mg butorphanol + 80-mg azaperone IM dart	For crate reversal: 20-mg butorphanol per mg M99 OR 5- to 20-mg nalorphine per mg M99 or 1–1.8 mg MSO:50 IV For field/boma reversal: naltrexone at 40 mg per mg M99 IV (full reversal) Same	Morkel (1989); higher M99 doses for <i>Diceros bicornis bicornis</i> Kock (1992); Kock et al. (2006) Hyaluronidase is always recommended to speed induction, especially as black rhino (unlike white rhino) often run themselves into trouble Rogers (1993b)	<ul style="list-style-type: none"> Give 5-mg butorphanol IV to increase respiration and heart rate and lighten the anesthesia. A 10-mg dose will considerably lighten anesthesia and rhino may stand. Animal less likely to stand if kept in lateral position and rhino can be easily pushed down, if necessary <i>Note:</i> Do <i>not</i> use the white rhino respiratory protocol in black rhino as it will cause arousal <i>Instead:</i> 5 mg nalorphine IV; titrate to effect <i>Important</i> to have animal lateral and “pump” legs every 20 minutes 	M. first doses were considered inadequate and the authors subsequently recommended 10-mg butorphanol plus 10-mg detomidine IM followed 20 minutes later with 1.2-mg etorphine and 5-mg acepromazine IM, plus 50-mg supplemental doses of ketamine IV to extend the anesthesia period (Walzer et al. 2010). Darting of this animal likely contributed to long induction times (up to 40 minutes)—Sumatran rhinoceros are easily conditioned for hand injection in a chute. As with the African species, muscle rigidity and cardiopulmonary depression are common with use of the potent opioids, and preanesthetic administration of a tranquilizer is prudent to limit muscle tremors and improve respiratory function. Total azaperone doses should be kept to 100 mg or less as ataxia has been noted upon recovery with higher doses in this species. Butorphanol has been combined with detomidine for standing sedation while the author routinely uses a mixture of butorphanol and azaperone for standing sedation and full recumbent procedures (Table 54.1; Radcliffe et al. 2004).

As with the African species, butorphanol combinations are preferred in captive Sumatran rhinoceros to preclude the adverse cardiopulmonary changes associated with use of more potent opioids. For adult animals, butorphanol at a dose of 60–80 $\mu\text{g}/\text{kg}$ with azaperone at 80–100 $\mu\text{g}/\text{kg}$ and a range of 30- to 50-mg and 50- to 60-mg butorphanol and azaperone, respectively, is recommended with higher butorphanol doses being used on occasion to induce recumbency. Antagonism of the butorphanol effects is accomplished with naltrexone at a dose of 2.5 times the dose of butorphanol (Table 54.1; Radcliffe et al. 2004). Other tranquilizers may be used in place of azaperone, such as the alpha-2 agonists, but care should be exercised as hypoxemia has been reported with use of these sedatives. Local anesthetics may facilitate invasive procedures; however, use of more potent narcotics such as etorphine or other pharmacologic agents, such as ketamine and medetomidine, may be indicated to induce surgical anesthesia.

New Captive Anesthesia Techniques

Although much has been learned about rhinoceros anesthesia, limitations still hinder safe and reliable procedures for these large mammals, especially where prolonged recumbency or surgery is required (Heard et al. 1992; Klein et al. 1997). Standing restraint where possible using mixed agonist-antagonists show promise (Radcliffe et al. 2000a, 2000b). For the black rhinoceros, where potent opioids are still often preferred over mixed agonists, challenges include marked respiratory depression, inadequate muscle relaxation, need for frequent redosing, and incomplete analgesia in painful procedures. The incorporation of the potent alpha-2 agonist medetomidine with etorphine or butorphanol enhances sedation and analgesia in captive rhinoceroses (Citino 2008). Because alpha-2 agonists exacerbate respiratory depression and hypotension, contribute to dehydra-

tion, and alter thermoregulatory mechanisms they must be used with caution in rhinoceroses of unknown health status, especially old and debilitated animals. However, under captive conditions, where the health of an animal is known and a specific type of anesthesia is desirable, alpha-2 agents are effective supplements.

For the black rhinoceros, medetomidine (2–3 mg representing 2–2.9 $\mu\text{g}/\text{kg}$ IM; 20 mg/mL solution) is combined with etorphine (1.5–2 mg representing 1.5–1.7 $\mu\text{g}/\text{kg}$ IM; Citino 2008) and given by dart. The investigators were able to begin safe animal manipulations at approximately 9 minutes, with full recumbency achieved in 15 minutes. This combination facilitated very painful procedures, including molar extraction and foot surgery with the additional supplement of an intravenous guaifenesin-ketamine drip (1 g of ketamine in one liter 5% GGE solution) to enhance peripheral analgesia. Relaxation was excellent with easy access to the oral cavity for dental surgery. Physiologic parameters were considered normal with concomitant nasal oxygen insufflation. Recovery from anesthesia was smooth and rapid with no evidence of re sedation or renarcotization using naltrexone at 30 mg per mg etorphine and atipamezole HCl (Antisedan) at 5 mg per mg medetomidine.

For white rhinoceros, where butorphanol has proven so effective in captive settings, the same investigator is using medetomidine (5–7 mg representing 2.47–2.81 $\mu\text{g}/\text{kg}$ IM) and butorphanol (120–150 mg IM representing 62.5–64.9 $\mu\text{g}/\text{kg}$ IM) to provide enhanced muscle relaxation and analgesia properties (Citino 2008). The animals can be manipulated within approximately 11 minutes of intramuscular drug delivery with full recumbency in 20 minutes. The addition of medetomidine into these protocols has significantly improved muscle relaxation and analgesia properties for such painful ophthalmic procedures as eye enucleation and conjunctival flap surgery. As with the black rhinoceros, a 5% guaifenesin-ketamine drip was deemed useful for long procedures and to enhance peripheral analgesia. Antagonism was complete using naltrexone at 1 mg per mg butorphanol (204–262 $\mu\text{g}/\text{kg}$ naltrexone) and atipamezole at 5 mg per mg medetomidine (25.4–31.2 $\mu\text{g}/\text{kg}$ atipamezole).

RHINOCEROS ANESTHESIA IN THE WILD

Guidelines for Anesthesia of Wild Rhinoceroses

Field anesthesia of Asian and African rhinoceroses is often undertaken to facilitate urgent conservation actions, such as dehorning, ear-notching, microchip application, radio-collaring, and horn transmitter implantation or translocation to safe areas (Dinerstein et al. 1990; Flamand et al. 1984). Ideally, rhinoceros capture operations should be conducted when temperatures are lower than 25°C, usually in the early

morning or late afternoon. Darting free-ranging rhinoceros when ambient temperatures are high increases the risk of elevated body temperatures and associated physiological stress. If working in the late afternoon, a rhinoceros should not be darted unless there is sufficient daylight remaining (an hour is a minimum time to process the animal and deal with potential problems; Rogers 1993a, 1993b). If a rhinoceros has run hard enough for its skin to become dark with sweat, the rhinoceros's body temperature will often exceed 39°C. Such an animal should not be darted or if it has already been darted, it must be drenched with water and processed quickly. If the temperature of an immobilized rhinoceros rises above 41°C, the antidote should be administered immediately and the animal released.

With good dart placement, recumbency should follow within 3–6 minutes post drug delivery (Kock et al. 2006; Morkel 1989, 1994). Induction is usually quicker in young rhinoceroses and longer in large bulls and heavily pregnant cows. If there are no signs at about 6 minutes, the rhinoceros should be darted again. Induction times of less than 3 minutes may indicate an overdose and it is important to get to such an animal quickly so that the respiration and other vital functions can be monitored; oxygen combined with a partial antagonist should be given, if necessary. In protocols incorporating thiafentanil, rapid inductions are expected and less of a concern. Intravenous opioid use should be avoided due to risks of apnea; however, if necessary, give the opioid slowly while keeping a close eye on respiration. For the same reason, caution must be exercised when giving midazolam or alpha-2 agonists by the intravenous route.

As a rhinoceros becomes affected by etorphine, its pace shortens, the forelegs are lifted higher in a classic "Hackney gait," and the head is elevated (Fig. 54.6).

Figure 54.6. Typical induction posture in adult white rhinoceros (*Ceratotherium simum*) under the effects of etorphine, illustrating characteristic head elevation, raised hackney action of forelimbs and muscle rigidity (image courtesy of Rolfe Radcliffe, Living Fossil Productions).

The rhinoceros then starts to blunder through bushes and slows down before going into lateral or sternal recumbency. In rough terrain, rhinoceros have a tendency to run downhill once they are heavily narcotized and may easily injure themselves by running into a gully or water source. With a quick induction, rhinoceroses tend to go down in sternal recumbency. Occasionally, the forelegs collapse first and the hindquarters remain elevated. In this situation, the full weight of the abdominal organs press on the diaphragm, and respiration may be compromised, especially in heavily pregnant females, who have the weight of the fetus, adding additional pressure. Such animals must be immediately pushed onto their sides. Usually, a rhinoceros will become fully recumbent; however, if it is still on its feet, the brake rope can be placed around one of its rear legs, the blindfold over its eyes, and cotton wool in its ears.

On arrival at an immobilized rhinoceros, a quick estimate of its age and body condition should be made. Older or debilitated rhinoceros need special care. Nothing should impede respiration or push against the rhinoceros's belly, chest, or nostrils. On a slope, the rhinoceros should face uphill to alleviate pressure against the diaphragm. Field personnel must work quickly while the rhinoceros is recumbent—it helps to prepare a prioritized checklist before beginning each field capture exercise (Flamand et al. 1984; see also *Practical Strategies for Rhinoceros Field Anesthesia*).

African Rhinoceros Wild Anesthetic Regimens

White Rhinoceros (*Ceratotherium simum*) With the high doses of opioids used to speed induction under field conditions, the safe anesthesia of wild white rhinoceroses represents one of the most challenging branches of rhinoceros anesthesia (Table 54.2). Hypoxia, hypercapnia, hypertension, tachycardia, and acidosis are common physiologic abnormalities reported in anesthetized white rhinoceros (Bush et al. 2004; Heard et al. 1992). A variety of techniques have been adopted to help alleviate the significant opioid-induced cardiopulmonary depression in African rhinoceroses. These include use of partial agonist-antagonist agents to reverse the μ -regulated opioid respiratory depression, respiratory stimulants, such as doxapram, nasal or tracheal insufflation of oxygen, and incorporation of mixed agonist-antagonist agents into more potent opioid-based protocols to influence receptor effects (Bush et al. 2004, 2005; Fahlman et al. 2004; Kock et al. 1995; Radcliffe et al. 2000a).

Opioid doses for field anesthesia of adult white rhinoceroses range from 3 to 4.5 mg of etorphine plus 40- to 60-mg azaperone or 10- to 20-mg detomidine (Table 54.2; Bush et al. 2004; Kock et al. 1995; Rogers 1993a). Hyaluronidase (Hylase; 5000 IU) is often incorporated into darting protocols for rhinoceros to shorten induction times (Morkel 1989). White rhinoceroses

stopped moving 2–3 minutes sooner with hyaluronidase, but often remained standing (Kock et al. 1995). Fentanyl was once incorporated into drug cocktails for white rhinoceros but is rarely used today (1 mg of etorphine being equipotent to 15 mg of fentanyl; Rogers 1993a). The parasympatholytic agent, hyoscine, was historically combined with opioids for its sedative and amnesic properties, as well as to induce “temporary blindness” by pupillary dilation (Player 1972; Rogers 1993a). However, its use is no longer widely accepted because of undesirable side effects and is now considered obsolete (Kock et al. 1995; Raath 1999).

An extensive study of white rhinoceros anesthesia incorporating several drug protocols and 141 immobilizations over a 2-year period was conducted in Zimbabwe to enable dehorning operations (Kock et al. 1995). Initial immobilization mortality was quite high at 7% and was primarily attributed to hypoxemia and cardiovascular collapse. Subsequent captures utilized lower opioid immobilizing doses and simultaneously incorporated routine use of nalorphine (10–20 mg) or nalbuphine HCl (20–40 mg) to help improve respiration—especially in longer procedures, where mortality was most prevalent. Of the various drug combinations tested (etorphine alone and in combination with fentanyl, xylazine, or detomidine), the etorphine-detomidine combination was considered superior because it was empirically judged as smoother and more rapid (no statistical significance). Pulse rates and creatinine phosphokinase (CPK) levels were significantly lower with the etorphine-detomidine combination, suggesting improved cardiac function and less muscle damage, respectively (Kock et al. 1995). Good muscle relaxation was observed without the rigidity and paddling common with use of potent opioids in the white rhinoceros. The ratio of etorphine to tranquilizer was critical and dose dependent, likely reflecting differences in drug pharmacology and onset of action.

An effective alternative for mitigating muscle rigidity in wild white rhinoceroses is the use of midazolam (Radcliffe & Morkel 2007; Table 54.2). Since immobilized white rhinoceros are often first encountered in a standing position with a rigid body posture, intravenous midazolam at 5–20 mg is effective in inducing good muscle relaxation and recumbency. The Zimbabwe workers noted that even small incremental increases in etorphine in the initial immobilizing dose or redosing with etorphine resulted in poorer muscle relaxation and increased head shaking, jerking, and limb paddling (Kock et al. 1995). Midazolam has excellent muscle relaxation properties and is a useful adjunct in these situations.

Black Rhinoceros (*Diceros bicornis*) Capture-related stress is a significant factor in field immobilization of the black rhinoceros, resulting in morbidity and mor-

tality in the postcapture period (Keep 1973; McCulloch & Achard 1969). Rapid immobilization using high opioid doses in combination with hyaluronidase is the single most critical factor in reducing stress during black rhinoceros capture operations (Kock 1992; Morkel 1989, 1994). Furthermore, higher etorphine doses and use of hyaluronidase were associated with significantly shorter induction times, lower body temperatures, shorter distances moved, and reduced muscle damage, as evidenced by lower CPK and lactate dehydrogenase levels (Kock 1992). Although two accounts list 3-mg etorphine as a standard opioid immobilizing dose for wild black rhinoceros (Kock et al. 1990; Rogers 1993b), subsequent study suggests that 3 mg of etorphine is inadequate due to prolonged induction periods and associated capture stress (Kock 1992). Based on review of published material and considerable author experience, 4 mg of etorphine is recommended as a good standard dose for an adult black rhinoceros bull or cow in good body condition (Table 54.2; Morkel 1989, 1994).

A scaled-down opioid dose should be utilized in young animals or those in poor body condition; however, in all other circumstances, a low dose of etorphine is contraindicated for free-range capture of the black rhinoceros (Kock et al. 2006). Azaperone is incorporated into etorphine-based African rhinoceros immobilization protocols at 40–60 mg total dose (Table 54.2). Concentrated (100 mg/mL) azaperone solutions should be carefully examined before use as they often crystallize under field conditions. Xylazine or Detomidine (100 or 10 mg per adult, respectively) can be substituted for azaperone based on individual preference.

A disparity is evident in the opioid dose required for immobilization of the various subspecies of black rhinoceros. The desert subspecies (*Diceros bicornis bicornis*) needs a slightly higher dose than the other subspecies. While 5 or even 6 mg etorphine may be necessary for an adult *D. b. bicornis* in good condition, 4 mg is usually more than adequate for a comparable response in animals of the *Diceros bicornis minor* or *Diceros bicornis michaeli* subspecies. Not only is there variation between subspecies, but there also appears to be some difference among individuals. The capture veterinarian must therefore be aware of these vagaries in dose response and be prepared to respond if an animal reacts unfavorably.

Asian Rhinoceros Wild Anesthetic Regimens
Indian or Greater One-Horned Rhinoceros (*Rhinoceros unicornis*) Techniques for field anesthesia of the greater one-horned rhinoceros were developed to meet research needs, including the elucidation of basic ecology, genetics, social organization, and dispersal biology (Dinerstein 2003; Dinerstein et al. 1990). Furthermore, translocation programs are proving essential for reaching long-term population management goals

for *R. unicornis* in India and Nepal. Capture of wild greater one-horned rhinoceros is usually conducted from atop trained elephants to facilitate finding and darting of rhinoceroses among the dense tall-grass habitats in the floodplain grasslands and riverine forests, where these rhinoceroses flourish. In addition to providing an elevated platform, elephants (10–15 animals) are used to surround the target rhinoceros before and after darting to facilitate observation of the animal during induction and to prevent escape into open water (Dinerstein et al. 1990).

Adult greater one-horned rhinoceros weigh an estimated 2000 kg, with males slightly larger than females. Dinerstein and colleagues immobilized 39 animals (representing 51 events) using a combination of etorphine and acepromazine (2–2.5 and 10 mg, respectively) delivered via remote intramuscular injection either in the shoulder or rump using Cap-Chur darts with 5-cm needles (Table 54.2; Dinerstein et al. 1990). One adult female was immobilized with carfentanil (0.7 mg), and all animals were successfully reversed in the field using diprenorphine HCl (M50:50). Induction times were found to be significantly longer in breeding versus nonbreeding males, with the former group rarely moving far from the site of darting. A large disparity in induction times was noted across all age and sex groups, presumably related to variable drug delivery from dart placement among the thick skin folds characteristic of the species (Dinerstein et al. 1990).

Javan or Lesser One-Horned Rhinoceros (*Rhinoceros sondaicus*) There have been no published reports describing field capture or anesthesia of the Javan rhinoceros. As with the Sumatran rhinoceros, pitfall trap methodologies rather than stockade style traps are recommended for capture of lesser one-horned rhinoceros in the rainforest environment, provided the risks of flooding can be controlled (Nardelli 1987b; Sadmoko 1990). Field anesthesia is also possible—especially where animals are pushed out of the forest by human activities—and should be based on extrapolation of the best available information from the other Asian species.

Sumatran Rhinoceros (*Dicerorhinus sumatrensis*) Several intensive operations have been conducted to capture wild Sumatran rhinoceroses using corral or stockade traps with little or no success (Abdullah 1987; Sadmoko 1990). In one instance, an adult female Sumatran rhinoceros suffered severe head injuries and acute death following capture in a stockade trap from apparent panic-related self-trauma (Nardelli 1987a). Planned capture of wild Sumatran rhinoceros in the forests of Southeast Asia has been most effective by use of the pitfall trap. Pitfall traps measured 10' × 4' × 8' (length × width × depth) and incorporated strong plywood walls to preclude landslides and a breakaway

false ceiling that drops the animal into the excavated pit beneath (Fig. 54.7). Site selection favoring heavily used rhinoceros trails was considered the single most important criteria for success or failure of the pitfall trap (Abdullah 1987). Nevertheless, pitfalls suffer from significant problems. In many Sumatran rhinoceros areas, poor drainage results in flooding of the pit despite careful preventive measures. Interference from nontarget species is also a common hazard; tapir, elephants, cattle, and even human beings have fallen into pitfall traps despite sign boards erected for the benefit of man (Abdullah 1987)!

Due to the dense nature of the rainforest environment and rare sighting of individual rhinoceroses therein, routine chemical capture techniques developed for Asian and African rhinoceros are too dangerous, as an animal may be lost in the darting process. Increasingly, however, animals are being pushed from the jungle by human encroachment, and once beyond the protective boundary of the forest, are immediately threatened. In these circumstances, pitfall capture methods are not feasible and chemical capture techniques are indicated. Therefore, the capture process for an “at-risk” Sumatran rhinoceros found wandering within a Southeast Asian village or otherwise outside a protected area should be approached with careful planning of some urgency. Once the appropriate National Park, Rhinoceros Protection Unit (RPU) and Sanctuary staff have been contacted, the following stepwise approach to capture and translocation is suggested (Radcliffe et al. 2004).

Guidelines for Capture of Displaced Sumatran Rhinoceroses

Secure Immediate Area In the event a wild Sumatran rhinoceros is found wandering outside a protected area, the first priority should be to secure the area from villagers and would-be poachers to prevent the animal from being shot or otherwise harmed before capture or relocation of the rhinoceros is possible.

Determine Relocation Strategy If possible, a small core-group of decision makers should be formed to make immediate assessment of the risks and benefits of rhinoceros relocation. If the rhinoceros were unharmed and close to a protected area (<10 km), then it may be desirable to move the rhinoceros without capture by pushing it back toward the forest. If the animal was injured or otherwise in need of medical attention or far (>10 km) from the forest, a decision should be made to capture the animal.

Make a Plan for Rhinoceros Capture Considering the high risks associated with capture by the “chase to exhaustion” method (i.e., rhinoceros is captured following an extensive stressful chase without the use of routine chemical capture methods), this approach

Figure 54.7. Diagrammatic sketch of pitfall capture method used in Indonesia's Riau Province for capture of wild Sumatran rhinoceros (*Dicerorhinus sumatrensis*) (sketches adapted from Sadmoko 1990; image courtesy of Mohd Khan bin Momin Khan, Malaysia Department of Wildlife and National Parks).

should only be attempted as a last resort (Fig. 54.8). The following are suggested guidelines and methodology for capture of at-risk Sumatran rhinoceroses outside a protected area.

Capture Method 1: Field Capture Using Chemical Restraint If a trained capture team is available (i.e., within 5 hours' travel time), then it may be wise to have the RPU ranger staff carefully monitor and secure the rhinoceros and surrounding area from a distance without pushing the animal to run as the rangers await the capture team. A rapid induction and recumbency will be essential for safe capture of a tropical ungulate species, such as the Sumatran rhinoceros, that may risk drowning or suffer from capture myopathy.

For field anesthesia of the Sumatran rhinoceros, a combination of equal parts butorphanol and azaperone (80mg each) is recommended for simplicity, and its inherent safety for both rhinoceros and people alike (Table 54.2; Radcliffe et al. 2004). However, if a well-trained veterinary capture team is available then use of more potent opioids, such as etorphine combined with azaperone and hyaluronidase (2mg, 80mg, and

Figure 54.8. Like the other rhinoceros species, the Sumatran rhinoceros (*Dicerorhinus sumatrensis*) is prone to capture myopathy. Here, a wild "hairy" rhinoceros is restrained with a girth rope in hopes of moving the animal into a temporary boma. Hyperthermia is best avoided by limiting chase periods and liberal application of water (image courtesy of Sugiyo, Wildlife Conservation Society, Indonesia Program).

5000IU, respectively) or the newer etorphine-butorphanol-midazolam protocols, may be considered depending on the situation (Bush et al. 2011). If the rhinoceros is already compromised from a chase or is restrained by a snare, the use of the safer butorphanol protocol is preferable to the potent opioids (Table 54.2). The butorphanol-azaperone combination may require confinement within a temporary boma or some additional restraint via a body or head rope to facilitate crating in healthy animals.

Capture Method 2: Field Capture by Erecting Temporary Boma The Sumatran rhinoceros is perhaps the only species of rhinoceros that can be captured by human physical restraint alone, albeit after much chasing and associated capture stress. Therefore, if a trained capture team is not available and the rhinoceros is in immediate peril, physical capture can be a feasible option. To begin, the animal can be followed from a safe distance and without excessive chasing until the rhinoceros is located within an area where it is resting and approachable (i.e., in water or other suitable location; Fig. 54.9). Large rolls of shade cloth or tarpaulin are then carefully erected without disturbance to form a temporary boma surrounding the rhinoceros that will facilitate sedation, crating, and transport. Once the animal is restricted

Figure 54.9. A wild Sumatran rhinoceros (*Dicerorhinus sumatrensis*) undergoing “hand translocation” without use of chemical restraint after displacement from a protected forest reserve in Indonesia. Although this animal survived significant capture-related morbidity, chemical capture techniques are preferred if trained staff are readily available (image courtesy of Chandra Putra, Way Kambas National Park, Sumatra).

within the confines of the “artificial boma,” hand-injection or pole-syringe delivery of the butorphanol-azaperone combination will facilitate safe crating and transfer. The boma method is not likely to eliminate the long chase periods and accompanying stress, but it was effective in the recent capture and relocation of a young adult Sumatran rhinoceros in Indonesia (Fig. 54.7).

RHINOCEROS CRATING AND TRANSPORT

The moving or translocation of rhinoceroses is a specialized branch of rhinoceros anesthesia that has been practiced since the first African rhinoceroses were saved from the rising waters of Lake Kariba. The crating and relocation of rhinoceroses is now standard practice as urgent conservation measures, including enhanced animal monitoring and protected area management, have become effective tools in the fight against poaching (Flamand et al. 1984; Henwood 1989; Hitchens et al. 1972).

Walking a Rhinoceros

If a crate cannot be placed directly in front of the anesthetized animal, the rhinoceros can be “walked” a distance and guided into the crate (Fig. 54.10 and Table 54.3). When the rhinoceros becomes recumbent, the blindfold, cotton wool, head rope, and brake rope are applied. Four to six people are stationed on each rope, two people on each shoulder, one person to the side leading the team and two people walking in front of the rhinoceros, clearing obstacles in its path. The rhinoceros is given small incremental doses of intravenous nalorphine or diprenorphine depending on species; doses vary, but as little as 20- to 25-mg nalorphine may be needed in total (Table 54.3; Kock et al. 2006). Alternatively, butorphanol can be given IV at 10 times the etorphine dose to walk a white rhinoceros into a crate. Regardless of antidote used, a prodder is

Figure 54.10. “Walking” an etorphine-immobilized white rhinoceros (*Ceratotherium simum*) using ropes and trained personnel to guide and stabilize the narcotized animal.

Table 54.3. Suggested opioid reversal protocols for walking, crate loading and transport of adult African rhinoceroses

Method	Use	Reversal Drug or Opioid	Technique for Crating or Translocation
Butorphanol or nalorphine walking and crating method	For opiate (M99) immobilized rhinoceros	<p><i>White rhino</i> <i>Walking:</i> 10- to 20-mg BT per mg M99 Add 1- to 2-mg M50:50 for adult bulls for walking or crating (Hofmeyr)</p> <p>OR</p> <p>1-mg M50:50 plus 20-mg nalorphine. Give further incremental 10–20mg Nalorphine IV up to 75 mg (Kock et al. 2006)</p> <p><i>Crating:</i> 10- to 20-mg BT per mg M99</p> <p>OR</p> <p>Diprenorphine (M50:50) at 2.4× etorphine dose IV. Add 1- to 2-mg naltrexone to prevent pushing in crate. Can combine the naltrexone with diprenorphine—expect a relatively lively wake up so be properly prepared with head rope, position of crate, and so on!</p> <p><i>Black rhino</i> <i>Walking:</i> Start with 5-mg nalorphine IV. Give incremental 5-mg doses every 5–10 minutes up to 20- to 40-mg (Kock et al. 2006)</p> <p><i>Crating:</i> 1.5-mg butorphanol IV per mg M99 with rhino's head in crate door (Hofmeyr) Add 1- to 2-mg M50:50 to preclude pushing</p> <p>OR</p> <p>10- to 20-mg nalorphine per mg etorphine. 1- to 2-mg M50:50 IV may be necessary to prevent pushing (Morkel)</p> <p>OR</p> <p>Blindfold with tight muslin cloth and wake up with 1- to 2-mg IV M50:50</p> <p><i>Avoid myopathy in crating process by ensuring rhino does not squat in crate; use prodder plus repeat 1- to 2-mg M50:50 or 5-mg butorphanol doses</i></p>	<p>Blindfold rhino; after cleaning eyes of mud or other debris, wrap a 4-m piece of muslin (mutton) cloth to cover eyes completely; attach three zip ties to secure muslin cloth forward of posterior horn. (Note: The blind fold option is really for black rhino and although it can be used on white rhino as well there is much less need for it.)</p> <ul style="list-style-type: none"> Position rhino's head close to or inside crate door: black rhino very important to have head in door—white rhino not critical; keep ears plugged until crated or leave in for transport Place <i>head rope</i>; use 20-m soft nylon behind posterior horn with knot on side of head passing rope end through hole in crate Place <i>break rope</i> on rear leg just below hock; use 8 meter nylon rope Position 8 people on head rope and 4 people on break rope. Can use a 4 × 4 pick-up truck for back-up on rope if not enough people for head rope <i>Reverse; wait</i> 90–120 seconds. Use electric prodder or water in ear to stimulate rhino to stand if does not do so by itself <i>Walk</i> rhino into crate by pulling on head rope, slow rhino with break rope, or go slowly with head rope; guide rhino by ground personnel; slide and secure pipes in crate (most crates have horizontal pipes, some only have the doors) If black rhino pushes in crate, give 1-mg naloxone or 0.6- to 1.2-mg diprenorphine iv; if white rhino pushes, give 1- to 2-mg naltrexone iv; use prodder on head or shoulders and not on hindquarters since rhino will tend to push/squat more with stimulation of hindquarters.

Butorphanol alone Crating method	For awake rhinoceros in zoo or boma environment	<p><i>White rhino</i>: 50-mg butorphanol IV (Radcliffe)</p> <p><i>Black rhino</i>: 25- to 500-mg butorphanol IV at time of crating for conditioned animals (Radcliffe)</p> <p>Boma black rhinos: Start with 10-mg Butorphanol IV and increase in 5 mg increments (Hofmeyr)</p> <p><i>White and black rhino</i></p> <p>10- to 15-mg Diazepam IV 10 minutes before “waking” rhino with reversal protocol (Morkel)</p> <p>Use standard crating methodologies earlier for white and black rhinos after giving diazepam</p>	<ul style="list-style-type: none"> • Butorphanol is a useful agent for crating and transport of crate-conditioned rhinos in zoological settings—combine with azaperone as needed • Butorphanol provides excellent sedation without concerns of excessive head pressing in crate and occlusion of nostrils in corner • No reversal required for butorphanol once rhino is in crate • Give diazepam to recumbent rhino and wait 10 minutes • Use same crating procedure as earlier using diprenorphine alone (white rhino) or nalorphine combined with diprenorphine (black rhino) • This protocol eliminates much of the pushing often observed in the crate following diprenorphine or nalorphine reversal procedures • Diazepam provides good sedation for ~8 hours especially in white rhino • Use low doses etorphine to crate rhinos from boma; combine with Azaperone in black rhino; wave white flag on pole to lure rhino into crate • Etorphine is the <i>only agent</i> to calm an excitable rhino inside a crate • Butorphanol is replacing nalorphine and diprenorphine for both respiratory support and arousal for crate loading in both white and black rhinoceros—use small incremental doses (5 mg or less) in black rhinos as reversal is more dramatic and produces a lively rhino • For crate sedation: Nalorphine sedation wears off ~5 hours post crating; thereafter give etorphine every 2 hours for duration of trip • If rhino is not excitable, give azaperone up to 200mg per 6 hours • <i>Note</i>: More etorphine is not effective within 3–4 hours of diprenorphine use and 8–24 hours following reversal with naltrexone • Avoid perphenazine in white rhino (if going to boma) as it causes anorexia; low dose OK if going straight to field
Diazepam:nalorphine Crating method	For field immobilized rhinoceros	<p><i>White rhino</i></p> <p><i>Boma crating</i>: 1- to 2.5-mg etorphine IM (higher dose for adult bull) plus butorphanol at 10X M99 dose plus 20-mg (subadult) or 40-mg (adult) azaperone</p> <p><i>Note</i>: Butorphanol can also be given at time of recumbency rather than in the original dart, particularly if rhino requires medical care or other procedures under recumbency (Buss)</p> <p><i>White or black rhino</i></p> <p>0.7- to 1.2-mg etorphine IM (Kock et al. 2006)</p> <p>OR</p> <p>0.3- and 0.5-mg M99 for black and white rhino, respectively, without need to reverse</p> <p><i>Crate sedation</i>: 0.05- to 0.15-mg etorphine IM plus 100- to 200-mg azaperone (can put in same syringe) IM or 10 to 30 mg diazepam IM (not in same syringe)</p> <p><i>Transport</i>: 50- to 150-mg zuclopenthixol acetate IM</p>	
Etorphine:azaperone Boma crating	For loading and transport of boma rhinos

judiciously applied to the feet just above the nail, or to the muzzle or perineal area to get the rhinoceros to stand and keep it moving. After each dose, wait a few minutes (up to 10 minutes) and check the rhinoceros's response to the prodder or by squirting water in the ear. If there is no response, give another dose of antagonist. Once the rhinoceros stands, it should begin to stagger forward and can then be readily guided with the head rope and by the people on the sides. If the rhinoceros moves too fast, go slowly with the head rope and pull the brake rope to slow the moving rhinoceros. Particularly with young and fractious individuals, it is important to slow the rhinoceros as it approaches the crate so it does not traumatize itself upon entrance. A rhinoceros that charges too quickly into the crate can strike the far wall with such force to avulse the horn or crush the nasal bones. To preclude problems with loading, 10- to 15-mg intravenous diazepam 10 minutes before waking the rhinoceros helps to keep animals calm when aroused in the crate.

Black Rhinoceros Crating

The recent decline in availability and manufacture of the partial agonist-antagonist nalorphine in southern Africa has necessitated use of alternative techniques for partial reversal and crating of black rhinoceros in the field. Initial trials using similar agents, such as nalbuphine and butorphanol, have worked (sometimes quite well), although they have also been associated with irregular outcomes and responses in the black rhinoceros. Nalbuphine provides a satisfactory partial reversal that facilitates crating of black rhinoceros, but appears to predispose crated animals to dog-sitting and squatting that can lead to serious myopathy and inability to stand (Fig. 54.11). Butorphanol given in higher doses

Figure 54.11. Posttranslocation myopathy in a black rhinoceros; capture complications are more prevalent in animals that experience excessive chase periods, hyperthermia, or struggle to stand upon crating (image courtesy of Birgit Kötting, Etosha Ecological Institute, Namibia).

(25–30 mg for an adult animal) also provides a reliable partial reversal for crating of black rhinoceros. However, such animals seem prone to head pressing in the crate and require constant supervision.

A novel approach to crating the black rhinoceros currently practiced in Namibia combines diprenorphine together with methods to limit noise and visual stimulus during transport. A muslin (mutton) cloth works well for both white and black rhinoceros (Fig. 54.3). Animals remain remarkably tranquil, although some degree of chemical tranquilization is still necessary. The beauty of blindfolding is that a physical rather than a chemical means is used to calm the animal. The cloth must be placed with great care to avoid damage to the eyes or loss of the blindfold during crate transport. One must brush or blow any dirt from around the eyes and flush the eyes with saline, if necessary. Tying the blindfold properly takes two people—the secret is to start with a 4-m length of muslin cloth and place the middle point on the forehead directly behind the back horn. Both ends of the cloth are pulled tightly on either side of the head, making sure both eyes are closed in a normal manner. The cloth is wrapped under the jaw around the opposite side behind the back horn where it is tied securely. While wrapping, the cloth should be “spread” to cover the eye properly and hooked behind the jaw. Three heavy-duty cable ties 40 cm in length are used to secure the blindfold to the rhinoceros. Two ties are threaded through holes in the cloth fashioned above and forward of the eye and closed to form a loop. A third cable tie is threaded through the two loops in front of the back horn and pulled tight. The cable ties serve to pull the cloth forward securely over the eyes. If the cloth becomes loose during the journey, simply pull on a cable tie to tighten the blindfold.

Reversal and crating is then routine: a heavy hemp rope is secured around the head with blindfold and threaded through the front of the crate. This rope will provide the forward pull upon standing and will direct the rhinoceros into the forward part of the crate. A second rope is secured to one rear leg and is used as a “break rope” to simultaneously slow the momentum of the rhinoceros so it does not collide with the front of the crate, where horn or nasal trauma may result. A relatively high dose of diprenorphine (black rhinoceros adult, 1.5–2 mg; subadult, 1 mg) is given intravenously after positioning immediately in front of the crate door. Two minutes are allowed to pass while all staff is quiet and the animal undisturbed. Upon standing, the rhinoceros is pulled forward into the crate while the break rope on the back leg slows the rhinoceros. Once inside the crate, the rhinoceros is secured by sliding three pipes into place at the rear of the crate and the rear doors closed. This protocol consistently produces a lively and relatively awake rhinoceros inside the crate that remains calm because of the combined use of a secure blindfold and earplugs.

Rhinoceroses blindfolded with muslin cloth travel well and can be given other sedatives, including azaperone (60–100 mg) or additional opioids (etorphine or butorphanol) during transport as needed. From about 4 hours onward, an additional 0.05- to 0.1-mg etorphine (usually with about 60 mg azaperone) is administered, and is usually repeated every 2 hours. The veterinarian (or someone with a high level of experience with opiates) must remain with the animal for the entire trip to evaluate and top-up as needed. “Straightening” with a prodder applied lightly to the forehead, neck, or shoulder is often necessary in the first few hours. The mutton-cloth can be kept on for as much as 36 hours. It is essential to put the cloth on tightly and to make sure it is 100% clean and that no sand or dirt gets into the rhinoceros’s eyes.

The beauty of the tight blindfold and blocked ears is that you can wake up the rhinoceros to a large degree (and therefore prevent pushing), but because the animal can’t see or hear, it is very unresponsive and rarely gets excited—the effect is quite remarkable. However, the muslin cloth blindfold is inadequate by itself for crate transport, and additional tranquilization using repeated ultra low doses of etorphine and azaperone is essential along the road.

Tranquilization during Transport

All black rhinoceros require tranquilization during transport (even most crate-conditioned animals) to preclude excessive struggle and associated trauma (Table 54.3). Other rhinoceros species tolerate transport better than black rhinoceroses, but still often benefit from some sedation. The veterinarian must always travel with the rhinoceros and be prepared to give additional sedatives or even narcotics if needed. It is imperative that the veterinarian anticipates the animal’s tranquilization needs as waiting until the rhinoceros is alert and bouncing around, will risk unnecessary trauma to both animal and attendant. Additionally, a cool animal is generally more relaxed than an overheated one.

Rhinoceroses settle into the rhythm of transport quite well after just a few hours. However, as the short-acting tranquilizers begin to wear off, the animal may become excited if suddenly startled (i.e., from stopping, off-loading, etc.). The rhinoceros can be redosed with tranquilizers while the vehicle is in motion or alternatively, stop, inject, and start moving again immediately. In most instances, hand-injection is the best method to deliver additional tranquilizer. A 20-gauge, 1.5-in needle is inserted into the lateral muscles of the neck while avoiding the nuchal region. Beware of the head and horn during neck injections. For restless individuals, the gluteal region also works well. Once the rhinoceros has settled, attach the syringe and inject the drug. A pole-syringe can also be used, but hand injection is preferred because it precludes the startled response resulting from the jab of the pole. Beware of

coring where the rhinoceros’s skin may block the needle lumen. An intramuscular injection takes 5–10 minutes for first effect; for a faster response, an intravenous injection into the ear vein is sometimes possible, although care must be taken to avoid the dangerous area around the animal’s head and horn.

Resting by the rhinoceros during transport can be beneficial or a potential problem, depending on the rhinoceros’s position and duration of recumbency. If the rhinoceros lies down while the vehicle is moving, the rocking and bouncing action of the truck helps to facilitate limb circulation. Beware, however, if the rhinoceros lies down for a long period (>60 minutes) in a stationary vehicle, unless you are very comfortable with its position. Rhinoceroses heavily sedated with opioids often struggle to work out a way to lie down; however, if they manage to do it once, they will lie down more easily thereafter.

Short-acting tranquilizers, such as azaperone, xylazine or detomidine, and diazepam or midazolam, are useful agents to produce a calming effect in rhinoceroses during transport. Azaperone is the tranquilizing agent of choice at 100–250 mg per adult and can be repeated every six hours as needed (Kock et al. 2006; Rogers 1993a, 1993b). A forty mg per mL azaperone solution is a convenient preparation and mixes well with etorphine for intramuscular administration to a fractious, crated rhinoceros. The administration of opioids, either alone or in combination with intramuscular azaperone or diazepam, is the only effective way to preclude an excited black rhinoceros from traumatizing itself inside a crate (Table 54.3). Etorphine and azaperone (0.05–0.15 mg and 100–200 mg, respectively) are delivered by hand injection or pole-syringe with sedation achieved in 5–10 minutes for durations of 2 hours or more.

Long-acting tranquilizers can help to calm an animal, however, are inadequate by themselves to sedate an excited animal during transport. Zuclopenthixol acetate (Clopixol Acuphase; 25–150 mg per adult rhinoceros up to 400 mg) takes about an hour to provide sedative effects after administration, while perphenazine enanthate (Trilafon; 200–400 mg per adult) takes about 12 hours for first noticeable effects (Kock et al. 2006; Swan 1993; Table 54.3). Perphenazine works well for the translocation of black rhinoceros while caution should be exercised in white rhinoceros as its use has been implicated in anorexia (Kock et al. 2006; Portas 2004).

Black Rhinoceros Off-Loading from Crate

Black rhinoceros, and especially juveniles and subadults, are notorious for being aggressive and sometimes even self-destructive to themselves and the crating equipment (trucks, crates, etc.) at offloading sites. In Namibia, where rhinoceros are often moved from veldt to veldt without the use of bomas and

adaptation periods, the capture team uses a technique for off-loading that is effective and largely eliminates the aggressive phase. At the off-loading site, the rhinoceros is resedated inside the crate using a low dose of etorphine (adult, 0.1–0.2 mg) combined with azaperone (adult, 80–120 mg) and allowed to narcotize over a several minute period. Once the rhinoceros is head pressing or otherwise sedated, the muslin blindfold and earplugs are removed and the etorphine antagonist administered. A standard dose of 12–18 mg of diprenorphine for an adult animal is administered by intramuscular (not IV) injection and the crate doors are opened. As the rhinoceros regains first levels of awareness, it walks slowly from the crate even while still sedated and partially narcotized. These black rhinoceroses tend to walk directly away from the crate and into the veldt without the characteristic aggression and attack of the crate or related equipment. As the animal continues to walk away from the off-loading site, it becomes more fully aware of its surroundings and ambulates from the site in a normal fashion. This protocol has largely eliminated the aggression and self-trauma that is often characteristic of black rhinoceros at off-loading.

ALTERNATIVE RHINOCEROS ANESTHESIA TECHNIQUES

Antidote Choice

Following intravenous antidote administration, a rhinoceros will stand within 60–80 seconds. Response to the antidote is first noted as an increase in the depth and rate of respiration and movement of the ears and eyes. Rhinoceroses get to their feet quickly and are immediately strong and aggressive. A rhinoceros should always be moved into sternal recumbency before giving the antidote or it may *bash* its head on the ground as it attempts to rise from the lateral position. Intramuscular dosing of the antidote is often preferred for arousal of rhinoceros cow–calf combinations so that the pair awake slowly and have time to join together without dashing off in opposite directions. If intravenous dosing is desired with recovery of cow–calf pairs, the cow is injected first, thirty seconds before the calf.

Out of tradition, opioid antagonists are dosed using empirically derived ratios rather than on a mg per kg basis; for the pure opioid antagonist, naltrexone, dosage ratios of 20–50 times the etorphine mg dose and 90–100 times the carfentanil mg dose are considered standard for captive rhinoceros (Allen 1996; Kock et al. 2006; Swan 1993). Renarcotization has been reported in the white rhinoceros, but it is a rare occurrence in the black rhinoceros (Kock et al. 1990; Portas 2004). Field workers frequently use lower naltrexone doses (12.5:1 naltrexone to etorphine ratio) without a problem (Kock et al. 1995); however, sedative signs at these doses have been reported in white rhinoceroses and a minimum of 40:1 is therefore recommended to preclude renarcotization

(Kock et al. 1995; Portas 2004; Rogers 1993a). While naltrexone is considered the agent of choice for complete reversal of narcotic anesthesia, a number of scenarios arise under both captive and field conditions where a full reversal of an opioid-based procedure is undesirable.

The choice of antagonist and its desired action is dependent on two factors: species and location. Black rhinoceros are reversed into a crate with nalorphine, nalbuphine, or butorphanol, alone or in combination (Kock et al. 2006; Radcliffe & Morkel 2007: Table 54.2 and Table 54.3). In the boma, *Diceros bicornis* are reversed with naltrexone, although very nervous or aggressive individuals may benefit from reversal with diprenorphine for its sedative properties. *Diceros bicornis* are completely reversed in the field using naltrexone; however, because it is expensive, a combination of naltrexone and diprenorphine is often used for field reversal. In this case, the standard diprenorphine dose (2–2.5 times the etorphine dose; Swan 1993) is administered by intramuscular injection together with 50–100 mg of naltrexone.

In marked contrast to black rhinoceroses, white rhinoceroses are reversed into a crate using diprenorphine, with perhaps 1–2 mg of naltrexone. In the boma and in the field, *Ceratotherium simum* are similarly reversed with naltrexone. Diprenorphine is often used for translocation of *Ceratotherium simum*, since its partial agonist-antagonist actions provide significant narcosis during travel. However, diprenorphine has minimal agonist effects in *Diceros bicornis* and therefore should be used judiciously for transport in this species. For any partial antagonism in a crate situation, it is critical that the rhinoceros be monitored very carefully to prevent excessive head pressing and occlusion of the airway or damage to the neck and limbs. A cattle prod is a vital piece of equipment in managing sedated rhinoceroses during travel.

Other Drugs and Immobilization Doses

Rhinoceros can also be immobilized with the other potent opioids carfentanil, fentanyl and thiafentanil. The following drug dosages are indicated for adult free-ranging rhinoceroses in good condition:

- Carfentanil at 1–1.2 and 0.9 mg (captive adult white and black rhinoceros, respectively; Portas 2004; Rogers 1993a) and 3 mg for wild adult rhinoceros (De Vos 1978; Hofmeyr et al. 1975). Carfentanil produces a quick induction and it is not necessary to combine with azaperone or xylazine.
- Etorphine at 1.8-mg plus 30-mg fentanyl (black rhinoceros; Kock et al. 2006; Rogers 1993b).
- Fentanyl alone at 60 mg (black rhinoceros; Rogers 1993b).
- Thiafentanil can be mixed equally with etorphine. The adult rhinoceros dose is 2- to 2.5-mg thiafentanil

plus 2- to 2.5-mg etorphine. This mixture gives a faster induction time than etorphine alone. The usual antidotes for etorphine work well.

Rhinoceros Anesthesia Complications

With opioid-induced cardiopulmonary depression common in anesthetized rhinoceros, the need may arise to deliver artificial ventilation. For emergency respiratory support in a rhinoceros, the animal is first pushed onto its side. A large person forces the knee and lower leg (with foot placed firmly on the ground) into the abdomen to vigorously force the abdomen diagonally upward and forward against the diaphragm. This moves the diaphragm, forcing air into and out of the lungs and keeps the animal alive while the intravenous opioid antagonist takes effect. When one leg is tired, use the other leg and recruit additional people to assist. Jumping on the ribs or back of the rhinoceros is ineffective and does nothing but fracture ribs and inflict unnecessary trauma.

Myopathies are common in rhinoceros that experience excessive chase periods or hyperthermia during capture. An especially critical period occurs at the time of crate loading and initial transport during field translocation of rhinoceroses. If stimulated to rise too early after partial reversal, animals may enter the crate and assume a rigid, semi-squatting position with their hind legs. This is undesirable and must be resolved quickly before the muscles are irreversibly damaged (Fig. 54.11). Use of the electric prod on the head can often stimulate the animal to rise and stand, but avoid prodding the hindquarters as this can exacerbate the problem. If this does not work, consider prompt intravenous administration of diprenorphine or nalorphine. A sling can also be placed under the belly of the animal, just in front of the rear legs to lift the hindquarters (using the crane on the recovery truck) until the strength has returned to the hind limbs.

A very small percentage of black rhinoceros develop an adverse reaction that the author refers to as the “fat nose syndrome” (Radcliffe & Morkel 2007). Essentially, the nostrils close up and appear edematous with a much-reduced opening to the nares. The anesthetist is often forced to hold open or pull the nostrils apart. This unusual response may indicate a hypersensitivity reaction; morphine is known to cause histamine release in humans and, perhaps etorphine—derived from the same group of opium alkaloids—can produce the same uncommon effect in susceptible rhinoceroses.

New Field Anesthesia Techniques

Today’s understanding of Rhinocerotidae anesthesia is truly the embodiment of many courageous pioneers who have led by exciting experimentation and hard-won experience (Harthoorn & Lock 1960; Kock et al. 2006; Player 1972; Young 1973). Yet with the immense challenges inherent in practical anesthesia of these

complex mammals, innovative procedures are welcome. The newest ideas for rhinoceros anesthesia are arising from a combination of practical experience and a desire to explore the depths of pharmacology. Nowhere are such explorations more exciting than the emerging science of mixed opioid receptor action on central nervous system activity (Chindalore et al. 2005). Various opioid receptor affinities and their pharmacologic action are well described in humans but remain little understood in animals—including the rhinoceros—which is certain to be unique in many respects. Indeed, the most exciting of these novel investigations is, at least for rhinoceros capture specialists, the incorporation of mixed agonist-antagonist opioid cocktails as part of routine field capture methodologies for the African rhinoceros (Bush et al. 2005).

Recent work by Bush and colleagues in white rhinoceroses combines a mixture of concentrated butorphanol (40–90 mg; 30-mg/mL solution) with etorphine and midazolam (2–3.5 mg and 25–50 mg, respectively; Table 54.2; Bush et al. 2005, 2011). The addition of butorphanol to the anesthetic combination of etorphine and midazolam produces enhanced muscle relaxation and oxygenation with improved physiological parameters compared with the standard protocol of etorphine and azaperone in the white rhinoceros. Butorphanol is a mixed opioid agonist-antagonist; its agonist κ receptor produces analgesia and marked sedation, while the weak μ receptor antagonism reduces respiratory depression and rigidity. The weak σ (non-opioid) receptor agonist stimulates respiratory drive. Etorphine is a μ agonist causing respiratory depression and muscle rigidity—these adverse μ agonist actions are reversed by butorphanol and significantly reduce the cardiopulmonary depression typical of the pure opioids alone. In black rhinoceroses, the butorphanol antagonism of μ -opiate actions will result in a lively rhinoceros not suitable for handling without additional sedation.

Besides the marked improvement in oxygen saturation, there is a decrease in heart rate closer to normal, making the heart a more effective pump. Blood gas values reveal a more normal pH and PCO_2 , while blood pressures remain lower than with the standard pure opioid agonist protocols. Administering diprenorphine, a μ antagonist, intravenously 12 minutes into the anesthetic episode reverses etorphine, but not butorphanol, further counteracting adverse μ effects of etorphine while preserving butorphanol sedation effects. Therefore, if inadvertent opioid overdosage should occur, compromised physiological parameters can be rapidly corrected without losing control of the animal. These discoveries may help to bring field rhinoceros capture into the realm of safety realized with captive animals where butorphanol-based protocols are now standard replacements for more potent opioids (Portas 2004; Radcliffe et al. 2000a).

RHINOCEROS CALF ANESTHESIA

Captive Calf Protocols

Anesthesia of captive white and black rhinoceros calves is safely accomplished with butorphanol alone or in combination with detomidine (Gandolf et al. 2006; Langan et al. 2001; Radcliffe et al. 2000c). Due to high sensitivity to opioid agents, rhinoceros calves respond very well to sedation and anesthesia with mixed agonist-antagonists, precluding many of the adverse cardiopulmonary depressant effects observed with more potent pure agonists of this class. Furthermore, a rapid onset of action is attained by intravenous delivery or a slower induction by intramuscular administration, with both methods proving safe and effective for serial anesthesia (Gandolf et al. 2006; Table 54.4). The combination of the alpha-2 agonist, detomidine, along with the butorphanol was thought to enhance muscle relaxation and depth of anesthesia with intramuscular use in white rhinoceros calves. Complete reversal is achieved using naltrexone at four to five times the butorphanol mg dose and yohimbine HCl (Yobine) or atipamezole at 0.125 mg/kg for antagonism of the alpha-2 agent.

Cow and Calf Field Capture

Field immobilization of juvenile rhinoceros is not without inherent risk as calves may separate from their dams after darting or become recumbent at different times despite concurrent drug delivery (Fig. 54.12). Additionally, calves are more susceptible to capture stress, hyperthermia, and postcapture morbidity and mortality in boma situations (Kock et al. 1995). Translocation of cows with calves less than 18 months of age can be traumatic and is best avoided, while movement of very young calves 2–3 months old is particularly high risk. Even with successful translocation, it can be difficult to reunite the cow and calf as the stress of capture and confinement often results in adult aggression directed toward the calf or the cow drying up. Methods for opioid sedation (0.2- and 0.05-mg etorphine for a cow and calf, respectively) have been used to facilitate boma reintroduction of cow-calf combinations (Kock et al. 2006). The wild black rhinoceros cow is solitary by nature and usually retreats to a quiet spot to calve and will stay there for the first month afterwards. Therefore, if a black rhinoceros gives birth in a boma, she rarely manages to raise the calf.

Opioid doses lower than those reported for adult animals are utilized for juvenile rhinoceros, with subadults receiving approximately one-half the adult dose. For example, when combined with a tranquilizer subadult African rhinoceros (age ~2.5 years) should receive 1.75- to 2-mg etorphine while very young calves (age 2–3 months) can be immobilized with as little as 0.5–1 mg etorphine (Rogers 1993a, 1993b; Table 54.4). A marked difference is observed in the escape behavior

of African rhinoceros cow-calf pairs and should be anticipated during the chase and capture. White rhinoceros calves run ahead of their mothers while black rhinoceros calves run close at their mothers' heels (Kock et al. 2006).

When darting a cow with a calf from a helicopter, a fixed-wing aircraft is desirable to circle the capture site to assist with spotting. As a general rule, the cow is darted first, and about a minute, later the calf is darted (Kock et al. 2006). If the timing and darting are good, the pair will often go down together. Should the pair split up, the fixed-wing aircraft can stay with one animal. In open country where visibility is good, the calf can be darted once the cow shows early signs of narcosis. In more thickly vegetated country, where it is difficult to observe two separated animals, it is better to wait until the cow shows marked effects or is even recumbent before darting the calf. If the calf splits from its mother, the position of the immobilized mother can be taken by GPS or marked with a smoke grenade or toilet paper and the calf followed. Losing sight of a darted rhinoceros must be avoided, and it is therefore mandatory to have experienced trackers as part of the ground team. When darting a cow-calf pair on foot, the calf will usually stay close to its immobilized mother. If approached carefully, the calf can be darted and will generally become recumbent close to its mother; note that black rhinoceros calves are skittish and run off more easily than white rhinoceros calves.

Wild subadult greater one-horned rhinoceroses have been immobilized using the same dosage as adult animals (2- to 2.5-mg etorphine plus 10-mg acepromazine; Dinerstein et al. 1990). However, subadult animals proved more difficult to capture and often evaded darting attempts by outrunning the trained elephants that are commonly utilized for field immobilization of greater one-horned rhinoceroses in the tall grassland habitats of India and Nepal. Indian rhinoceros calves were immobilized with 0.5- to 1-mg etorphine and 5-mg acepromazine using shorter 2.5-cm Cap-Chur needles. As with capture of African rhinoceros cow-calf pairs, it is recommended that greater one-horned cows be immobilized before their calves. Calves did not run away and were easier to capture if the mother was immobilized first to avoid trampling risk to calves or aggression toward the ground crew (Dinerstein et al. 1990).

Conclusion

During the Indian Mutiny, a British soldier fired a bullet into the regiment's cherished mascot, a rhinoceros. In a spirit of scientific inquiry, the soldier tested the long-held belief—a conviction still strongly held by many since Durer's famous rhinoceros—that its skin was held together with rivets like a knight's armor and impenetrable to any volley man could throw its way.

Table 54.4. Suggested doses for immobilization and anesthesia of rhinoceros calves in both *captive* and *wild* environments

Captive Calves		Wild Calves	
Rhino Species	Protocol	Reversal	Reference and Comments
White rhinoceros	10- to 20-mg butorphanol (BT) IV for 66- to 159-kg calf (Dose 0.13–0.15 mg/kg IV)	Naltrexone at 5 mg per mg BT	Gandolf et al. (2006) Heavy sedation Light anesthesia Mild resedation noted 8 hours post-reversal in one calf
	2.5- to 5-mg butorphanol + 1.5- to 1.8-mg detomidine (DEF) IM for 69–122-kg calf (Dose 0.03 mg/kg BT plus 0.07 mg/kg DEF)	Naltrexone at 4 mg per mg BT Yohimbine at 0.125 mg/kg	Gandolf et al. (2006) Surgical anesthesia
Black rhinoceros	25-mg butorphanol IV for ~500-kg subadult calf	Naltrexone at 5 mg per mg BT	Radcliffe et al. (2000c) Heavy standing sedation
Greater one-horned rhinoceros	Butorphanol IV or IM Use white rhino as model	Naltrexone at 5 mg per mg BT	Author suggestion based on use in African rhino calves

Figure 54.12. Anesthesia of rhinoceros calves is challenging, particularly under field conditions where darting of the cow–calf pair must be well coordinated in order to limit stress on both parent and offspring.

To the surprise of royalty and commoners alike, the rhinoceros quickly expired.

The future of the world's rhinoceroses will remain tenuous as human conflicts over shared resources escalate and rhinoceros horn continues to be cherished by traditional Asian societies for supposed unicorn-like mythical properties. Nevertheless, it is comforting to know that man—while solely responsible for the current crisis—is also simultaneously making strides to save the relic rhinocerotoids from their greatest enemy, ourselves. Safe anesthesia of wild and captive rhinoceroses alike will help scientists realize these conservation goals. Let us not make the same mistake as the British soldier and believe, naïvely, that the *armored* rhinoceros is invincible to the actions of our kind.

Practical Strategies for Rhinoceros Field Anesthesia

- Darts should be tested and prepared ahead of time leaving only the drug loading process to complete immediately prior to capture. Load the dart once you have visualized the rhinoceros—tailoring the dose for size, age, and condition of the animal. The rhinoceros should not be chased while the dart is being loaded. When darting from a helicopter, get the dart in quickly and back off until drugs considerably affect the rhinoceros.
- Dart sites must be given special care in rhinoceroses because of the propensity for abscess formation. Rhinoceros skin is thick and tough, making drainage of subcutaneous infections unlikely without appropriate wound care. Intramammary antibiotic preparations are common; however, the authors prefer infusion of 500-mg oxytetracycline directly into the dart wound. Oxytetracycline is a broad-spectrum antibiotic in high concentration, stable at room temperatures, viscous (does not easily run back out of wound) and readily available.
- Tranquilizers are often combined with potent opioids to improve muscle relaxation in recumbent animals and to help sedate and calm the rhinoceros during transport.
- The addition of hyaluronidase, a hydrolytic enzyme that increases tissue permeability, greatly improves drug absorption and can markedly shorten the induction time.
- A lower opioid dose must be used for rhinoceroses that are in bomas, debilitated, old, or where you cannot get to the immobilized animal quickly (e.g., when darting on foot). *Be very careful with animals in poor body condition.* In most other situations, underdosing of opioids is contraindicated for free-range capture of rhinoceroses.
- In general, any need for repeat darting of animals following partial or incomplete injection of immobilizing agents should redeliver the original full immobilizing dose. This is a useful rule for captive animals as well since repeat darting is often associated with excitation and prolonged drug effects if titration is attempted.
- A rapid induction shortens the period the rhinoceros is moving in a semi-narcotized state and thereby lessens the chance that the rhinoceros will injure itself by encountering a hazard. This is especially true when immobilizing rhinoceroses in rough terrain. A quick induction also limits the exertion and the physiological stress associated with increased body temperature, heart rate, oxygen consumption, and related physiologic changes. Caution must be used, however, as very rapid induction times are often associated with marked respiratory depression, especially in the more susceptible white rhinoceros.
- *Nalorphine (Nr)*, *nalbuphine (Nb)*, and *butorphanol (B)* are useful in African rhinoceros (Table 54.2 and Table 54.3):
 - To improve respiration, give 5-mg *Nr* IV for black rhinoceros and 20- to 30-mg *Nr* for white rhinoc-

eros. Black rhinoceroses are very sensitive to *Nr* and *B*, so administer small incremental 5 mg doses given intravenously to effect. *Nb* and *B* may be used at approximately twice the *Nr* dose (20–40 mg) in a similar fashion for improving respiration in the white rhinoceros.

- To walk a rhinoceros, start with 10-mg *Nr* IV in black rhinoceros up to a total dosage of 20- to 40-mg *Nr* in 5 mg increments. For white rhinoceros standard practice is now to give *B* at 10× (up to 20×) the etorphine (M99) dose (10- to 20-mg *B* per mg M99). *B* can be incorporated into the initial dart or given at the time of loading. Others

give 1-mg diprenorphine plus 20-mg *Nr* IV followed by small incremental doses of 10- to 20-mg *Nr* up to 75 mg.

- For transport, wake the black rhinoceros up into the crate with 10–20 mg of *Nr* IV per 1 mg of M99. May also need to give 1- to 2-mg diprenorphine IV if animal is pushing or collapsing in crate. Wake white rhinoceros with 10 to 20 mg of *B* per mg M99 or give diprenorphine at 2.4 times M99 dose (generally a “lively” wake up). Can also give 1–2 mg of naltrexone with diprenorphine or later in transport to prevent pushing in crate.

Nondomestic Suids

Luis R. Padilla and Jeff C. Ko

INTRODUCTION

A large amount of information has been published on anesthesia and immobilization techniques of domestic swine. In contrast, studies pertaining to anesthesia of free-ranging or nondomestic suid species are limited in the documentation of physiological responses to anesthetic drugs, focusing instead on efficacy, induction and recovery times, and subjective descriptions of anesthetic quality. The domestic pig is still the most appropriate physiological model for anesthesia of other species, but readers seeking protocols for anesthesia of captive domestic pigs are referred to specific literature reviews on the subject (Swindle 1998; Thurmon & Smith 2007). We have included specific comments on Vietnamese potbellied pigs, since these are common exhibit animals in zoological institutions.

TAXONOMY

The suborder Suiformes includes the families Suidae and Tayassuidae, which encompass all pigs, hogs, babirusa, and peccaries. The generic term “suid” is commonly used to refer to members of both families. Table 55.1 is a list of known suid species, and adult weight ranges have been listed where available. The family Suidae includes pigs, hogs, and babirusa, and total 14 species in 5 genera. The Eurasian wild boar (*Sus scrofa*) is the wild ancestor of the domestic pig. Numerous breeds of the domestic pig (*Sus scrofa*) exist, and in many places, feral populations have been established in a free-ranging state, blurring the distinction between wild boar and domestic pig. The family Tayassuidae includes the peccaries or javelinas, currently found in three genera with one species each. A third family in the suborder Suiformes, Hippopotamidae, is the subject of a separate chapter in this book.

The main anatomical differences between the Tayassuidae and Suidae families are in dentition, tail length, hind limb anatomy, and the presence of a scent gland dorsally in the lumbosacral region in peccaries. Sexual size dimorphism is more prominent in the Suidae than the Tayassuidae. The babirusa (*Babirusa babirusa*) has distinct features from the other members of the Suidae family, including a complex, sacculated stomach suggestive of foregut fermentation (Leus et al. 1999), and remarkable canines in the males.

GENERAL CONSIDERATIONS OF SUID BIOLOGY AND PHYSIOLOGY

All suids can be dangerous animals when approached. Most species have powerful jaws with sharp dentition, and individuals can be extremely fast and capable of inflicting severe wounds on humans. Canines grow as sharp tusks in many species, which is accentuated in males of the Suidae family. In addition, the short, strong limbs and a muscular neck, limit the possibility of physical restraint to juveniles or very small individuals. Many individuals will fight aggressively when cornered or restrained, and sows can be very protective of their offspring. Suids can be capable climbers and agile jumpers that can escape from many situations or evade restraint.

Physiological or social stress should be minimized prior to anesthetic induction in order to achieve the desired results. Gregarious, social individuals are likely to be highly stressed if isolated prior to anesthesia. If prolonged isolation is necessary, stress can be decreased by allowing visual contact between group mates. During anesthetic induction, it is preferable to isolate the target animal from the rest of a group to minimize the risk of inadvertent trauma or misdirected aggression from companions.

Table 55.1. Species of suids by family and weight ranges

Species	Adult Weight	Common Name	Comments
Family Suidae			"True" pigs
<i>Sus scrofa</i>	40–300kg	Eurasian wild boar	Domesticated into farmed pigs, many wild "races" exist
<i>Sus salvanus</i>	32–100kg	Vietnamese potbellied pig	Breed of domestic pig, commonly seen in zoos
<i>Sus bucculentus</i>	6–10kg	Pygmy hog	
<i>Sus verrucosus</i>	35–185kg	Vietnamese warty pig	
<i>Sus barbatus</i>	35–185kg	Javan warty pig	
<i>Sus philippensis</i>	100–200kg	Bearded pig	Three subspecies are recognized, although at least one may be a full species.
<i>Sus philippensis</i>		Philippine warty pig	
<i>Sus cebifrons</i>	20 – 80kg	Visayan warty pig	
<i>Sus celebensis</i>	40–70kg	Sulawesi warty pig	
<i>Potamochoerus porcus</i>	45–120kg	Red river hog	
<i>Potamochoerus larvatus</i>	50–115kg	African bush pig	
<i>Hylochoerus meinertzhageni</i>	100–275kg	Giant forest hog	
<i>Phacochoerus africanus</i>	50–150kg	Common warthog	
<i>Phacochoerus aethiopicus</i>	45–140kg	Desert warthog	
<i>Babirusa babyrussa</i>	40–100kg	Babirusa	
Family Tayassuidae			Peccaries or Javelinas
<i>Catagonus wagneri</i>	30–45kg	Chacoan peccary	
<i>Tayassu (Pecari) tajacu</i>	15–35kg	Collared peccary	
<i>Tayassu pecari</i>	25–40kg	White-lipped peccary	

Domestic pigs should be fasted for 24 hours (Moon & Smith 1996), and nondomestic suids should be fasted for 12–18 hours (Calle & Morris 1999) or longer. In addition to being at risk for vomiting and aspiration, inadequately fasted pigs are prone to gastric distension, which may physically compromise ventilation by altering pleural pressure and chest wall mechanics (Mutoh et al. 1991). When food is withheld, suids may consume other things accessible to them, including shavings, bedding material, or ground and wall substrates.

Suid skin is tough, tight, and not very pliable, and contains a significant subcutaneous adipose tissue layer. Areas with thick fat deposits are less desirable for reliable injections, as administration into the adipose tissue layers will result in variable or altered responses when compared to true intramuscular injections, which should not be mistaken for decreased drug efficacy or variable species susceptibility. The amount and distribution of fat varies with age, between species, subspecies, and breeds. Injection into leaner muscle masses, such as the semimembranosus, semitendinosus, or the dorsal prescapular muscle mass (Calle & Morris 1999), will result in more predictable effects. The choice of needle length is crucial to obtaining deep muscle injections, and a minimum length of 1.5 in (3.8 cm) is suggested to assure intramuscular placement in adult animals.

Suids are prone to hyperthermia. All species have a relatively low surface area in a proportionately large-volume body with a significant layer of subcutaneous body fat, and limited sweating capabilities for heat dissipation. Physical excitement or increased exertional activity prior to successful immobilization may result in muscular heat generation and elevations in core

body temperature. Severe elevations in body temperature can be treated by cooling the skin surface with alcohol baths or placing ice packs around large vessels (Moon & Smith 1996), using cool intravenous fluids, or, in extreme cases, using cold water enemas. Close temperature monitoring and good clinical judgment must be used to prevent overtly aggressive rapid cooling and hypothermia.

Although hyperthermia can occur in any suid species, the syndrome known as malignant hyperthermia only occurs in domestic swine. The malignant hyperthermia syndrome of swine is a well-documented, autosomal recessive condition of domestic pigs resulting in abnormal skeletal muscle function due to defective calcium handling (Moon & Smith 1996). Large white breeds of domestic swine are considered most susceptible, but it can occur in any breed or mixed-breed individual, including miniature pot-bellied pigs (Claxton-Gill et al. 1993). Manifestations of hyperthermia and muscle rigidity can be induced by stress, elevated ambient temperatures, inhalant and injectable anesthetics, paralytic agents, and other drugs. The body temperature of affected pigs can increase as high as 110°F (43.3°C) (Moon & Smith 1996), and muscle rigidity, tachycardia, tachypnea, hypoxemia, and cardiac arrhythmias can develop. Serum chemistries may show elevations in potassium, ionized calcium, myoglobin, and creatine kinase. Clinicians suspecting this condition should immediately institute supportive symptomatic therapy and discontinue inhalant anesthetics. Dantrolene is an effective treatment for this condition (Gronert 1980), and can be used prophylactically in pigs considered at risk. Azumolene, a dantrolene analog, has greater water solubility, and may be a more practical

treatment option (Dershwitz & Sréter 1990). Other drugs that cause muscle relaxation might be used in managing hyperthermia by reducing continued muscle activity.

Neonatal suids are prone to hypothermia during the first few days after birth. Managers should provide supplemental heat sources and protection from environmental temperature fluctuations. Sows, in particular inexperienced ones, should be monitored to ensure adequate maternal care is provided, and that denning sites are safe for the piglets.

TRAPPING AND PHYSICAL RESTRAINT

Manual restraint of nondomestic suids should be reserved for juveniles or small domesticated individuals. Juvenile suids and small pigs can be restrained with one hand under the sternum and one hand over the back. The handler should anticipate that loud vocalizations may occur in response to physical restraint and manipulations. Prolonged or rough handling should be avoided, especially during hot weather, as it can result in hyperthermia. Juvenile and neonates may vocalize and struggle to the point of exhaustion and collapse during prolonged or strenuous restraint.

The use of snares, ropes, and similar physical restraint devices used in domestic swine production is not generally recommended in nondomestic suid species due to the high probability of injury to restrainer or animal, but can be done by experienced personnel. A description of translocations of collared peccaries detailed the use of a pole snare loop placed behind the upper canines and drawn tight while a second person physically restrained the hind legs (Porter 2006). This restraint was sufficient for placing ear tags and loading onto a trailer for relocation.

A variety of net restraint devices have been designed for domestic swine restraint, and have been modified for the capture of free-ranging suids. Warthogs have been captured using a funnel-shaped net set at the entrance of their sleeping burrows, occasionally resulting in the capture of multiple individuals as they emerge (Cumming 1975). Modified deer traps, "box traps," and corral traps have been used for capturing free-ranging suids with variable rates of success.

VASCULAR ACCESS

The subcutaneous adipose tissue layer and the tight skin of most suids can make vascular access a challenging task. Sedation or anesthesia should be used to facilitate blood collection in nondomestic species, except in very small individuals. Blood can be collected from the jugular, femoral, cephalic, saphenous, tail (coccygeal), and auricular veins. Catheter placement is possible in the cephalic, saphenous, and auricular veins. Although other sites are described in this section, they are not

recommended in most situations due to inherent technique risks.

Blood collection from the femoral vein can be done in most species, although the amount of adipose tissue and thick muscle mass can make it difficult in certain individuals. Caution must be taken to avoid lacerating the femoral artery. The femoral vein can be accessed with the animal on dorsal recumbency and slightly extending the hind leg caudally. The clinician palpates between the muscle bellies to find the femoral groove and a long needle (1 in or longer, depending on the size and body condition of the animal) is advanced with slight negative pressure. After successful collection, pressure should be applied to minimize hematoma formation. Venipuncture on this site can be painful, and some individuals may show some lameness after recovery, associated with deep hematoma formation or soft tissue trauma. With aggressive repositioning of the needle, there is also a risk of creating an iatrogenic arteriovenous fistulation.

The cephalic and lateral saphenous veins can sometimes be palpated under the skin. In individuals of some species, such as warthogs and red-river hogs, these veins are easily palpated and accessible, but in others, the veins can roll under the skin. A clinician familiar with the orientation of these veins might be able to blindly advance a small needle and obtain a blood sample. Blind catheterization of these veins is possible, although it is recommended that a scalpel blade be used to puncture the thick skin and avoid damaging the catheter stylette, or that a true "cut down" procedure be used for optimum visualization and securing an intravenous catheter in place.

The coccygeal or tail vein is a marginally adequate venipuncture site for collecting small volumes of blood in most species. In peccaries, the tail is relatively shorter, and venipuncture is more challenging, but small volume samples (at 1–3 mL) can still be collected if the needle is heparinized. The vein is located on the ventral mid-point of the tail. An individual can be placed on lateral recumbency and the vein is approached ventrally at the base of the tail, using a 21- to 23-gauge needle. If too much negative pressure is used, the vein can be easily collapsed.

Suids have thick, muscular necks, and the jugular vein is not palpable or externally visible. Redundant folds of skin around the neck, or extensive adipose tissue stores, may limit access to the jugular vein. However, if accessed, the jugular vein is large in all species. A long needle advanced cranially in the direction of the jugular furrow, with a slightly medial orientation while applying negative pressure, can be successful at venipuncture.

Anterior vena cava puncture is widely used for blood collection in domestic pig production, but is not without potentially detrimental effects, and its application should be judiciously employed by clinicians on

a case-by-case basis. Risks of improper anterior vena cava puncture include blood vessel laceration and cardiac tamponade (Moon & Smith 1996). In small pigs, or with improper restraint, an overtly aggressive clinician may accidentally induce a pneumothorax, hemothorax, or other intrathoracic lacerations if using an improper length needle. A technique has been described for chemically restrained collared peccaries, and has been used in large numbers of anesthetized collared peccaries (*T. tajacu*) to obtain large (>20 mL) volumes of blood, with no fatalities (Lochmiller et al. 1984). After placing a peccary in dorsal recumbency in a "V-shaped" trough, the head is extended slightly to stretch the sternocephalicus musculature. The site of needle entry is found by placing a thumb against the anterior portion of the manubrium of the sternum. The needle is inserted at a point equal to the width of the thumb anterior and lateral to the edge of the sternocephalicus muscle. The needle is directed caudally and angled dorsomedially at a 30–40° angle formed by the point of the sternum. In an adult peccary, the authors preferred a 21-gauge, 1.5-in long needle.

The auricular veins on the ears of domestic pigs are a common site for intravenous access, catheter placement, and blood collection. The veins are present on the dorsolateral aspect of the ear. Their usefulness in exotic suid species varies, but should be considered for quick vascular access or when injecting small volumes. Large-eared species, such as red river hogs and warthogs, may have prominent veins, but they are of negligible size in other species (babirusa, warty pigs and peccaries). Using a warm compress or topical alcohol may induce superficial vasodilation, and applying pressure at the base of the ear may help identify the veins. A butterfly catheter can be secured around the flat (posterior) part of the ear, or a short catheter can be glued in place with the inside of the ear rolled around gauze to provide rigidity and support in securing the catheter. A clinician should keep in mind that most suid species have very sensitive ears, and even seemingly minor manipulations have resulted in auricular discomfort (abnormal ear posture and rubbing ear on surfaces) for days after a procedure.

Orbital sinus puncture is used in some research laboratories for blood collection in domestic pigs, and a variation has been used and described for anesthetized collared peccaries (Lochmiller et al. 1984). A peccary is placed in dorsal recumbency, with the head extended and stabilized by holding the snout. A 16-gauge, 1-in long needle without a syringe is placed at the medial canthus of the eye, medial to the nictitating membrane. The needle is advanced approximately 2 cm at a slightly ventral, posterior angle through the conjunctiva, until the orbital sinus is reached. Blood will flow through the needle and can be freely collected in a tube placed under the hub. When collection is completed, the needle is removed and pressure is applied to the

closed eyelid to stop blood flow. As described, this technique may have value in research settings, but is not likely to be popular with zoo staff or pet owners, and potential complications exist. Orbital sinus puncture is not recommended for venipuncture in most situations, since more readily accessible sites exist.

ENDOTRACHEAL INTUBATION AND ANESTHETIC MONITORING AND SUPPORT

Sternal recumbency is recommended for ease of endotracheal intubation, but lateral recumbency is more practical for very large individuals, animals with large tusks, obese and brachycephalic animals. Some clinicians may prefer positioning individuals with large abdominal girth in lateral or dorsal recumbency. In these cases, suspending the head slightly at the end of an elevated table or platform may facilitate positional manipulation. A common hurdle to successful endotracheal intubation is the difficulty in opening the mouth sufficiently to visualize and advance an endotracheal tube. This might be facilitated with a deeper plane of anesthesia or different drug combinations, but one must consider that the mouth does not open widely in some species, even in extremely relaxed individuals. In addition, the larynx of most suids is difficult to reach due to the elongated shape of the head and distal location in most species.

Using soft gauze strips behind the upper and lower canines, an assistant can open the mouth and simultaneously position and extend the head slightly. Anatomical idiosyncrasies in suids make endotracheal intubation challenging, but familiarization with the anatomy and visualization of the tortuous route to the airway will facilitate success. A long laryngoscope blade can be used to push the epiglottis and expose the larynx. A long stylette can be passed into the larynx and the endotracheal tube can be threaded over the stylette or guided through the eye of Murphy while rotating at the point of contact with the larynx. If advanced too aggressively, a stylette can damage the laryngeal mucosa, resulting in edema and subsequent airway obstruction. A stylette that is advanced too far into the trachea may damage the peribronchial tissues, causing a pneumothorax (Thurmon et al. 1996). If the larynx is physically stimulated, laryngospasms, apnea and subsequent cardiovascular collapse may occur as part of the laryngochemical reflex (Ko et al. 1993a). The reflex occurs commonly in domestic pigs, but the response can be ameliorated with a topical anesthetic, such as lidocaine or cetacaine, applied on the larynx prior to attempts at intubation.

The endotracheal tube can be advanced into the larynx with the normal curvature of the tip pointing ventrally. The tube will encounter resistance as it reaches the posterior floor of the larynx, and rotating the tube slightly at this point facilitates advancement.

Figure 55.1. Intubation of a Chacoan peccary (*Catagonus wagneri*) utilizing a Miller laryngoscope blade (photo by Gary West).

Suids are obligate nasal breathers, and caution should be used when securing the endotracheal tube. Tying a tube too tightly around the nose or muzzle may cause significant congestion of upper respiratory passages, leading to difficulty breathing during and after recovery. This consideration should be emphasized in brachycephalic individuals, such as potbellied pigs (Fig. 55.1).

When endotracheal intubation is not feasible, the intranasal route is an easy and practical way to administer supplemental oxygen or anesthetic gas to suids, but should not be used for positive ventilation. Attempts at ventilating domestic pigs through nasal intubation have resulted in significant gastric distension, anterior displacement of the diaphragm, and decreased functional lung capacity (Thurmon et al. 1996). Improper intubation (i.e., esophageal instead of endotracheal) may result in similar complications.

The same monitoring equipment used in other mammalian species can be used in anesthetized suids (Fig. 55.2). However, the clinician should not rely on monitoring equipment alone, and visual or palpable assessment of respirations, pulse or heart rate, and mucous membrane coloration and capillary reflex times should not be ignored. Ocular positioning is not an adequate indicator of anesthetic depth in suids due to the shallowness of the orbital socket.

A pulse oximetry probe can be placed on the tongue, ear, or vulvar or preputial folds. A rectal probe can be used, but mucosal contact must be confirmed by removal of feces. Interpretation of pulse oximetry values is more accurately done if respiration and

Figure 55.2. An anesthetized Chacoan peccary (*Catagonus wagneri*) being monitored with mainstream capnography and pulse oximetry. An intravenous catheter had been placed in a cephalic vein (photo by Gary West).

ventilations are concurrently monitored. Capnography is a useful indicator of physiologic state of anesthetized suids. In domestic pigs, elevations in end-tidal CO_2 are seen early in the onset of malignant hyperthermia before other signs appear (Moon & Smith 1996), and early recognition of elevations in end-tidal CO_2 may help identify other physiological derangements that are significant to anesthetic management. Capnography trends can be monitored nasally in nonintubated animals by tightly fitting a tube inside the nostril and attaching the reading device to the end. Most suids tend to hypoventilate under anesthesia, which may be a reflection of the most popular anesthetic protocols used, a large (possibly full) stomach, obesity in most captive animals, or a combination of these. End-tidal CO_2 readings higher than 45 mmHg warrant ventilatory support, and possibly oxygen supplementation. Positive pressure mechanical ventilation should not exceed what is necessary for minimal visible chest expansion, and caution should be used to avoid exceeding 20 cm H_2O , which has been seen to cause spontaneous pneumothorax in healthy pot-bellied pigs (Lukasik & Moon 1996).

Indirect blood pressure monitoring is recommended. Placing direct, invasive blood pressure monitors in anesthetized suids is impractical and time consuming for most nondomestic species, mostly due to difficulties in arterial catheterization. Although no specific studies have been done in any exotic suid species, a close correlation between oscillometric methods of blood pressure monitoring and direct arterial blood pressure methods have been shown in domestic pigs,

and trends seen in indirect blood pressure readings are more useful than absolute numbers recorded (Moon & Smith 1996). If a commercially available indirect blood pressure monitor is not available, a simple method is to use a Doppler flow probe on the second digit to locate a pulse and place a cuff with a sphyngomanometer proximally over the metatarsus. A study done on domestic sows showed that similar cuff placement with a pulse oximetry probe positioned distally on the second digit (instead of a Doppler flow probe), correlated closely with direct arterial blood pressure (Caulkett et al. 1994). Cuffs placed on the legs should be of a width between 40% and 60% of the limb circumference (Moon & Smith 1996). Cuff placement on the legs can be above or below the carpus or tarsus, but the cuff bladder should be over the medial aspect of the leg. If the cuff is placed on the tail, the bladder should face ventrally (Moon & Smith 1996).

Traditional electrocardiography “alligator” clips may be difficult to attach to the tight suid skin. Instead, 25-gauge needle electrodes can be inserted subcutaneously, or patch electrodes can be adhered to the skin after degreasing with acetone, as has been described for domestic swine (Moon & Smith 1996). Temperature can be measured easily rectally, or with an esophageal probe.

ANESTHETIC COMBINATIONS

General Principles

The majority of immobilization scenarios for nondomestic suids will be to facilitate routine, minimally invasive procedures (such as relocation, physical exam, hoof trimming, blood collection, and placement of radio collars), where a light plane of anesthesia or deep sedation will suffice. After induction, deeper planes of anesthesia can be achieved with inhalant anesthetics or supplemental doses of injectable anesthetics.

Many injectable anesthetic protocols have been reported and are summarized in Table 55.2. Most balanced combination protocols have fewer side effects than any single-drug protocol, since the different drugs may potentiate anesthetic effects and decrease the effective necessary dose of any single drug. In choosing a balanced anesthetic combination, it has been suggested that suids may be relatively more resistant to opioids and alpha-2-adrenergic agonists than other species, but relatively more sensitive to the effects of benzodiazepines (Moon & Smith 1996). However, this assumption should be taken with caution when extrapolating to different suid species, as significant species and individual variation exists, and there have been reports of individuals with profound sensitivity to opioids.

Sedatives and Preanesthetic Medications

Preanesthetic sedatives can be used to decrease anesthetic drug doses, facilitate administration of the

induction agent, or ease preanesthetic anxiety. Oral diazepam or midazolam has been given to suids prior to anesthetic induction, resulting in calmer individuals prior to immobilization, facilitating darting, and minimizing complications (such as hyperthermia) associated with preanesthetic excitement.

Oral alpha-chloralose was historically used to capture feral pigs in the United States. The sites would be prebaited with food for several days to attract pigs to the area, before adding drug-laced bait for the capture. Different mixtures are used to enhance the adherence of alpha-chloralose to bait, such as corn. The minimum effective dosage for hog capture has been reported as 2.2g/40 kg of body weight, and the maximum safe dosage for feral hog capture has been reported as 2.2g/10 kg of body weight (Carpenter & Brunson 2007).

The use of xylazine (1.1–2.1 mg/kg IM) prior to anesthetic induction with tiletamine-zolazepam has been reported in babirusa (James et al. 1999), and midazolam (0.15 mg/kg IM) and medetomidine (0.02–0.07 mg/kg IM) have been similarly used prior to induction of anesthesia with other agents. However, the use of preanesthetic drugs is impractical in animals that cannot be confined or where the anxiety of multiple injections clearly outweighs the practicality of a single darting event.

The use of anticholinergics as adjunct premedications with a sedative before anesthesia has been advocated in domestic pigs (Moon & Smith 1996), and should be considered in Vietnamese potbellied pigs. Anticholinergics decrease the likelihood of bradycardia, avoid bronchoconstriction, minimize airway secretions, and decrease salivation. Atropine (0.04 mg/kg) or glycopyrrolate (0.005–0.02 mg/kg) can be administered intramuscularly as part of premedicants. Glycopyrrolate is a more potent antisialogogue than atropine, but is also longer acting. Caution should be used when administering anticholinergics in conjunction with drugs that can cause peripheral hypertension, such as alpha-2 adrenergic agonists.

Anesthetic and Sedation Protocols

Butyrophenones and Phenothiazines Azaperone is a short-acting butyrophenone neuroleptic designed for intramuscular injection with a wide safety margin in domestic swine. Although its main use has been to decrease aggression in domestic swine, azaperone can be used alone as a reliable sedative, or as an anesthetic adjunct with dose-dependent effects. Doses of 0.25–0.5 mg/kg produce mild sedation without ataxia in domestic pigs (Braun 1993). Doses of 0.5–2.0 mg/kg reduce intraspecies aggression and cause mild ataxia, while doses of 2–4 mg/kg result in significant sedation and possible recumbency in adult pigs (Braun 1993). However, doses exceeding 2 mg/kg are also more likely to cause negative drug effects, which are similar to those caused by phenothiazines, including hypotension,

Table 55.2. Common immobilization protocols used in nondomestic suids

Drug Combination	Dose (mg/kg)	Species Documented	Comments	References
Ketamine (K)	20 (K)	Collared peccaries	Not recommended. Induction and recoveries are prolonged and violent, and high mortality possible	Gallagher et al. (1985); Hellgren et al. (1985)
Ketamine (K)/xylazine (X)	7.7 (K)/4.3 (X)	White-lipped peccaries	Field use for radio-collaring 17 free-ranging animals, but no physiologic parameters reported. Recoveries were prolonged (1–3 hours) with no mention of antagonism	Reyna-Hurtado et al. (2009)
Ketamine (K)/Tiletamine-zolazepam (TZ)/Medetomidine (M)	3.9 (K)/0.63 (TZ)/0.03 (M)	Chacoan peccaries	Prolonged recoveries despite atipamezole antagonism, residual ataxia	Sutherland-Smith et al. (2004)
Tiletamine-zolazepam (TZ)	2–5 (TZ)	Multiple species	Smooth induction, poor muscle relaxation, prolonged recoveries might be rough. Duration of recovery is dose dependent, not induction	Allen (1992); Calle and Morris (1999)
	2.18 (TZ)	Chacoan peccaries	Prolonged recoveries, poor relaxation	
Tiletamine-zolazepam (TZ)/Xylazine (X)	2.35 (TZ)/2.35 (X)	Collared peccaries	Prolonged recoveries, but study did not antagonize xylazine; fatality associated with a double dose	Gabor et al. (1997)
	1.23(TZ)/1.23 (X)	White-lipped peccaries	Dose of 1.51 TZ and 1.51 X not successful in Collared peccaries	Selmi et al. (2003)
	1.2–2.1 (X)/1.8–3.3 (TZ)	Babirusa	(X) administered as a premedicant, followed by TZ 20 minutes later. Antagonism with 0.14-mg/kg yohimbine and 1-mg flumazenil for every 20-mg zolazepam. Bradycardia seen in some cases.	James et al. (1999)
			Concurrent administration of TZ and X can be used at similar doses with same effects	
Tiletamine-zolazepam (TZ)/romifidine (R)	3 (TZ)/0.5 (X)	Warthogs	Recoveries >90 minutes	Sonntag et al. (2004)
Tiletamine-zolazepam (TZ)/butorphanol (B)	3.3 (TZ)/1.6 (X)	Feral pigs		Sweitzer et al. (1997)
	3–6 (TZ)/0.1 (R)	Wild pigs		Siemon et al. (1992)
	1.46 (TZ)/0.14 (B)	White-lipped peccaries	Similar doses ineffective for collared peccaries	Selmi et al. (2003)
Medetomidine (M)/butorphanol (B)/ketamine (K)	1.26 (TZ)/0.36 (B)	Babirusa	Reverse with naltrexone, poor overall relaxation	Padilla (2004)
	0.06–0.1 (M)/0.3–0.4 (B)/0.6–1.1 (K)	Bearded pigs		
Medetomidine (M)/butorphanol (B)/midazolam (Mz)	0.04–0.07 (M)/0.15–0.3 (B)/0.08–0.3 (Mz)	Multiple species	<i>Preferred combination can be used in all suid species.</i> Antagonize medetomidine with atipamezole, butorphanol with naltrexone. Lower dose range used in calm, captive individuals.	Morris and Shima (2003) (upper range of doses)
			Midazolam or medetomidine can be administered as a premedicant 10–15 minutes prior to rest of anesthetic cocktail, or all can be administered concurrently	
Detomidine (D)/butorphanol (B)/midazolam (Mz)	0.06–0.125 (D)/0.3–0.4 (B)/0.2–0.4 (Mz)	Multiple species	Dexmedetomidine can be used as a substitute for medetomidine. See text. Antagonize detomidine with atipamezole or yohimbine, and naltrexone. Detomidine or midazolam can be administered as a premedicant or concurrently. Animals may resedate within hours after antagonism.	Morris et al. (1999)
Xylazine (X)/butorphanol (B)/midazolam (Mz)	2–3 (X)/0.3–0.4 (B)/0.3–0.4 (Mz)	Multiple species	Antagonize with atipamezole or yohimbine, and naltrexone.	Morris et al. (1999)
Detomidine (D)/butorphanol (B)/tiletamine-zolazepam (TZ)	0.06–0.125 (D)/0.3–0.4 (B)/0.6 (TZ)	Multiple species	Xylazine or midazolam can be administered as a premedicant or concurrently	Morris et al. (1999)
Xylazine (X)/butorphanol (B)/tiletamine-zolazepam (TZ)	2–3 (X)/0.3–0.4 (B)/0.6 (TZ)	Multiple species		Morris et al. (1999)

bradycardia, and decreased cardiac output and contractility. Priapism has been reported in adult boars (Moon & Smith 1996).

Although the use of azaperone in exotic suid immobilization protocols has not extensively documented, it has a lot of potential as an anesthetic adjunct in non-domestic species, and has been used reliably in Vietnamese potbellied pigs. The recommended dose for potbellied pig sedation is 0.25 to 2.0 mg/kg IM, and doses of 2.0–8.0 mg/kg are suggested for anesthesia (Calle & Morris 1999). Caution should be used at the higher range of the suggested dose, as prolonged recoveries may be seen.

Acepromazine is a phenothiazine compound used as a sedative adjunct in domestic pigs, but considered an inadequate sedative when used by itself (Moon & Smith 1996). Its negative side effects are dose dependent and can be severe, including hypotension, decreased heart rate, hypothermia, and decreased respiratory rate. However, acepromazine can be used to manage hyperthermia (Moon & Smith 1996) and hypertension, or as a mild sedative adjunct.

Ketamine Combinations Ketamine has been used extensively in suid immobilizations. Ketamine should not be used as a sole anesthetic agent due to the poor quality of anesthesia, extreme muscle rigidity, and rough recoveries, but is the base for balanced anesthetic protocols, and understanding its effects is important for the formulation of these combinations. To produce immobilization, ketamine alone requires relatively high doses (15–25 mg/kg), and the muscle rigidity precludes endotracheal intubation. Despite a relatively minor cardiorespiratory depressant effects (Tranquilli et al. 1983), ketamine can increase systemic and pulmonary arterial blood pressure, cause tachycardia, and increase in cardiac output and myocardial oxygen consumption. Recoveries are rough, including hypersensitivity to stimulus and increased activity of the limbs (padding), which may lead to hyperthermia, predisposing suids to self-trauma, pulmonary edema, and even death.

Domestic pigs absorb ketamine rapidly, and almost completely, after intramuscular injection (Loscher et al. 1990). Anesthetic recovery in pigs occurs as ketamine is redistributed from the brain to other tissues, with drug excretion and metabolism being less critical for anesthetic duration. This is a significant consideration when choosing drugs for individuals with compromised organ function, since prolonged excretion is unlikely to affect duration of anesthesia. The elimination half-life of ketamine in healthy pigs is approximately 2 hours after intramuscular or intravascular administration.

Ketamine has been used safely as a sole anesthetic agent in numerous peccary immobilizations (Hellgren et al. 1985). In collared peccaries (*Tayassu tajacu*),

ketamine was used without detrimental, permanent effects at 20 mg/kg (Hellgren et al. 1985) administered intramuscularly. Prolonged recoveries (>120 minutes) should be expected when peccaries are immobilized with 15–25 mg/kg ketamine administered intramuscularly, and heat stress may be seen in relation to ambient weather (Gallagher et al. 1985).

Some of the negative effects of ketamine anesthesia can be ameliorated with anesthetic adjuncts, which also decrease the ketamine dose required to achieve effective immobilization. Alpha-2-adrenergic agonists, such as xylazine, detomidine, medetomidine, or dexmedetomidine, are popular adjuncts to ketamine as a suid anesthetic. These combinations offer the advantage of being reversible to result in faster recoveries, but the reversal of the alpha-2-adrenergic agonists is independent of the patient's ability to metabolize and clear ketamine. If the alpha-2 adrenergic agonist is reversed before ketamine is fully metabolized, recoveries can be undesirable, characterized by hyperkinesia of all limbs while recumbent, severe and prolonged ataxia, and distress vocalizations. It has been shown cardiac output decreased significantly for 30 minutes after administration of a ketamine (10 mg/kg) and xylazine (1 mg/kg) combination in domestic pigs, and arterial PO₂ decreased for 10 minutes while total vascular resistance was significantly increased (Trim & Gilroy 1985). It is likely that other alpha-2-adrenergic agonists in combination with ketamine have similar effects in exotic suids, and should be used with caution, but the more specific receptor affinity of the newer generation drugs is likely to result in less undesirable effects.

The wide availability of ketamine and xylazine has made this combination a popular choice used by field biologists studying wild or feral suids. Xylazine decreases the induction dose of ketamine, and can be antagonized with atipamezole or yohimbine. Although the effects of anesthetic monitoring were not reported, Reyna-Hurtado et al. (2009) reported safely immobilizing 17 white-lipped peccaries (*Tayassu pecari*) using a combination of ketamine (7.7 mg/kg) and xylazine (4.3 mg/kg) delivered by dart rifle. The animals recovered in 1–3 hours, and the authors did not report administering any antagonists.

Ketamine, used in conjunction with benzodiazepines (diazepam, clonazepam, or midazolam) offers better relaxation and smoother recoveries than ketamine alone. Midazolam is a more reliable intramuscular sedative than diazepam because it is water soluble. Recoveries after ketamine-benzodiazepine combinations can be prolonged, usually taking several hours. Recovery times can be shortened by the administration of flumazenil.

Tiletamine-Zolazepam Combination A commercially available 1:1 formulated ratio of tiletamine-zolazepam

combination has been used extensively in exotic suids (Calle & Morris 1999), and can be used safely in any species if the recovery effects are anticipated and properly managed. Kumar et al. (2006) reported the half-lives for tiletamine and zolazepam in the terminal elimination phase in domestic pigs anesthetized with a 10 mg/kg combined dose as 3.7 and 8.4 hours, respectively. These prolonged half-lives are significantly prolonged when compared with other domestic species (Lin et al. 1993). The authors also commented on the observation of a secondary peak in a concentration-time profile of zolazepam, which could be attributed to enterohepatic recycling or differential absorption rates from the injection site.

Despite the prolonged recovery times and possible undesirable effects, the combination of tiletamine-zolazepam offers the advantages of relatively low cost, wide availability, and a relatively wide margin of safety. Commercially available formulations can be reconstituted to different concentrations, allowing for smaller volumes of induction. Induction times are rarely affected by increasing dose, but recovery times can be prolonged at higher doses. The dissociative anesthetic portion of this combination, tiletamine, is considered more potent than ketamine. Zolazepam, the benzodiazepine part of the combination, is likely responsible for prolonged recoveries. The use of flumazenil (1-mg flumazenil for 20-mg zolazepam IV or IM; Calle & Morris 1999) as a benzodiazepine antagonist may shorten recovery times, but the effects may be of short duration and animals may relapse into a more sedate state as the flumazenil is metabolized.

Tiletamine-zolazepam anesthesia is characterized by relatively fast inductions, moderate muscle relaxation that is inadequate for endotracheal intubation, and prolonged, sometimes violent, recoveries. Most suids retain some degree of hyperresponsive reflexes, such as exaggerated limb withdrawal when stimulated. Heart rate and arterial blood pressure may increase. Respiration rate may decrease initially, but minute ventilation is well maintained. Recoveries may show repetitive motion of the legs (paddling) prior to standing, excessive salivation, altered thermoregulation, increased vocalizations, and prolonged ataxia (Moon & Smith 1996). Deaths have been occasionally reported after using tiletamine-zolazepam, due to complications of rough recoveries (Morris & Shima 2003).

Chacoan peccaries (*Catagonus wagneri*) were immobilized reliably and safely with tiletamine-zolazepam at a mean dose of 2.18 mg/kg intramuscularly (Allen 1992). Anesthesia was induced in 7.6 minutes, but recoveries were prolonged (90–240 minutes), and some animals retained a dull mentation for up to 8 hours after immobilization. A more recent study (Sutherland-Smith et al. 2004) mentions that Chacoan peccaries anesthetized with 3.2 mg/kg tiletamine-zolazepam took longer than 8 hours to recover, which may be a

function of higher doses resulting in prolonged recoveries, as had been previously suggested (Allen 1992).

Tiletamine-Zolazepam/Alpha-2 Adrenergic Agonist Combinations The addition of alpha-2 adrenergic agonists adjuncts to tiletamine-zolazepam anesthetic protocols allows the usage of lower doses of tiletamine-zolazepam to achieve desired effects while improving overall muscular relaxation. The negative cardiovascular side effects involved with this addition are offset by the benefits of faster, smooth recoveries and better relaxation, often allowing for endotracheal intubation.

Xylazine has been a popular, inexpensive, and widely used adjunct to tiletamine-zolazepam immobilization protocols in nondomestic suid immobilizations. Commercially available formulations of tiletamine-zolazepam can be reconstituted with xylazine (Gabor et al. 1997), and immobilization protocols can be predetermined by volume per weight to simplify dose calculations in the field. In domestic pigs, it has been shown that the addition of xylazine to tiletamine-zolazepam-based immobilization protocols increases relaxation to facilitate intubation (Ko et al. 1993b). Increasing the xylazine dose in xylazine-tiletamine-zolazepam anesthesia of domestic pigs enhances the quality of anesthesia, sedation, and muscle relaxation without prolonging recovery times (Ko et al. 1995).

Wild feral pigs (*Sus scrofa*) in North America have been reliably immobilized with a xylazine (1.6 mg/kg) and tiletamine-zolazepam (3.3 mg/kg) intramuscular combination delivered to trapped pigs by blowdart (Sweitzer et al. 1997). Animals recovered and were released within 120 minutes of initial injection. Authors reported slight decreases in heart rates and body temperatures, but adequate respiration rates and blood oxygen saturation levels. Immobilization of a large number ($n = 107$) of collared peccaries (*Tayassu tajacu*) has been described using a tiletamine/zolazepam (2.35 mg/kg) and xylazine (2.35 mg/kg) combination, although the authors reported it as a combined average dose of 4.7 ± 0.9 mg/kg (Gabor et al. 1997). One fatality was reported in a peccary receiving an overdose (9.78 mg/kg combined dose). Recovery times in peccaries were prolonged, being described as conscious at 64 ± 29 minutes and first standing at 92 ± 33 minutes from injection, but xylazine was not antagonized in the study. Selmi et al. (2003) used intramuscular tiletamine-zolazepam (1.23 ± 0.26 mg/kg) in combination with xylazine (1.23 ± 0.26 mg/kg) successfully in white-lipped peccaries, but similar doses (1.51 ± 0.29 mg/kg tiletamine-zolazepam and 1.51 ± 0.29 mg/kg of xylazine) were unsuccessful at providing immobilization in collared peccaries, undermining that species-specific differences must be taken into account.

A combination of 3.9 mg/kg ketamine, 0.63 mg/kg tiletamine-zolazepam, and 0.03 mg/kg medetomidine

was used to immobilize captive Chacoan peccaries (*Catagonus wagneri*) (Sutherland-Smith et al. 2004). Sufficient immobilization for handling was achieved at 12.6 ± 3.7 minutes, and good muscle relaxation was produced, although animals that were approached too soon after recumbency would be aroused and stumble away. Heart and respiratory rates declined, but oxygen saturation increased during anesthesia. Atipamezole was used to antagonize the medetomidine, but recoveries were still very prolonged (55–455 minutes) and showed residual ataxia.

In babirussa, xylazine (1.2–2.1 mg/kg IM) premedication followed by tiletamine and zolazepam (1.8–3.3 mg/kg) produced good relaxation, smooth inductions, and sufficient immobilization for minimally invasive procedures, although additional drugs were necessary to deepen or prolong anesthesia (James et al. 1999). The authors report bradycardia in some animals (range of 35–111 beats per minute) while maintaining good oxygen saturation and stable respiratory rates (James et al. 1999). Female babirussa required slightly higher induction doses to reach similar effects. A small study (Sonntag et al. 2004) showed that warthogs can be immobilized safely with tiletamine-zolazepam (3.0 mg/kg) and xylazine (0.5 mg/kg), although recoveries were prolonged (>90 minutes).

Romifidine has not been used extensively in suids, but one report describes its use (0.1 mg/kg) as an anesthetic adjunct to tiletamine-zolazepam (3–6 mg/kg) in wild boars (Siemon et al. 1992). Since these doses of tiletamine-zolazepam alone may be sufficient to sedate swine, the benefits of romifidine are likely to be supplemental and improve overall relaxation.

Tiletamine–Zolazepam/Butorphanol Tiletamine-zolazepam (1.46 mg/kg) has been used successfully in conjunction with butorphanol (0.14 mg/kg) to immobilize white-lipped peccaries (*Tayassu pecari*), but similar doses are ineffective to immobilize collared peccaries (Selmi et al. 2003). However, similar doses of tiletamine-zolazepam (1.26 mg/kg IM) combined with higher doses of butorphanol (0.36 mg/kg) resulted in adequate immobilization of babirussa for elective procedures (Padilla 2004), and similar doses can be used in peccaries and warthogs, although relaxation is inadequate for intubation. Caution is prudent when using higher doses of butorphanol, as some practitioners have reported profound sensitivity and characteristic opioid effects (respiratory depression and muscle tremors) in certain individuals, notably babirussa. Antagonism of opioid effects with naltrexone or naloxone may shorten recoveries.

Medetomidine- and Dexmedetomidine-Based Anesthesia Medetomidine has been shown to induce deeper planes of sedation than xylazine in domestic pigs (Sakaguchi et al. 1992a), making it a useful and more

complete anesthetic agent for suid immobilization. At higher doses of medetomidine (>0.08 mg/kg), depth of sedation does not seem to increase significantly in domestic pigs, but the duration of sedation does. The study also showed better analgesia with medetomidine when compared with xylazine. The anesthetic properties of medetomidine can be potentiated in domestic pigs by administering butorphanol concurrently at 0.2 mg/kg (Sakaguchi et al. 1992b), and the combination is safe when administered to atropinized pigs (Sakaguchi et al. 1993). Medetomidine effects in domestic pigs can be antagonized with atipamezole at two to four times the medetomidine dose (Nishimura et al. 1992), although most clinicians prefer to use a 5:1 atipamezole:medetomidine ratio for antagonism (Morris & Shima 2003).

Medetomidine effects can also be potentiated when used in combination with midazolam (Nishimura et al. 1993). The cardiopulmonary effects of a medetomidine (0.04 mg/kg) and midazolam (0.2 mg/kg) combination in swine include a rapid increase in arterial and pulmonary arterial pressure due to peripheral vasoconstriction (Nishimura et al. 1994). The antagonism of medetomidine with atipamezole resulted in a decrease in peripheral vascular resistance, decrease in blood pressure and increased cardiac output and heart rate (Nishimura et al. 1994).

The ability to potentiate medetomidine with both butorphanol and midazolam has made the combination of the three a very popular anesthetic choice in nondomestic suids. A 0.07 mg/kg medetomidine, 0.3 mg/kg butorphanol, and 0.3 mg/kg midazolam protocol has been extensively used in captive suids of multiple species (Morris & Shima 2003) and is the preferred protocol across suid species at most captive zoological institutions (Morris et al. 1999). Medetomidine can be administered 5–15 minutes prior to the rest of the drugs, having a premedicant effect. This protocol offers the advantages of being almost entirely reversible and producing consistently good results across species (Morris & Shima 2003). However, at the doses published, significant bradycardia and hypoxemia are common side effects, and unexplained severe hypoglycemia has been seen in fasted and unfasted suids at one institution (Morris & Shima 2003). Lingering sedation from which suids can be aroused is often seen at high doses using this drug combination for immobilization. Lower doses, as low as 0.04 mg/kg medetomidine, 0.08 mg/kg midazolam, and 0.15 mg/kg butorphanol, have been used successfully in babirussa, red river hogs, and warthogs, and might be used in other species. These lower ranges were derived from the domestic swine literature (Nishimura et al. 1994; Sakaguchi et al. 1992b), and may reflect variations in individual temperament and species susceptibility. For most animals, a large volume of induction drugs is needed, although the recent availability of highly concentrated or

compounded formulations of medetomidine, midazolam, and butorphanol allows smaller volumes of induction. Clinicians have also reported sudden arousals when suids are approached too soon after recumbency or when stimulated, and recently, there have been anecdotal reports of profound sedation within hours after initial antagonism. These anecdotal reports may be due to a recycling of the medetomidine when used at higher doses.

Dexmedetomidine is a dextroisomer of medetomidine, and responsible for the anesthetic effects seen with medetomidine. When compared to medetomidine, dexmedetomidine has not been available as long for veterinary usage. In addition, because it is only commercially available as a 0.5 mg/mL formulation in the United States, its application to nondomestic suid anesthesia has been limited by volume. Medetomidine (which is available in more concentrated, often compounded, formulations) is still more widely used and practical in the anesthesia of non-domestic suid species. Dexmedetomidine can replace medetomidine in balanced anesthetic combinations at a dose range of 0.02–0.04 mg/kg (which is roughly 50% of the mg/kg dosage used for medetomidine) in most species. The manufacturer of 0.5 mg/mL dexmedetomidine recommends antagonism with 5 mg/mL atipamezole at a 1:1 volume (or 10:1 atipamezole to dexmedetomidine in a mg:mg basis). When compared with medetomidine, dexmedetomidine produces similar anesthetic effects, although controlled comparisons are limited and primarily anecdotal in non-domestic suid species. In a recent study done in propofol-sedated domestic swine, dexmedetomidine administered intravenously at rates of 0.2, 0.4, and 0.7 μ g/kg/h resulted in decreased bispectral index, mean arterial pressure, heart rate cardiac output, and mixed venous oxygen saturation, although the effects were dose dependent (Sano et al. 2010). This study suggests that relatively low doses of dexmedetomidine may be adequate as an adjunct in balanced anesthetic protocols. Due to limited reports of its use in nondomestic suid species, dexmedetomidine-based protocols are not included in Table 55.2.

Variations of the medetomidine-based protocols have been described. A combination of butorphanol (0.3–0.4 mg/kg), detomidine (0.06–0.125 mg/kg), or xylazine (2–3 mg/kg) and midazolam (0.3–0.4 mg/kg) has been used in Vietnamese potbellied pigs, Eurasian wild boars, red river hogs, warthogs, bearded pigs, and babirussa (Calle & Morris 1999). This protocol is characterized by rapid, smooth induction with excellent relaxation. In these combinations, medetomidine has been replaced by xylazine or detomidine, and it is likely that the other two drugs (midazolam and butorphanol) result in similar potentiation of the alpha-2 agonist effects. Another variation has been the substitution of tiletamine-zolazepam (0.6 mg/kg) for midazolam, used in some species with similar results (Calle & Morris

1999) and having the distinct advantage of smaller induction volumes. The authors suggest that some species are more sensitive to this drug combination based on temperament (red river hogs, babirussa, and potbellied pigs), and lower dosages of butorphanol can be used. Bearded pigs, warthogs, and Eurasian boars may require the higher end of the suggested dosage range.

Propofol Because propofol must be administered intravenously, it is an impractical choice for induction of anesthesia in exotic suids, but some individuals could be potentially conditioned to tolerate intravenous injections and anesthetic induction with propofol. More commonly, propofol has been used as an anesthetic supplement to reach a deeper plane of anesthesia after induction with different agents, or used for maintenance of anesthesia as a continuous intravenous infusion. At higher infusion rates, heart rate and cardiac index decrease in domestic pigs (Moon & Smith 1996). Propofol can be a significant respiratory depressant if administered rapidly, or if high doses are used.

Inhalant Anesthetics The use of inhalant anesthetic gases as induction agents is impractical in most exotic suid species. However, inhalant anesthetics can be used in small or severely debilitated animals, for supplementation or maintenance of anesthesia after induction with an injectable agent. Sevoflurane is the safest inhalant anesthetic agent currently available. Minimum alveolar concentrations (MAC) for domestic pigs are estimated at 0.9–1.25 for halothane, 1.5–2.0 for isoflurane and 2.0–2.7 for sevoflurane (Thurmon et al. 1996). A study done on newborn swine comparing halothane, isoflurane, and sevoflurane showed that mean systemic arterial pressure and heart rate decreased the least with sevoflurane when compared with awake piglets, but heart rate decreased the least with isoflurane (Lerman et al. 1990). Mean measurements of systemic arterial pressure were also lower in isoflurane- and halothane-anesthetized piglets than when sevoflurane was used. Sevoflurane is associated with faster recoveries than other inhalants. Caution should be used with domestic pigs known to be susceptible to malignant hyperthermia, as this condition can be triggered by inhalants, and traditionally associated with halothane usage.

Long-Acting Tranquilizers Limited objective information is available on the use of long-acting tranquilizers in suids. Perphenazine, a long-acting phenothiazine, has been used at 30–50 mg per warthog prior to translocations (Ebedes 1993). Two young warthogs overdosed with perphenazine at 5 mg/kg died 3 days later. Although it is unclear if the animals died directly from the overdose, the warthogs were anorexic after drug administration (Ebedes 1993).

CONCLUSIONS

Balanced anesthetic protocols using multiple drug combinations allow for less detrimental side effects with better anesthetic qualities. Although the combination of butorphanol-medetomidine and midazolam is a reliable and safe combination for inducing anesthesia in most captive nondomestic suids, it is not applicable or practical in all situations. Clinicians should choose an anesthetic protocol that is likely to achieve the desired level of anesthesia while balancing against the detrimental effects most likely to be significant for an individual patient.

As newer monitoring equipment becomes available and is applied to document the physiological effects in nondomestic suid anesthetic episodes, the literature should evolve into more scientific and objective descriptions of different anesthetic protocols. Ultimately, this will help in refining techniques applicable to the captive and free-ranging management of these species.

Hippopotamidae

Michele Miller, Gregory J. Fleming, Scott B. Citino,
and Markus Hofmeyr

INTRODUCTION

With the use of newer and different drug combinations, higher concentrations of injectable agents, and improved techniques, safer and more effective sedation and general anesthesia can be successfully achieved in both species of hippopotami. However, they continue to present unique challenges due to their physical size, physiology, aquatic nature, and potential danger to staff. This chapter will describe both historical as well as newly developed techniques for captive and free-ranging common and pygmy hippo anesthesia.

TAXONOMY AND ANATOMY RELATED TO IMMOBILIZATION

The two extant species of hippopotamus, Nile hippo (*Hippopotamus amphibious*) and pygmy hippo (*Choeropsis liberiensis*), belong to different genera and both are indigenous to Africa. *Hippopotamus amphibious* has a weight range of 1179–2500 kg, with adult males typically larger than females (Miller 2003). Length along the back ranges 119–302 cm, with an average of 270 cm. Captive hippos tend toward obesity, which may complicate anesthesia due to pressure on the diaphragm during recumbency. If a scale is not available, weight estimates should be carefully considered since this may have significant impacts on anesthetic effects.

Nile hippos have an hourglass-shaped skull with nostrils and eyes set on the top of the head to allow access above water without lifting their entire head. Nostrils have a valve-like closure that activates when submerged and opens upon surfacing, even when sleeping.

The pygmy hippo, *Choeropsis liberiensis*, ranges in weight from 160 to 350 kg. They are approximately 70–80 cm high at the shoulder and 140–160 cm in length (Eltringham 1999). Males are usually only

slightly larger than females. Their skull is more of a pear shape, with eyes set on the sides rather than top of the head. Both hippo species have opening jaw angles of greater than 90°, facilitating oral exams and intubation, although the heavy masseter muscles and weight of the skull may make opening the mouth of an anesthetized hippo difficult without accessory items or repositioning.

Hippos have a four-compartment stomach and are considered “pseudoruminants.” The slow gastrointestinal transit time may lead to increased pressure on the diaphragm due to gastrointestinal contents during recumbency. Some studies suggest that the stomach content represents two nights’ feeding (Eltringham 1999). Therefore, a minimum of 12–24 hours fasting is recommended for captive hippos, with overnight water restriction, to minimize abdominal content fill (Loomis & Ramsay 1999; Ramsay et al. 1998).

Both species of hippopotamus are semi-aquatic mammals, spending their days in or near water, coming out to feed primarily between dusk and dawn. The common hippo, widely distributed in sub-Saharan Africa, is a social animal, lives in pods ranging in size from a few to over 100 animals led by a dominant bull with a harem of cows and their offspring.

Pygmy hippos are found only in West Africa and are solitary by nature. They can be aggressive toward conspecifics, especially when housed together in captive situations. Similar to the Nile hippo, they thermoregulate by spending time in water during the day.

ANATOMY AND PHYSIOLOGY RELATED TO CAPTURE AND IMMOBILIZATION

Skin and Thermoregulation

Due to their large volume to surface area ratio, thermoregulation is a critical function for hippos and should

be carefully monitored during an immobilization. Hippo skin is uniquely designed to assist in control of temperature and water loss. Although it appears thick, the epidermal layer is thin, with a thick dermis containing blood vessels and subdermal glands, which secrete frothy white or reddish viscous material (Eltringham 1999). The role of the secretions is incompletely understood but is speculated to assist in evaporative cooling and wound healing. Increased secretions are often observed during times of excitement. These secretions increase the difficulty of handling a recumbent hippo.

CARDIOVASCULAR SYSTEM

Vascular Access Sites for Blood Collection

The pigmented epidermis and thick dermal connective tissue surrounding peripheral blood vessels make visualization difficult. In young or some free-ranging animals, veins may be visible due to increased blood pressure after exertion or lean body condition. Other methods for locating blood vessels include Doppler and ultrasound probes, or blind approximation. Most peripheral veins on hippos are relatively thin-walled and may easily collapse with negative pressure from a syringe (Fig. 56.1).

One technique is to collect blood by allowing it to drip from the hub of a needle into an open tube containing the appropriate anticoagulant. In some cases, if a good blood flow is obtained, the use of an extension set may assist with the long blood draw times. Clotting is a potential problem, and pretreatment of tubing or syringes with anticoagulant is recommended.

Peripheral veins that can be accessed include cephalic, median (located on the medial aspect of the antebrachium), palmar and plantar digital (located on the caudal aspect of the distal limb), medial saphenous, ventral abdominal, interdigital (located midway

Figure 56.1. Blood collection from hub of needle using a digital vein on the forelimb of a Nile hippopotamus.

between the toes just proximal to the webbing), and sublingual veins (Miller 2007; Stalder et al. 2012). In young or small individuals, blood can be collected from the vena cava using a technique similar to a domestic pig. Auricular veins tend to collapse, yield minimal blood volume, and are very sensitive, even under anesthesia. The ventral tail artery, on the midline at the base of the tail, lies very close to the ventral tail vein. Both the artery and vein are sensitive to movement of the needle and can constrict, preventing any further blood collection.

Samples should be prioritized due to potentially limited volume due to collection difficulties. Ideally, dedicated personnel should be assigned to acquire the most essential samples to minimize time required during the immobilization.

Vascular Access for Fluid and Drug Administration

Intravenous catheterization is typically reserved for critically ill or young animals, since it requires a surgical cut-down for placement. Fluid replacement therapy alternatives include nasogastric tube, enema, or intraperitoneal fluids. Intravenous medications may be diluted in isotonic fluids and administered intraperitoneally with caution.

Intraosseous catheters can be used in juvenile or small hippos as an alternative to intravenous fluid or drug administration. Spinal needles or intraosseous biopsy needles placed in the greater trochanter of the femur have been used successfully in one case of a juvenile Nile hippo.

In anesthetized Nile hippos, the paired sublingual veins can be palpated and catheterized. The vein on the ventral aspect of the tongue can be accessed with a 20-gauge butterfly catheter or a conventional intravenous catheter. This vessel can be used for injection of intravenous fluids, anesthetic drugs, or collection of venous blood samples (Stalder et al. 2012).

Cardiovascular System Monitoring

Auscultation and palpation of pulses are difficult due to size in most adult hippos. However, positioning may facilitate success and periodic attempts should be made. Using one of the new electronic stethoscopes can enhance audible detection of heart sounds. Positioning the animal leaning slightly left will also place the heart closer to the thoracic wall. The stethoscope should be placed near the left elbow in the axilla when the animal is in sternal recumbency. Pulses can sometimes be palpated interdigitally or occasionally near the cephalic, medial saphenous, and sublingual vessels. Doppler probes placed directly on the cornea using copious amounts of gel have also been used to monitor heart rates in immobilized hippos. Heart rates vary significantly depending on the level of exertion and excitement prior to anesthesia, drugs, and dosages

administered. Typical heart rates in immobilized animals are 20–60 beats per minute, but trends are more critical than actual numbers.

RESPIRATORY SYSTEM

With some drug combinations (nonpotent narcotic combinations), anesthetized hippos appear to exhibit a respiratory pattern similar to a “dive reflex” in which they may take several breaths in short succession then breath hold (Stalder et al. 2012). This may result in erratic minute respiratory rates, oxygen saturation, and end-tidal CO₂ values (Fleming et al. 2010). Hippos anesthetized with potent opioids are often apneic and tend not to show this dive response. Therefore, it is critical to visually monitor respiratory cycles over several minutes and assess trends since apnea, hypoxemia, and hypercapnia are common complications.

Nasal Insufflation

When feasible, nasal insufflation with oxygen using a 12-mm endotracheal tube for a common hippo (and smaller for pygmy hippo) can increase both dead space and alveolar oxygen partial pressures, resulting in increased arterial oxygen (Ramsay et al. 1998). Supplemental inhalant anesthetics can also be administered by nasal insufflation. This may reduce the need for additional injectable anesthetic drugs during prolonged procedures. Typically, 0.5–2.5% isoflurane administered through a nasal tube can provide sufficient analgesia and restraint.

Intubation

For extended procedures or when using inhalant agents for supplemental or maintenance anesthesia, intubation is recommended. Necessary equipment and personnel should be available to assist in repositioning the animal to open the jaws, although some drug combinations provide adequate muscle relaxation for manual opening. This is usually easier in lateral recumbency. An inflated tire inner tube from a small vehicle may be used under the head to keep the head in line with the body and keep the airway straight. Ropes or straps placed behind the canines can be used to open the mouth and place different-size wooden wedges, with rope pull strings between the upper and lower molar arcades to keep the mouth open. This technique allows for easier access to the oral cavity. Rope handles, or pulls, should be attached to each rope block for ease of removal. Other equipment may be needed, including poles with nooses (“rabies poles”), ropes, duct tape, ratchet straps, and headlamps or flashlights for visualizing tube placement. Due to the redundant folds of buccal and oropharyngeal tissue, fleshy tongue, and long soft palate, it is easier to place an endotracheal tube in an adult hippo by blind manual insertion than using a laryngoscope, which are typically too short.

Adult common hippos usually require 24- to 30-mm endotracheal tubes (ETT) and 14-mm ETT for pygmy hippos. The smaller narrow oral cavity of the pygmy hippo makes intubation slightly more difficult but can be accomplished by manual palpation of the glottis and insertion of the tube in a similar manner. A large-animal anesthesia machine should be used with the flow rate set at approximately 5–10 mL/kg/min. For nonemergency procedures, ensure that there are adequate supplies of oxygen cylinders and inhalant anesthetics during the planning phase. If a large animal anesthetic machine is not available, a high pressure demand valve may be used to insufflate the lungs. A double-demand valve system developed for elephant anesthesia could also be used for hippo anesthesia (Horne et al. 2001).

Respiratory System Monitoring

Respiratory monitoring is one of the most important components of hippo anesthesia since it is the area where complications most commonly occur (Miller 2007; Ramsay et al. 1998). The most common method of monitoring is visualization of thoracic excursions or anesthetic bag movements, although nostril air flow can also provide information on depth as well as rate of breaths. Respiratory rates are influenced by drug combinations, but ideal ranges are 4–20 breaths/min.

Respiratory complications include apnea, hypoventilation, hypoxemia, hypercapnia, and respiratory acidosis (Flach et al. 1998; Fleming et al. 2010; Loomis & Ramsay 1999; Miller 2003). Administration of doxapram, supplemental oxygen, partial or complete reversal should be considered to address respiratory issues, depending on the degree of other physiological impairments (Dumoncaux et al. 2000; Ramsay et al. 1998).

THERMOREGULATION AND BODY TEMPERATURE

Since thermoregulation is critical when taking a hippo out of water for a period of time, temperature monitoring should ideally be performed throughout the procedure. Water, ice, a hose for enema, methods to provide evaporative cooling (e.g., fans), and shade should be available to control temperature and cool the animal if necessary. Expected body temperatures of anesthetized hippo are 35–38°C (using a thermometer inserted 6 in into the rectum). However, due to the large mass of the hippo, this may not reflect core temperature. Readings over 39°C should be considered hyperthermic and cause for concern (Stalder et al. 2012).

SPECIFIC USE OF ANESTHETIC MONITORING EQUIPMENT ON HIPPOS

As mentioned earlier, commonly used anesthetic monitoring equipment can be used on immobilized hippos

but may be limited to certain locations or placement due to anatomy. This section describes techniques to improve accuracy and success.

Pulse Oximetry

Pulse oximetry can be used to measure heart rates but should not be the sole method due to unreliability associated with probe placement (difficult to keep in place), possible vasoconstriction due to drugs, poor reflectance through the dense dermal connective tissue, and interference by skin secretions. However, oxygen saturation readings above 90% can be achieved in anesthetized hippopotamus (Dumonceaux et al. 2000). Auricular pulse oximetry may be attempted by using a dull knife blade (common butter knife) to scrape off the auricular dermal pigmentation and then apply the pulse oximeter probe. Cooler environmental temperatures may also cause auricular vasoconstriction, resulting in decreased sensitivity of pulse oximetry readings.

Other sites that have been used to obtain pulse oximeter readings in hippos include conjunctiva/nictitating membrane, oral mucous membrane, vulva, prepuce, and rectal mucosa (Miller 2007; Morris et al. 2001). One technique is to remove the sensors from the "C" or "V" clamp and tape or hold them side-by-side in close proximity to function as reflectance probes when using them at some of these sites (e.g., conjunctival membrane) and shield them from light. Depending on the site, readings may range from 70% to 90%, but trends should be monitored and interpreted in conjunction with other observations, such as color of mucous membranes and capillary refill time.

Capnography

Capnography can be useful for measuring both respiratory rate and end tidal CO₂. The capnograph can be attached to a small (9–12 mm) endotracheal tube that is placed into one of the nostrils. This will provide adequate flow rate for the capnograph to work. ETCO₂ during the first breath after breath holding may be 70–80 mmHg, which usually decreases to levels around 40–50 mmHg after a few breaths. Animals that have a regular respiratory pattern should have values ranging 35–55 mmHg when breathing air.

Temperature Monitoring Devices

A constant-reading digital thermometer with a long flexible probe placed rectally may provide the most accurate readings. Another method for assessing temperature is to use a thermometer placed in the muscle at the dart site. Small digital thermometers, if used, should be placed in direct contact with the rectal mucosa to improve accuracy.

Blood Gas Analysis

Blood gas measurements provide a more complete analysis of cardiorespiratory function, when available.

Figure 56.2. Sample collection for arterial blood gas analysis using ventral tail artery from a Nile hippopotamus.

The ventral tail artery is the ideal site for obtaining arterial blood gas samples. When performing arterial sampling, it is best to utilize a 1-cc syringe. When the artery is penetrated, the syringe will fill by arterial pressure alone, ensuring proper placement and not a venous sample. Repeated samples from the ventral tail artery are possible. Ventral tail blood samples may be more difficult to obtain in obese captive animals as their tails become enlarged with adipose stores, making vessel location difficult (Fig. 56.2).

Portable veterinary blood gas analyzers have been used with hippos. Although normal values have not been established, reference ranges for other large ungulates can be extrapolated to these species. Morris et al. (2001) reported average venous blood values from an immobilized juvenile common hippo as follows: pH = 7.4 ± 0.1, PCO₂ = 61.5 ± 8.1 mmHg, PO₂ = 71 ± 30 mmHg.

PLANNING FOR A HIPPO IMMOBILIZATION PROCEDURE

Any procedure requiring extensive equipment, supplies, and personnel should be planned well in advance to increase a successful outcome. It is important that all involved staff have clearly defined roles and responsibilities. Regular communication and checklists can be helpful to determine progress. Defined priorities and contingency plans should be discussed prior to the procedure. Safety for animal and personnel must be included in the planning.

Induction

Most hippos are darted with immobilization drugs. Less commonly used options are pole syringe, hand injection, or oral administration (Clyde et al. 1998; Dumonceaux et al. 2000; Weston et al. 1996; Zoli

Gymes, pers. comm.). Preferred dart sites due to thinner skin thickness are just behind the ear, caudal thigh, and biceps area. In common hippos, a 60- to 64-mm needle is used and must be at right angles to the skin to ensure an intramuscular injection. A 38- to 40-mm needle should be adequate for adult pygmy hippos. Longer 75-mm needles are available and may provide some extra penetration if the dart is not at right angles to the skin for use in the common hippo. Administration in crates, some chutes, or from remote sites may limit choice of injection sites. Intradermal injection of drugs will result in a slower or incomplete induction, which can result in sudden arousal with stimulation. Signs of induction usually include head lowering, sweating, salivation, ataxia, "dog-sitting," and recumbency. Tail tone in anesthetized hippos may be one measure of anesthetic depth. When reaching a safe anesthetic plane for handling, the tail will be limp and easily manipulated with nonpotent narcotic combinations. However, with potent opioids, tail movement may be maintained despite being at an adequate anesthetic plane. Adequate time after recumbency should be allowed before approaching since stimulation and arousal is possible especially with the nonpotent opioid combinations (Clyde et al. 1998; Morris et al. 2001).

During induction, a hippo may raise its head to take a breath as if in water. This behavior occurs at the start of the anesthesia. Once the animal reaches a deeper plane, this behavior ceases in most individuals.

Placing a blindfold and ear plugs minimizes external stimuli. For added safety, a "muzzle" or ratchet strap can be placed around the jaw just caudal to the canines to prevent accidental opening of the mouth when working around the head.

Positioning

Hippos should be left in their initial position until they reach an adequate plane of anesthesia since movement can also stimulate arousal. The short limbs and barrel-shaped body of a hippo make positioning and transport difficult during anesthesia. Weight on limbs is a concern during extended procedures due to the potential for neuropathy, compromised tissue perfusion, and myopathy. Ideally, limbs should be positioned to optimize circulation and minimize weight on pressure points, such as elbows and hocks, by placing the animal on a soft or padded surface. If the procedure requires an extended period of recumbency, "pumping" or massaging the limbs periodically can aid perfusion, if positioning permits.

Positioning to optimize cardiorespiratory function especially during prolonged procedures is critical. Abdominal contents create pressure on the diaphragm and compromise respirations if left in sternal for longer procedures unless ventilation is assisted (Morris et al. 2001; Ramsay et al. 1998). Therefore, attempts to roll the hippo laterally should be made if respiratory

compromise is suspected. This may also assist with increasing perfusion to extremities. Rolling hippos back up into a sternal position is difficult due to their body shape and size.

Recovery

Once the anesthetic procedure is completed, all personnel and equipment should be removed to a safe distance. The hippo should be left in a sternal or semi-sternal position for recovery, although if this is not possible, recovery from lateral position has been performed (Miller 2007; Morris et al. 2001).

Reversal drugs should be administered intramuscularly for ease and to minimize time. Intramuscular reversal can be achieved by inserting a 3-in spinal needle then into the neck fold or the triceps muscle. This deep insertion should increase the likelihood of intramuscular versus intradermal administration. The tongue muscle may be used for intramuscular injection of reversal drugs (Fleming et al. 2010). However, care must be taken if large drug volumes are injected (e.g., atipamezole) due to swelling and trauma.

Recovery times depend on the drugs used and a successful deep intramuscular injection. Immediate short-term ataxia is often observed. In captive hippos immobilized with butorphanol-detomidine, access to water was allowed as soon as 2 hours post anesthesia (Morris et al. 2001).

Anesthetic Records

Detailed records are critical to advancing knowledge of safe and effective immobilization techniques for hippopotamus. Reviews of records reveal trends and additional areas for investigation as well as potential answers when complications occur. Minimum data should include animal information, date, weight (or estimate), drugs administered (dose, route, and time), time to initial effect, time to recumbency, heart rates, respiratory rates, temperatures, other monitoring parameters, any complications, antagonists administered (dose, route, time), and recovery time and effect. Standardized forms are available through many computerized medical records programs. Final reports should become part of the individual animal's medical record.

Safety

Both hippo species are extremely dangerous and can inflict mortal wounds to humans if charged or trapped in a pen. If the hippo is to be moved or handled without anesthesia, then this must occur from a protected position. Push boards can be used in habituated pygmy or young Nile hippo, but care needs to be taken that adequate escape routes exist if the animal cannot be managed with the board.

Under field conditions, a heavy-caliber rifle (0.375 or bigger) must be on hand to deal with emergency dangerous situations. If there is any concern regarding

immobilization, administering supplemental drugs before handling the animal reduces the risk of spontaneous arousal and can help facilitate body repositioning. Other safety measures, such as placing a jaw strap, using a blindfold and earplugs, reducing noise levels, and minimizing stimulation have been covered but are crucial for personnel safety. Continuous monitoring of anesthetic depth should also be considered part of the safety procedures and staff made aware of any changes.

HISTORICAL REVIEW OF HIPPO IMMOBILIZATION

Common Hippo

Due to the historically high mortality rate associated with hippo anesthesia, there have been few published reports prior to the 1970s. As with other large ungulates, potent narcotics were initially used alone or with xylazine or acepromazine. Frequent complications included apnea, cyanosis, bradycardia, and death. In one review of Nile hippo immobilizations, 6/16 (37.5%) resulted in complications (Ramsay et al. 1998). However potent opioids have been used successfully. Etorphine at 0.001–0.005 mg/kg (total dose 2–6 mg) with or without xylazine (0.061–0.083 mg/kg; total dose 100–150 mg) intramuscularly will induce general anesthesia (Ramsay et al. 1998). This combination can be reversed with 100-mg naltrexone to 1-mg etorphine IM and yohimbine 0.1–0.3 mg/kg IM. Close monitoring for adverse signs is essential when using narcotics in hippos and preparation for complete reversal considered if signs worsen.

Administration of nasal oxygen or intubation with intermittent positive pressure ventilation appears to improve oxygen saturation, especially with the narcotic combinations (Dumonceaux et al. 2000; Loomis & Ramsay 1999; Ramsay et al. 1998). Doxapram administration intramuscularly also has been used to mitigate respiratory depression.

In more recent years, the use of restraint devices and husbandry training has facilitated medical procedures with captive hippos so that only restraint or minor sedation can be used (Krueger et al. 1996). Azaperone and acepromazine provide mild sedation but no analgesia (Burroughs et al. 2006; Loomis & Ramsay 1999).

Detomidine and butorphanol combinations can be administered for minor procedures requiring analgesia and sedation, or as induction agents for immobilization based on dosage. Other drugs can also be added to change or extend the level of anesthesia. Typical dosages are 0.02- to 0.06-mg/kg detomidine with 0.06- to 0.20-mg/kg butorphanol IM. Supplemental doses can be administered at a ratio of 1 : 3 detomidine : butorphanol based on effect (Morris et al. 2001). Initial effects may be observed as early as 10–20 minutes depending on injection placement with recumbency at 20–30 minutes. However, full effect may take longer

and stimulation may cause arousal. Therefore, invasive, painful, or prolonged procedures should be supplemented with isoflurane, ketamine (0.1–1 mg/kg IM), propofol, low dose etorphine, or supplemental detomidine (or medetomidine) and butorphanol (Miller 2007; Morris et al. 2001). Propofol can be administered as a bolus at 0.5 mg/kg or 50–100 µg/kg/min as an infusion IV.

Inhalant anesthetics are useful alternatives to injectable drugs for extending general anesthesia. Ideally, this should be provided through intubation, although it can be effective by nasal insufflations (Dumonceaux et al. 2000). Staff and environmental safety should be considered when using this later method.

Reversal of the detomidine-butorphanol combination is accomplished with naltrexone at a 20 : 1 ratio of butorphanol (in milligrams) or 0.4–0.6 mg/kg IM (Morris et al. 2001). Atipamezole at five times the milligram dose of medetomidine or detomidine IM, or yohimbine 0.1–0.3 mg/kg IM or IV, antagonizes the effects of the alpha-2 agonists (Clyde et al. 1998). Arousal is relatively rapid, usually within 5–20 minutes, unless the hippo has received supplemental drugs.

Pygmy Hippo

There are fewer historical anesthetic reports in pygmy hippos. Nonetheless, they present the same types of challenges as their larger counterparts. In order to minimize the need for immobilization, many facilities have instituted training programs and modified structures to permit minor medical procedures, such as wound treatment, to be performed.

There have been a few anesthetic events using narcotics in pygmy hippos combining etorphine or carfentanil with xylazine (Miller 2003). The commercial combination of etorphine and acepromazine has also been used. However, similar complications were observed in pygmy hippos, and use of potent opioids has fallen out of favor.

For minor sedation or as an adjunct for initial induction, oral detomidine or diazepam, and injectable midazolam (0.1 mg/kg IM) have shown promising results (Weston et al. 1996; K. Mehren, pers. comm.).

Although there are fewer reports, the experience with butorphanol-detomidine in pygmy hippos has been generally good. Since the introduction of concentrated medetomidine, the combination of medetomidine-butorphanol has been more commonly used. The ratio of alpha-2 agonist to butorphanol is approximately 1 : 5, which is different than that used in the Nile hippo (Miller 2007). This resulted in dosages of 0.04–0.06 mg/kg of medetomidine or detomidine and 0.1–0.2 mg/kg of butorphanol IM (P. Morris, pers. comm.). Anesthesia can be extended with supplemental doses of ketamine or gas anesthesia. Reversal agents are similar to those used in the common hippo.

For prolonged, painful or invasive procedures, intubation and maintenance on isoflurane is recommended.

If this is not feasible, other alternatives include using local blocks combined with supplemental ketamine or additional medetomidine-butorphanol as needed. However, this requires continuous monitoring and recalculation of reversal agents.

NEW ADVANCES IN HIPPO RESTRAINT AND IMMOBILIZATION

General Anesthesia of Captive Common Hippos

The recent development of a reversible combination of medetomidine (0.04–0.05 mg/kg), butorphanol (0.05–0.10 mg/kg) and azaperone (0.05 mg/kg, to a max of 125 mg total) has been used successfully in both wild ($n = 20$) and captive common hippos ($n = 5$) (Fleming et al. 2010). This combination was derived from standing sedation dose for captive elephants (Neiffer et al. 2005) (Table 56.1).

Procedures on captive hippos were possible to perform that lasted as long as 3 hours using butorphanol- α -2 agonist induction with isoflurane supplementation. An additional dose of 1–2 mg/kg of ketamine in a second dart may provide some additional anesthesia and provide a higher level of safety. Reversal drugs were naltrexone at 0.12 mg/kg IM ($3\times$ butorphanol dosage) and atipamezole at 0.36 mg/kg IM ($3\times$ medetomidine dosage). In captive hippo, if the animal is not standing by 45–60 minutes, it is advisable to give an additional dose of naltrexone and atipamezole by dart. Yohimbine (0.1 mg/kg) can also be used but does not appear to be as effective as atipamezole in reversing medetomidine.

Table 56.1. New anesthetic combination dosages for captive hippos^a

Immobilizing Drugs		Reversals
Nile hippos		
Butorphanol	0.04 mg/kg	Naltrexone ($3\text{--}5\times$ butor dosage)
Azaperone	0.05–0.1 mg/kg	
Medetomidine	0.06–0.08 mg/kg	Atipamezole ($3\text{--}5\times$ medet dosage)
Ketamine	1 mg/kg	
Pygmy hippos		
Medetomidine	0.035 mg/kg	Atipamezole ($3\text{--}5\times$ medet dosage)
Butorphanol	0.20 mg/kg	Naltrexone ($3\text{--}5\times$ butor dosage)
Detomidine	0.07 mg/kg	Atipamezole ($3\text{--}5\times$ detom dosage)
Butorphanol	0.15 mg/kg	Naltrexone ($3\text{--}5\times$ butor dosage)
Ketamine	0.88 mg/kg	

^aDosages may require supplemental drugs depending on individual circumstances.

In a recent study, 10 captive hippopotamus were kept anesthetized for castration using a combination of medetomidine (60–80 μ g/kg) and ketamine (1 mg/kg) administered IM, with supplemental ketamine (0.1–0.4 mg/kg IV) three to five times in the sublingual vein (Stalder et al. 2012). Transient periods of apnea were noted in 6 of 10 animals. This protocol provided approximately 97 minutes \pm 35 minutes of anesthetic time. Reversal with atipamezole 0.3 mg/kg (50% IV, 50% IM) resulted in standing animals in 5–7 minutes.

Capture and Immobilization of Free-Ranging Common Hippos

Wild hippos frequently use trails from the water to feeding sites that can be used for camera trapping and capture (D. Cooper, pers. comm.). Knowledge of these locations provides potential capture sites. Generally, trap capture of Nile hippo is done at the edge of the pool or dam that they live in, and alfalfa hay is used as the bait into the capture corral, which can be closed remotely trapping the hippo inside. This method is time-consuming, but usually the only way in which large numbers of common hippo are captured safely and cost-effectively in Africa.

Free-ranging hippos create another level of complexity due to their tendency to be in or near water and other hippos during daytime hours when capture usually is planned. Immobilization of free-ranging Nile hippos can be accomplished by darting at night when the animal is at least 1 km from the water. A combination of medetomidine (0.04–0.05 mg/kg), butorphanol (0.05–0.10 mg/kg), and azaperone (0.05 mg/kg to a max of 125 mg) was utilized. If darted, and left alone, undisturbed hippos usually will only run 10–30 m and then resume grazing. Free-ranging hippo should only be darted in or close to water, if they are on their own, or can be separated from the pod. Once in the pod, the animal can become lost or pushed under water when anesthetized. Helicopter darting is an effective way to dart single or individuals that have broken away from the pod. From a helicopter, the gluteus muscles or the muscles along the spine are ideal targets for perpendicular darts. Longer needles are required due to the thicker skin over the dorsum; recommended lengths are 75–80 mm.

Preliminary studies done on captured hippos showed they would stop running or walking at 5 minutes, rest their head, dog sit, and then become recumbent within 10 minutes if the dart went deeply intramuscular. If the drug went subcutaneous, induction could take as long as 45 minutes and require supplemental doses for safe handling.

Several hippos immobilized with both the medetomidine, butorphanol, and azaperone combination (Fleming et al. 2010), and medetomidine and ketamine combination (Stalder et al. 2012) had transient apnea and exhibited the breath-holding behavior for

approximately 20–30 minutes post darting. With regular respirations, SPO₂ values were in the high 90s and ETCO₂ were between 30 and 50 mmHg. Higher ETCO₂ and lower SPO₂ values were initially recorded during the initial breath-holding phase. Other physiologic values followed a similar trend suggestive of acidosis (PCO₂ 35–70 mmHg, PO₂ 35–75 mmHg, SO₂ 82–95%, pH 7.15–7.35, and rectal temperature 35–38°C). Procedure length was variable but averaged about 80 minutes in the field without any anesthetic supplementation.

Recovering hippos in field conditions may have additional challenges such as water or other topographical challenges that should be considered. A large rubber mat can be slid under the hippo and used to move the animal prior to reversal.

New Advances in Captive Pygmy Hippo Immobilization

The frequency of immobilization of captive pygmy hippos has increased since development of the newer anesthetic combinations. Drugs can be administered by either pole syringe, hand syringe, orally, or dart. Successful dental and other procedures can be accomplished under general anesthesia using the following dosages. Oral premedication with midazolam (0.1 mg/kg), diazepam (0.5 mg/kg), and detomidine (0.045 mg/kg) have been used prior to immobilization with alpha-2-agonist-butorphanol combinations (with or without ketamine) (J. Napier, Z. Gyimesi, and E. Baitman, pers. comm.). In general, no obvious drug effect was reported, although some synergistic effects may have occurred since overall ratings for the procedures were good to excellent. Ranges for intramuscular detomidine-butorphanol-ketamine combinations were as follows: detomidine (0.07–0.08 mg/kg); butorphanol (0.15–0.20 mg/kg); ketamine (0.8–2.0 mg/kg). Other successfully used drugs were medetomidine (0.035 mg/kg) and butorphanol (0.2 mg/kg) given IM (Z. Gyimesi, pers. comm.). Nasal insufflation and intubation with administration of isoflurane have also been used to supplement oxygen and anesthesia in pygmy hippos.

The alpha-2 agonists were reversed with atipamezole at five times the dosage of medetomidine or detomidine administered IM. Naltrexone was typically used to butorphanol at a ratio of 5–16 times the dosage of the opioid. Recovery times were reported as mild sedation at 2–17 minutes after administration of the reversal agents.

Capture of Free-Ranging Pygmy Hippos

Pygmy hippos browse on a variety of natural leaves, as well as crop leaves, such as sweet potato and okra. Similar to their larger counterparts, they use trails to travel to and from the water and these provide opportunities for camera and pit traps (A. Conway, pers. comm.). Few attempts have been made to capture

free-ranging pygmy hippos in recent years. Since free-ranging pygmy hippos live in dense vegetation along rivers, darting is not a feasible option. Successful capture of a pygmy hippo in Sierra Leone has been accomplished using a pit trap system (A. Conway, pers. comm.). Pit traps are dug along trails with dimensions of 2 m deep, 2 m long, and 1 m wide. Rice bags containing dirt are placed at the bottom to prevent injury, and a series of small branches are used to support a reed mat to cover the entrance of the pit, which is covered by leaves. The hippo stepping on the mat results in the animal falling into the trap. Immobilization after restraint is feasible. Although not field-tested, a recommended protocol for this procedure would be 0.375-mg/kg medetomidine, 0.9-mg/kg butorphanol, 0.5-mg/kg ketamine, and ±0.4-mg/kg azaperone IM. The total volume for an adult pygmy hippo would fit in a 3-mL dart. Reversal agents should be naltrexone at three to five times the butorphanol dosage and atipamezole at five times the medetomidine dosage IM.

57 Camelids

Khursheed R. Mama and Chris Walzer

INTRODUCTION

Anesthesia may be required for diagnostic and corrective procedures in veterinary hospitals, in zoological parks, in the field, or in the animal's natural habitat. This chapter will attempt to provide information relevant to anesthetic management of camelids so as to maximize chances of a favorable outcome.

It is important to recognize that camelids are native to very different geographical areas, ranging from the high altitude of the Andes to the deserts of India, Africa, and the Middle East. As such, even though they are all camelids, their physiological adaptations differ. For example, camels are well adapted to drought conditions and may store and draw on water reserves. Llamas and alpacas have a left-shifted oxygen hemoglobin dissociation curve (Chiodi 1970), and their red blood cell configuration and hemoglobin content differs from many other mammalian species (Fowler & Zinkl 1989; Van Houten et al. 1992). These are likely adaptations for survival at high altitudes, where the oxygen tension is low.

PATIENT RESTRAINT AND HANDLING

Fasting prior to general anesthesia is recommended to minimize regurgitation, aspiration, and bloating. Depending on the nature of the procedure and anticipated duration of recumbency, a 12- to 18-hour fasting period is recommended in adult llamas and alpacas; a 24- to 36-hour fast has been recommended for camels. Many recommend withholding water in addition to feed for at least a portion of that time. Fasting of nursing juveniles is not necessary and may increase their stress and likelihood of metabolic derangement.

Camelids may be trained to a halter and led using this. A towel may be hung loosely over the nostrils and mouth in the event that an animal attempts to spit at the handler. A small corral may be used to facilitate catching an individual animal from a herd. An arm placed around the neck of llamas and alpacas will help restrain the patient until a halter can be placed. Chutes designed especially for llamas and alpacas greatly facilitate restraint for procedures, such as catheter placement. Domesticated camels may be restrained in stocks designed for horses or eased to sternal recumbency using a rope placed around the forelimb. They may also be trained to a seated ("cush") position by their handler.

INSTRUMENTATION

Intravenous catheterization and endotracheal intubation have historically been considered challenging in camelids. Success can be maximized with proper knowledge of the anatomy and availability of appropriate equipment.

The most common site for venous access in camelids is the jugular vein. The greatest challenge in placing a jugular catheter in adult camelids is lack of animal compliance. Many patients will "cush" and rise during the procedure, making for a moving target. Restraint in an appropriate chute or stanchion can help significantly. The other difficulty faced when placing a jugular catheter is locating the vein. Many camelids, especially males, have thick (up to 1 in) skin in the proximal portion of their neck and balloting the vein can prove challenging especially as the vein is fairly deeply located. Knowledge of the anatomical landmarks is

therefore important. In the proximal neck, the jugular vein is located at the bisection of a line drawn caudally from the lower jaw with a line drawn ventrally from the base of the ear (Davis et al. 1996). Despite difficulty palpating the vessel in the proximal portion of the neck, many prefer this site for catheter placement due to better separation between the jugular vein and carotid artery (Davis et al. 1996; Riebold et al. 1989). This approach should also be considered when performing venipuncture for administration of drugs as cerebral injury has been reported following inadvertent intracarotid injection of anesthetic drugs (Valentine et al. 2009), and it can be difficult to differentiate arterial from venous blood in South American camelids due to the brightness of venous blood (Grint & Dugdale 2009). Distention of the vein is best accomplished by holding off behind the palpable ventral projection of the C6 vertebra. If one is still unable to palpate the vein, a narrow gauge (25 or 23) inch to inch and a half needle may be used to locate the same prior to catheter placement.

Once the vein is located and the site appropriately prepared, an incision through all the layers of the skin is recommended in the adult camelid. This incision is best made with a scalpel blade after subcutaneous local anesthetic (1–2 mL of 2% lidocaine) is infiltrated at the site (Heath 1989). In order not to accidentally lacerate the vessel, do not distend the vein while making this incision through which the catheter may then be placed. Continue to distend the vein while the catheter is advanced to minimize the chances of it getting caught on valves within the same. Valves have been anecdotally reported to impede threading the jugular catheter. Secure the catheter so that it does not “kink” at the point of entry through the skin.

Alternate sites for catheter placement include the lateral thoracic vein in adult camels and the cephalic or saphenous vein in juvenile patients. Auricular vessels may be used in anesthetized patients. The size of the catheter used should be appropriate for the size of animal with consideration given to the reason for its placement. For example, a large-gauge catheter similar to that placed in adult patients is generally unnecessary in a 10-kg cria. Alternatively, if significant hypotension is expected in an adult patient due to the disease process or because of anticipated hemorrhage, at least one large-gauge catheter is recommended.

The technique for endotracheal intubation varies with the camelid species in question. For llamas and alpacas, visual orotracheal intubation is facilitated by appropriate equipment and positioning. Ideally, the animal should be placed in sternal recumbency with the head extended. A ruminant mouth gag or strips of tape/gauze may be used to spread the jaws and facilitate visualization using a long, but narrow laryngoscope blade. Intubation may be performed directly using an endotracheal tube or either directly or retro-

grade by first placing a flexible guide to help direct the endotracheal tube into the trachea (Sanchez et al. 1993). Topical local anesthetic (lidocaine) is used to facilitate intubation in the lightly anesthetized patient. The tube is generally secured behind the ears after the cuff is inflated. Passage of the tube via the nasal passage (nasotracheal intubation) may also be performed in llamas and alpacas. (Riebold et al. 1994) The tube is passed into the trachea via the ventral medial nasal meatus after proper lubrication. While this usually necessitates a smaller tube (e.g., 8- or 9-mm internal diameter vs. 12- or 14-mm internal diameter in an adult llama) than via the oral route and there is a potential for hemorrhage during placement, the tube may be left in place until the animal is fully recovered without fear of the patient chewing it. Vasoconstrictors, such as phenylephrine, may be administered topically to minimize hemorrhage during nasotracheal tube placement. Since camelids are nasal breathers, this method helps minimize the risk of upper airway obstruction in the recovery period. This technique may also be utilized to minimize the need to work around the endotracheal tube during procedures involving the oral cavity.

In adult camels, intubation is usually performed blindly or by manual palpation of the arytenoid cartilages. After the patient is adequately anesthetized, a large animal mouth gag may be used to facilitate introduction of the arm into the oral cavity. If the oral cavity is too narrow, a guide tube may first be inserted into the trachea. Caution must be exercised to prevent laceration of the endotracheal tube on the rear teeth. Depending on the size of the patient, a range of tubes from 16- to 26-mm internal diameter may be necessary (Alsobayil & Mama 1999) (Fig. 57.1).

ANESTHETIC TECHNIQUES

Regional and general anesthetic techniques may be used in camelids. General anesthesia may be achieved with injectable agents, inhaled agents, or a combination of these. For the reader who wishes to pursue this further, detailed reviews of anesthetic drugs and techniques for camelids are available (Ali 1988; Alsobayil & Mama 1999; Fowler 1989; Mama 2000). Regardless of the drugs selected, keep in mind that the range of body weights is very broad among camelids, ranging from an 8- to 10-kg newborn cria to a 500-kg camel. Hence, it is important to try to get an accurate weight and calculate dosage based on this. Fiber in adult llamas and alpacas can be very misleading, and when a scale is not available, palpation of the patient may assist in determining weight. Typically, adult alpacas weigh 40–60 kg, and whereas body weight in adult llamas may range from 120 to 300 kg. Body weight also influences equipment requirements, ranging from endotracheal tubes and the anesthetic machine to the type of padding used.

Regional Anesthesia

Regional administration of local anesthetics can facilitate surgical intervention and minimize the need for administration of drugs with systemic effects. Local anesthetics may be used to facilitate a host of procedures. Blocking individual nerves, for example, the mandibular nerve, for dental procedures involving the lower jaw are commonly utilized in awake or sedated patients and as an adjunct to general anesthesia. The anatomy and location of the mandibular and mental foramina to facilitate regional anesthesia at these nerves has been well described (Zhu et al. 2009). Paravertebral blocks similar to those described in both horses and cattle have been used in camelids. (Fowler 1989; Said 1964) as have epidural techniques.

Caudal epidural administration of 12–15 mL of 2% lidocaine in a sternally recumbent adult camel provides anesthesia of the perineum and udder or scrotum for 1–2 hours without influencing motor control (White 1986). Lidocaine (0.22 mg/kg) and xylazine (0.17 mg/kg) have been used to facilitate diagnostic and surgical procedures involving the rectum, vagina and perineum in llamas (Grubb et al. 1993). The onset of anesthesia was 3–4 minutes following either lidocaine or xylazine and lidocaine, but the duration varied significantly lasting about 1 hour in the lidocaine group and 6 hours in the group receiving both drugs. Analgesia following xylazine alone was evident after about 20 minutes and lasted 3 hours. Mild sedation is reported in animals receiving xylazine. Clinical evaluation of efficacy of caudal epidural analgesia with lidocaine, or a combination of lidocaine and xylazine in alpacas undergoing castration, revealed that while a combination or epidural xylazine and lidocaine had the best efficacy, incomplete blockade of the spermatic cord was observed in

many animals (Padula 2005). Epidural morphine at doses similar to those used in other species may provide longer-term analgesia and may have value for postoperative analgesia for procedures involving the hind limbs or caudal abdomen and perineum.

Drugs for Sedation and Field Anesthesia in Domesticated Camelids

Many techniques and drugs for sedation and anesthesia have been used in camelids and for detailed information on the same and individual drug effects, the reader is referred to more comprehensive reviews and references therein. (Ali 1988; Alsobayil & Mama 1999; Fowler 1989; Mama 2000). This section of the manuscript will highlight commonly used techniques for domesticated animals.

Intramuscular (IM) and intravenous (IV) administration of xylazine or xylazine and ketamine has been extensively described for use in llamas, alpacas and camels (Bolbol 1991; DuBois et al. 2004; Fowler 1989; Gavier et al. 1988; Prado et al. 2008a; White et al. 1987). While these drugs alone and in combination do provide effects ranging from sedation to short-term anesthesia, the degree (level of sedation or anesthesia) and duration (may range from 10 to 60 minutes) of response in individual animals is variable. The addition of butorphanol to an IM combination of xylazine and ketamine has also been evaluated in llamas and alpacas. Xylazine (0.03 or 0.04 mg/kg, IM), butorphanol (0.3 and 0.4 mg/kg, IM), and ketamine (3 or 4 mg/kg, IM) was administered to seven male llamas and seven male alpacas based on dose recommendations from Dr. LaRue Johnson (Mama et al. 2000). Most animals became recumbent in an average of 4.3 (llamas) and 6.7 (alpacas) minutes. Induction quality was good, with animals generally showing some degree of ataxia before assuming a sternal or lateral position. Despite receiving lower drug doses, llamas appeared more deeply anesthetized and remained recumbent for a longer duration (mean time to standing 63 minutes) than did alpacas (mean time to standing 22 minutes). All animals recovered without apparent complications, but hypoxemia (average PaO₂ of 45–55 mmHg, barometric pressure 640 mmHg), and mild hypoventilation (average PaCO₂ was 46–49 mmHg), associated with recumbency, was commonly seen in this study. Direct mean auricular arterial blood pressure was well maintained, averaging 131 mmHg in llamas and 144 mmHg in alpacas; heart rate ranged from 29 to 37 beats/min in llamas and 37 to 49 beats/min in alpacas.

Other alpha-2/dissociative and/or benzodiazepine combinations include xylazine and tiletamine/zolazepam or medetomidine and ketamine (DuBois et al. 2004; Hammer et al. 1999; Waldridge et al. 1997) and medetomidine, butorphanol and ketamine (Georoff et al. 2010). Selection of a specific alpha-2 or dissociative agent is in large part based on drug availability,

circumstance, and familiarity on the part of the veterinarian. Effects may vary in duration and magnitude but tend to be qualitatively similar between the different agents.

Butorphanol (0.1 mg/kg, IM) has also been used in combination with intratesticular lidocaine (2%, 2–5 mL/testicle) for chemical restraint to facilitate standing castration in over 100 llamas (Barrington et al. 1993). The authors' impression was that the animals receiving butorphanol appeared less stressed than those receiving only intratesticular lidocaine.

Similar drug combinations are utilized for anesthesia in field conditions for camels. White et al. (1987) describe the use of intramuscular xylazine and ketamine individually and in combination. Behavioral responses and measured cardiovascular parameters of the combination were thought to be improved over individually administered drug. Detomidine and medetomidine have also been used alone to provide sedation or in combination with ketamine for anesthesia. In studies evaluating the effect of these drugs on platelet function and coagulation, xylazine, but not detomidine or ketamine, was shown to decrease platelet numbers which might be of relevance for procedures in which bleeding is anticipated (Almubarak 2007). The effects of the alpha-2 drugs may be reversed with yohimbine or atipamezole at the conclusion of the procedure to facilitate a more rapid recovery (Riebold et al. 1986; Waldridge et al. 1997). While tolazoline has also been used successfully in the research environment for reversal of alpha-2 effects (DuBois et al. 2004; Prado et al. 2008a), there have been anecdotal reports suggesting complications following its administration is possible in camelids.

The phenothiazine tranquilizers are a class of drug that seem to be more widely used in camels than in llamas and alpacas. While acepromazine is the tranquilizer most veterinarians are familiar with, other drugs in this class include propionyl promazine, chlorpromazine and triflupromazine. These drugs tend to have prolonged effects and are not reversible, but in many circumstances, camels are quieted and seem generally less responsive to their surroundings (Alsobayil & Mama 1999). Prado et al. (2008b) report no sedation with acepromazine or acepromazine and butorphanol in young llamas. However, they did demonstrate a longer period of antinociception during anesthesia maintained with Telazol following these treatments.

Drugs for Sedation and Field Anesthesia in Nondomesticated Camelids

Conservation efforts often require capture and handling of animals. Wildlife capture and anesthesia is a complex operation that can cause significant injury or death. Although skill, experience, and appropriate veterinary training can minimize the risk, it is necessary to evaluate whether the procedure is necessary and

whether the potential gains in knowledge for conservation of the species outweigh the risks (Osofsky & Hirsch 2000). Many of the aforementioned techniques may be used at modified dosages to provide chemical restraint for nondomesticated camelids. Additional suggestions are provided in the subsequent text.

Wild South American Camelids (SAC) Traditionally, SAC are physically restrained for fiber (wool) harvest using various herding techniques (Bonacic et al. 2006). There are very few reports in the literature detailing the capture and field anesthesia of wild SAC for conservation purposes. One describes the use of tiletamine and zolazepam for immobilization of guanacos in a Chilean national park, but results of this combination were thought to be largely unsatisfactory (Karesh et al. 1998; Sarno et al. 1996). Recently, Georoff et al. (2010) describe use of a combination of IM medetomidine, butorphanol, and ketamine followed by reversal with atipamezole and naltrexone in captive (zoological park) guanacos. They report a reliable onset of anesthesia and effective reversal with no noted behavioral side effects. Due to these favorable qualitative aspects, further evaluation in the field situation is warranted. However, bradycardia, hypertension, and hypoxemia as reported by authors will need to be managed during drug-induced recumbency.

As with guanacos, descriptions of field anesthesia for the smallest SAC, the vicuna (*Vicugna vicugna*) are extremely limited. Ketamine (7.8 mg/kg) and xylazine (1.2 mg/kg) sometimes in combination with midazolam (0.35 mg/kg) and atropine (0.07 mg/kg) has been used successfully in the field setting to collect semen via electroejaculation (Hoyos 2009; Urquieta et al. 1992).

Wild Bactrian camel (*Camelus ferus*) The range of the wild Bactrian camel has been reduced to only three locations worldwide: two in China (Lop Nur and Taklamakan Desert) and one in Mongolia (Great Gobi A SPA). The population is listed by IUCN as critically endangered and there remain an estimated ~600 animals in China and between 350 and 1950 in the Great Gobi A SPA (Walzer et al. 2008).

Potent opioids, such as etorphine, have been used in camels either alone or in combination with acepromazine, ketamine, xylazine, detomidine, butorphanol and tiletamine, and zolazepam (Blumer et al. 1999; deMaar et al. 1998; Walzer et al. 2005). Pacing is commonly described prior to recumbency when potent opioids are used without a tranquilizer. Significant respiratory depression is a potential complication. Availability of a mechanical breathing device and oxygen supplementation are therefore highly recommended when potent opioids are utilized. Alpha-2 agents, when used, and potent opioids may be reversed at the conclusion of the procedure.

As has been described for other species such as the Asiatic wild ass (*Equus hemionus*) and Przewalski's horse (*Equus ferus przewalskii*) a chase method (in this instance the animal was darted from a moving jeep) was used to capture a single wild Bactrian camel for radio collaring. This method is similar to that traditionally employed by poachers (Blumer et al. 1999; Walzer 2003). However, whereas poachers use a shot gun, veterinary and conservation personnel typically use a CO₂-powered dart gun (Daninject JM,™ Dan-Inject ApS, Børkop, Denmark) often with a short (4-cm) barrel to facilitate mobility in the confines of the chase vehicle (jeep). When using the chase technique personnel must be sensitive to ambient conditions and to limiting chase time to 15 minutes (or less) to prevent hyperthermia. Additionally, when tracking the animal post injection in the rump, caution must be exercised so it is not disturbed until fully immobilized. Animals are then typically approached from the rear.

Walzer and Kaczensky (2005) describe using the chase technique to induce anesthesia in one male and two female camels with etorphine (4.4 mg), butorphanol (10 mg), detomidine (13 mg), and tiletamine-zolazepam (160 mg). Because ambient temperature varied between –15 and –30°C during the day, all drug combinations were supplemented with propylene glycol to prevent freezing. Anesthesia was reversed with naltrexone (200 mg IV), a long acting opioid antagonist and atipamezole (25 mg IV).

During subsequent expeditions, 10 additional camels were immobilized using the method described above. In 9 of 10 camels, anesthesia and subsequent recovery was uneventful, but one animal, an old bull (>15 years), died during capture. While the cause is unknown, the animal was extremely bloated and appeared to have regurgitated when located approximately 40 minutes post injection (Walzer et al. 2008).

Based on these experiences, the author (Walzer) currently recommends a combination of etorphine (4.4 mg IM), butorphanol (10 mg IM), and detomidine (15 mg IM) for the immobilization of wild adult camels. Butorphanol is used in this combination to a potentially alleviate the marked respiratory depression induced by the etorphine at the μ receptor while potentiating sedation at the κ and σ opioid receptors. This combination can be varied as necessary for the circumstance. For example, the addition of tiletamine-zolazepam provides a more rapid transition to sternal recumbency. Alternatively, by decreasing the etorphine dose by 1 mg and omitting tiletamine and zolazepam, the animal appears sedated but often remains standing or in sternal recumbency. This can be helpful when locating the animal in the steppe landscape, but can also lead to prolonged pacing phase in which the animal can cover a greater distance and potentially injure itself.

While not specific to anesthesia management, a unique drug that has received some consideration for

Figure 57.2. Pursuing a herd of wild Bactrian camels in the Great Gobi “A” Strictly Protected Area in Mongolia in order to place a dart (photo courtesy of Petra Kaczensky).

handling and transportation of camels is reserpine, an indole alkaloid that *irreversibly* blocks uptake of norepinephrine and dopamine (Al-Ani 2004). Its availability in many developed nations, however, is limited, due to significant side effects (Fig. 57.2, Fig. 57.3, Fig. 57.4, Fig. 57.5, and Fig. 57.6).

Anesthetic Techniques for a Hospital Environment

Anesthetic Induction and Short-Term Maintenance The hospital setting provides a more controlled environment and allows one to better titrate drugs to achieve sedation, short-term anesthesia or to transition a patient to inhalation anesthesia. The placement of an intravenous catheter facilitates this titration of the drugs to a given end-point for an individual patient.

Most induction combinations include either ketamine (2–5 mg/kg titrated to effect) or propofol (2 mg/kg titrated to effect) in conjunction with a centrally acting muscle relaxant, such as guaifenesin (25–75 mg/kg), diazepam, or midazolam (0.02–0.1 mg/kg). Use of chloral hydrate alone or with magnesium sulfate has also been described for induction and short term anesthesia maintenance in camels (Ali 1988). Alpha-2 agonists, such as xylazine and medetomidine, may also be used, especially in larger and more unruly animals. These may be administered IM to facilitate catheterization or IV prior to ketamine or propofol. Keep in mind that the dose for xylazine in camelids is in between that reported for cattle (0.03–0.1 mg/kg) and horses (0.3–1.0 mg/kg).

Ketamine combinations have been routinely used for anesthetic induction in camelids. Typically, animals become recumbent about 45 seconds following IV administration, and intubation conditions are good in most circumstances if one is fairly efficient. Additional drugs may be safely administered if the patient maintains pharyngeal tone or is swallowing. A retrospective study describes successful anesthesia maintenance in dromedary camels for a variety of surgical procedures with repeated doses of xylazine and ketamine (Al-Mubarak et al. 2008).

While propofol combinations are not used as frequently, studies do report its safety and efficacy in camelids. For example, propofol was used in camels premedicated with xylazine and diazepam to induce and maintain short-term anesthesia (Fahmy et al. 1995). The same dose has also been used for induction in llamas (Duke et al. 1997).

Inhalation anesthetic induction has been successfully used in llamas and alpacas on occasions where intravenous catheterization prior to anesthetic induction has proved challenging. While regurgitation and aspiration concerns are valid, fasted animals are less likely to manifest these complications. However, this process can be quite time consuming; anesthetic induction was reported to take an average of 17–19 minutes from time of first isoflurane breath to orotracheal intubation in unpremedicated healthy adult llamas (Mama et al. 1999, 2001). This time may be significantly reduced in debilitated patients, and in those receiving premedication.

Anesthetic Maintenance When available, inhalation anesthetic techniques are used to maintain anesthesia in patients undergoing highly invasive surgical procedures (e.g., celiotomy and fracture repair). Halothane, isoflurane, and sevoflurane have all been used to maintain anesthesia in camelids, but studies are limited. One report provides the minimum alveolar concentration (MAC) of isoflurane in llamas $1.05 \pm 0.17\%$ (Mama et al. 1999), whereas another provides the same information for sevoflurane in both llamas

($2.29 \pm 0.14\%$) and alpacas ($2.33 \pm 0.09\%$) (Grubb et al. 2003). These values are similar to those reported in other species and one presumes that adult camels would be similar. A small animal anesthetic machine and breathing circuit are appropriate for llamas and alpacas, whereas a large animal breathing circuit is necessary for adult camels.

Cardiopulmonary and behavioral responses are described with inhalation agents in anesthetized camelids. In adult llamas, a decrease in mean arterial blood pressure and an increase in heart rate were observed with increasing isoflurane dose during both spontaneous and controlled ventilation. Cardiac output and PaCO₂ were higher during spontaneous ventilation than during controlled ventilation (Mama et al. 2001). The broadest base of experience in camels is with halothane. Following anesthetic induction with injectable agents, anesthesia has been successfully maintained with halothane vaporizer settings between 1% and 3% (Singh et al. 1994; White et al. 1986). Blood pressure is reported to be in the same range as for other domestic species, but with a tendency toward higher values much like those observed in cattle. Rapid shallow breaths and rising PaCO₂ values are also described. During inhalation-induced recumbency, spontaneous behaviors (e.g., swallowing and limb movement) decreased with increasing anesthetic depth. Jaw tone and palpebral reflex activity also decreased as isoflurane dose increased. Recovery from anesthesia was also reported to be uneventful (Mama et al. 1999, 2001; Singh et al. 1994; White et al. 1986).

Inhalation anesthetics are the mainstay for anesthetic maintenance, but the need for specialized delivery equipment generally limits the use of this technique to the hospital environment. While expensive, the advent of short-acting, rapidly cleared IV drugs, such as propofol, provides veterinarians with the option of maintaining general anesthesia using continuous infusions. Two intravenous infusion doses of propofol (0.2 mg/kg/min and 0.4 mg/kg/min) used for anesthetic maintenance in llamas have been assessed after a 2 mg/kg induction dose (Duke et al. 1997). The infusions were maintained for 60 minutes during which time llamas receiving the higher dose appeared adequately anesthetized and generally unresponsive to external stimuli, whereas llamas receiving the lower dose were noise sensitive and made some weak attempts to raise their head. Animals stood an average of 13–22 minutes following termination of the low and high dose infusion, respectively, and showed little to no ataxia.

During anesthetic maintenance with both infusions of propofol the heart rate was increased (to approximately 90 beats/min) over predrug values (of approximately 55 beats/min). Mean carotid arterial pressure was similar to predrug values and ranged from an average of 103 to 147 mmHg during drug-induced recumbency. The PaCO₂ increased and PaO₂ decreased

in recumbent animals but were felt to be within a clinically acceptable range. Three llamas did, however, become dyspneic and required placement of a nasopharyngeal tube to ensure a patent airway.

Combinations of inhalation agents and injectable drugs may also be of benefit in managing general anesthesia. In one study, authors describe a mean reduction in isoflurane dose requirement of 37% when receiving 40 µg/kg/min of ketamine by IV infusion (Schlipf et al. 2005). Another report describes a small but not statistically significant decrease in bispectral index values following 0.1 mg/kg IV of butorphanol in isoflurane-anesthetized alpacas, indicating a potential benefit (Garcia-Pereira et al. 2007). Except for a decrease in systemic vascular resistance, cardiovascular parameters were largely unchanged after butorphanol; as animals were ventilated, effects on respiration could not be assessed. Larenza et al. 2008 describe the successful use of a more complex protocol using fentanyl s-ketamine, midazolam, and isoflurane in an alpaca with increased anesthetic risk. Respiratory function was, however, negatively affected.

Muscle Relaxation during General Anesthesia When muscle relaxation provided by the anesthetic agents alone is not adequate (e.g., intraocular surgery and reduction/repair of a displaced long bone fracture), drugs that block the neuromuscular junction (peripherally acting muscle relaxants) are used as adjuncts during general anesthesia. The efficacy of atracurium, administered via intermittent IV bolus (0.15 mg/kg initial dose, followed by 0.08 mg/kg) or IV infusion (0.15 mg/kg initial dose, followed by 0.4 mg/kg/h), has been evaluated in halothane anesthetized, mechanically ventilated llamas (Hildebrand & Hill 1993). Another report suggests that both succinylcholine and gallamine may be used successfully to supplement relaxation during general anesthesia in camels (Held & Paddleford 1982). When using these agents, it is essential to be aware that they provide no analgesic or sedative properties and that ventilation will be significantly depressed.

ANESTHETIC RECOVERY

Although the occasional patient may have a violent recovery, in general, camelids recover well from anesthesia. When possible, it is ideal to place the camelid in a sternal posture with the head elevated. This allows both for eructation and helps minimize any nasal edema. Oxygen insufflation during this period is also beneficial. If the patient is orotracheally intubated, the endotracheal tube should be protected so it does not get lacerated by the molars. In the alpaca and llama this is relatively easy to do with a partially used 2-in roll of tape which can be placed over the tube in the mouth with a tab hanging out. It is important not to remove the endotracheal tube until one is sure that the patient

can control their airway. Camelids frequently show early arousal and chew their tube and raise their head briefly and then seemingly “fall asleep” again. Removal of the tube in this early period therefore can result in airway obstruction. Often, this is silent and only evident when observing the chest move inward (as opposed to outward) during inspiration. Intervention is critical and may be as simple as extending the head and trying to get the patient to swallow and providing oxygen; in extreme cases, reintubation is necessary.

ANALGESIC TECHNIQUES

While efficacy of local and regional anesthetic techniques is reported in camelids (Barrington et al. 1993; Grubb et al. 1993), there is very little published regarding benefits or side effects of systemically administered analgesics in these animals. Hence, much of the use is based on personal preference and extrapolation from other species. Evaluation is further confounded by difficulty in assessing clinical signs of and hence resolution of pain. While no animal should suffer because of pain, one should continue to obtain evidence for efficacy of analgesic drugs to ensure appropriate therapy for the patient.

Nonsteroidal anti-inflammatory drugs and opioids have been used and studied to a limited extent in South American Camelids (llamas). The pharmacokinetics of ketoprofen, phenylbutazone, and flunixin meglumine are described in llamas (Navarre et al. 2001a, 2001b, 2001c). However as authors state, the determination of serum or plasma concentrations associated with analgesia are only extrapolated from other species; serum concentrations between 0.4 and 0.6 $\mu\text{g}/\text{mL}$ of ketoprofen are considered effective in humans, and a target of 5–15 $\mu\text{g}/\text{mL}$ is suggested for phenylbutazone in horses. As plasma or serum concentrations may not truly represent therapeutic effects at the site of the lesion within the tissue, relating kinetic data to clinical efficacy is further confounded. However, these drugs continue to be used in camelids with apparent clinical success.

Use of the opioids in the clinical environment is perhaps more controversial. While potent opioids have been used to provide immobilization, information on the use of these drugs as analgesics is limited. There is one report suggesting use of intramuscular butorphanol (0.1 mg/kg) is of some benefit in animals experiencing somatic pain; the short half-life following intravenous butorphanol was thought to limit its clinical usefulness (Carroll et al. 2001). Mixed results were described by authors assessing analgesia produced by morphine in healthy llamas. A dose of 0.25 mg/kg IV produced the most consistent increase in tolerance to a cutaneous electrical stimulus in this report (Uhrig et al. 2007). While studies such as these may not represent the true clinical condition, the variability in response when compared with the effects of these drugs in

studies conducted in other species (e.g., dog) suggest the need for further evaluation.

MONITORING DURING ANESTHETIC-INDUCED RECUMBENCY

Monitoring anesthetic depth in camelids can be challenging as they maintain ocular reflexes at seemingly all planes of anesthesia. In addition to a brisk palpebral, the globe also tends to rotate periodically during anesthesia and to the inexperienced individual, this is quite disconcerting, but seems to bear little correlation with movement in response to a noxious stimulus. Eyelid aperture (or the distance between eyelids) has been correlated and widens with increasing inhaled anesthetic depth in llamas (Mama et al. 2001). Jaw tone is another useful method for monitoring anesthetic depth in the smaller camelids. Assessment of prepuccial and rectal tone, drooping of the lower lip, relaxation of neck, and abdominal and tail musculature have been advocated by some as another means to assess depth of anesthesia and muscle relaxation (Alsobayil & Mama 1999).

Guidelines for monitoring physiologic responses during drug-induced recumbency are much the same as for any other species. The degree of monitoring should be appropriate for the patient's health status and with regard to the procedure; monitoring a young animal undergoing a castration will differ significantly from a patient needing abdominal exploratory surgery.

Monitoring for short-term chemical restraint in a field situation may include auscultation of the heart and lungs, palpation of the pulse, and evaluation of mucous membrane color and refill time. Changes in muscle tone or gross movement are commonly used to assess anesthetic depth. For longer procedures or those in which the animal may be at more risk, noninvasive battery-powered monitors, such as a pulse oximeter and Doppler or oscillometric blood pressure monitor, may easily be placed. A rectal thermometer is used to monitor body temperature if deemed necessary. While it is recommended that record notations be made at 5-minute intervals, it is ideal to observe the patient continuously.

In a referral hospital setting, monitoring is generally more extensive as patients are often significantly compromised. Typically, in addition to pulse palpation and observation of mucous membranes, the cardiovascular system is evaluated using an electrocardiogram (ECG) to assess heart rate and rhythm, and an arterial catheter is placed for direct (invasive) blood pressure monitoring. ECG leads function best when clips are placed in areas with less fiber (axilla and flank or upper lip/base of the ear). Depending on the procedure, leads should be placed on either side of the heart or cranial and caudal to the heart. Arterial catheters (20- or 22-gauge 3–5 cm) are commonly placed in the auricular or medial

saphenous artery, but the carpal, cranial tibial, or middle coccygeal artery may also be used in camels. Heart rate ranges from 60 to 120 beats per minute in llamas and alpacas during inhalation anesthesia, but may be significantly lower if alpha-2 agonists are used. In camels, heart rate is more typically 40–50 beats per minute, but bradycardia and second-degree AV block may be observed with use of alpha-2 agonists (White et al. 1987). Blood pressure in llamas and alpacas seems to be quite labile and may vary from a mean pressure of 50–60 mmHg to 100 mmHg for seemingly no apparent reason. Despite this, studies have shown that there is a trend and blood pressure decreases with increasing inhalation anesthetic depth, as has been shown for other species (Mama et al. 2001).

A thermistor probe is placed nasally or rectally for evaluation of body temperature and either a pulse oximeter (SpO_2) and capnograph or arterial blood gases ($PaCO_2$, PaO_2) are used to evaluate pulmonary function. Values are similar to those observed in other domestic species or in the range of 95–100% for SpO_2 and 40–50 mmHg for end tidal and $PaCO_2$. PaO_2 values are influenced by the inspired oxygen and may range from 80 to 100 mmHg at sea level for a patient breathing room air to 500 mmHg for a patient breathing 100% oxygen. Keep in mind that altitude will significantly decrease these values.

For critically ill patients, glucose, electrolyte, and acid–base monitoring, and measurement of PCV and TP can add useful information. Note that unlike most other species, apparently healthy llamas and alpacas frequently have a packed cell volume (PCV) ranging upwards from the mid-20s.

Monitoring abdominal distention and for the presence (and volume) or absence of regurgitation, and for degree of nasal edema during drug-induced recumbency are also important as they may indicate the need for intervention to ensure a favorable outcome (Fig. 57.7 and Fig. 57.8).

SUPPORT DURING ANESTHETIC-INDUCED RECUMBENCY

As with monitoring, supportive care should also be related to patient's needs with some exceptions. For example, the eye should always be protected and lubricated in camelids as they tend to protrude from the head and are easily traumatized. Attention should always be given to patient positioning so as not to cause neural or muscle damage; lower forelimb pulled forward in lateral recumbency and upper limbs supported in a natural position (not hanging). In dorsal recumbency, the limbs should be flexed. For longer procedures or larger patients, padding becomes increasingly important. Air or foam mattresses and water beds have all been utilized successfully.

Figure 57.7. Placement of an arterial catheter in the medial saphenous artery (photo courtesy of Gary West).

Figure 57.8. Placement of an arterial catheter in the auricular artery of a llama.

In cool environments or in young and small patients, external heat should be provided, whereas active cooling may be necessary in warm environments. Circulating air or water blankets or radiant heat lamps may be used for warmth, whereas providing shade or using a fan or simply hosing the patient with water will help keep the patient cool.

A balanced electrolyte solution should be administered intravenously to patients undergoing inhalation anesthesia or those in whom recumbency is expected to last greater than 1 hour. An administration rate of 5 mL/kg/h is suggested for most patients. Dehydrated patients should receive a fluid volume appropriate for the perceived level (e.g., 5% of a 100-kg animal is equivalent to 5 L). If heart rate or blood pressure values fall out of the normal range, additional intervention may be necessary. This may include anticholinergics, such as atropine, and inotropes/vasopressors, such as ephedrine, dobutamine, or phenylephrine. A recent study describes the use of both dobutamine (4 and 8 μ g/kg/min) and norepinephrine (0.3 and 1 μ g/kg/min) in isoflurane-anesthetized alpacas. Both drugs increased cardiac output and appeared safe and effective at the

lower dose studied for each drug. At higher doses, increased arrhythmogenicity was observed for dobutamine, and excessive vasoconstriction was a noted side effect for norepinephrine (Vincent et al. 2009).

In critically ill patients, electrolytes may need to be adjusted and acid–base balance corrected. In very young patients, glucose supplementation may be necessary. Methods for calculating and adjusting these values are available.

While oxygen is routinely used in patients during inhalation anesthesia, this is less common when using injectable techniques. Since llamas and alpacas have been shown to become hypoxic during injectable anesthetics, oxygen supplementation is highly recommended especially for patients at altitude. Camels are also prone to hypoxemia due to their body mass, and oxygen supplementation should always be considered during recumbency. Availability of lightweight aluminum tanks and flow meters has made this easier to achieve in field conditions. The flow meter is connected to a small flexible hose placed in the ventromedial nasal meatus up to the medial canthus of the eye. An ambu bag should be available in case of a need to ventilate a patient in the field. For a patient connected

to a breathing circuit, manual or mechanical ventilation is easily accomplished.

While uncommon in llamas and alpacas, recumbent camels may bloat, and placement of a “bloat” tube may be necessary to help relieve this and minimize the influence on venous return and pulmonary function. Because these animals are obligate nasal breathers, nasal edema can be problematic following extubation. When possible, the head should be positioned to allow drainage of regurgitant fluid while still minimizing edema. Alternatively, vasoconstrictors, such as phenylephrine, may be diluted and gently placed in the nasal passages prior to extubation. If food material is observed from the nose, gentle lavage (after ensuring the endotracheal tube cuff is sealed) is recommended.

SUMMARY

Chances of a favorable outcome are increased with an understanding of basic physiological differences between camelids and other species, and selection of appropriate drug, monitoring, and supportive techniques (Table 57.1 and Table 57.2).

Table 57.1. Drug protocols for sedation and anesthesia in domesticated healthy adult camelids^a

Drug or Drug Combination	Dose (mg/kg) and Route of Administration	Approximate Onset (Minute) of Action and Anticipated End Point	Approximate Duration of Anesthetic Action	Anticipated Recovery for Drugs Resulting in General Anesthesia
Sedation				
Acepromazine	0.05–0.1, IM	5–15, tranquilization	1–4 hours	N/A
Xylazine	0.25, IM	15, sedation	1–4 hours	N/A
	0.1–0.2, IV	5, sedation	1–4 hours	N/A
Anesthesia				
Xylazine	0.1–0.2, IM	5–10, recumbency	10–20 minutes	45 minutes to 2 hours
Ketamine	2–3, IM			
Xylazine	0.03–0.05, IM	5–10, recumbency	10–20 minutes	20 minutes to 1 hour
Butorphanol	0.3–0.5, IM			
Ketamine	2–4, IM			
Xylazine	0.1–0.2, IM	45 seconds after guaifenesin and ketamine, recumbency	10–20 minutes	45 minutes to 2 hours
Guaifenesin	50–100, IV			
Ketamine	1–2, IV			
Xylazine	0.1–0.2, IM	45 seconds after diazepam and ketamine, recumbency	10–20 minutes	45 minutes to 2 hours
Diazepam	0.1–0.25, IV			
Ketamine	1–2, IV			
Xylazine	0.1–0.25, IV	1 minute after propofol, recumbency	10–20 minutes	45 minutes to 2 hours
Diazepam	0.25, IV			
Propofol	2, IV			
Maintenance				
Halothane	Vaporizer set between 0.8% and 1.5%	Administered to effect	Administered to effect	30–90 minutes following discontinuation
Isoflurane	Vaporizer set between 1% and 2%	Administered to effect	Administered to effect	20–60 minutes following discontinuation
Sevoflurane	Vaporizer set between 2% and 3%	Administered to effect	Administered to effect	20–60 minutes following discontinuation

^aDosages are approximate and may need adjustment for the individual patient and scenario.

Table 57.2. Drug protocols for sedation and anesthesia in domesticated neonatal camelids^a

Drug or Drug Combination	Dose (mg/kg) and Route of Administration	Approximate Onset of Action and Anticipated End Point	Approximate Duration of Anesthetic Action	Anticipated Recovery for Drugs Resulting In General Anesthesia
Sedation				
Butorphanol	0.05–0.1, IV	30 seconds–1 minute	10–20 minutes	N/A
Diazepam	0.05–0.2, IV	30 seconds–1 minute	10–20 minutes	N/A
Anesthesia				
Isoflurane	1–3% by mask, to recumbency	Variable but within 5 minutes	While being administered	15–30 minutes after discontinuation
Sevoflurane	2–4% by mask, to recumbency	Variable but within 5 minutes	While being administered	15–30 minutes after discontinuation
Diazepam	0.05–0.1, IV	30–45 seconds after administration	10–20 minutes	30 minutes
Ketamine	1–2, IV	30–45 seconds after administration	5–15 minutes	20–30 minutes
Diazepam	0.05–0.1, IV	30–45 seconds after administration	5–15 minutes	20–30 minutes
Propofol	1–2, IV	30–45 seconds after administration	5–15 minutes	20–30 minutes

^aDosages are approximate and may need adjustment for the individual patient and scenario.

Giraffidae

Scott B. Citino and Mitchell Bush

TAXONOMY AND BIOLOGY

Giraffids were once very diverse and widespread throughout Africa, Asia, and Europe. Presently, only two genera with one species per genera are extant within the family *Giraffidae*: the giraffe, *Giraffa camelopardalis*, and the okapi, *Okapia johnstoni*. Historically, nine subspecies of giraffe have been described based on body size, color, coat pattern, and geographic distribution (Dagg & Foster 1976; Nowak & Paradiso 1983). Recent mitochondrial DNA and nuclear microsatellite analysis show that there are at least six genealogically distinct lineages of giraffe with little evidence of interbreeding between them, and five of the six lineages also contain genetically discrete populations, yielding at least 11 genetically distinct populations (Brown et al. 2007). Shared characteristics of giraffids include long legs with forelegs longer than rear legs, elongated necks, large eyes and ears, long, dark, prehensile tongues, lack of a gallbladder in most animals, thick skin with coat patterns that provide camouflage, and the presence of skin-covered ossicones that arise over the parietal bones in giraffe and the frontal bones in okapi (Bush 2003; Dagg & Foster 1976; Nowak & Paradiso 1983). Giraffids are browsing ruminants that are highly selective feeders. Their stature allows them to exploit feeding niches unavailable to other terrestrial herbivores. Giraffe dwell primarily in *Acacia*-, *Commiphora*-, and *Terminalia*-dominated savannahs and semi-arid, open woodlands, while the okapi lives in the mid-elevation, equatorial hardwood forests of north-east Democratic Republic of the Congo (Dagg & Foster 1976; Nowak & Paradiso 1983). Okapi live relatively secretive, solitary lives, while giraffe are more social, living in loosely organized female herds and subadult male bachelor groupings with solitary adult males.

ANATOMY AND PHYSIOLOGY RELATED TO ANESTHESIA

The art and science of giraffe anesthesia remains a challenge due to their unique anatomy and physiology, which presents inherent risks during chemical restraint and, consequently, can result in unacceptable morbidity or mortality. Their large size and cumbersome shape limits physical control during critical times of induction and recovery, and limits manipulation once the giraffe is down. Adult giraffes range from 4.5- to 5.5-m tall and can weigh from 500 to 1950kg, with males being larger (Bush 2003; Dagg & Foster 1976; Nowak & Paradiso 1983). Even weighing giraffe during anesthetic procedures can be difficult due to their size and shape. Formulas have been published to estimate weight from body measurements (Hall-Martin 1977). Adult okapi range in weight from 240 to 350kg and have shoulder heights of 1.5–1.8m, with females being larger (Nowak & Paradiso 1983; S. Citino, pers. obs. and unpubl. data, 2011). Giraffes have a characteristic long neck, which if not controlled, acts as a lever arm during inductions and recoveries, creating a danger to the giraffe and/or the support staff. Malpositioning of the neck can lead to airway obstruction and/or cramping or focal myopathies of neck muscles, which can produce fatalities (Bush et al. 2002; S. Citino, pers. obs. and unpubl. data, 2011). The giraffe's long neck also presents unique problems in regards to regulation of systemic arterial blood pressure, maintenance of cerebral circulation, and generation of respiratory dead space (Bush 1993, 2003; Bush et al. 2002; Hargens 1988; Hargens et al. 1987; Hugh-Jones et al. 1978; Langman 1973; Mitchell & Skinner 1993; Pedley et al. 1996; Warren 1974). To maintain cerebral circulation, giraffe maintain the highest mean arterial pressure at the level of the heart

of any animal thus far studied (approximately 200 mmHg) (Hargens 1988; Hargens et al. 1987). In dependent areas, such as the legs and feet, the mean arterial pressure may exceed 400 mmHg (Hargens 1988; Hargens et al. 1987). To prevent edema and pooling of fluids in dependent areas, giraffe have capillaries highly impermeable to plasma proteins, precapillary sphincters and pronounced arterial and arteriolar wall hypertrophy, a prominent lymphatic system, one-way valves in lymphatics and veins, and tight skin and fascial layers that provide a functional “antigravity suit,” and pumping mechanism during movement (Hargens 1988; Hargens et al. 1987). Because of the giraffe’s unique cardiovascular physiology, the giraffe heart may be more prone to injury from oxygen debt during periods of hypoxemia (Linton et al. 1999). Giraffe are speculated to have a large respiratory dead space generated by their long trachea, which appears to be compensated for by a smaller than expected tracheal diameter, slow deep respirations, and a large tidal volume (Bush 2003; Hugh-Jones et al. 1978; Langman et al. 1982). The long legs of giraffe make them prone to stumbling and splaying during induction and recovery, which can lead to fractures, luxations, muscle and ligament tears, and/or nerve damage. Recumbent giraffe require good footing and sufficient room to be able to rock forward with their long neck to get their long legs underneath them to stand. Giraffe and okapi have elongated skulls (elongated diastema) with narrow interdental spaces, which can make endotracheal intubation challenging, and the posterior position of the larynx impedes drainage of pharyngeal fluids and enhances the potential for aspiration (Bush et al. 2002; Dagg & Foster 1976; Nowak & Paradiso 1983). Giraffe and okapi have a tendency to regurgitate while under the influence of certain chemical restraint agents, which can lead to morbidity and mortality from aspiration pneumonia (Bush 1993, 2003; Bush et al. 2002). The thick skin of giraffids requires the use of long, robust needles to assure good intramuscular injections. Giraffe can alter their body temperature to minimize water loss and help with heat regulation (Bush 2003; Langman et al. 1982). Besides having a tendency toward hyperthermia from overexertion during field captures, giraffe are reported to sometime suffer from a malignant hyperthermia-like syndrome during anesthesia (Citino et al. 1984). Conversely, if ambient temperatures are low, giraffe and okapi tend to lose body temperature rapidly during anesthesia and can become hypothermic (S. Citino, pers. obs. and unpubl. data, 2011).

The most commonly used vascular access site in giraffids is the jugular vein. Due to thick cervical skin, the jugular vein may not always be visible but can usually be palpated and is generally more accessible closer to the head. Auricular and facial veins are also very accessible during anesthetic procedures (see Fig.

Figure 58.1. Indirect blood pressure monitoring utilizing an oscillometric blood pressure monitor and cuff on the tail of an immobilized giraffe.

58.1). Through-the-needle catheters are more effective for jugular catheterization in these species. If over-the-needle catheters are used for jugular catheterization, a stab incision or partial cut-down is generally required. The auricular artery on the dorsal ridge of the ear is most often used for arterial blood collection and for arterial catheterization for invasive blood pressure measurements. Pulse oximetry transmission sensor placement is generally most effective across a scraped ear or across vulvar, mammary, prepuccial, or scrotal skin. End-tidal CO₂ adapters can be attached to an endotracheal tube or to a small tube placed in a nostril. Tail cuffs appear to work best for noninvasive blood pressure measurements. Lead placement for electrocardiography is best accomplished with needles placed through the thick skin of giraffids.

ANALGESIA

The most commonly used drugs for analgesia in giraffids are nonsteroidal anti-inflammatory drugs (NSAIDs) (Teare 2000). Flunixin meglumine (IV, IM, or PO, 1.0–2.0 mg/kg SID), phenylbutazone (PO, 1.0–3.0 mg/kg SID to BID), and ketoprofen (IV or IM, 0.5 to 2.0 mg/kg SID) have been used most often (S. Citino, pers. obs. and unpubl. data, 2011; Teare 2000). Other NSAIDs used in giraffids include etodolac (PO, 2.5–5.0 mg/kg, SID to BID), carprofen (PO, 2.0 mg/kg, SID to BID), and meloxicam (PO, 0.10 mg/kg, SID) (S. Citino, pers. obs. and unpubl. data, 2011). Gabapentin (PO, 2.0–5.0 mg/kg SID), a GABA analog, has shown promise as an analgesic for neuropathic and orthopedic pain in giraffids (S. Citino, pers. obs. and unpubl. data, 2011). Low doses of butorphanol may also be effective for some types of pain.

PHYSICAL AND MECHANICAL RESTRAINT

Only very young giraffe and okapi calves can be safely restrained manually. Mattresses or flexible padding can be wrapped around older calves, or they can be pushed into a padded corner with push boards to safely restrain them for minor procedures.

Mechanical restraint of giraffes is appropriate for minimally invasive procedures, such as blood sampling, tuberculin testing, rectal examinations, and minor hoof trimming, but giraffes can present dangers to handlers and themselves during such procedures. Giraffes have powerful kicks; can strike outward with their forelegs; and can swing and bash with their neck and head. If the footing is slippery, they can fall and injure themselves or ground support staff. Giraffe restraint devices vary from crates and walk-through chutes to small stalls or hallways with moveable walls to innovative mechanical or hydraulic squeeze chutes (Calle & Bormann 1988). All restraint devices should be designed to prevent entrapment of the neck or legs and to allow easy removal of a giraffe that goes down in the device. Successful mechanical restraint of giraffe is dependent on facility design, training, and conditioning of the giraffe, plus a well-trained staff. A well-designed chute, with a side that opens, can also be a valuable giraffe anesthesia induction device that allows close confinement, head control, and controlled progression to sternal recumbency. Mechanical restraint has been infrequently used on okapi; however, okapi have been conditioned to a special crate for venipuncture and other minor procedures (Mehrdadfar et al. 2003). Okapi are excellent kickers and the head and ossicones of males are formidable weapons.

For more extensive or invasive procedures on standing giraffe such as hoof trims, obstetrics, minor surgeries, percutaneous biopsies, and so on, chemically assisted mechanical restraint can sometimes be used. This generally involves the use of an α -2-adrenergic agonist alone or α -2-adrenergic agonist-azaperone combination given just prior to placing a giraffe into a mechanical restraint device. Xylazine (0.10–0.2 mg/kg IM), detomidine (15–40 μ g/kg IM), xylazine-azaperone (0.10 to 0.12 mg/kg IM–0.20 to 0.50 mg/kg IM), and detomidine-azaperone (15 to 30 μ g/kg IM–0.25 to 0.35 mg/kg IM) have been most commonly used for this purpose (Bush 2003; Bush et al. 2002; S. Citino, pers. obs. and unpubl. data, 2011). To increase sedation and analgesia, low doses of butorphanol (10–20 mg IV total) can be given to adult giraffe (S. Citino, pers. obs. and unpubl. data, 2011). Giraffe given these drugs in a restraint device can potentially become ataxic and go down, so handlers should always be prepared for this. Xylazine and detomidine can be partially reversed with yohimbine (0.10–0.20 mg/kg IV or IM) or atipamezole (0.10–0.20 mg/kg IV or IM), and butorphanol can be reversed with naltrexone (2.0 mg naltrexone/mg of

butorphanol IV or IM) (Bush 2003; Bush et al. 2002; S. Citino, pers. obs. and unpubl. data, 2011). A few sudden deaths have occurred after IV administration of α -2-adrenergic and opioid antagonists in giraffes, so these drugs are preferentially given IM (S. Citino, pers. obs. and unpubl. data, 2011).

SEDATION AND TRANQUILIZATION

Standing sedation for hands-on procedures is rarely attempted in older giraffe outside of a restraint device due to the potential danger these animals pose to handlers (Table 58.1 and Table 58.2). α -2-adrenergic agonists at the suggested doses earlier can be used for safer manipulations in enclosures and chutes, for getting reluctant dams to allow calves to nurse, and to calm animals in stressful or dangerous situations (Bush 2003; Bush et al. 2002; S. Citino, pers. obs. and unpubl. data, 2011; Fischer et al. 1997). It should always be remembered that giraffe under α -2-adrenergic agonist sedation can still kick, strike, and rapidly arouse from sedation and become very dangerous. Azaperone has also been used at 0.20–0.50 mg/kg IM as a short-acting, calming, and stress-reducing agent in giraffe (S. Citino, pers. obs. and unpubl. data, 2011). Intermediate and long-acting neuroleptics that have been used in adult giraffe include haloperidol (male, 20–30 mg IM; female, 15–20 mg IM), zuclopenthixol acetate (100–300 mg IM), and perphenazine enanthate (100–250 mg IM) (S. Citino, pers. obs. and unpubl. data, 2011; Ebedes & Raath 1995). Haloperidol has its onset in about 15 minutes and its effects last for 15–24 hours; zuclopenthixol acetate has its onset in 1–6 hours and its effects last about 3 days; and perphenazine enanthate has its onset in about 2–3 days and its effects last for 7–10 days (Ebedes & Raath 1995). Giraffe appear sensitive to these neuroleptic agents, with untoward effects, such as anorexia and extrapyramidal effects, common (S. Citino, pers. obs. and unpubl. data, 2011). Due to a significant potential for disorientation, unsteadiness on their feet, and collapse in their transport container, the use of sedatives and/or neuroleptic agents in giraffe during transport is considered risky and should only be done with great care.

Standing restraint in adult okapi for minor procedures, such as venipuncture, physical exam, obstetrics, radiography, ultrasound, and catheter placement, has been accomplished with xylazine given at 125–300 mg IM (0.50–1.20 mg/kg IM) (Citino 1996; Citino et al. 2006; Raphael 1999; Teare 2000). Xylazine can be partially reversed with yohimbine (0.10 to 0.20 mg/kg IV or IM) or tolazoline (0.50 mg/kg IV or IM) (Citino 1996, pers. obs. and unpubl. data, 2011; Raphael 1999). More complete reversal of xylazine has been achieved with the experimental α -2-adrenergic antagonist RX821002 (5.0 mg total dose IV) or combinations of yohimbine or tolazoline and atipamizole (30–100 μ g/kg IV or IM)

Table 58.1. Drugs used for chemical restraint in giraffe

Drug	Dosage	Reversal Agent/Dose	Purpose
Xylazine	0.10–0.20 mg/kg IM	Yohimbine (0.10–0.20 mg/kg IV or IM) Atipamezole (0.10–0.20 mg/kg IV or IM)	Sedation or chemically assisted mechanical restraint
Detomidine	15–40 µg/kg IM	Yohimbine (0.10–0.20 mg/kg IV or IM) Atipamezole (0.10–0.20 mg/kg IV or IM)	Sedation or chemically assisted mechanical restraint
Azaperone	0.20–0.50 mg/kg IM	None	Tranquilization, calming, or stress reduction
Haloperidol	Adult male: 20–30 mg IM Adult female: 15–20 mg IM	None	Neuroleptic, untoward effects possible
Zuclopenthixol acetate	Adult: 100–300 mg IM	None	Intermediate-acting neuroleptic, untoward effects possible
Perphenazine enanthate	Adult: 100–250 mg IM	None	Long-acting neuroleptic, untoward effects possible
Xylazine (X) + azaperone (A)	X: 0.10–0.12 mg/kg IM A: 0.20–0.50 mg/kg IM	Same as above for xylazine B: Naltrexone 2.0-mg/mg butorphanol IV	Chemically assisted mechanical restraint
Butorphanol (B) if needed	B: 10–20 mg total IV	Same as above for detomidine	Chemically assisted mechanical restraint
Detomidine (D) + azaperone (A)	D: 15–30 µg/kg IM A: 0.25–0.35 mg/kg IM	B: Naltrexone 2.0-mg/mg butorphanol IV	
Butorphanol (B) if needed	B: 10–20 mg total IV	Same as above for xylazine	Staged protocol for anesthesia of captive giraffe
Etorphine (E) + xylazine (X)	X: Adult: 70–100 mg IM X: Yearling: 30–40 mg IM After sedation followed by: E: Adult: 1.5–2.5 mg IM E: Yearling: 0.5–1.25 mg IM	E: Naltrexone 50- to 100-mg/mg etorphine IV or IM	
Carfentanil (C) + xylazine (X)	X: Same as for etorphine + xylazine After sedation followed by: C: Adult: 1.2–2.1 mg IM C: Yearling: 0.20–0.90 mg IM	Same as above for xylazine C: Naltrexone 100-mg/mg carfentanil IV or IM	Staged protocol for anesthesia of captive giraffe
Thiafentanil (T) + medetomidine (M) + ketamine (K)	T: 5.8 ± 1.5 µg/kg IM M: 12.9 ± 5.1 µg/kg IM K: 0.65 ± 0.18 mg/kg IM	T: Naltrexone 30-mg/mg thiafentanil IV or IM M: Atipamezole 3–5 times the medetomidine dose IV or IM	Protocol for captive giraffe, medetomidine resedation can occur, good analgesia for surgery
Medetomidine (M) + ketamine (K)	M: 150 µg/cm Shd Hgt K: 3.0 mg/cm Shd Hgt or M: Male: 50–70 mg IM M: Female: 40–50 mg IM M: Subadult: 18–20 mg IM K: Male: 1000–1200 mg IM K: Female: 800–900 mg IM K: Subadult: 300–500 mg IM	Atipamezole (350 µg/cm) Shd Hgt or 3–5 times the medetomidine dose IM	Protocol for captive giraffe, medetomidine resedation can occur, inadequate analgesia for surgery
Etorphine	Adult: 8–15 mg IM	Naltrexone 30- to 100-mg/mg etorphine IV or diprenorphine 2.0-mg/mg etorphine IV	Protocol for free-ranging giraffe
Etorphine (E) + thiafentanil (T)	E: Adult: 4.0 mg IM T: Adult: 8–16 mg IM	Naltrexone 30–100 mg/mg opioid IV or diprenorphine 2.0 mg/mg opioid IV	Protocol for free-ranging giraffe
Thiafentanil	Adult: 8–16 mg IM	Naltrexone 30-mg/mg thiafentanil IV or diprenorphine 2.0-mg/mg thiafentanil IV	Protocol for free-ranging giraffe

(Citino 1996, pers. obs. and unpubl. data, 2011; Raphael 1999; Teare 2000). For okapi that appear resistant to xylazine alone, the addition of azaperone (0.20–0.40 mg/kg IM) may improve the standing restraint (S. Citino, pers. obs. and unpubl. data, 2011). Good standing restraint for venipuncture, catheter placement, vaginal insemination, and so on has also been achieved with xylazine (0.40–0.80 mg/kg IM) or detomidine

(40–100 µg/kg IM) with butorphanol (80–200 µg/kg IM) (S. Citino, pers. obs. and unpubl. data, 2011; Teare 2000). Recently, medetomidine (60–90 µg/kg IM) with butorphanol (45–55 µg/kg IM) has successfully been used for standing restraint of okapi at one institution (J. Raines, pers. comm., 2011). Butorphanol has been reversed with naltrexone (1.0 mg/mg butorphanol IV or IM) (S. Citino, pers. obs. and unpubl. data, 2011),

Table 58.2. Drugs used for chemical restraint in okapi

Xylazine (X) And can add if needed: Azaperone (A)	X: 0.50–1.20 mg/kg IM X: Adult: 125–300 mg IM A: 0.20–0.40 mg/kg IM	Partial reversal: yohimbine 0.10–0.20 mg/kg IV or IM or tolazoline 0.50 mg/kg IV or IM Better reversal: RX821002 5.0 mg IV or yohimbine or tolazoline + atipamezole 30–100 µg/kg IV or IM	Standing restraint for minor procedures
Azaperone	0.20–0.50 mg/kg IM	None	Tranquilization, calming, or stress reduction
Haloperidol	80–100 µg/kg IM 0.90–1.5 mg/kg PO	None	Neuroleptic
Zuclopenthixol acetate	0.40–1.0 mg/kg IM	None	Intermediate-acting neuroleptic
Xylazine (X) + butorphanol (B)	X: 0.40–0.80 mg/kg IM B: 80–200 µg/kg IM	Same as above for xylazine B: Naltrexone 1.0-mg/mg butorphanol IV or IM	Standing restraint for minor procedures
Detomidine (D) + butorphanol (B)	D: 40–100 µg/kg IM B: 80–200 µg/kg IM	D: Same as for xylazine above B: Same as above for butorphanol	Standing restraint for minor procedures
Medetomidine (M) + butorphanol (B)	M: 60–90 µg/kg IM B: 45–55 µg/kg IM	M: Atipamezole 5.0-mg/mg medetomidine IV or IM B: Same as above for butorphanol	Standing restraint for minor procedures
Carfentanil (C) + xylazine (X)	X: 0.12 ± 0.02 mg/kg IM X: Adult: 30–45 mg IM After sedation followed by: C: 4.7 ± 0.8 µg/kg IM C: Adult: 0.9–1.5 mg IM	X: Same as for xylazine above C: Naltrexone 100-mg/mg carfentanil 1/2 IV 1/2 SQ	Staged protocol for anesthesia of captive okapi
Thiafentanil (T) + xylazine (K) or detomidine (D) + ketamine (K)	X: 0.12 ± 0.03 mg/kg IM X: Adult: 30–45 mg IM Or: D: 0.05 ± 0.01 mg/kg IM D: Adult: 12–20 mg IM After sedation followed by: T: 5.3 ± 0.3 µg/kg IM T: Adult: 1.4–2.0 mg IM K: 0.6 ± 0.1 mg/kg IM K: Adult: 120–220 mg IM	X: Same as for xylazine above D: Same as for xylazine above T: Naltrexone 30-mg/mg thiafentanil IM	Staged protocol for anesthesia of captive okapi. Rapid inductions with shorter working times. Characteristics of anesthesia very similar to carfentanil combinations.
Etorphine (E) + xylazine (X)	X: Adult: 40–50 mg IM After sedation followed by: E: Adult: 4.0–5.0 mg IM	X: Same as for xylazine above E: Naltrexone 30–50 mg/mg etorphine IV or diprenorphine 2.0-mg/mg etorphine IV	Staged protocol for anesthesia of captive okapi, greater risk of regurgitation with etorphine
Medetomidine (M) + ketamine (M) +/- Midazolam (Mi)	M: 60–155 µg/kg IM K: 1.0–3.9 mg/kg IM Mi: 0.1 mg/kg IM	Atipamezole 5 times the medetomidine dose IV or IM	Protocol for captive okapi, better restraint at the higher end of dose range
Medetomidine (M) + butorphanol (B) + ketamine (K)	M: 60–70 µg/kg IM B: 50–100 µg/kg IM K: 2.0–3.0 mg/kg IM	M: Same as above for medetomidine B: Same as above for butorphanol	Protocol for captive okapi

and medetomidine has been reversed with atipamezole at five times the medetomidine dose (J. Raines, pers. comm., 2011). Azaperone (0.20–0.50 mg/kg IM) and haloperidol (80–100 µg/kg IM) have been used to tranquilize flighty animals when moved or manipulated in enclosures (Citino 1996, pers. obs. and unpubl. data, 2011; Raphael 1999). Haloperidol (0.90–1.50 mg/kg) has also produced mild calming effects when given orally to okapi (S. Citino, pers. obs. and unpubl. data, 2011). The intermediate-acting neuroleptic zuclopenthixol acetate (0.40–1.0 mg/kg IM) has been used to reduce stress and calm animals during transport (S. Citino, pers. obs. and unpubl. data, 2011; Raphael 1999). A combination of zuclopenthixol acetate (100 mg IM 15 hours before move) and haloperidol (10–20 mg

IM to facilitate crating) was used to load and transport two okapi that were not crate trained (Redrobe 2003).

ENDOTRACHEAL INTUBATION

A 40- to 60-cm laryngoscope blade is required to visualize the glottis in adult giraffe, while a 30- to 40-cm laryngoscope blade will suffice in okapi (S. Citino, pers. obs. and unpubl. data, 2011). Adult giraffe will generally take endotracheal tubes with internal diameters of 24–30 mm, while adult okapi generally take tubes of 20 to 26 mm (S. Citino, pers. obs. and unpubl. data, 2011). Giraffids are best intubated using the “Bush technique”—visualizing the glottis with a laryngoscope, passing a tracheal exchange catheter through the

glottis, threading the exchange catheter through the Murphy's eye of the endotracheal tube, and passing the tube through the glottis using the exchange catheter as a guide (Bush 1996). In large giraffe, the glottis can be digitally palpated and an endotracheal tube manually placed. Giraffids can also be intubated by passing a fiberoptic endoscope through the endotracheal tube, visually passing the endoscope into the trachea, and then using the endoscope as a stylet to place the tube. The authors recommend using a cuffed endotracheal tube to intubate giraffe that will be anesthetized for longer than 15 minutes. Oxygen can then be supplied by insufflation or jet ventilation, and respiratory support can be given with a one or two demand valve system or field ventilator (Citino et al. 2007). If giraffids are inadequately anesthetized (tongue movement and swallow reflex present), stimulation of the pharynx during endotracheal intubation can initiate active regurgitation.

ANESTHESIA OF GIRAFFE

Even with the development of newer and safer drugs and improved physiological monitoring equipment, giraffe anesthesia remains a major challenge due to their unique anatomy and physiology (Table 58.1). Despite the frequent need to capture and relocate this species *in situ*, giraffe are still considered a high risk species to chemical capture due to their large size and unique physiology and handling problems. Due to their awkward shape, weight estimation and dosage calculation is difficult, especially in the field. All of these special characteristics predispose them to life-threatening, anesthesia-related complications, including (1) vomiting/passive regurgitation leading to fatal inhalation pneumonia; (2) respiratory depression and hypoventilation with resulting hypoxemia and hypercarbia; (3) tachycardia, hypertension, bradycardia, hypotension, or other significant cardiac emergencies; (4) self-induced trauma during induction and/or following reversal; and (5) hyperthermia and/or capture myopathy secondary to prolonged and stormy induction and incomplete anesthesia reversal (Bush 1993, 2003; Bush et al. 2002; Citino et al. 1984). The historical high morbidity and mortality encountered during giraffe anesthesia, in both captive and free-ranging settings, leads to a hesitancy to anesthetize them.

Historical verbal and published reports describe the use of several drugs and drug combinations for giraffe anesthesia. Drugs used alone or in combination have included succinylcholine, gallamine, hyoscine, atropine, hyaluronidase, glycerol guaiacolate, acepromazine, azaperone, xylazine, detomidine, medetomidine, ketamine, telazol, barbiturates, butorphanol, fentanyl, etorphine, carfentanil, and thiafentanil (A3080) (Bush 1976, 1993, 2003; Bush & de Vos 1987; Bush et al. 1976, 1997, 2001, 2002; S. Citino, pers. obs. and unpubl.

data, 2011; Fischer et al. 1997; Gardner et al. 1986; Geiser et al. 1992; Hirst 1966; Lamberski et al. 2004; Langman 1973; Morkel 1992, 1993; Rapley et al. 1975; Vahala 1990; Vogelnest & Ralph 1997; Wiesner & von Hegel 1989; Williamson & Wallach 1968; York 1975; York et al. 1973; J. Raath, pers. comm., 2006).

Many of the problems associated with anesthesia can be minimized in captive giraffe with careful pre-planning and forethought. An experienced staff to assist with the critical induction and recovery phases of anesthesia and for monitoring the patient is essential. Fasting of giraffids is probably overemphasized and detrimental and should occur for no longer than 12 hours, with concentrate being the primary foodstuff to withhold. Animals should be prevented from drinking large quantities of water just prior to anesthesia by withholding water for 2–6 hours depending on climatic conditions. The site and method of induction are also critical for success. The use of a well-designed chute for giraffe induction can greatly reduce risk and allow a staged and controlled induction to occur (Bush 2003; Calle & Bormann 1988; S. Citino, pers. obs. and unpubl. data, 2011). The chute must be designed so forward pressing or falling will not compromise respiration, with no potential foot, leg, or neck traps, and with a complete side that swings open to allow easy removal and positioning of the giraffe. If a suitable chute is not available a confined space with smooth, solid walls, lack of trip and fall hazards, and a catwalk for access to the animal's head during the procedure can be used. If a catwalk is absent around the induction area and a halter can be placed before or during induction, a ceiling pulley and rope apparatus can be used to suspend the giraffe's head and neck during induction to reduce falling injuries and prevent head slamming. If the giraffe must be induced in a larger area without head control, all tripping and falling hazards should be removed or minimized and methods for keeping the giraffe away from dangerous pressing points and head and neck traps should be determined. No matter where giraffe anesthesia is accomplished, good footing is mandatory to prevent slipping and splaying. Also, adequate staff and/or equipment should be present to move an animal quickly, if necessary. Since complications can occur rapidly in anesthetized giraffe, close physiologic monitoring is essential for patient safety and should include both the usual visual and tactile monitoring, as well as electronic monitoring (i.e., temperature, pulse oximetry, capnography, invasive and noninvasive blood pressure, electrocardiography, and arterial blood gas and pH measurements). Perhaps the hardest thing to do is back off from a procedure. Many procedures involving giraffe require extensive coordination to make sure that people, facilities, and equipment are ready. Unless conducting an emergency procedure, if something is not going right or if there is a factor that can be changed to enhance the success of

the procedure, it should be stopped and rescheduled. Even with the most careful planning and preparation, procedural complications can still occur in captive situations but are amplified in free-ranging giraffes since there is minimal control of the situation.

There are standardized procedures for handling an anesthetized giraffe in lateral recumbency, which include supporting the neck with a board or ladder so the head is maintained above the rumen with the nose pointed down to facilitate drainage of fluids. The neck should be kept straight without kinks or angulations. The angle of the neck is altered every 10–15 minutes and the neck can be massaged to minimize muscle spasms that in the postrecovery period can be life-threatening. Padding should be placed under the giraffe, particularly under the shoulder and radius to prevent pressure trauma to the radial nerve. Oxygen should be supplied by either nasal insufflation or endotracheal tube (see Fig. 58.2, Fig. 58.3, and Fig. 58.4).

Recovery is a very critical time in a giraffe anesthetic procedure. Good footing is essential during recovery,

as is adequate space for the giraffe to rock forward and get momentum to stand. If the giraffe does not regain its feet within 45 minutes of administration of the antagonist, the prognosis is poor for the animal's recovery. The route of administration of the antagonist can greatly influence recovery. Intramuscular administration of the antagonists will generally provide a slow, controlled recovery, which is generally preferred (Bush 2003; Bush et al. 2002; S. Citino, pers. obs. and unpubl. data, 2011; Lamberski et al. 2004). Many times with IV

Figure 58.2. Endotracheal intubation of an anesthetized giraffe, note that the head and neck are held in a straight position.

Figure 58.3. An intubated giraffe receiving supplemental oxygen and ventilatory support.

Figure 58.4. Staged induction of a captive giraffe in a chute system.

administration of antagonists, giraffe will become excited, head slam and try to stand before ready, and will fall, potentially injuring themselves.

The most widely used anesthetic regimens for giraffe have involved use of opioids alone or in combination with sedatives (e.g., xylazine), tranquilizers (e.g., azapalone), and/or absorption accelerants (e.g., hyaluronidase) and, most recently, the potent specific α -2-adrenergic agonist medetomidine with ketamine (Bush 1976, 1993, 2003; Bush & de Vos 1987; Bush et al. 1976, 1997, 2001, 2002; Geiser et al. 1992; Hirst 1966; Lamberski et al. 2004; Langman 1973; Morkel 1992, 1993; Rapley et al. 1975; Vahala 1990; Vogelnest & Ralph 1997; Wiesner & von Hegel 1989; Williamson & Wallach 1968; York 1975; York et al. 1973).

A staged protocol using etorphine and xylazine has been used commonly in the past for anesthesia of captive giraffe (Bush 1976, 1993, 2003; Bush et al. 1976, 2002). This approach tends to cause less respiratory depression since etorphine doses can be titrated to the needs of the individual animal and situation. This protocol is ideally carried out in a chute or confined area where head control can be maintained. Initially, giraffe are given xylazine (70–100 mg/adult or 30–40 mg/yearling IM). Atropine (7.0–8.0 mg/adult or 2.0–3.0 mg/yearling IM) can be given simultaneously to prevent xylazine-induced bradycardia. Five to 10 minutes after xylazine administration, signs of sedation occur (i.e., stargazing, ataxia, and tongue protrusion with slight salivation). About 15–20 minutes after the xylazine, a narcotizing dose of etorphine (1.5–2.5 mg/adult or 0.5–1.25/yearling IM) is administered. This dose may induce recumbency within 15–20 minutes. Ideally, a head halter, placed when the animal is narcotized, is used to help control the head and assist the animal to the ground, without tumbling over backwards. If the giraffe does not become recumbent after etorphine administration, it can be supplemented with etorphine (0.5–1.0 mg IM or IV), 5% guaifenesin solution IV to effect, or ketamine (100–400 mg IV), or can be physically cast. For reversal of etorphine, naltrexone (50–100 mg/mg etorphine, 1/2 IV, 1/2 IM or all IM) is given and for xylazine, yohimbine (0.10–0.20 mg/kg IV or IM) or atipamezole (50–100 mg total 1/4 IV 3/4 IM or all IM) is given. It is possible to substitute carfentanil (1.2–2.1 mg/adult or 0.30–0.90/yearling IM) for etorphine in this protocol (S. Citino, pers. obs. and unpubl. data, 2011). See Fig. 58.5, Fig. 58.6, and Fig. 58.7.

Current methods for capture of free-ranging giraffe utilize high doses of opioids alone for rapid induction and no lingering drug effects during transport. Etorphine (8.0–15.0 mg/adult), thiafentanil (8.0–16.0 mg/adult), or a combination of etorphine (4.0 mg/adult) and thiafentanil (8.0–16.0 mg/adult) with or without hyaluronidase are most commonly used (S. Citino, pers. obs. and unpubl. data, 2011; Morkel 1992, 1993). Giraffe become narcotized rapidly, but many must be

cast with ropes. Once down, muscle relaxation is poor, animals require significant restraint, and most must be fully or partially reversed with diprenorphine or naltrexone to prevent severe hypoxemia while hoods, ear plugs, and ropes are applied. This anesthetic technique greatly limits what can safely be done to a giraffe while it is recumbent. Once reversed, giraffe are very active and can be a danger to themselves and the ground crew during loading for transport. This method is for capture only and requires a well-trained and experienced capture team to safely cast, restrain, and load giraffe for transport (see Fig. 58.8 and Fig. 58.9). Most recently, a combination of thiafentanil and butorphanol has been

Figure 58.5. Staged induction of a captive giraffe; note that the whole side of the chute opens, allowing the giraffe to be positioned in lateral recumbency.

Figure 58.6. Chute system for captive giraffe. Note padding, attached deck for handlers to access the head, and one side swings open for access to the animal during induction.

Figure 58.7. Chute system for handling captive giraffe. Note that the animals walk through the chute daily to access the outside yard.

Figure 58.8. Free-ranging giraffe in Kruger National Park, South Africa shortly after reversal of thiafentanil anesthesia. Notice blindfold, halter, lead rope, body ropes, and capture crew in place for loading giraffe into field chariot for transport out of veldt. Notice potential for hind limb splaying despite good footing in the field and the requirement for the giraffe to rock forward to stand.

used for capture of free-ranging giraffe, with less respiratory depression, probably due to the partial mu opioid receptor antagonist effect of butorphanol (J.P. Raath and L. Venter, pers. comm., 2006.).

A nonnarcotic alternative for giraffe chemical restraint is the combination of medetomidine and ketamine. This combination has been used successfully in captive and free-living giraffes with dosages correlated to the giraffe's shoulder height. In "calm" animals, 150 µg medetomidine + 3.0 mg ketamine/cm of shoulder height provided a rapid and relatively uneventful induction (Bush 2003; Bush et al. 1997, 2001). Larger giraffes experienced a less desirable immobilization,

Figure 58.9. Free-ranging giraffe starting to stand after reversal of thiafentanil-medetomidine-ketamine anesthesia. Notice blindfold, earplugs, halter, and ropes in place for loading giraffe into the chariot in the background. Notice potential for rear limb splaying despite good footing in the field.

which may indicate the dosage correlation to shoulder height may not be appropriate in larger animals. Another retrospective study in 30 captive giraffe recommends doses of medetomidine (subadult, 18–20 mg; adult female, 40–50 mg; adult male, 50–70 mg) and ketamine (subadult, 300–500 mg; adult female, 800–900 mg; adult male, 1000–1200 mg) (Lamberski et al. 2004). A nice characteristic of this combination is smooth inductions with animals usually sitting down in sternal recumbency before rolling over laterally. With medetomidine-ketamine, an inverse relationship is observed between the level of excitement and the quality of the immobilization—the more excited the giraffe prior to and after darting, the more physical restraint is required to bring the animal to a sternal position. This combination also produces a characteristic tachypnea (50–60 breath/min) and inadequate analgesia for painful procedures. Administration of atipamezole (350 µg/cm of shoulder height or five times the medetomidine dose IM) results in a rapid and usually complete reversal. Resedation has been seen in some giraffe given medetomidine 3–28 hours after reversal, therefore giraffes should be monitored closely during this time, and additional atipamezole should be administered if signs of resedation occur (S. Citino, pers. obs. and unpubl. data, 2011; Lamberski et al. 2004). Resedation appears to occur most commonly in the Rothschild's (*Giraffa camelopardalis rothschildi*) and Southern giraffe (*Giraffa camelopardalis giraffa*) subspecies and less commonly in the reticulated (*Giraffa camelopardalis reticulata*) subspecies (S. Citino, pers. obs. and unpubl. data, 2011). Signs of medetomidine resedation include decreased awareness to surroundings, dull eyes, inappetance, lowered neck, widened

stance, salivation, tongue protrusion, excessive licking, ataxia, leaning against objects, and recumbency (S. Citino, pers. obs. and unpubl. data, 2011; Lamberski et al. 2004).

A newer drug combination, thiafentanil-medetomidine-ketamine, has safely and successfully been used for chemical restraint of captive and free-ranging giraffe (Citino et al. 2006). Dosing requirements are markedly different between captive (thiafentanil $5.8 \pm 1.5 \mu\text{g}/\text{kg}$ + medetomidine $12.9 \pm 5.1 \mu\text{g}/\text{kg}$ + ketamine $0.65 \pm 0.18 \text{mg}/\text{kg}$ IM), free-ranging, ground-darted (thiafentanil $6.6 \pm 1.5 \mu\text{g}/\text{kg}$ + medetomidine $15.9 \pm 3.7 \mu\text{g}/\text{kg}$ + ketamine $0.50 \pm 0.19 \text{mg}/\text{kg}$ IM), and free-ranging, helicopter-darted (thiafentanil $10.0 \pm 4.0 \mu\text{g}/\text{kg}$ + medetomidine $14.0 \pm 9.4 \mu\text{g}/\text{kg}$ + ketamine $0.39 \pm 0.20 \text{mg}/\text{kg}$ IM) giraffe. The degree of excitement associated with helicopter darting appears to negate the effects of medetomidine and makes this combination less suitable for helicopter darting. In calm animals, onset of action is ultra-rapid, with most animals down in 2–5 minutes. Giraffe exhibit excellent muscle relaxation and are very safe to work around with this combination. Analgesia appears very good, and there is a long duration of action, so it appears useful for surgical and prolonged major procedures (Borkowski et al. 2009; Quesada et al. 2011). A marked apneustic breathing pattern is often seen and moderate to severe hypoxemia can occur, so oxygen supplementation and/or respiratory support are recommended. Anesthesia is reversed with naltrexone (30 mg/mg thiafentanil IV or IM) and atipamezole (three to five times the medetomidine dose IV or IM). Recoveries are best when antagonists are administered IM. As with medetomidine-ketamine, evidence of medetomidine-associated re sedation is seen in some giraffe postreversal requiring additional supplements of atipamezole (S. Citino, pers. obs. and unpubl. data, 2011). Re sedation can be a potentially life threatening problem in giraffe, especially during transport and when giraffe are not observed closely for signs of re sedation post recovery.

The reader is referred to this chapter's references for published methods of giraffe anesthesia and for more detailed descriptions of these procedures.

OKAPI ANESTHESIA

In comparison with giraffe, there are far fewer inherent problems that can occur during okapi anesthesia due to their more conventional size and shape (Table 58.2). However, complications associated with anesthesia are still one of the most significant causes of adult morbidity and mortality in the international captive population (S. Citino, pers. obs. and unpubl. data, 2011; Raphael 1999). The most common anesthesia-associated problems reported in okapi are regurgitation and aspiration of rumen contents and postanesthesia gastroin-

testinal stasis or ileus (S. Citino, pers. obs. and unpubl. data, 2011).

Chemical immobilization of okapi is most commonly accomplished with an opioid (carfentanil, etorphine, or thiafentanil) in combination with an α -2-adrenergic agonist (xylazine) or tranquilizer (acetylpromazine) (Citino 1996, pers. obs. and unpubl. data, 2011; Mortelmans 1978; Raphael 1999; Teare 2000). Okapi should not be fasted for longer than 12 hours prior to anesthesia as hypoglycemia and electrolyte imbalances can be induced (S. Citino, pers. obs. and unpubl. data, 2011). Water can be withheld for 2–6 hours, depending on climatic conditions. Inductions with opioid combinations can sometimes be stormy, with okapi stumbling, crashing, exhibiting opisthotonus, falling backwards, and flailing and head-slammng once down. It is important to induce okapi in relatively small enclosures with good footing, smooth walls, and lack of trip and fall hazards. Once an okapi is well narcotized, two to three well-trained handlers should use controlled restraint to smooth the induction and prevent injury. A padded stall with a hinged crush wall also works nicely for preventing injuries during induction. Once down, the animal is placed sternal with its head above its rumen and nose down, is blindfolded, and given oxygen by nasal insufflation. If the okapi must be placed in lateral recumbency, adequate padding should be placed under pressure points. As with most ruminants, okapi should not be rolled onto their back unless intubated, as this can stimulate regurgitation of rumen contents. Okapi should be kept warm during anesthesia as they have a tendency to become hypothermic (S. Citino, pers. obs. and unpubl. data, 2011) (Fig. 58.10, Fig. 58.11, and Fig. 58.12).

Figure 58.10. Standing sedation in a captive okapi with xylazine and butorphanol for an echocardiography examination.

Figure 58.11. Anesthesia of an okapi in a field situation. Note that there is adequate padding of the okapi in lateral recumbency. Side-stream capnography is being used by placing a sampling adapter in the nostril, to estimate end-tidal carbon dioxide readings on exhalation.

Figure 58.12. Anesthesia of an okapi in a field situation. Note that the pulse oximeter is placed on the tongue and a side-stream capnograph sampling adapter is placed in the nostril.

Over 170 successful okapi procedures without mortality have been completed using carfentanil and xylazine in a staged technique (Citino 1996, pers. obs. and unpubl. data, 2011). Xylazine (0.12 ± 0.02 mg/kg IM, adult total dose = 30–45 mg IM) is given first and is followed in 15–20 minutes with carfentanil (4.7 ± 0.8 μ g/kg IM, adult total dose = 0.9–1.5 mg IM). This staged technique requires less opioid and produces a much smoother induction, with better muscle relaxation, than combining the opioid and xylazine together. The better the initial sedation from xylazine, the smoother the induction will generally be. Azaperone (50.0 mg average total adult dose) can be added to the xylazine

to increase sedation and improve inductions in problem animals. For okapi receiving significant stimuli during anesthesia (e.g., electroejaculation), ketamine (1.0–1.5 mg/kg) can be added to the carfentanil dart to potentiate the xylazine and carfentanil. If supplements are needed to prevent struggling, improve muscle relaxation, or deepen anesthesia, xylazine (2.0–5.0 mg boluses IV), ketamine (50–200 mg boluses IV), and 5% guaifenesin solution IV drips have been used. Naltrexone (100 mg/mg carfentanil 1/2 IV 1/2 SQ or IM) is used to reverse the carfentanil, and yohimbine (0.10–0.20 mg/kg IV or IM), tolazoline (100 mg IV or IM total adult dose), RX821002 (5.0 mg IV total adult dose), or atipamezole (0.125 mg/kg IV or IM) is used to reverse the xylazine. Reversals tend to be smoother when all antagonists are given IM (S. Citino, pers. obs. and unpubl. data, 2011). After reversal, two experienced handlers should stay with the okapi to prevent injury until it is standing. Renarcotization is occasionally seen in okapi anesthetized with carfentanil, so animals should be observed closely for 24 hours and supplemented with naltrexone if necessary (S. Citino, pers. obs. and unpubl. data, 2011).

Etorphine can also be used in a staged anesthetic technique with xylazine (Citino 1996; Raphael 1999; Teare 2000). As discussed earlier, xylazine (40–50 mg IM total adult dose) is first given, followed in 15 to 30 minutes by etorphine (4.0–5.0 mg IM total adult dose). There appears to be a greater risk of regurgitation with etorphine versus carfentanil in okapi (Citino 1996; Raphael 1999; Teare 2000). Etorphine is reversed with naltrexone (30–50 mg/mg of etorphine IV) or diprenorphine (2.0 mg/mg of etorphine IV).

The newest potent opioid, thiafentanil (A3080), has recently been used in staged techniques with either xylazine or detomidine for short anesthetic procedures in okapi (S. Citino, pers. obs. and unpubl. data, 2011). Xylazine (0.12 ± 0.03 mg/kg IM, adult total dose = 30–45 mg IM) or detomidine (0.05 ± 0.01 mg/kg IM, adult total dose = 12–20 mg IM) is given first and is followed in 15–20 minutes with thiafentanil (5.3 ± 0.3 μ g/kg IM, adult total dose = 1.4–2.0 mg IM) and ketamine (0.6 ± 0.1 mg/kg IM, adult total dose = 120–220 mg IM). Inductions are rapid after thiafentanil-ketamine administration (2–6 minutes), and the characteristics of the anesthesia are very similar to the carfentanil-xylazine combination described earlier; however, working time with this combination is much shorter (25–40 minutes). If longer working times are required, supplemental drugs will be needed. Naltrexone (30 mg/mg of thiafentanil IM) is used to reverse the thiafentanil, and yohimbine (0.10–0.20 mg/kg IM), tolazoline (100 mg IM total adult dose), RX821002 (5.0 mg IV total adult dose), or atipamezole (0.125 mg/kg IM) is used to reverse the xylazine or detomidine. Renarcotization has not been seen in okapi anesthetized with thiafentanil.

The nonnarcotic combination of medetomidine (60–155 µg/kg IM) and ketamine (1.0–3.9 mg/kg IM) can be used to induce a deep sedation in okapi adequate for most minor procedures (Citino 1996; Raphael 1999; Teare 2000; L. Klein, pers. comm., 2011). Deep IM injection (50–60 mm needles) is required with this drug combination and the higher end of the dosage range for medetomidine (100–155 µg/kg) generally produces a better anesthesia without the need for supplementation (L. Klein, pers. comm., 2011). First signs generally occur in 1–7 minutes, and animals are recumbent in 3–34 minutes, with an average of 15–20 minutes. Induction is generally much smoother than with opioid combinations. Adding midazolam (0.1 mg/kg) to this combination seems to speed induction and makes it smoother (L. Klein, pers. comm., 2011). In contrast to opioid combinations, okapi are aware and will still kick or flee during induction with this drug combination, so should not be approached until down and relaxed. Okapi should not be reversed for 15–20 minutes post induction to reduce unsteadiness from residual ketamine. Some regurgitation can occur if animals are in lateral recumbency with their head and neck flat out, so the head should be kept elevated with nose point down. Medetomidine is reversed by atipamezole (5.0 mg/mg medetomidine IV or IM). There have been reports of postanesthesia ileus, with some fatalities, in okapi receiving medetomidine and ketamine (S. Citino, pers. obs. and unpubl. data, 2011).

Recently, a combination of medetomidine (60 to 70 µg/kg IM), butorphanol (50 to 100 µg/kg IM), and ketamine (2 to 3 mg/kg IM) has been used for anesthesia of okapi at one institution for minor surgical procedures and hoof trimming (J. Raines, pers. comm., 2011). For longer or more invasive procedures, okapi were intubated and placed on isoflurane inhalation anesthesia.

Cervids (Deer)

Nigel Caulkett and Jon M. Arnemo

INTRODUCTION

A variety of deer species are distributed worldwide. It is beyond the scope of this chapter to discuss each species; therefore, the emphasis will be placed on general principles, with a brief discussion of current techniques in selected species. A complete description of dose requirements for individual species can be found in Kreeger and Arnemo (2012).

SPECIES-SPECIFIC PHYSIOLOGY

Deer are prone to rumenal tympany, regurgitation, hypoxemia, hyperthermia, and capture myopathy. Maintenance in sternal recumbency will help prevent the development of rumenal tympany. If rumenal tympany is a problem, the animal may be rocked gently to stimulate eructation. A rumen tube can be used, but may predispose to regurgitation and aspiration. Generally, if rumenal tympany is severe, it is advisable to finish the procedure quickly and antagonize the anesthetic agents. If alpha-2 agonists have been used, the administration of tolazoline, yohimbine, or atipamezole will stimulate rumenal activity and relieve rumenal tympany.

Capture myopathy is a potentially serious complication that can be very difficult to treat (Spraker 1993). Capture myopathy can be acute. In the acute form of capture myopathy, the animals' oxygen demand is far in excess of oxygen supply. Animals often present with hyperthermia, cyanosis, acidosis, tachycardia, and hypotension. The animal may die during the anesthesia or soon after. If the animal survives the acute stage, it may develop subacute or chronic capture myopathy. This can have a variety of manifestations, including paraplegia, ruptured muscles, myoglobinuria, or oliguria (Spraker 1993). The treatment of acute capture

myopathy is directed at symptomatic treatment for shock, correcting acid-base disturbances, maintaining normothermia, and oxygenation. Treatment is extremely difficult in a field situation and often unsuccessful. Animals with chronic capture myopathy generally need to be euthanized. It is best to prevent capture myopathy by keeping chase times to a minimum and avoiding prolonged physical restraint. A complete review of capture myopathy can be found in Chapter 15.

Trauma is not uncommon during capture. White-tailed deer can be very flighty and, as such, they are prone to self-trauma.

PHYSICAL CAPTURE AND RESTRAINT

In zoo and game-farmed situations, deer may be effectively handled in drop-floor or hydraulic squeeze chutes (Fig. 59.1).

It is always best to minimize physical restraint times to decrease the risk of trauma or stress-related complications. Long-acting neuroleptic drugs can be used to decrease the stress of repeat handling (Read et al. 2000). Free-ranging deer may be captured with the use of net guns, drive nets, or clover traps. As mentioned earlier, restraint times should be minimized, and supplemental sedation should be considered during handling (Cattet et al. 2004).

CHEMICAL RESTRAINT AND ANESTHESIA

Vascular Access

Venous access is not difficult in deer. The cephalic vein, lateral saphenous vein, and jugular vein can all be easily accessed (Fig. 59.2). The auricular artery can be easily cannulated in most species for direct blood pressure monitoring or to facilitate sampling for arterial blood gas analysis. Arterial blood samples may also be

Figure 59.1. Reindeer restrained in a drop floor chute.

Figure 59.2. Jugular blood sampling from a pampas deer.

obtained from the femoral artery when auricular arterial catheterization proves to be difficult.

Intubation

Intubation can be difficult in cervids. The best technique is to maintain the animal in sternal recumbency with the head and neck extended upwards. Use a laryngoscope with a long flat blade and stiffen the endotracheal tube with a stylet. The epiglottis is long and mobile in cervids. The flat blade of the laryngoscope should be carefully placed on the dorsum of the

epiglottis, depressing it ventrally. The opening to the glottis can then be visualized and intubation can proceed. Animals induced with xylazine and ketamine may swallow, or close the glottic opening during intubation. The depth of anesthesia may be increased, to facilitate intubation, with an additional dose of ketamine (1–2 mg/kg) or propofol (2–4 mg/kg) (Woodbury et al. 2005).

Preanesthetic Concerns

Several factors can influence the method of anesthesia, and the means of drug administration. It is important to plan the capture carefully, as prolonged chase times can result in capture myopathy, trauma, or hyperthermia.

Elective procedures, in captive animals, should be planned for the cool hours of the day. Rumenal tympany can be a complication during anesthesia. If the procedure is elective, captive deer should be fasted for 24 hours. Deer are prone to hypoxemia during anesthesia (Moresco et al. 2001; Murray et al. 2000; Paterson et al. 2009; Read et al. 2001). Hypoxemia is exacerbated by positioning in dorsal or lateral recumbency. Alpha-2 agonist drugs, such as xylazine or medetomidine, will also exacerbate hypoxemia (Read et al. 2001). Chronically debilitated animals and animals with severe fluid deficits or blood loss are generally not good candidates for anesthesia, and will be at increased risk for complications.

MONITORING AND SUPPORTIVE CARE

Pulmonary Function

Whenever possible, deer should be positioned in sternal recumbency. The head and neck should be extended to maintain a patent airway. The animal should be monitored for hypoxemia, ideally with a pulse oximeter. A multi-site sensor applied to the tongue generally provides a good signal. Normal hemoglobin saturation should be 95–98%, below 85% is considered hypoxemic. Severely hypoxemic animals are often tachycardic. Heart rates above 150 in mature deer may result from a stress response due to hypoxemia, hypercarbia, pain, or hypotension. Supplemental inspired oxygen should be considered in hypoxemic animals. Oxygen can be easily delivered via nasal insufflation (Read et al. 2001). A nasal catheter should be placed and threaded as far as the medial canthus of the eye. A flow rate of 1–2 L/min is generally sufficient for smaller species, such as white-tailed deer (Fahlman et al. 2011). Higher flow rates may be required in larger deer species, such as red deer and moose (Paterson et al. 2009).

In order to conserve oxygen and prolong tank life, the flow should be adjusted downwards to find the minimum flow that will allow maintenance of $SpO_2 \geq 95\%$. An alternative strategy is to use a portable oxygen concentrator; these devices have proven effective

in treating hypoxemia during anesthesia of reindeer (Fahlman et al. 2012).

Monitoring the Cardiovascular System

Heart rate should be monitored, at minimum, every 5 minutes. The auricular artery is easily palpated in deer. If the auricular artery cannot be palpated, a femoral pulse can be used. Blood pressure can be easily measured with an oscillometric cuff placed proximal to the carpus.

Thermoregulation

Rectal temperature should be monitored every 5–10 minutes. Deer are prone to hyperthermia (Moresco et al. 2001; Read et al. 2001). Rectal temperatures greater than 40°C are cause for concern, and attempts should be made to cool the animal. Rectal temperature in excess of 41°C is an emergency and should be treated aggressively. It is difficult to actively cool large animals and often the best option is to antagonize the immobilizing agents and allow the animal to recover. Hyperthermia, in the face of hypoxemia, is a particularly serious complication, as hyperthermia increases metabolic oxygen demand. Hyperthermic animals should receive supplemental inspired oxygen to offset hypoxemia.

PHARMACOLOGICAL CONSIDERATIONS FOR ANESTHESIA OF DEER

This section is an overview of pharmacological agents that can be used for anesthesia of deer. Attention must be paid to hunting seasons and appropriate marking of wild captured animals, to avoid consumption of drug residues in meat.

Anesthesia of Captive or Game-Farmed Deer

Game-farmed and other captive deer often have very different drug requirements compared with free-ranging animals. The following sections deal with anesthetic management of captive deer.

Sedation of Captive Deer White-tailed deer and mule deer usually require 2–3 mg/kg body weight (BW) of xylazine, IM, to produce recumbent sedation. American elk require approximately 1 mg/kg, IM, to produce recumbent sedation (Caulkett 1997). Once the xylazine has been administered, the animal should be left alone until it assumes a position of lateral recumbency or sternal recumbency with its head down. The deer can be cautiously approached and a towel should be placed over its eyes to decrease stimulation; noise should be kept to a minimum. Animals may appear to be very sedate under xylazine sedation, but they can rouse suddenly. To decrease the chance of sudden arousal, administer 1 mg/kg of ketamine into the jugular vein. Anesthesia can be maintained with 1–2 mg/kg of

ketamine IV, as required (generally at 10–15 minute intervals).

Yohimbine is effective in most cervids at a dose of 0.1–0.2 mg/kg BW. Administer 0.1 mg/kg IV and 0.1 mg/kg IM. Tolazoline is also effective, and can be used at a dose of 2–4 mg/kg. Atipamezole can be used at 1 mg IM per 10 mg of xylazine.

Local Analgesia for Velvet Antler Removal The simplest way to block velvet antler is to perform a ring block at the base of the antler pedicle. Lidocaine HCl (without epinephrine) is administered at a dose rate of 1 mL/cm of pedicle circumference (Wilson et al. 2000). The block will produce surgical analgesia in 1–2 minutes and will last approximately 90 minutes.

Inhalational Anesthesia

Inhalational anesthesia is recommended for prolonged, or very invasive procedures. Either halothane or isoflurane can be used. A small animal circle system can be used on animals weighing up to 150 kg (Fig. 59.3). Use a 3- to 6-L rebreathing bag and fresh gas flows of 10–20 mL/kg BW/min. Cervids premedicated with xylazine can usually be maintained on approximately 1% halothane or 1.3% isoflurane. Induction of captive adult cervids can often be achieved with xylazine sedation followed by IV ketamine at a dose of 2–3 mg/kg BW, using the techniques described earlier. Xylazine-tiletamine-zolazepam can also be used for induction, at the dosage quoted later. Fawns are usually easy to handle. Fawns can be induced with IV diazepam, 0.2 mg/kg, followed by 0.05 mg/kg of butorphanol IV, followed by 2–3 mg/kg of ketamine.

Airway protective reflexes are absent under inhalational anesthesia, and regurgitation and aspiration can occur; therefore, intubation is recommended. Hypoventilation may be encountered, necessitating

Figure 59.3. Maintenance volatile anesthesia of fawns can easily be achieved with a small animal anesthetic machine.

intermittent positive pressure ventilation. Usually, cervids maintain a relatively high blood pressure; hypotension may be encountered if rumenal tympany is present. The respiratory and hemodynamic compromise produced by rumenal tympany can be severe. The incidence of rumenal tympany can be decreased if food is withheld for 24–36 hours prior to anesthesia. Water should be withheld for 12 hours prior to anesthesia. Rumenal tympany may be resolved by passage of a stomach tube. If not, the anesthesia may be terminated, or emergency rumenal trocharization performed. Passive regurgitation can occur. Inflate the cuff on the endotracheal tube to ensure an adequate seal of the airway. The animal should be extubated when the swallowing reflex occurs, and the ETT should be removed with the cuff partially inflated. Animals that have had xylazine premedication should receive yohimbine, to reverse the effects of the xylazine, at a dose of 0.1–0.2 mg/kg BW. Divide the dose, give half IM and half IV. Postoperative analgesia can be achieved with 0.025–0.05 mg/kg BW of butorphanol.

Capture of Free-Ranging Deer

Wild deer will generally be at a greater risk for complications than captive deer. Drug requirements are higher and the risk of capture myopathy, hyperthermia, or trauma is potentially higher. There are a variety of protocols for capture of deer. This section describes some of these protocols.

Xylazine-Tiletamine-Zolazepam Xylazine-tiletamine-zolazepam is a useful mixture for capture of wild deer (Millspaugh et al. 1995; Murray et al. 2000) and for chemical immobilization and light anesthesia in game-farmed or zoo animals. The effective dose for American elk is 1 mg/kg of xylazine + 2 mg/kg of tiletamine-zolazepam. White-tailed deer and mule deer require 1.5 mg/kg of xylazine + 3 mg/kg of telazol. Excited animals often require a higher dose. This combination will provide approximately 45 minutes–1 hour of anesthesia. Anesthesia may be prolonged with IV ketamine at a dose of 1–2 mg/kg, Q 15 minutes. Once the procedure has been completed antagonism of xylazine is recommended with tolazoline or yohimbine at the earlier dosage. The major complication associated with this technique is hypoxemia. Read et al. (2000) conducted a trial to measure the respiratory effects of a xylazine-tiletamine-zolazepam mixture. All elk exhibited mild to marked hypoxemia ($\text{PaO}_2 = 43 \pm 11.8$ mmHg) and showed marked improvement after 5 minutes of nasal insufflation of oxygen at 10L/min ($\text{PaO}_2 = 207 \pm 60$ mmHg).

Medetomidine-Ketamine Medetomidine is a very useful alpha-2 agonist drug for wildlife anesthesia when it is formulated at a concentration of 10–30 mg/mL.

Medetomidine is 20–40 times more potent than xylazine. However, its use alone is not generally recommended as induction times are unacceptably long. Medetomidine is generally used in combination with ketamine. The major advantage of medetomidine-ketamine is that ketamine requirements are much lower than with xylazine. This factor allows for an earlier antagonism of the combination that is, the alpha-2 agonist can be antagonized with less risk of unmasking convulsive activity or rigidity from residual ketamine. Hypoxemia and hypertension are the major complications that may be encountered with medetomidine-ketamine (Caulkett et al. 2000). Medetomidine should always be antagonized with atipamezole at a 3–5:1 ratio. Less specific alpha-2 agonist drugs (yohimbine and tolazoline) are usually not effective.

Potent Opioids Potent opioids, such as, etorphine, carfentanil, and fentanyl, have been widely used for immobilization of several different deer species (Caulkett et al. 2000; Haigh 1990, 1991; Moresco et al. 2001). In most cases, they have been combined with xylazine, acepromazine, or other sedatives in order to achieve optimum immobilization. The choice of opioid for use in deer may be governed as much by availability as by any other factor.

Thiafentanil is another potent opioid anesthetic that has proven to be extremely useful for capture of deer. Doses in North American elk as high as 100 µg/kg provided very rapid immobilization (<1 minute in some cases), and numerous elk have been immobilized at doses near 50 µg/kg (Smith et al. 1993). A very complete overview of thiafentanil can be found in (Lance & Kenny 2011).

A variety of opioid antagonists have been used in deer. They include nalorphine, diprenorphine, naloxone, nalmefene, and naltrexone; of these products, naloxone has the shortest half-life. Narcotic recycling, or re sedation, especially of animals immobilized with carfentanil or etorphine, has been reported when naloxone is used (Haigh 1991). Naltrexone has a much longer duration of action than any of the other antagonists listed (Kreeger & Arnemo 2012), and when adequate doses of naltrexone are used, recycling is generally not a problem (Haigh 1990).

Sedation of Free-Ranging Deer

Intranasal Alpha-2 Agonist Administration Intranasal drug administration has the advantage of a rapid onset time, reliability, and ease of administration. It is a useful technique to produce sedation in deer that are captured by physical means (Fig. 59.4). Xylazine administered intranasally at a dose of 1.5–2 mg/kg will produce reliable sedation, and stress reduction in American elk (Cattet et al. 2004). Onset is rapid (often less than 1 minute), and the effects can be antagonized with yohimbine.

Figure 59.4. Intranasal drug administration to a white-tailed deer.

Neuroleptic Agents

Neuroleptics can be extremely useful in the management of wild and semi-domesticated deer. These drugs will facilitate transport of deer and will decrease stress in acutely captured deer. They have the potential to decrease the risk of trauma, and capture myopathy. Azaperone (0.2 mg/kg) can be used immediately post reversal to facilitate short translocations (6 hours or less). Zuclopenthixol acetate (1 mg/kg) will provide up to 4 days of tranquilization (Read et al. 2000). Animals treated with this drug demonstrate decreased flight distance, decreased indices of stress, and improved water and food consumption compared to untreated animals (Read et al. 2000).

Anesthetic Protocols for Various Deer Species

White-Tailed Deer (*Odocoileus virginianus*) & Mule Deer (*Odocoileus hemionus*) Mature white-tailed deer weigh 60–150 kg (Kreeger & Arnemo 2012). Mature mule deer weigh 75–135 kg. They are not difficult to anesthetize as long as they are kept calm during immobilization. Excited deer tend to override the sedative effects of alpha-2 agonists and often require higher doses for induction. Common complications include the following: trauma, hyperthermia, and potentially capture myopathy. Rumenal tympany is not commonly encountered during anesthesia of these species. A variety of techniques have been used to induce immobilization. Hypoxemia is not uncommon, and supplemental inspired oxygen should be considered.

White-tailed deer can be effectively anesthetized with 2.2 mg/kg of xylazine, combined with 4.4 mg/kg of tiletamine-zolazepam (Murray et al. 2000). This combination is equally effective on mule deer, and immobilization can be partially antagonized with 0.1–0.2 mg/

kg of yohimbine. Medetomidine at a dosage of 0.1 mg/kg, combined with 2.5 mg/kg of ketamine, will produce a good quality of immobilization in mule deer and white-tailed deer (Caulkett et al. 2000). Atipamezole administered at three to five times the medetomidine dose will effectively antagonize immobilization. Thi-fentanyl can be used in white-tailed deer at a dosage of 0.1 mg/kg, combined with 1 mg/kg of xylazine, reversal can be achieved with 2 mg/kg of naltrexone, combined with 2 mg/kg tolazoline. In mule deer, a thi-fentanyl dose of 0.15 mg/kg, combined with 1 mg/kg of xylazine, is recommended (Kreeger & Arnemo 2012).

North American Elk (*Cervus canadensis*) and Red Deer (*Cervus elaphus*)

Elk or red deer may be captured via physical or chemical means. If physical capture (net gunning) is used, sedation can be quickly induced with intranasal xylazine (Cattet et al. 2004). Mature elk weigh 230- to 318-kg, red deer weigh 60–180 kg (Kreeger & Arnemo 2012). Chemical immobilization can be induced with opioids or alpha-2 agonists combined with dissociatives. Hypoxemia is common in anesthetized elk; it has been described during anesthesia with carfentanil-xylazine (Moresco et al. 2001). In this study, hypoxemia was effectively treated by partial antagonism of carfentanil with a low dose of naloxone. Hypoxemia has also been characterized during immobilization with xylazine-tiletamine-zolazepam (Read et al. 2001). Elk can be immobilized with 10 µg/kg of carfentanil combined with 0.1 mg/kg of xylazine (Moresco et al. 2001). Immobilization should be antagonized with naltrexone. A mixture of 0.4 mg/kg of xylazine, combined with 3 mg/kg of tiletamine-zolazepam, is also effective (Millspaugh et al. 1995). Immobilization, with this combination, can be partially antagonized with 0.125 mg/kg of yohimbine.

Red deer are distributed throughout Europe; they are smaller than elk but considerations are similar. The drug of choice for red deer capture is 0.11 mg/kg of medetomidine, combined with 2.2 mg/kg of ketamine (Arnemo et al. 1994a). Medetomidine should be antagonized with 0.5 mg/kg of atipamezole. A good alternative is 2.5–3.0 mg/kg of xylazine, combined with 2.5–3.0 mg/kg of tiletamine-zolazepam (Janovsky et al. 2000). Atipamezole should be used to antagonize xylazine at a dose ratio of 1:8 (mg:mg). However, due to the long elimination time of tiletamine-zolazepam, recoveries are often prolonged.

American Moose and European Moose (*Alces americanus* and *Alces alces*)

Anesthesia of moose is very similar to anesthesia of other deer. One of the major complicating factors with moose is their large size. Mature moose can weigh 400–800 kg (Kreeger & Arnemo 2012). All of the same precautions apply, and particular attention must be paid to the prevention of capture myopathy and hyperthermia. There are several drug

choices for anesthesia of moose. Carfentanil-xylazine has been advocated, as in other deer (Seal et al. 1985). The addition of xylazine to carfentanil will decrease the incidence of muscle rigidity; unfortunately, the addition of xylazine will also increase the risk of regurgitation and aspiration pneumonia (Kreeger 2000). For this reason, if carfentanil is used in moose, it should be administered as the sole agent at a dose of 10 µg/kg. In addition to the risk of regurgitation, they are at risk for hyperthermia and capture myopathy. Thiafentanil at a dose of 0.03 mg/kg is good alternative (Kreeger et al. 2005). Reversal of immobilization can be achieved with 0.6 mg/kg of naltrexone.

European moose have been effectively immobilized with 60 µg/kg of medetomidine, combined with 1.5 mg/kg of ketamine. (Arnemo et al. 1994b). Immobilization can be antagonized with 0.3 mg/kg of atipamezole. Currently, the drug of choice for free-ranging moose is etorphine, alone, at a dose of 7.5 mg of etorphine per adult, and half this dose in calves (Arnemo et al. 2004). We have also seen good results with xylazine-tiletamine-zolazepam in moose captured for translocation from urban areas. A dose of 1.5 mg/kg of xylazine combined with 3 mg/kg of tiletamine-zolazepam has proven effective (N. Caulkett unpubl. data, 2005), but recoveries may be prolonged following xylazine reversal. Immobilization can be partially antagonized with yohimbine or tolazoline.

Caribou and Reindeer (*Rangifer tarandus*) Caribou often have high drug requirements, when compared with other deer species. Their speed and agility can make them a difficult target for remote delivery. *Rangifer* sp. range in size from 80 to 300 kg (Kreeger & Arnemo 2012), with woodland caribou being the largest subspecies. The drug combination of choice for reindeer is 0.1–0.2 mg/kg of medetomidine plus 1–2.5 mg/kg of ketamine (Arnemo et al. 2000, 2011; Kreeger & Arnemo 2012). Dose rates in *Rangifer* are very variable depending on the capture technique, the degree of human conditioning (domestic vs. wild), and the subspecies being captured.

Fallow Deer (*Dama dama*) Adult fallow weigh 40–100 kg (Kreeger & Arnemo 2012). A variety of techniques have been used to anesthetize fallow deer, often with unreliable effects. One potentially reliable drug combination for fallow deer is 0.1 mg/kg of medetomidine + 1 mg/kg of tiletamine-zolazepam (Fernandez-Moran et al. 2000).

Axis Deer (*Axis axis*) and Hog Deer (*Axis porcinus*) In Asia, drive nets are often used to capture free-ranging axis deer and hog deer. To reduce stress and to facilitate handling, sedation can be induced with 3–4 mg of xylazine IM (with subsequent reversal with 1-mg

atipamezole/8-mg xylazine) (Kreeger & Arnemo 2012). The effect of xylazine, however, is unpredictable in excited individuals, and a combination of medetomidine and ketamine is preferred both for physically restrained animals and for chemical capture by remote drug administration. In axis deer, 0.1-mg/kg medetomidine + 3.5-mg/kg ketamine, and in hog deer, 0.5-mg/kg medetomidine + 1.5-mg/kg ketamine (Kreeger & Arnemo 2012). If needed, ketamine at 1–2 mg/kg IM can be used to deepen or prolong anesthesia. The effects of medetomidine can be effectively reversed by atipamezole IM at 5-mg/mg medetomidine (Kreeger & Arnemo 2012).

Neotropical Deer Species Midazolam at a dose of 0.5 mg/kg has been combined with ketamine (7 mg/kg) and xylazine (0.3 mg/kg) in brown brocket deer (*Mazama gouazoubira*), Midazolam (0.5 mg/kg) has also been combined with ketamine (5 mg/kg) and xylazine (0.5 mg/kg) for the chemical immobilization of marsh deer (*Blastocerus dichotomus*). Free-ranging marsh deer have also been successfully anesthetized with 0.8 mg/kg of xylazine and 2 mg/kg IV of tiletamine-zolazepam, with rapid, smooth recovery following antagonism of the xylazine, with yohimbine (Pinho et al. 2010). Pampas deer (*Ozotoserus bezoarticus*) can also be successfully immobilized with either xylazine-midazolam-ketamine or xylazine-tiletamine-zolazepam. A complete review of capture and restraint of neotropical cervids can be found in *Neotropical Cervidology: Biology and Medicine of Latin American Deer*.

Antelope

Ray L. Ball and Markus Hofmeyr

INTRODUCTION

The group of mammals referred to as antelope are a diverse collection of ruminants ranging from dik-dik to eland. Antelope are one of the groups of animals classically associated with game capture and translocation. Historically, anesthesia in captive antelope was one of the veterinarians' most difficult challenges. Improvements in captive management, including training techniques and restraint devices, have made the need for anesthesia much less and facilitated it when it is necessary. But the anesthesia of antelope, which are very diverse and different to each other, is a skill that will never totally be replaced with advances in restraint and training, and veterinarians with antelope in their care should strive to improve their anesthetic management.

TAXONOMY AND ANATOMY RELATED TO ANESTHESIA

Antelope is a common name given to various members of the family Antilocapridae and Bovidae. The pronghorn, *Antilocapra americana*, is the only member in the Antilocapridae. The antelope are scattered in several subfamily in the Bovidae. They are all ruminant Artiodactyla and range from a 3-kg dik-dik to 900-kg giant eland. The subfamilies Caprinae (goats and sheep), the genus *Gazella* (gazelle), *Bison*, and *Bos* (cattle) will be dealt with in separate chapters.

There are several anatomical considerations to consider when anesthetizing antelope. The lack of upper incisors can help facilitate tracheal intubation, but the depth of the larynx and the limitations in visualizing it can complicate intubation. The larynx itself is deep in the throat and difficult to visualize with a laryngoscope and appropriate blade. One must ensure adequate depth of anesthesia before attempting to intubate

an antelope as excessive stimulation to the larynx can induce regurgitation. Dysplastic tracheae has been reorted in blue duikers but should be readily apparent at intubation efforts (Lombardini et al. 2010). The bovine lung is smaller, is divided into separate lobes, each with distinct lobules separated by complete septa. The diaphragm is more vertical and flatter in cattle (most antelope do not have published anatomical descriptions) than in horses, and most of the bovine lung is cranial to the abdomen. A flatter conformation of the diaphragm results in decreased ventilator efficiency (Lumb 2000). Tympany, regurgitation, and aspiration pneumonia are all serious potential complications with ruminants. Pharmacological effects of many anesthetics will increase the chances of regurgitation. Recumbency, especially left lateral, will increase tympany and regurgitation. This may be especially important in antelope that are darted for anesthetic induction and become malpositioned. The rumen occupies approximately three-fourths of the abdomen may become distended when a ruminant is recumbent. Therefore, increased intragastric pressure represents an additional unique pathophysiological condition for the diaphragm (Pypendop & Steffey 2001). With moderate to high intragastric pressure, a pattern of decreased respiratory rate, decreased end-expired lung volume, and breath holding at the end of inspiration is observed (Pypendop & Steffey 2001). Increased gastric pressure, gastric distension, and cranial displacement of the diaphragm can result in a significant decrease in lung dynamic compliance, tidal volume, and minute ventilation (Pypendop & Steffey 2001) resulting in PaCO₂ increases and PaO₂ decreases.

All large antelope should have adequate padding while recumbent. In dorsal recumbency, antelope should be balanced flat on their backs with the gluteals sharing the weight and all limbs should be flexed and

Figure 60.1. Endoscopic view of epiglottis and glottis of gerenuk (*Litocranius walleri*) with head and neck slightly extended.

relaxed. The neck needs to be supported as well to prevent hyperextension. Antelope in dorsal recumbency at any plane of anesthesia should be intubated. In lateral recumbency, there should be adequate padding for the radial nerve. To improve venous return, an inner tube can be placed on the dependent forelimb and pulled cranial while the other limbs are lightly supported and moved perpendicular to the long axis of the body. The dependent eye must also be protected. The eye should be closed and padded with a towel or an inner tube. Often times, most diagnostic procedures can be performed with the animal in sternal recumbency. In a sternal position, all four limbs should be tucked under the animals in a natural sitting posture. The head is tucked in a flexed position to prevent any regurgitated material from being aspirated. This can have very serious drawbacks as it will also reduce the airflow during respirations. It is the authors' preference to keep the head extended and the airway as open as possible—it is best to hold the head up, neck extended and nose pointing downward—this facilitates flow of possible regurgitated content out the mouth and away from the larynx. If regurgitation is likely, intubation is a better alternative than closing the airway (Fig. 60.1 and Fig. 60.2).

BIOLOGY AND PHYSIOLOGY

The pronghorn is found only in western North America. The feet have two digits and the horns consist of a bony core covered with a keratinized sheath that is shed annually (Huffman 2014). All antelope males and some females of certain species have unbranched horns attached to the frontal bones of the skull. The horns are composed of a bony core and are covered with a keratin sheath that is never shed. As a general rule, antelope are herding animals and live in small groups

Figure 60.2. Same gerenuk and endoscope position as in Figure 60.1. Head is now flexed with nose down as is recommended to allow drainage of rumen reflux.

to very large herds; exceptions are small antelopes, which are found on their own or in pairs. All antelope are ruminants and spend a majority of a 24-hour period actively feeding or ruminating.

VASCULAR ACCESS SITES AND MONITORING

Over-the-needle catheters are often utilized in antelope veins. In areas where the skin may be thicker, a cut down with a scalpel or large-gauge needle will facilitate catheter placement. Butterfly catheters can also be used for shorter-duration venous access or during emergencies. Common sites are the auricular, jugular, cephalic, medial and lateral saphenous, and lateral thoracic vein. Arterial access is most readily found in the radial, caudal auricular, and common digital arteries. The facial artery is palpable in most antelope species but can be difficult to catheterize in some species.

Several variables can be used to monitor the cardiovascular system including heart rate, pulse strength, color of mucus membranes, and capillary refill time. The color of venous blood (as can quickly be accessed in the earvein) is also a crude but useful indicator of blood oxygen levels. Resting heart rates are generally not known in antelope species, but in domestic cattle, resting heart rate is on average 80 beats per minute. Heart rate will vary with size and age. Smaller ruminants will be as high as 110 beats per minute (Riebold 1996). Initial heart rates in darted animals or those that are physically restrained are likely to be significantly higher. Overall heart rate will tend to drop as the anesthetic level deepens. Pulse pressure can be used in the field to estimate blood pressures indirectly. They can be evaluated at any of the sites mentioned above for arterial catheterization. Typically, the strength of a palpated

pulse will decrease with depth of anesthesia. If digital pressure on the artery is easily accomplished during diastole, the arterial pressure can be assumed to be low (Riebold 1996). Mucus membrane should be pink in anesthetized antelope. The use of alpha-2 agonists often makes the mucus membranes pale in color at the start of the anesthetic procedure. The color will often return to a normal pink after 20–30 minutes or if the alpha-2 drugs are antagonized. Capillary refill time should be less than 2 seconds, indicating good perfusion of peripheral tissues. Respiratory adequacy can be judged by monitoring respiratory rate and depth. Thoracic excursions or breaths felt from the nostrils are easy methods to monitor respiratory function. Ocular reflex and eye position do not appear to be as useful in many antelope anesthesia due to the likelihood that the induction often takes place remotely.

Monitoring core body temperature is essential in antelope anesthesia. Hyperthermia and subsequent capture myopathy is one of the most commonly encountered problems with antelope anesthesia. A rectal temperature is the most common location for temperature monitoring. Core temperatures may be better assessed with a flexible thermometer lead placed down the esophagus. Hyperthermia commonly occurs during high ambient temperatures but can occur in temperature controlled environments. Hyperthermia may be induced by psychological factors regardless of ambient temperatures in impala. (Meyer 2008b). Common causes of hyperthermia include prolonged inductions, stress, and the depression of normal thermoregulatory mechanisms by anesthetic drugs. Underdosing and poor dart placement with partial drug delivery will inevitably lead to excessive running and pacing, capture stress, and resulting hyperthermia. To emphasize this point, thermometric data loggers were surgically implanted in 15 impala (*Aepyceros melampus*) to investigate the consequences of chemical capture (Meyer et al. 2010). Four combinations of induction agents were compared: etorphine and azaperone; etorphine and medetomidine; thiafentanil and azaperone; and thiafentanil medetomidine. The impala developed an extremely high rise in body temperature, which peaked 20–30 minutes after reversal of the immobilization regardless of drug combination used. The magnitude of the rise in body temperature was similar for all the drug combinations. Changes in body temperature were related to the time that it took for an animal to become recumbent after darting and not to the effect of the drug combination on time to recumbency. The relationship between time to recumbency and body temperature change, and also to plasma cortisol concentration, indicated that physiological consequences of capture were related to the duration of exposure to a stressor (the induction), and not to the pharmacology of the capture drugs (Meyer 2008a). Although shorter time to recumbency in individuals resulted in the benefit of

smaller stress responses and body temperature changes, those individuals were predisposed to developing hypoxia and possibly induction apnea due presumably to higher doses used to achieve quicker inductions. As a general rule, quicker inductions with resultant anesthetic management have less complications than low dose extended induction periods (authors' personal experience).

Common approaches to treating hyperthermia in antelope have utilized topical water or cold water enemas. Another approach to cooling the patient is to deepen the anesthesia, intubate, and place the antelope on a ventilator. This will allow an exchange medium, oxygen and air, to contact a large surface and help dissipate heat. The ventilator will also reduce the muscular effort required by the antelope. Paralytics can be used to quickly intubate and allow less resistance against the ventilator. Moderate fluid therapy and nonsteroidal and steroidal anti-inflammatory drugs are useful adjuncts to this therapy. This approach has proven more successful in the author's hands than trying to cool the antelope externally, especially in larger species.

When anesthetic events in antelope are prolonged, as in a hospital setting, several additional anesthetic monitoring devices may be utilized to ensure the adequacy of the respiratory and cardiovascular systems. Pulse oximetry is now commonly employed in zoological anesthesia routinely. Probes are typically placed on the tongue, ear, vulva, or prepuce. Reflectance probes can also be placed in the oral cavity against the gingiva, or placed vaginally, or rectally. Indirect blood pressure can be measured with standard blood pressure cuffs. The tail and distal limbs are the most common site for cuff placement. Blood pressures in sheep and goats should be maintained at 100 mmHg systolic, 60 mmHg diastolic, with a mean of 75 mmHg, while cattle tend to have higher pressures normally (Riebold 1996). These can serve as good guidelines for smaller and larger antelope respectively. A mean of 60 mmHg has been recommended as a minimum value for zoo bovids (Citino 2003). Addax anesthetized with carfentanil, acetlypromazine, and ketamine had initial mean arterial pressures of 118 mmHg (Klein et al. 1994). Addax anesthetized with carfentanil and xylazine had initial mean arterial pressures of 120.5 mmHg (R. Ball, unpubl. data, 2006). Changes in blood pressure are often sensitive indicators of in assessing the change in depth of anesthesia. Electrocardiography can also be utilized in hospital settings. Lead placement can be a base–apex for large species or standard three-lead placement for smaller animals. Premature ventricular contractions (PVCs) are the most common arrhythmias seen in ruminants (Pypendop & Steffey 2001). A run of three or more PVCs are serious and warrant attention. Common causes of PVCs include hypoxemia and hypercarbia. Administering lidocaine and correcting the cause are essential. Arterial blood gases can also be used to monitor anesthesia.

INTUBATION

Intubation is recommended for any anesthetized antelope that needs to be transported or anesthetized for greater than 1 hour. In species that are prone to regurgitation, such as giant eland, duiker, roan, and addax, intubation should be considered during any anesthetic event. It is advisable to be prepared to intubate antelope even during routine field procedures if complications arise. An adequate plane of anesthesia must be obtained before attempting to intubate. Blind intubation attempts are successful only about 50% of the time in cattle and are not recommended in antelope (Riebold 1996). An effective technique for endotracheal intubation in antelope has been described (Bush 1996). In summary, the larynx is visualized using a laryngoscope with a long straight blade and a stylet, or endotracheal tube exchanger is placed into the trachea. With the laryngoscope removed, the stylet can then be placed through the Murphy's eye of the endotracheal tube and the tube is passed over the stylet and into the trachea. Intermittent positive pressure can be used in ruminants to treat unacceptable hypercarbia (PaCO₂ greater than 60 mmHG) (Pypendop & Steffey 2001).

Portable battery driven oxygen concentrators (EverGo™ Portable Oxygen Concentrator Respironics®, Murrysville, PA) provide an alternative to the use of oxygen cylinders for treatment of hypoxemia during field anesthesia (Fahlman et al. 2010). This has been shown to improve arterial oxygenation in reindeer but not bighorn sheep. The potential for this to provide support in field situations needs to be further explored. Another technique described to ventilate large ungulates is the use of an electric or gas power leaf blower as a ventilator (Citino et al. 2007). Caution should be used with gas-powered devices and inadvertent inhalation of carbon monoxide.

REVIEW OF REPORTS ON ANTELOPE ANESTHESIA

Opioids have been the mainstay of antelope anesthesia in wildlife and captive care. Recently, the addition of the potent opioid thiafentanil has allowed it to be evaluated for antelope immobilization. Thiafentanil alone seems to have little advantage when compared with carfentanil in impala, as induction times and all physiological parameters were comparable (Jansen et al. 1991). The same authors successfully used thiafentanil in eland (*Taurotragus oryx*), greater kudu (*Tragelaphus strepsiceros*), and waterbuck (*Kobus ellipsiprymnus*) with good results. More trials have been conducted utilizing thiafentanil in combination with medetomidine and ketamine. Roan antelope (*Hippotragus equinus*) have been captured with combinations of thiafentanil, medetomidine, and ketamine (Citino et al. 2001). Naltrexone, IV or IM, is used at 30 times the thiafentanil dose and atipamezole at 3 times the medetomidine

dose for recovery. Free-ranging gemsbok (*Oryx gazella*) have been anesthetized with a combination of thiafentanil, medetomidine, and ketamine (Grobler et al. 2001). Intramuscular naltrexone and atipamezole effectively reversed anesthesia. Lichtenstein's hartebeest (*Sigmoceros lichtensteinii*) were successfully anesthetized in bomas using thiafentanil, medetomidine, and ketamine (Citino et al. 2002). Naltrexone was given IV at 30 times the thiafentanil dose along with atipamezole at 4 times the medetomidine dose. Anesthesia of boma-conditioned and free-ranging nyala (*Tragelaphus angasii*) was successful using thiafentanil, medetomidine, and ketamine (Cooper et al. 2005). Free-ranging pronghorn (*Antilocapra Americana*) were anesthetized with thiafentanil and xylazine, and this combination was judged to be superior to previously used anesthetic combinations (Kreeger et al. 2001).

Thiafentanil (57 µg/kg) and azaperone (0.46 mg/kg), TA, has been compared with thiafentanil (15.16 ± 3.3 µg/kg)-medetomidine (15.16 ± 3.3 µg/kg)-ketamine (0.99 ± 0.04 mg/kg), TMK, in free-ranging Uganda kob (*Kobus kob thomasi*) (Caulkett et al. 2006). While the quality of the overall anesthesia was better with TMK, the authors recommended TA for field use due to potential complications with recoveries and profound hypoxia with TMK mixtures. The TMK mixture may have a place in captive situations or if only thiafentanil and medetomidine are used in field situations.

A recent study compared immobilization of gemsbok (*O. gazella*) using thiafentanil (0.036 µg/kg) and 20-mg xylazine (TX) versus carfentanil (0.021 µg/kg) and 20-mg xylazine (CX) (Kilgallon et al. 2010). While there were few physiologic differences between the groups, and minimal differences in overall quality of the anesthesia, the authors suggest that TX is preferable to CX when anesthetizing adult gemsboks.

Carfentanil and etorphine are still the most commonly used opioids antelope anesthesia. Opioids are often combined with alpha-2 agonists or tranquilizers when anesthetizing antelope. The benefits of these combinations include lowering the narcotic dose, smaller drug volumes, shorter induction times, and better muscle relaxation and analgesia than with the opioid alone. Table 60.3 lists several carfentanil and xylazine combinations used by the author. In some species, etorphine in combination with xylazine may have a better quality of anesthesia and shorter recovery times (Howard et al. 2004). Detomidine has been used in addax and blue wildebeest in combination with opioids (Portas et al. 2003) (see Table 60.3). Arabian and Scimitar-horned oryx have been anesthetized for long periods with combinations of etorphine and medetomidine, and there were fewer complications with this combination versus carfentanil and xylazine (Ancrenaz et al. 1996) (see Table 60.3).

A 1:1 mixture of xylazine and ketamine added to etorphine (M99KX) was found to lower the narcotic dose by as much as 30% and provide better overall

anesthesia than etorphine and xylazine (Riebold 1996). Anesthesia in captive bongo was found to be superior with carfentanil-ketamine-xylazine (CKX) combination than either carfentanil alone or carfentanil and acepromazine (Miller-Edge & Amsel 1994). Carfentanil and xylazine combinations will cause hypoxemia and hypertension in captive bongo and blood gas analysis is mandatory during anesthesia with these drugs (Schumacher et al. 1997).

Alternatives to opioids are possible and sometimes the only option if highly regulated narcotics are not available. Tiletamine-zolazepam in combination with butorphanol and an alpha-2 agonist has been used in addax (*Addax nasomaculatus*), eland (*Taurotragus oryx*), scimitar-horned oryx (*Oryx dammah*), impala (*Aepyceros melampus*), wildebeest (*Connochaetes taurinus*), and blackbuck antelope (*Antilope cervicapra*) (Parás et al. 2002). Induction was faster with the xylazine-tiletamine-zolazepam-butorphanol combination than the medetomidine-tiletamine-zolazepam-butorphanol combination. The xylazine-tiletamine-zolazepam-butorphanol combination appeared to have a shorter duration of effect, as some animals arose suddenly during handling. The detomidine-tiletamine-zolazepam-butorphanol combination had the longest duration of action. Atipamezole was used to antagonize the alpha-2 agonist. Tiletamine-zolazepam and xylazine has been used to immobilize sable, scimitar-horned, and Arabian oryx (Bush et al. 1992). Disadvantages with this combination were prolonged and stormy recoveries, hypersalivation, and some muscle rigidity. Doxapram was a useful adjunct to hasten recovery in several of these cases. Blue wildebeest (*Connochaetes taurinus*) have been immobilized with a combination of fentanyl (0.055 mg/kg), azaperone (0.2 mg/kg), and xylazine (0.2 mg/kg) all given IM via dart (Bertelsen et al. 2006). Light anesthesia was obtained, but the authors note an initial hypoxia with combination, but this appeared to be self-limiting and improved with time. Oxygen supplementation was still recommended.

Ketamine and medetomidine combinations have been investigated in antelope in recent years. Addax has been successfully immobilized with medetomidine and ketamine (Portas et al. 2003). Ketamine and medetomidine were effective for immobilizing captive impala (*Aepyceros melampus*) (Phillips et al. 1998). Atipamezole is given to antagonize the medetomidine; usually, it is administered IM or one-half of the dose IV and one-half IM.

STRATEGIES FOR FIELD CAPTURE AND ANESTHESIA IN REMOTE LOCATIONS

The evolution of capture and field anesthesia in antelope species has been well documented (McKenzie 1993; Kock & Burroughs 2011). South African veterinarians have been at the forefront of this development and continue to set standards for wildlife capture.

While better drug combinations and drug delivery systems have made field anesthesia safer for both humans and antelope, the importance of organization cannot be underestimated. The coordination of the capture, using extraordinary amounts of people and equipment, can be overwhelming. The veterinarian overseeing such operations has the welfare of the antelope and the safety of their staff as the highest priority. Many antelope species can be captured with mass capture techniques. In these instances, sedation or tranquilization can be utilized in selected species. Quick, smooth, efficient captures are the key to avoiding animal losses during mass captures and will facilitate the effectiveness of tranquilizations. Proper placement of the capture boma and using a skilled helicopter pilot to drive the antelope into the boma are critical. Commonly used tranquilizers and sedatives used by the South African National Parks (SANParks) are listed in Table 60.1.

Field anesthesia of individuals is done on a less frequent basis but still occurs in wild settings and in boma confinement. While anesthetizing antelope, smooth, quick inductions are best. Depending on the scenario, darting from the ground or a helicopter may be indicated. Animals should not be chased for over 2 minutes prior to darting to help reduce the incidence of hyperthermia and capture stress. Darting techniques and equipment are covered in earlier book chapters. Table 60.2 has specifics on commonly handled species by SANParks.

GUIDELINES FOR ANESTHESIA IN SPECIFIC ANTELOPE SPECIES

Anesthesia Planning and Preparations

Most anesthetic events in antelope are planned events so proper preparations can be made. The goal of the procedure (routine exam, diagnostics, and transport) should be detailed well enough so that it moves forward efficiently. Equipment needed to move the antelope if needed should be available in case of emergency. Staff should be briefed and given specific responsibilities for the procedure. A checklist of basic equipment needs is useful for every anesthetic procedure and should be developed based on individual needs, preferences, and goals of the procedures themselves. Routine equipment needed for antelope anesthesia include ropes, blindfolds, inner tubes, towels, slings, and ear plugs. Portable scales are important to get accurate weights when possible. Medical equipment should consist of an endotracheal intubation kit or nasal insufflation equipment, demand valves, an oxygen supply, intravenous access kits, fluids, and emergency drugs. Monitoring equipment for field procedures should at a minimum be a stethoscope and a thermometer. Portable pulse oximeters are now readily available and highly recommended for all anesthetic events.

Table 60.1. Drugs used by SANParks in the mass capture of various species

Species Route		Tranquillizers and Sedatives								
		Haloperidol (mg)			Perphenazine Enanthate (mg)			Diazepam (mg)		
		AM	AF	SA/J	AM	AF	SA/J	AM	AF	SA/J
Eland	IM	25	20	14–18	100	80	40–60	25	20	14–18
Kudu	IM	15	10	6–8	60	40		15	10	
Gemsbok	IM	10	8					20	15	
Roan	IM	12	10		60–80	40–60		15	12	
Sable	IM	14	12		60–80	40–60		14	12	
Waterbuck	IM	20	15		60–80	40–60		20	15	
Blue wildebeest	IM	14	12	6–8	60–80	40–60		20	15	
Black wildebeest	IM/IV	14	12	6–8	60–80	40–60		14	12	
Red hartebeest	IM/IV	16	14	6–8	60–80	40–60		16	14	
Tsessebe	IV	15	15	7	60–80	40–60		15	15	7
Blesbok	IV	12	12	6	50	40		12	12	6
Bontebok	IV	12	12	6	50	40		12	12	6
Impala	IV	14	12	6				14	12	6
Grey reedbuck	IV	8	8	4				8	8	4
Mountain reedbuck	IV	10	10	5				10	10	5
Springbok (Kalahari)	IV	14	12	7	40–60	40		14	12	6
Springbok (Karoo)	IV	12	10	5	40–60	40		12	10	5
Klipspringer	IV	5	5	3				5	5	3
Steenbok	IV	5	5	3				5	5	3
Duiker	IV	8	8	4				8	8	4

Notes:

- The above doses are for wild animals in good condition.
- Animals that are in poor condition tend to show greater sedation and often develop extra-pyramidal symptoms (EPS).
- Diazepam is the drug of choice to treat EPS.
- Diazepam has a shorter duration of action, and it may necessary that it be repeated after a few hours.
- Use of midazolam has replaced diazepam as a tranquilization in African situations due to the multidose and higher concentration that is available in South Africa.

The abbreviations used in the column headings indicate the different age classes as follows: AM, adult male; AF, adult female; SA/J, subadult or juvenile.

Table 60.2. Drugs used in South African National Parks for the immobilization of various antelope species

Species	Immobilizing Drug Mixture			
	Etorphine (mg)		Azaperone (mg)	
	Adult Male	Adult Female	Adult Male	Adult Female
Sable	4–5	3–4	100	100
Roan	4–5	3–4	100	100
Blue wildebeest	4–5	3–4	100	100
Black wildebeest	3–4	3	80	80
Tsessebe	3–4	3	80	80
Eland	10–12	6–8	180–200	180–200
Red hartebeest	4–5	3–4	80	80
Gemsbok	4–5	3–4	80	80
Kudu	5–6	4–5	100	100
Waterbuck	5–6	4–5	150	150

Notes:

- All doses should be administered intramuscularly.
- Diprenorphine at 2.5 times the etorphine dose in milligram.
- Naltrexone at 15 times the etorphine dose in milligram.
- Hyaluronidase is frequently added to the immobilizing drugs to assist drug absorption and thereby reduce the induction time.

A review of previous anesthesia records is an excellent opportunity to critically examine previous procedures. Accurate, organized medical records will make critical evaluation much easier. For major procedures, a planning session with all parties involved will also make for a smoother anesthetic episode. General recommendations are to fast adult ruminants for 18–24 hours. This fasting will in itself induce bradycardia and will not ensure that the ruminant will not regurgitate (Riebold 1996). It is the author's preference to only remove any concentrate ration from the diet, and allow access to hay, grass, and water. The propensity for most ruminants, notably duikers, addax, and giant eland, to regurgitate may revolve around a subclinical rumenitis. Isolation may stress an individual prior to anesthetic induction. In general, the closer conditions can be kept to the antelope's normal routine, the less the impact the procedure will have on the individual and the herd.

ANESTHETIC REGIMENS FOR ANTELOPE IN MANAGED CARE

An extensive review of chemical restraint regimens was recently provided for numerous antelope species (Citino 2003; Kock & Burroughs 2011). Table 60.3 provides data collected from various facilities from 1996 to 2010 by the author. In general, a 1:10 cocktail of carfentanil to xylazine is used routinely for most species of antelope. Most doses of narcotics listed in Table 60.3 are somewhat higher than those commonly reported. With these doses, induction times are quick and the antelope are typically immobilized in a few

minutes. Adequate support should be available for animals immobilized in quick fashion. Naltrexone is used to antagonize the carfentanil at 100 times the carfentanil dose, on a per milligram basis, split one-half IV and one-half IM. The dose of naltrexone is effective at much lower doses for etorphine and thiafentanil, and effective reversal has been achieved at 20× the opioid dose of the etorphine and thiafentanyl doses (authors' personal experience). Xylazine is not routinely antagonized, and it will provide some post-anesthetic tranquilization. Xylazine will cause some sedation, but no problems have been encountered due to this and all animals are readily accepted back into the herds. Dexmedetomidine has started to find its way into antelope anesthesia, especially with the smaller species. Most clinicians report such a wide array of doses and results that it is difficult to summarize or even comment on the usefulness of this drug.

Serotonergic ligands have been shown to have the potential to reverse opioid-induced respiratory depression (Meyer et al. 2010). Etorphine-immobilized impala (*Aepyceros melampus*) received intravenous injections of metoclopramide buspirone, pimozide, and doxapram. Metoclopramide (10 mg/kg IV) and buspirone (0.05 mg/kg IV) increased the PaO₂ similar to those of doxapram. Neither metoclopramide nor buspirone significantly increased ventilation, but they increased PaO₂ by significantly improving the alveolar-arterial oxygen partial pressure gradient.

Techniques for regional anesthesia from domestic ruminants can be directly applied to antelope. These can be complimentary to general anesthesia as with line blocks for cesarean section or epidurals with xylazine or 95% grain alcohol (Gyimesi et al. 2008).

Table 60.3. Anesthetic induction regimens for selected antelope species with average adult captive body weights

Impala (<i>Aepyceros melampus</i>)	
•	Males 57 kg, female 42 kg
•	30- μ g/kg carfentanil and 0.2-mg/kg xylazine μ g
•	Use lower dose of xylazine in this species as respiratory depression can be significant
Greater kudu (<i>Tragelaphus strepsiceros</i>)	
•	Male 210 kg, female 149 kg
•	26- μ g/kg carfentanil and 0.26-mg/kg xylazine
•	Higher dose of narcotic reduces pacing but still a common finding
Defassa waterbuck (<i>Kobus ellipsiprymnus defassa</i>)	
•	Male 215 kg, female 177 kg
•	22- μ g/kg carfentanil and 0.22-mg/kg xylazine
•	Nervous species, prone to prolonged induction. Tough skin, dart placement critical. Recommend use of hyaluronidase. Obesity also common.
Blue wildebeest (<i>Connochaetes taurinus</i>)	
•	Male 182 kg, female 142 kg
•	21- μ g/kg carfentanil and 0.21-mg/kg xylazine
•	32- μ g/kg etorphine and 40- μ g/kg detomidine
•	Herd members can be aggressive to narcotized animal. Tends to be obese in captivity and hence prone to hyperthermia
Uganda kob (<i>Kobus kob</i>)	
•	Male 100 kg, female 62 kg
•	35- μ g/kg carfentanil and 0.35-mg/kg xylazine
•	Flighty species. Prone to excessive running after darting. Quick induction required to help avoid hyperthermia.

(Continued)

Table 60.3. (Continued)

Sable antelope (<i>Hippotragus niger</i>)
• Male 265 kg, female 166 kg
• 17.5- μ g/kg carfentanyl and 0.17-mg/kg xylazine
• Dangerous when under-dosed. Heavily muscled and can be obese in captivity; prone to hyperthermia. Hyaluronidase useful.
Roan antelope (<i>Hippotragus equinus</i>)
• Male 310 kg, female 235 kg
• 18- μ g/kg carfentanyl and 0.18-mg/kg xylazine
• Dangerous when underdosed. Heavily muscled and often obese in captivity; prone to hyperthermia. Hyaluronidase useful.
Common eland (<i>Taurotragus oryx</i>)
• Male 570 kg, female 300 kg
• 16- μ g/kg carfentanyl and 0.16-mg/kg xylazine
• Can be dangerous when underdosed. Incredible leaping ability. Males are heavily muscled; excessive pacing will lead to hyperthermia. Be prepared to supplement or recover about 20 minutes in to the anesthesia.
Bongo (<i>Tragelaphus eurycerus</i>)
• Male 410 kg, female 249 kg
• 24- μ g/kg carfentanyl and 0.24-mg/kg xylazine
• Typically sedate animals but good leapers.
Scimitar-horned oryx (<i>Oryx dammah</i>)
• Male 180 kg, female 123 kg
• 29- μ g/kg carfentanyl and 0.29-mg/kg xylazine
• 56- μ g/kg etorphine and 5- μ g/kg medetomidine
• Renarcotization more common with carfentanyl. Tends to be obese and prone to hyperthermia.
Arabian oryx (<i>Oryx leucoryx</i>)
• Male 102 kg, female 89 kg
• 37.5- μ g/kg carfentanyl and 0.25-mg/kg xylazine
• 48.5- μ g/kg etorphine and 48.5- μ g/kg detomidine
• Etorphine recommended over carfentanyl due to renarcotization. More slender and delicate in structure than scimitar horned but tends to be obese in captivity.
Addax (<i>Addax nasomaculatus</i>)
• Male 108 kg, female 88 kg
• 22.7- μ g/kg carfentanyl and 0.22-mg/kg xylazine
• Moderate amount of renarcotization if higher dose of carfentanyl used. Etorphine is likely a better choice but limited experience to report.
Bontebok (<i>Damaliscus pygargus</i>)
• Male 80 kg, female 58 kg
• 25- μ g/kg carfentanyl and 0.25-mg/kg xylazine
• Can be difficult to dart, runs excessively afterwards. Prone to hyperthermia. Hyaluronidase recommended; doses even higher than those listed (40 μ g/kg) should be considered for very quick recumbency in large pens.
Sitatunga (<i>Tragelaphus spekii</i>)
• Male 85 kg, female 58 kg
• 40- μ g/kg carfentanyl and 0.30-mg/kg xylazine
• Can be dangerous kickers when recumbent. Hyaluronidase highly recommended. Higher doses useful for quicker recumbency. Tends to run and moderate risk of regurgitation. Will run into water.
Nyala (<i>Tragelaphus angasii</i>)
• Male 105 kg, female 63 kg
• 28.5- μ g/kg carfentanyl and 0.25-mg/kg xylazine
• Very shy and nervous

INDUCTION

Prior to any antelope anesthetic induction, the veterinarian must ensure that there is adequate support staff and necessary equipment. All inductions need to be carried out in a calm, quiet environment to lessen any stress on the antelope. The purpose of the anesthetic procedure may dictate the level of anesthesia needed and perhaps even the choice of drugs used. This may also figure into the delivery method of the induction dose. The delivery of the induction dose should be smooth, quick, and as controlled as possible to also lessen stress.

Anesthetic induction can take place with an antelope physically restrained or with the animal in a confined space. A significant number of anesthetic inductions in antelope will be from a remote delivery system. Dart placement is critical, and personnel experienced with the use of darting equipment should dart the antelope. The muscle masses of the shoulder, neck, and upper hind leg are ideal targets for dart placement. From a helicopter, the rump muscles or those adjacent to the spine are the best targets for remote dart delivery. Adequate velocity on the dart is needed to ensure deep intramuscular injections. Incomplete or slow inductions can occur if the dart is placed in subcutaneous

tissue, or in intraperitoneal, or intrathoracic spaces. Incomplete drug delivery and slow inductions can cause the animal to pace excessively and become hyperthermic. The skin thickness should be considered in certain species and needle sizes and dart velocity adjusted. Poor dart placement contributed to a 30% anesthetic-related mortality rate in captive Defassa waterbuck (*Kobus ellipsiprymnus*) (R. Ball, unpubl. data, July 2008). All animals had prolonged induction times and died as a result of complications from hyperthermia. Waterbuck that received the same doses in the muscle mass of the hind limb had unremarkable anesthetic events. Obese animals in captivity may also have prolonged inductions due to the injection of drug into fatty tissue. The addition of hyaluronidase to the induction drugs can reduce induction times and is especially important in obese animals and those with thick skin. Once the antelope is safe to approach, it should be blindfolded to decrease stimulus. Ear plugs may be considered to decrease auditory stimulus. If the antelope is not recumbent, it should be blindfolded and can be eased into recumbency. If the antelope is not intubated, then intranasal oxygen can be given and routine monitoring can commence.

Advances in physical restraint systems for antelope can allow for hand injection of induction agents, and in certain cases, intravenous inductions are possible (Atkinson et al. 1999; Wirtu et al. 2005). Reduced doses of induction drugs can be used intramuscularly or intravenously if the antelope is physically restrained. A series of nyala were successfully anesthetized in a drop chute system (The Tamer TM, Fauna Products Inc., Red Hook, NY) with intravenous ketamine (4 mg/kg), medetomidine (8 µg/kg), and butorphanol (0.3 mg/kg) intravenously for diagnostics prior to euthanasia (R. Ball, unpubl. data, 2002). Supplemental induction doses may be needed at times in either remote delivery situations or once the antelope is handled. If supplemental dosing is required via a dart, a full induction dose of the narcotic drug is preferred by the author. Once control of the antelope has been obtained, the clinician can determine if it is safe to proceed or to antagonize the entire narcotic dose and recover the animal. If the antelope is restrained and needs supplemental dosing, intravenous ketamine, 0.5–1 mg/kg, can be given to facilitate better control or allow intubation. Higher doses can be given, but the antelope may become apenic and need respiratory support. Ketamine is metabolized relatively quickly, but the narcotic antagonist should not be given for at least 20 minutes to allow a smooth recovery.

A potential life-threatening complication resulting from prolonged induction or inadequate induction is capture myopathy. Capture myopathy is also more specifically termed exertional rhabdomyolysis in wildlife capture and anesthesia. There are four clinical syndromes described: acute death syndrome, delayed per-

acute death, ataxic-myoglobinuric syndrome, and muscle rupture syndrome (Nielsen 1999). The acute death syndrome occurs within a few hours of the anesthetic event and often the antelope will expire during the anesthesia. The most notable clinical finding in the authors' experience is the pronounced hyperkalemia. If immediate electrolyte analysis is not possible, an ECG tracing may suggest hyperkalemia in antelope. Corrective measures include administering calcium gluconate as a cardioprotective agent followed by insulin and dextrose to stabilize the potassium levels. Addressing the inciting causes of hyperkalemia (hyperthermia, lactic acidosis, etc.) can then be addressed. The delayed peracute syndrome occurs within 24 hours and is again believed to be due to potassium sensitizing the heart to catecholamines. The third syndrome is the ataxic-myoglobinuric syndrome, which may occur within several days from the anesthesia. The urine is often brown-red, and muscle, liver, and renal values are elevated. Death is typically from renal failure associated with myoglobinuria. Some animals will recover spontaneously with adequate fluid therapy. In some selected cases, dobutamine can be given intravenously to increase renal perfusion (R. Ball, unpubl. data). Dantrolene is utilized in equine patients with postanesthetic myositis and may be considered in antelope that are experiencing complications of capture myopathy.

RECOVERY

A major advantage of opioid induction is the ability to antagonize the drugs and produce a smooth recovery. Naltrexone is the preferred antagonist and can be administered at 100 times the carfentanil dose or 15 times the etorphine dose. The dose is often split between intravenous, intramuscular, and subcutaneous administration. The product label recommends giving one-quarter of the dose intravenously and three-quarters subcutaneously. A recent study in goats suggests that there is no advantage to splitting the dose when antagonizing carfentanil (Mutlow et al. 2004). Mild renarcotization was noted in many of the study animals. Although renarcotization is not fully understood, there appears to be more episodes of renarcotization in species from arid climates. Water conservation mechanisms in these species may have a role in this, but it has not been investigated as of yet.

Recovered animals can be placed back into the herd immediately if conspecifics do not pose a threat to the recovering animal. Once the opioid fraction of the induction is antagonized, recovery generally takes a few minutes. In most circumstances, the sedative drugs is not antagonized. The sedative may keep the recovering antelope calmer, and this is the preferred method of recovery by the author. Arousing from anesthesia to a fully awake state can be a startling experience, and may in itself be stressful for the animal. A calm slow

recovery is the preferable way to recover an antelope. Antelope that have been under inhalation anesthesia should be recovered away from other animals until fully recovered. Opioid antagonists are not given until the anesthetic gas can no longer be detected from the endotracheal tube. The tube is left in place until a strong swallowing reflex is seen. The cuff is only slightly deflated to help clear the airway of any regurgitated material.

ANESTHESIA RECORDS

An accurate record of the anesthetic procedure is essential. Anesthetic records allow the creation of a database that can be critically evaluated and used as a reference. Drug delivery, dosages, drug effects, physiological data, and the notation of complications are important parts of an anesthetic record. A dedicated person should be assigned to record this information as it occurs. Compilation into an electronic record-keeping system is also a valuable tool for planning future events.

ACKNOWLEDGMENTS

The author wishes to thank Dr. Peter Buss, Dr. David Zimmerman, Dr. Danny Govender, Ms. Cathy Dreyer, and Dr. Markus Hofmeyr from the South African National Parks for their contributions and the numerous opportunities they have provided.

61 Gazelle and Small Antelope

An Pas

INTRODUCTION

Gazelles are nervous and flighty animals that when handled can inflict serious injuries on themselves and on their handlers. Improved handling techniques and capture systems have, however, reduced these risks significantly making it possible to perform basic procedures, such as blood sampling and vaccination, without the need for anesthesia. Several immobilization drugs are available if sedation or anesthesia is required.

The most common gazelle and small antelope species kept in captivity are listed and their body-weights are indicated in Table 61.1.

UNIQUE PHYSIOLOGY, ANATOMY, AND BEHAVIOR

Many gazelle species have developed adaptations for the hot and often dry climate in which they live. The color patterns of most desert gazelles help them to gain heat during cold mornings and to dissipate heat during the hot parts of the day by directing the darker flank or the white rump respectively to the sun. Their long fine legs, long necks, and large ears further help them to regulate their temperature (Willmer et al. 2000). They have developed effective water conservation mechanisms, resulting in low rates of water loss and the production of very dry fecal matter (Willmer et al. 2000).

During extreme exertion, such as when trying to evade a predator, the amount of heat produced will exceed the amount that can be dissipated, especially in hot climates. The animal can, however, store this heat and allow an increase in its body temperature. A mechanism has been described in several species that at the

same time can keep the brain at a lower temperature than the body by utilizing a countercurrent heat exchange mechanism known as the carotid rete. Before the arterial blood reaches the brain, it is cooled while passing via smaller arteries through the venous sinus cavity, which is filled with cooled blood returning from the nasal region. In this way, the organ most sensitive to heat stress can remain at a safe temperature lower than 41°C, while the body temperature can reach over 44°C (Schmidt-Nielsen 1997; Vaughan et al. 2010).

Gazelles can reach very high speeds. A Thompson's gazelle, for example, can run at up to 80 km/h (Feldhamer et al. 2007). Most gazelles have maximum speeds of around 60–70 km/h.

As prey animals, gazelles are constantly aware of their environment and of possible predators. When anything unusual is noticed, the animals will warn each other with a snorting noise and the group will start moving immediately. Many gazelle species perform stylized near-vertical jumps with all four legs extended, called stotting or pronking, before running away at high speed. This behavior makes capture and darting of these animals challenging, as they keep a safe distance from humans, stay in almost constant motion, and any unfamiliar behavior is picked up by and communicated among the group.

When gazelles are caught, some resist violently, using their sharp hooves to kick, but others just lie down and freeze. A quiescent gazelle, however, is not necessarily unstressed. In general, species that live in dense habitats will tend to hide more while species from open savanna areas will tend to run. Good knowledge of the specific behaviors of the different species is essential to capture, handle, and treat these animals safely and successfully.

Table 61.1. Weights

Common Name	Scientific Name	Average (Range) Weight Adult in kg
Beira antelope	<i>Dorcatragus megalotis</i>	11 (9–14)
Blackbuck	<i>Antilope cervicapra</i>	29 (25–35)
Gazelle, Arabian Mountain	<i>Gazella gazella cora</i>	13 (11–16)
Gazelle, Chinkara	<i>Gazella bennettii</i>	17 (15–20)
Gazelle, Dama	<i>Nanger dama ruficollis</i>	57 (50–75)
Gazelle, Idmi	<i>Gazella gazella</i>	15 (13–18)
Gazelle, Pelzeln's	<i>Gazella pelzelni</i>	15 (13–18)
Gazelle, red- fronted	<i>Eudorcas rufifrons</i>	23 (20–25)
Gazelle, Rheem	<i>Gazella subgutturosa marica</i>	19 (12–24)
Gazelle, Soemmering	<i>Nanger soemmerringii berberana</i>	32 (30–40)
Gazelle, Speke's	<i>Gazella spekei</i>	13 (11–15)
Gazelle, Subgutturosa	<i>Gazella s. subgutturosa</i>	19 (17–24)
Gazelle, Dorcas	<i>Gazella dorcas</i>	15 (13–18)
Gerenuk	<i>Litocranius walleri</i>	35 (30–40)
Phillip's dik-dik	<i>Madoqua saltiana phillipsi</i>	3.5 (2–4)

PHYSICAL RESTRAINT

In a Captive Environment

Many gazelles can be hand-caught by experienced staff, and immobilizing drugs can be subsequently administered if required. For physical capture, animals are separated from the group and restricted to a small enclosure. Enclosures can be designed so that the animal can slowly be pushed with a board, canvas, or blanket into a transport box. Boxes should have sliding doors at the front and back, and be able to be opened from the top. In this way, more docile gazelles can be injected in the box, can be taken out from the front, or even can be lifted from the top, especially with the help of a blind-fold. An alternative method involves using a thick blanket, which is slipped under the top lid of the box to avoid light entering the box and then being lowered slowly over the gazelle. The gazelle will thus remain recumbent and calm in the darkened and enclosed environment. This way, simple procedures, such as heart and lung auscultation, temperature taking, and administration of injectable or oral drugs, can be carried out with minimal stress even in the more nervous animals (Figure 61.1).

The initial phase of hand capture is the most critical to minimize self-inflicted trauma. Two handlers are needed that work in a well-synchronized manner. Larger gazelles may require more than two people for safe and proper restraint. The horns of the gazelle are grabbed first (at the base of the horn), and an eye cover is placed immediately. Extreme care needs to be taken when catching young gazelle to avoid permanent

**Figure 61.1.** Use of thick blanket to manually restrain a gazelle.**Figure 61.2.** Gazelle restrained in lateral recumbency.

damage to the horn. Therefore, young animals (and animals without horns) are better grabbed at the neck. The animal can be then quickly lifted off of its feet while the body is supported and the legs are restrained. The first handler holds the horns (or neck) and head with one arm, while partially supporting the neck and torso with the other arm. The additional handler restrains and supports the hind part of the body and restrains the legs by folding them in under the body as in a normal physiological resting position. Another way of holding smaller gazelle is by keeping the legs hanging in the air, with a first handler holding the horns and torso and the second handler keeping hold of the skin in the flanks instead of folding the legs in. Sometimes, it is better to first gently push the animal down into sternal position before lifting it up.

Instead of lifting up the animal, it can also be placed on its side with the neck slightly stretched backwards while the handlers are positioned at its back restraining the neck and legs (Figure 61.2). Legs should always be

held close to the body, never at the distal part, as the gazelle will kick violently and will injure itself and the handlers.

To move small species (up to 35 kg), the animal can also be held upside down in the air. The handlers will hold the animal at the legs and support the back. Although holding animals on the side and especially on the back might seem counterintuitive and even controversial, this unnatural positioning makes the animal resist less and calms them down. The authors have used these handling techniques for many years with good results and no side effects. This can, however, only be done in nonsedated animals. However, as mentioned previously, the safest and least stressful way to move an animal is to place it in an appropriate dark crate.

As soon as animals are caught, blindfolds and ear-plugs (made of cotton, wool, or gauze) should be used to reduce stimuli and to keep the animal as calm as possible. Eye covers should be large enough to cover the eyes but leave the nose open for proper breathing. Horn covers made of plastic or rubber (such as hose pipe, rubber balls, or syringes) can be placed over the tips of the horns for safer handling. Care needs to be taken when holding the horns of young animals since they are easily damaged as the horn sheath is only loosely attached. Detachment can result in moderate to severe bleeding and disfigured horns.

In addition to puncture wounds from the horns, potential injury to handlers can also come from the sharp hooves. Care should be taken that animals do not become entangled in handlers' loose clothing or pockets.

All handling should be carried out in a quiet and gentle way, and any noise or sudden movements should be avoided. The specific amount of restraint needed to safely handle an animal requires experience, as too much restraint can cause the animal to fight back or can cause trauma, while too little restraint can result in the handler being injured or in the animal escaping. It is most important, however, to never let go of the animal. How easily an animal can be handled will depend not only on the species, but also on individual temperament, the degree of habituation, the environment where the capture takes place, and its position in a group's hierarchy.

Nets can be used when an individual animal needs to be separated from a large group for emergency treatment or other procedures. A small mesh net (which has a guide rope fitted on the top and bottom) is suspended from an adjoining fence or other firm structure and then laid across the normal path the gazelle takes to an area where an operator has a clear view of oncoming animals (usually behind a hide). The net is allowed to sit on the ground, and when the animal passes, the top rope on the net is pulled back quickly, raising the net and capturing the gazelle. Once the animal hits the net,

the operator releases their hold on the net, allowing the animal to carry it away and entangle itself. An extra handler should make the animal run at enough speed toward the net as otherwise they will have enough time to shy away as the net is lifted. Once the net is dropped, the animal has to be restrained and removed (starting at the nose) as quickly as possible to avoid any major trauma. An eye cover is fitted, and the legs and head are securely held while the net is removed. Nets are however, potentially dangerous for the animal. The fine long legs can become entangled and injured as the animal struggles, and species such as Spekes (*Gazella spekei*) or Chinkara gazelle (*Gazella bennetti*) easily injure their horns. The area where the capture takes place needs to be well considered. Hard substrate and the presences of big stones will increase the risk for trauma. Nets caught in woody vegetation can result in the escape of the animal. It is therefore important to select and clear the area before installing the net for capture.

Capture in Large Enclosures or Open Areas

Historically, many gazelle species were simply herded into enclosures and then individually caught by hand as described earlier. While this form of capture and restraint is still practical, and indeed essential in some cases, it can lead to a large number of injuries both to the animal and handlers. When multiple animals or large groups need to be restrained, such as for group vaccination and sampling, darting is not a viable option either and capture systems are required. Many different manual restraint systems have been developed in the past for cattle and other large ungulates. Over the years, these systems have been adapted and improved, and a number of restraint devices have been developed which take into account the size, conformation, and behavior of the different nondomesticated species (Blumer & deMaar 1993; McKenzie 1993).

Capture of free- or semi-free-ranging gazelles is done by first confining the animals in a boma, from where they will be led into a raceway system in which they are then separated from each other to finally be captured by hand, slowly pushed into boxes, or held in a tamer system (Figure 61.3).

The first step, bringing the animals into a holding enclosure, can be done by driving and further confining the animals with the use of canvas screens (Rietkerk et al. 1994). The use of modified feeding areas (O'Donovan & Bailey 2006) is however, in our experience, the best method of aggregating animals from large holding pens into a smaller boma. As with any behavioral modification procedure, patience and advance planning, sometimes several weeks beforehand, is required to accustom the animals to any changes to their normal environment. Capture pens or chutes should be in place and operating normally well in advance of the event. All doors and equipment

Figure 61.3. Gazelle capture system.

Figure 61.4. Raceway for gazelle handling.

should be checked to make sure they work smoothly without the risk of them becoming jammed during the capture. Normal feeding practice is used as an incentive to habituate the animals to any new areas and to ensure that they enter the capture fence without fear. These areas usually have a single way in and out and will have a guillotine drop gate to allow the quick closing of the gate once all the animals are held within. These gates can be operated manually or via a remote control.

On the day of capture, the gates are closed and the animals are quickly moved into a mobile raceway (Fig. 61.4) as soon as they have all entered the boma. Tarpaulin sheets, canvas, blankets, or boards are used depending on the size of the animals and the size of the boma area. Within the raceway, animals are segregated into small groups ($n = 1-3$) by sliding doors to reduce the potential for intraspecific aggression or accidental injury. These sliding doors can be navigated from the top or from the side, but all need to run smoothly and allow quick separation. Smaller gazelle species, such as Rheem gazelle (*Gazella subgutturosa marica*), mountain gazelle (*Gazella gazella cora*), and Speke's gazelle (*G. spekei*), can then be hand captured by experienced handlers. This is usually accomplished by entering the last part of the raceway with a hand board, cornering the animal and restraining by hand.

Figure 61.5. Gazelle restraint in Tamer chute.

The animals can also further be gently boarded into a transport box and then handled as has been described above for individual capture. The use of mobile restraint devices such as the Junior Tamer (Fauna Research, Redrock, NY) (Fig. 61.5) has also proved invaluable in the safe restraint of the captured animal and is especially useful for larger species. The tamer system quickly suspends the animal from the ground, while the handlers grab the horns and place an eye cover.

Small gazelles up to 35 kg can also be moved into a "box tunnel." Transport boxes are lined up with all vertical sliding doors open, except for the last box. A group of four to five animals can then be pushed into the tunnel and animals are separated one per box by closing the vertical doors.

Any procedure is conducted as quickly as possible to minimize stress and reduce the risk of capture

myopathy, hyperthermia, or other complications. Once the restraint is completed, the animal can either be released or placed in a transport box for movement elsewhere if required.

For any capture in a confined area, it is extremely important that the holding and transfer areas are closed and provide complete visual barriers to prevent attempted flight through the walls or gates. The smallest gap caused by a loose canvas or hole in the cover will be immediately detected by the animal and will be used in an attempt to escape resulting in animals jumping at high speed into the fence.

Transfer gates between holding pens, or from pens to transfer alleys, should be placed in corners to produce a funnel effect. Long transfer alleys should contain turns to prevent the animal from building up speed during transfer. Catwalks should be provided (on the outside of the pen/alley) to allow operator access for control.

The capture and restraint of any wild animal, and in particular for prey animals such as gazelles, is a very stressful event. It is therefore essential that all procedures are planned and executed with precision and professionalism. One of the primary requirements when carrying out any mass capture is that all people involved understand their roles and responsibilities and that one person takes the lead. The use of checklists and precatch meetings are essential to avoid undue stress or harm to the animals and handlers. Safe and effective restraint of any animal requires a complete understanding of the behavior and flight responses of the species concerned. The use of the equipment should be rehearsed beforehand and handling of animals should be practiced on dummies or first demonstrated by experienced people. Accidents are most likely to happen due to inexperience or miscommunication between the people involved. In the authors' experience, most of the animals restrained on multiple occasions did not show a noticeable shyness to the restraint equipment or handlers. However, animals that were not exposed to regular keeper/animal interactions and that were held in larger enclosures were more difficult to move within the raceway and often sat down as a protective measure.

An example of a comprehensive checklist as used by the author is shown in Appendix 61A.1.

VASCULAR ACCESS

Venipuncture and the placement of catheters are straightforward and can be done in the same way as for small domestic ruminants. The jugular vein is easily accessible for blood sampling or catheterization, as well as the cephalic and lateral saphenous vein. Intravenous fluids or crystalloid solutions are typically given as a supportive measure for prolonged procedures or during surgery. Jugular veins can be catheterized with 18-gauge

catheters of about 50 mm, and the cephalic or lateral saphenous vein is catheterized with shorter (30 mm) 20- to 22-gauge catheters. If intravenous access is necessary post-immobilization, the jugular vein is advised to be used. Cephalic and saphenous catheters can be more difficult to maintain during surgical procedures and after recovery, but are in the authors' experience viable alternatives.

INTUBATION

Gazelles should preferably be intubated for any procedure that takes longer than 20 minutes, to avoid aspiration pneumonia and hypoxemia. However, most often, induction protocols will have to be further supplemented by masking the gazelle with inhalant anesthetics or IV anesthetics, such as ketamine, to make intubation possible and avoid laryngospasm and regurgitation. The need for an increased level of anesthetic depth and thus prolonged recovery, and the circumstances in which the procedure takes place (e.g., field immobilization) has to be weighed against the advantages of placing an endotracheal tube.

In most species, intubation is a straightforward procedure when using the correct technique and with some practice. There may, however, be difficulty intubating Goitered gazelles (*Gazella subgutturosa*) due to thyroid cartilage impingement on the larynx (Foster 1999), and in these species, a blind technique using a rigid catheter might be preferable. To intubate a gazelle, the head is hyperextended, and the maxilla is held open with rolled gauze or similar. Due to the narrow mouth of gazelle species, the laryngoscope blade, together with the tube, easily obscures the view, making straight positioning of the neck and head critical. The tongue is pulled laterally and the pharyngeal area may be cleared of secretions by swabbing, as anesthesia often increases the production of mucus in the throat. A flat, straight and narrow (maximum 1 cm wide) laryngoscope blade (20–35 cm long), is used to facilitate visualization of the larynx. Alternatively, intubation can be done "blindly" by using one hand externally and ventrally to manipulate and position the larynx while using the other hand to guide and advance the endotracheal tube. A stylet or nonflexible uterine catheter may be placed first and the endotracheal tube then slid over it into the tracheal lumen. Lidocaine spray applied to the larynx may help prevent laryngospasm that may occur.

Adult gazelles are typically intubated with 4- to 12-mm endotracheal tubes. As gazelle have, in comparison with many other mammal species, quite long jaws, the larynx lies deep, and the use of long straight nonflexible tubes or tubes containing a stylet makes intubation easier. Confirmation of intubation can be done by checking for condensation in the tube, feeling respirations, moving of the rebreathing bag, and monitoring exhaled carbon dioxide.

PREANESTHETIC CONSIDERATIONS

Gazelles often mask underlying disease and carrying out a general examination or obtaining diagnostic blood work preimmobilization is usually not feasible. Even severe disease conditions (e.g., renal disease due to medullary amyloidosis) (Duncan et al. 1997; Wallace et al. 1987) can be difficult to assess preimmobilization. If animals have an individual identification number (ear tags or ear notching), specific information, such as the general body condition and any previous diseases or interventions, should be recorded in detail. The collection of accurate weights at every opportunity will help to calculate accurate dosages and avoid over- or under-dosing.

Animals cannot usually be completely fasted before anesthesia when they are maintained in large outdoor exhibits, and isolating or confining gazelles is often stressful. When large capture systems are used, food is often restricted to lure animals into the boma system, where food is provided. It is important that animals do not gorge on this food, especially on green foods, as this will result in bloated rumens, causing problems in the tamer or when further anesthesia is required.

Fasting may reduce complications, such as tympany, regurgitation, and aspiration pneumonia. Ideally, food and water should be withheld for 12–24 hours. Fasting for longer than 24 hours has been associated with metabolic acidosis in small domestic ruminants and is not recommended (Gray & McDonnell 1986). Extended fasting may also promote liquid ingesta formation and increase the possibility of regurgitation (Gray & McDonnell 1986).

INDUCTION PROTOCOLS

In manually restrained gazelle, induction can be accomplished with intravenous (IV) administration of either propofol, ketamine/midazolam, ketamine/xylazine, tiletamine/zolazepam, or ketamine/medetomidine (Table 61.2 and Table 61.3). The advantage of administering the drugs IV is the quick and more reliable effect. This is especially useful when alpha-2 adrenergic antagonists are used, as they tend to be less effective when given intramuscularly in stressed animals (Foster 1999; Hammer & Hammer 2002). When animals are caught in handling systems, chutes or boxes they can be injected intramuscularly (IM) by hand. If gazelles are kept in holding pens or exhibits, they can be darted with a blowpipe using lightweight, low impact darts. In the authors' experience, using a plastic stabilizer and gun needle are beneficial, as a gun needle has two holes, which leads to a very quick injection and holds

Table 61.3. Dosages for anesthetic antagonists

Drug	Dosage
Naltrexone	100 mg per 1 mg of carfentanil IM or IV 25 mg per 1 mg of etorphine IM or IV
Diprenorphine (M5050)	2.66 mg per 1 mg of etorphine 50%IV and 50%IM
Atipamezole	2.5–5 mg per 1 mg of medetomidine or detomidine IM or SC 1 mg per 10–20 mg of xylazine IM or SC
Naloxone	0.01–0.02 mg/kg IV or IM
Tolazoline	0.5–1.0 mg/kg IM to reverse alpha-2 agonists

Table 61.2. Dosages used in gazelle and small antelope

Drug	Dosages	Remarks
Propofol	4–6 mg/kg IV	General
Ketamine + midazolam	4 mg/kg (K) + 0.2 mg/kg (Mi) IV	General
Tiletamine/zolazepam	2–4 mg/kg IV	General
Tiletamine/zolazepam + medetomidine	4 mg/kg (T) + 0.4 mg/kg (M) IM	Rheem gazelle
Ketamine + xylazine (mix of 125-mg xylazine and 100-mg ketamine per mL)	6.8 mg/kg (K) + 8.5 mg/kg (X) IM 5.6 mg/kg (K) + 7 mg/kg (X) IM 4.4 mg/kg (K) + 5.5 mg/kg (X) IM 3.6 mg/kg (K) + 4.5 mg/kg (X) IM 3.3–7.1 mg/kg (K) + 4.1–8.9 mg/kg (X) IV 5.4–5.9 mg/kg (K) + 6.8–7.4 mg/kg (X) IM 9.3–12.2 mg/kg (K) + 11.7–15.2 mg/kg (X) IM	Chinkara gazelle Soemmering, Idmi, and Speke's gazelle Red-fronted gazelle Dorcas gazelle Rheem gazelle Idmi gazelle
Ketamine + medetomidine (long induction time and needs quiet surroundings during induction)	4 mg/kg (K) + 0.05–0.07 mg/kg (M) IV 2.4 mg/kg (K) + 0.070 mg/kg (M) IM 3 mg/kg (K) + 0.075 mg/kg (M) IM	General Beira antelope Gerenuk
Ketamine	1–2 mg/kg IV as supplemental anesthesia	General
Carfentanil	0.018–0.022 mg/kg IM	General
Carfentanil + xylazine	0.02 mg/kg (C) + 0.2–0.5 mg/kg (X) IM	General
Medetomidine + ketamine + butorphanol	0.04–0.07 mg/kg (M) + 2–4 mg/kg (K) + 0.2–0.4 mg/kg (B) IM	General
Ethorphine + acepromazine + xylazine + butorphanol	0.028 mg/kg (E) + 0.114 mg/kg (A) + 0.16 mg/kg (X) + 0.05 mg/kg (B) IM	General (preferred in Dama gazelle)

longer in the tissue compared with a blowpipe needle. Care has to be taken that the bun used is well lubricated (with silicone or eye cream) so it moves easily backwards. Darting gazelles in open areas can be very challenging, as several species will not tolerate human approach and remain in perpetual motion (running or pacing) making it virtually impossible to fire a dart at a stationary target. Their relatively small body size, combined with the large distances they keep, make it difficult to fire an accurate shot. Hide blinds, habituation, darting from familiar vehicles, and darting during feeding may make animals less agitated and easier to approach. The use of small volume projectile darts, appropriate pressure, and the correct dart and needle size are critical as even lightweight darts may cause extensive tissue damage in gazelles (Cattet et al. 2004). Darts easily bump off small tensed muscle, as gazelle are always ready to run. The use of low pressure that is sufficient to cover the distance, and small volumes, are crucial.

Gazelle tend to "fight" anesthetics and when darted in an enclosure, will attempt to follow the group even if heavily sedated. Dosages required can be very variable depending on the temperament of the individual and the circumstances in which animals are caught. When one animal has been darted the rest of the group will become so wary that darting more animals becomes increasingly difficult.

Drug combinations for IM induction include opioid/alpha-2 adrenergic agonist, cyclohexamine/alpha-2 adrenergic agonists with benzodiazepines or opioids, or opioid/butyrophenone combinations. Preferred induction regimens will depend on availability of drugs, circumstances under which immobilization takes place, and personal preference. Most frequently and successfully used combinations are carfentanil with xylazine, or a combination of medetomidine, ketamine, and butorphanol, as well as combinations that include etorphine.

The carfentanil/xylazine combination allows a small injection volume, rapid induction, and mild cardiopulmonary side effects. Ketamine can be given intravenously as an anesthetic supplement if needed. Once the gazelle becomes recumbent, it is important to wait 5–10 minutes before approaching to allow the xylazine to reach maximum effect and further relax the animal (Allen et al. 1991). Carfentanil alone is effective for induction, but it produces bradycardia and hypertension (Schumacher et al. 1997). Antagonism is accomplished with naltrexone (100 mg per mg carfentanil, IV or IM) (Mutlow et al. 2004). Xylazine is antagonized with either tolazoline or atipamezole. Yohimbine may also be used as a low cost alternative to reverse xylazine effects, but it is less specific and less effective.

Etorphine, in combination with ketamine and/or xylazine, with azaperone, or with acepromazine/xylazine/butorphanol, has been used successfully to

immobilize gazelles. They give a rapid induction, and only small volumes are needed. Etorphine with ketamine/xylazine has the advantages of lowering the opioid dose by 30%, increasing analgesia, shortening induction times, and decreasing problems with renarcotization (Snyder et al. 1992). Etorphine in combination with azaperone, was used to capture gazelles in field conditions (Foster 1999; Molnar & Mckinney 2002). Hyperthermia, capture myopathy, and aspiration contributed to morbidity and mortality. The study concluded that when capturing these species in high ambient temperature conditions, the use of ketamine and xylazine combinations might be a better choice (Foster 1999; Molnar & Mckinney 2002).

The authors have good experience with a combination of etorphine/acepromazine/xylazine/butorphanol, but do advise the use of naltrexone or if not available, a double dosage of diprenorphine as an antagonist to avoid rebound effects. Only small dart volumes are needed and certain species, such as the Dama gazelle, that respond poorly to other combinations can be immobilized successfully with this combination. The addition of the partial antagonist butorphanol will improve respiration during anesthesia.

A combination of medetomidine, ketamine, and butorphanol has proved to be another useful alternative to opioids (Chittick et al. 2001). Gazelles immobilized with this combination are usually under light anesthesia. If painful procedures are performed, supplementation with IV ketamine or masking down with isoflurane to reach general anesthesia, or local anesthetic techniques, should be used (Chittick et al. 2001). Disadvantages of this combination include bradycardia, transient hypertension, hypoxemia, respiratory acidosis, long inductions, and the relatively large volumes needed for induction (Chittick et al. 2001). The use of concentrated medetomidine (10 mg/mL) and butorphanol (50 mg/mL), as available in some countries, significantly decreases the volume required. The personal experience of the authors with this combination in Rheem gazelle and Arabian mountain gazelle is that induction times can be prolonged, and that enough time needs to be allowed before the animal is approached, that anesthesia is only light in most individuals, and that the higher range of the suggested dosages needs to be used. The combination is most useful in confined areas, but has also successfully been used in large enclosures. This combination is partially reversed with atipamezole alone or with atipamezole and naloxone.

Ketamine and xylazine combinations have also been used to capture free and semi-free living gazelles as an alternative to potent narcotics (Foster 1999; Hammer & Hammer 2002; Molnar & Mckinney 2002). The authors have been using this combination with good success in Idmi, Chinkara, Speke's, and Rheem gazelle (Hammer & Hammer 2002) when given intravenously after netting. The only side effect seen

was regurgitation in two cases, which caused no problems afterwards, and a prolonged recovery in one case. No mortality was seen in the 50 animals that were anesthetized this way. The dosages used were very broad, as accurate weights were only taken after capture, and varied between 4.1–8.9 mg/kg xylazine with 3.3–7.1 mg/kg ketamine. Even higher dosages were used by Foster (1999) for darting of free-ranging Idmi gazelles (11.7–15.2 mg/kg(X) + 9.3–12.2 mg/kg(K)) and Rheem gazelle (6.8–7.4 mg/kg(X) + 5.4–5.9 mg/kg(K)). The broad dosages used indicate the wide safety range of this combination.

Combinations of ketamine and medetomidine, and of ketamine and detomidine, have been used by the authors with good success, but in-depth studies on their effect are lacking. As with the use of all alpha-2 adrenergic agonists, these combinations are more useful in captive situations as induction time can be prolonged. Atipamezole is used as antagonist and results in smooth recoveries at a dosage of 2.5–5 times the dosage (in mg/kg) of medetomidine or detomidine. Reversal drugs should only be given 30–40 minutes after the administration of ketamine to avoid adverse reaction, such as disorientation, tremors, and salivating. Medetomidine/ketamine combinations are preferred for use in Beira antelope (*Dorcatragus megalotis*) (Martin Jurado et al. 2007) and Gerenuk (*Litocranius walleri*).

Tiletamine-zolazepam in combination with either an alpha-2 adrenergic agonist (medetomidine or xylazine) or butorphanol may also be used. This combination has been studied in nondomestic bovids (Bush et al. 1992; Caulkett et al. 2000) and zoo animals (Röken 1997) with good results. Gazelle were successfully anesthetized with 10-mg/kg tiletamine-zolazepam and 1-mg/kg xylazine intramuscularly (Şindak & Biricik 2003), although the authors successfully anesthetized gazelle with less than half of this dosage. Disadvantages include longer induction and recovery times and hypoxemia (Bush et al. 1992). Tiletamine-zolazepam and butorphanol combinations have less severe cardiopulmonary alterations in ruminants than tiletamine-zolazepam combinations with an alpha-2 adrenergic agonist (Howard et al. 1990). These combinations are better after an animal has been physically restrained and the combinations are administered intravenously. In the authors' experience, this combination (using 4 mg/kg tiletamine-zolazepam and 0.4 mg/kg medetomidine) is a good alternative to opioids for darting of gazelle, as it has a faster induction time and smaller volumes are required than for ketamine and alpha-2 adrenergic agonist combinations. Severe disorientation and animals falling down abruptly and then trying to get up again during induction is, however, often seen. As only the alpha-2 adrenergic agonist can be reversed (with atipamezole), recovery times can be long.

A combination of fentanyl/azaperone immobilized mountain gazelles in large enclosures (Greth et al.

1993) allowing handling and blood collection. The addition of promethazine appeared to improve quality of relaxation (Greth et al. 1993). No postcapture mortality was seen, and the beneficial effects of azaperone (i.e., less fear of humans and some mild sedation) were seen post handling (Greth et al. 1993).

Thiafentanyl (A3080) is increasingly used in wildlife with very good results, but studies of gazelle are lacking. Impala and other ungulate species were darted in Kruger (Janssen et al. 1991) with thiaphenatanil alone. In Kob antelope, combinations of thiafentanyl, ketamine, and medetomidine (TMK), were compared with thiaphentanyl-azaperone (TA) mixtures (Caulkett et al. 2006). A combination of thiaphentanal with medetomidine and ketamine was also used in Nyala with good results, and recoveries were quick and complete with naltrexone and atipamezole (Cooper et al. 2005). Different antelope species have been anesthetized with combinations of thiaphentanal and butorphanol. The butorphanol partially antagonizes the opioid and thus improves respiration and reduces the chances for apnea. Ketamine was added to deepen the anesthesia if necessary (Van Zijll Langhout & Raath 2010).

MAINTENANCE AND MONITORING

Anesthesia can be maintained with isoflurane or sevoflurane given by mask or preferably after intubation. Since opioids as alpha-2 adrenergic agonists can cause respiratory depression, resulting in hypoxia, and cardiopulmonary changes, oxygen should be supplemented even for short procedures. Under field conditions, the use of small oxygen bottles and intranasal oxygen administration is a simple way to do this.

Basic cardiopulmonary physiology and anesthetic monitoring in gazelles is similar to small domestic ruminants (Riebold 1996). Published reports on anesthetic monitoring and support in small domestic ruminants can be consulted for these species. Small animal anesthetic machines and ventilators are adequate for maintaining anesthesia in gazelle species. Ruminants typically have higher respiratory rates and smaller tidal volumes under general anesthesia (Riebold 1996). Therefore, gazelles may require higher vaporizer settings to maintain adequate anesthesia than other species of similar size (Riebold 1996).

Local or regional anesthetic techniques can be utilized in gazelles, as they may help provide long-lasting analgesia with the need for less frequent handling. Techniques described for domestic goats and sheep could be used. These techniques are generally underutilized in zoo and wildlife species, likely due to the experience and comfort level of zoo and wildlife veterinarians. Epidural analgesia with lidocaine, after sedation with acepromazine, has been described in Addax for ultrasound-guided oocyst collection (Junge 1998). Local anesthesia, in addition to medetomidine/

ketamine/butorphanol induction, has been used for castration in Thomson's gazelle (Chittick et al. 2001).

When using the handling techniques described earlier, drugs can be administered postoperatively on a daily base with little stress involved. The use of long-acting sedatives, as discussed later, can aid to accomplish this. Long-acting analgesic techniques or those administered orally can reduce the need for handling. Oral aspirin at 100mg/kg per day, or phenylbutazone at 10–20mg/kg per day, could be used for short periods of time. Meloxicam, carprofen, and ketoprofen as licensed for domestic ruminants have been used. Research suggests that the elimination time of these drugs differs between different species (Mahmood et al. 2011; Shukla et al. 2007), so care needs to be taken when these drugs are used repeatedly in exotic species. Meloxicam has also been used orally in goats with good effect (Ingvast-Larsson et al. 2011). Fentanyl patches may be used for prolonged analgesia, but the onset of analgesia may be delayed for 24 hours. In sheep, transdermal fentanyl provided better postoperative analgesia than oral phenylbutazone (Dowd et al. 1997) or intramuscular buprenorphine (Ahern et al. 2010).

After induction, gazelles are handled by the horns with the head up and the nose down to prevent aspiration. Nonintubated gazelles should be placed in sternal position or right lateral recumbency when possible to prevent regurgitation. When laterally recumbent for procedures, the neck should be supported and the head pointed down to allow saliva and regurgitated material away from the pharynx. If the animal is being maintained for surgery, then it should be placed on the surgical table with at least 2 in (5 cm) of padding. Even under anesthesia, blindfolds and ear plugs are recommended to decrease sensory awareness or excitement. Ophthalmic ointment should be applied to eyes to prevent corneal damage. Eyes and mouth should be checked and cleaned if needed as often dirt and sand has entered especially when animals are darted outside.

Monitoring anesthetic depth can be challenging but should incorporate physical exam findings and cardiopulmonary monitoring. Rotation of the globe of the eye as used in domestic cattle is not an accurate measure of anesthetic depth in gazelles (Riebold 1996). Blood pressure can be monitored indirectly with oscillometric measurements from cuffs placed on the limbs. Direct blood pressure can be monitored from auricular or common digital arteries. Mean arterial blood pressure should be maintained between 70 and 110 mm of Hg. This can be done through lightening of anesthesia, administration of intravenous fluids, and the use of drugs with positive inotropic, chronotropic, or vasoconstricting effects. These drugs include dobutamine, dopamine, ephedrine, or phenylephrine.

Normal heart rates in unsedated animals are around 80–120bpm and respiratory rates should be between 20

and 40bpm. When alpha-2 adrenergic agonists are used for induction, heart rates will be significantly slower. As well opioids as alpha-2 adrenergic agonist can cause bradypnea and even apnea. Doxapram can be used to improve respiration, but will also hasten the recovery process in animals given alpha-2 adrenergic agonists (Bush et al. 1992; Riebold 1996). Combining opioids with butorphanol, which works as a partial antagonist, will result in better respiration. In case of severe bradycardia or apnea, antidotes such as atipamezole or naltrexone can fully or partially reverse the agonist when the animal is intubated and can be maintained on inhalant gas anesthesia.

Electrocardiography should be used to monitor the cardiac rate and to check for any cardiac arrhythmias. End-tidal CO₂ levels and blood gas measurements should also be monitored. With today's portable equipment, these monitoring devices have become affordable and easy to use. As pulse oximetry units are very easy to use and portable, they are often used as a sole monitor in many zoo practices. Pulse oximetry does, however, not replace blood gas measurements for assessing the degree of hypoxemia (Schumacher et al. 1997). An animal that is being maintained on nasal oxygen may have a normal pulse oximetry reading (>90%), even if hypoventilating. Pulse oximetry estimates the oxygen saturation of hemoglobin. When administering high partial pressures of oxygen (nasal oxygen), normal saturation may be maintained even in animals that are not adequately ventilating. If pulse oximetry is the only monitor, then the veterinarian may not be aware of potential impending hypoxic events. On the other hand, when using alpha-2 adrenergic antagonist, the peripheral vasoconstriction often creates inaccurate readings and will indicate incorrect low saturation. Therefore, the adequacy of ventilation should also be measured during prolonged immobilizations through the use of capnography and blood gas measurements. The availability these days of hand-held blood gas analyzers has made blood gas monitoring easier even in field situations. These analyzers have the advantage of also measuring the pH, potassium and sodium levels, and other minerals so that fluid therapy can be adapted accordingly.

RECOVERY CONSIDERATIONS

As gazelles are very nervous animals that will try to flee, they preferably should recover in a quiet, dark, and safe place, such as a closed box or a small enclosure. If the animal has been intubated, the oral cavity should be examined for regurgitated material and the mouth swabbed clean. Also, the endotracheal tube can be removed with the cuff partially inflated to help clear the pharyngeal area. During recovery, the gazelle is placed in sternal recumbency, with one handler holding the head up with the nose down to prevent aspiration until

the animal is able to keep the head up without support. The blindfold is removed when the animal is able to hold the head or shake the cover off by itself. When waking up in an enclosure, the gazelle's hind end should be placed near the door so that upon recovery, it can run away from the handler. The handler can also go out the door quickly to help prevent further excitement upon recovery. Animals can also be woken up in special boxes which create a safe dark environment. These boxes should be made of light but durable material strong enough to hold a specific species. The box must be high enough for the animal to comfortably stand up. The width should be either too narrow to turn, or wide enough to turn easily. It should also be wide enough to accommodate the horns. The authors advice box sizes of (length \times width \times height) 130 \times 40 \times 110cm for 30kg, 110 \times 40 \times 90cm for 20kg BW and 95 \times 40 \times 70cm for 10-kg animals. Vertical sliding doors with handles on top and bottom are provided at the front and the back of the box. At the sides, handles are made to easily carry the box. The floor should be nonslippery, and adequate ventilation is provided through holes in the side. The roof should have no holes to avoid horns becoming stuck in it. These boxes can be used for transport, for recovery, and for treatments.

Animals that have been handled without sedation or when fully awake again require the same care when being released. If two handlers are holding the gazelle, they will need to let go of the eye cover and of the animal at the same time and stand back so that the gazelle can run forward. Boxes should be opened from the front and people should stay behind the box. Nothing should be in front of the gazelle to give the animal a quick escape from where the handlers stand.

TRANQUILIZERS

Animals should be kept away from the group for as short a time as possible, as being isolated increases stress significantly. If gazelles need to be separated or confined for prolonged treatments, long-acting tranquilizers can be used. These drugs are also useful for groups when they need to be transported, have to adapt to new environments, or when new animals are introduced into an existing group.

Haloperidol lactate is a butyrophenone tranquilizer that will cause calming and adaptation to a new environment. Haloperidol is typically given at 0.1–0.3 mg/kg intramuscularly, but can also be given orally with the same effect. The onset of action of haloperidol usually occurs within 10 minutes of injection, and effects typically last 18–24 hours. This drug is very effective at calming gazelles and preventing self-trauma. The decanoate ester of haloperidol is an oil-based formulation that is much longer acting. This formulation is not commonly used because of the possibility of the extrapyramidal effect of prolonged anorexia. Other

long-acting tranquilizers are zuclopenthixol acetate or perphenazine enathate. Zuclopenthixol's effects occur within 1 hour, and tranquilization may last 3–4 days (McKenzie 1993). Haloperidol in combination with zuclopenthixol at a dose rate of about 0.3 and 2.5 mg/kg, respectively, used in Rheem gazelle (*Gazella subgutturosa marica*) gave better results than when haloperidol was used alone. Perphenazine effects may not be noted for 12–18 hours initially, and are therefore often combined with an initial dosage of haloperidol. Dosages of 3.5 mg/kg have been administered with good effect to Mohor gazelle (*Gazella dama mhorri*) used for assisted reproduction research purposes (González et al. 2008). The authors use total dosages of 50–100 mg for gazelles of 20–40 kg and effect lasts for about 10 days. Zuclopenthixol and perphenazine are not currently available in the United States, but formulations are being developed for their use in zoos and with wildlife species.

Diazepam can be given intravenously or intramuscular at a dosage of about 0.5 mg–1 mg/kg and results in a mild sedation for several hours. Directly after a capture it is advisable to give the diazepam intravenously for quick induction. The additional use of an eye cover is important to reach an optimal effect. An intramuscular injection is best given 15 minutes before handling in a hospital or confined situation.

Gazelle can be frustrating patients as they tend to waste away when separated from their group. The addition of other gazelles decreases stress and improves well-being, but can be harder to manage when regular handling is required. The design of hospitalization enclosures where animals still easily can be separated and moved into treatment boxes is useful for this purpose.

COMPLICATIONS

Anesthesia of overheated or extremely stressed animals should be avoided. Despite their ability to deal with high temperatures, this will increase likelihood of mortality due to hyperthermia and capture myopathy. Exertional myopathy has been associated with the use of etorphine combinations (Molnar & Mckinney 2002; Snyder et al. 1992; Wallace et al. 1987), as well as prolonged pacing activity following renarcotization events. Exertional myopathy can cause acute renal failure due to myoglobin-related toxic effects on the renal tubules. Exertional myopathy may also result in life threatening acid-base disturbances and potassium derangements.

Aspiration pneumonia from regurgitated ingesta is a potential problem in anesthetized ruminants. The use of endotracheal tubes is recommended during longer procedures and for procedures that require placing the animal in lateral or dorsal position. Without intubation a sedated animal should always be kept in sternal position with the head up and nose down and never be turned on its back.

Hypoxemia will often occur with most of the drugs used for induction and should be treated with intubation and ventilation. If the animal is not intubated, then the administration of nasal oxygen is recommended. Drugs such as doxapram can be used to improve respiration. Also, antagonizing drugs can be used to counteract the respiratory depressive effect of the anesthetics used.

Renarcotization is a phenomenon in which animals immobilized with potent opioids will exhibit resedation hours after being antagonized. With the use of naltrexone, which is a complete antagonist, this problem has not been seen anymore by the authors. When other antagonist, such as diprenorphine are used renarcotisation can occur.

In domestic ruminants, xylazine has an oxytocin-like effect on the uterus in the last quarter of pregnancy (Jansen et al. 1984). The use of detomidine or medetomidine may therefore be preferable in pregnant gazelles.

Alpha-2 adrenergic agonists, as well as opioids, can impair gastrointestinal motility. This could lead to tympany and postanesthetic ileus. Alpha-2 adrenergic agonists should be reversed in gazelles with tolazoline or atipamezole. Yohimbine may reverse alpha agonist effects, but it is less effective in ruminants than tolazoline (Hikasa et al. 1988; Hsu et al. 1987). Tolazoline may also bind alpha-1 receptors, which could improve rumenoreticular function post immobilization, and has been shown to more completely restore rumenoreticu-

lar function after the use of alpha-2 agonists when compared with yohimbine (Hikasa et al. 1988). Atipamezole is more effective at reversing CNS receptors in sheep, but can cause minor side effects (Carroll et al. 2005; Hartsfield et al. 1998). Sudden deaths have occurred in ruminants following reversal of alpha-2 adrenergic agonists (Hsu et al. 1987). The sudden vasodilatory effects of alpha antagonist drugs may be the reason for deaths. In the authors' experience, these vasodilatory effects are unlikely to occur when antagonists are administered intramuscularly rather than intravenously. It is advised to give a 5:1 ratio of atipamezole to medetomidine intramuscularly to accomplish full reversal and avoid resedation especially for free-ranging animals (Bush et al. 2004).

In particular, when alpha-2 adrenergic agonists are used intramuscularly, increasingly high dosages have to be given to stressed animals to be effective, with increased cardiopulmonary side effects.

Trauma is a common complication when handling and capturing gazelle. Animals can sustain serious stab wounds or fractures in capture systems where animals are herded together, resulting in death or the need for euthanasia. Quick and smooth separation is crucial to avoid aggression, especially between males. Proper planning of any intended procedure, communication between the people involved, and knowledge of and experience with the behavior of the species are critical in avoiding trauma.

APPENDIX 61A.1

Wild Sheep and Goats

Nigel Caulkett and Chris Walzer

INTRODUCTION

Capture of wild sheep and goats can be challenging. These animals frequently live in mountainous terrain, and are predisposed to stress-related complications, such as hyperthermia and capture myopathy. Wild sheep are frequently captured by physical methods, and manually restrained for short procedures. Remote drug delivery and chemical restraint can be an option if it is carefully planned. Chemical restraint may be more suited for capture of small numbers of animals. Captive sheep and goats may require anesthesia for a variety of reasons. This chapter will discuss physical capture methods and current anesthetic techniques for wild sheep and goats.

SPECIES-SPECIFIC PHYSIOLOGY

Domestic ovids are very prone to severe hypoxemia during immobilization with alpha-2 agonists. Severe hypoxemia has been observed in bighorned sheep (*Ovis canadensis*) immobilized with medetomidine-based combinations (Fahlman et al. 2012). Hypoxemia in wild sheep can be severe enough that it is difficult to treat with supplemental inspired oxygen (Fahlman et al. 2012). Wild sheep and goats are prone to ruminal tympany and regurgitation during chemical restraint.

PHYSICAL CAPTURE

In the 1980s, there were several excellent studies that critically evaluated capture methods in bighorn sheep (*Ovis canadensis*) (Kock et al. 1987a, 1987b, 1987c). This body of work evaluated a variety of outcomes to determine the safest capture method for this species.

The studies evaluated three methods of physical capture: drop net, drive net, and net gunning. They

also evaluated chemical capture with narcotic-xylazine combinations. The studies compared capture outcome, biological, biochemical, and hematological parameters against long-term survival (Kock et al. 1987a, 1987b, 1987c).

Capture outcome was evaluated by categorizing the animals as normal, stress-induced compromise, and mortality from capture myopathy or trauma. Compromised animals were defined as having one or more of the following signs: body temperature $> 42.4^{\circ}\text{C}$, prolonged pursuit, excessive struggling, shock, or any other signs of physical compromise.

It was determined that net gunning resulted in the lowest combined mortality rate at $<2\%$, drop netting had a 3% mortality, and drive netting resulted in a 4% mortality rate. Chemical immobilization was associated with the highest mortality at 8%. Chemical immobilization was also associated with the greatest number of compromised animals at 19%, drop netting resulted in 15% compromised animals, and drive netting resulted in 16%. Net-gunned animals demonstrated the lowest incidence of compromise at 11% (Kock et al. 1987a). These studies clearly demonstrated that physical restraint was the preferable method for short procedures.

In the Alpine and Balkan regions of Europe, chamois (*Rupicapra* spp.) are routinely captured using modified elastic leg snares, drop net systems, and box traps (Ballistros & Benito 1992; Struch & Baumann 2000). Snares pose a serious risk of digital frostbite in the winter months and thus this method should not be used in low temperatures (Delmas 1993). Box traps, which are also routinely used for Alpine ibex (*Capra ibex*) need to be well established with salt licks prior to actual capture attempts (Abderhalden et al. 1998). Drive nets have been used extensively in the Pyrenees to capture Southern

chamois (*Rupicapra pyrenaica*) and Spanish ibex (*Capra pyrenaica*). Significant mortality (3–10% and 18% in nonmonitored nets) has been associated with this method in chamois (López-Olvera et al. 2009). The use of acepromazine in conjunction with physically trapped chamois has been reported to decrease the stress response (López-Olvera et al. 2007). In contrast, drive nets appear to be suitable for the capture of the more docile ibex (López-Olvera et al. 2009). The use of azaperone and haloperidol has been reported in the drive-net captured Iberian ibexes. While haloperidol at 0.17 mg/kg (IM) did not prove beneficial, azaperone at 0.45–0.59 mg/kg (IM) was suitable to decrease the stress response to the capture event (Mentaberre et al. 2010).

Beyond the risk to the captured animals, these physical restraint methods also pose a significant risk for serious injury to the operators, this is especially true in the chamois, which has sharply pointed, backward curved horns (López-Olvera et al. 2009).

In central Asia, the capture of mountain goats and sheep is particularly difficult owing to the unavailability of helicopters due to the remoteness and general national security concerns about aircraft. However, argali sheep (*Ovis ammon*) have been successfully captured using drive nets (Kenny et al. 2008).

Generally, all these methods require a significant amount of manpower and constant monitoring in order to reduce the time of physical restraint.

For a complete description of these physical capture techniques please refer to Chapter 9.

CHEMICAL RESTRAINT AND ANESTHESIA

Vascular Access

Venous access is not difficult in sheep and goats. The cephalic vein, lateral saphenous vein, and jugular vein can all be easily accessed. The auricular artery can be cannulated in some species for direct blood pressure monitoring or to facilitate sampling for arterial blood gas analysis. Arterial blood samples may also be obtained from the femoral artery when auricular arterial catheterization proves to be difficult.

Intubation

Intubation is recommended during volatile anesthesia and in steep terrain when optimal positioning of the animal is compromised in order to minimize the of ruminal content aspiration. Intubation is not difficult in most sheep and goat species. The animal should be maintained in sternal recumbency with the head and neck extended toward the sky. The mouth is opened wide and gentle traction is placed on the tongue. A long flat-bladed laryngoscope is placed into the oral cavity. The tip of the laryngoscope is placed at the base of the epiglottis. The epiglottis is moved ventrally to reveal the glottis. A stylet should be placed inside the endotracheal tube to reduce the curvature of the tube.

Figure 62.1. Mountain goat in typical terrain. Capture personnel must be trained and prepared to work in steep, dangerous terrain.

The tube is placed into the glottis and advanced into the trachea. Typically, the tube should not be fully deflated on extubation; this will help to prevent any rumen contents entering the trachea if regurgitation has occurred.

Preanesthetic Concerns

Like all other ungulates, sheep and goats are prone to ruminal tympany and regurgitation during anesthesia. It is prudent to fast captive animals for 24 hours prior to anesthesia. Maintenance in sternal recumbency may help to prevent the onset of ruminal tympany.

Wild sheep and goats often inhabit mountainous terrain. Capture work in this type of terrain must be carefully planned to avoid trauma to the animal during induction of anesthesia (Fig. 62.1). Bighorn sheep are very prone to capture myopathy (Kock et al. 1987c). Capture events must be carefully planned to avoid prolonged chase times in an effort to prevent capture myopathy.

Monitoring and Supportive Care

Sheep and goats are prone to hypoxemia during anesthesia, particularly if alpha-2 agonists have been used as part of the anesthetic protocol (Caulkett et al. 1994; Jalanka 1989; Shury & Caulkett 2006). Hypoxemia may be less severe if the animal is maintained in sternal recumbency (Caulkett et al. 1996). Oxygenation should always be monitored in anesthetized sheep. Pulse oximetry or arterial blood gas analysis should be used to monitor oxygenation. Oxygen should be available during anesthetic procedures to offset hypoxemia.

Hyperthermia is another potential complication that may be encountered during capture and anesthesia. Hyperthermia has been linked with stress-related complications and capture myopathy (Kock et al. 1987c). It is best to minimize the risk of hyperthermia

by limiting pursuit times and planning capture events for cooler seasons when possible. Body temperature should be closely monitored during anesthesia. Body temperature in excess of 41°C should be treated by actively cooling the animal with a coldwater enema or snow. Antagonism of alpha-2 agonists should also be considered in emergent situations.

It is difficult to prevent ruminal tympany or regurgitation in free-ranging animals. Maintenance in sternal recumbency may help to prevent or treat ruminal tympany. A rumen tube or trocar should be carried to treat serious cases of ruminal tympany. Often, it is most advisable to complete the procedure and antagonize alpha-2 agonists; ruminal tympany typically resolves following administration of an alpha-2 agonist.

Blood pressure monitoring should be considered if the animal is to be maintained with volatile anesthesia. Indirect blood pressure monitors can be used to monitor trends in blood pressure. We typically place the blood pressure cuff midway between the carpus and pastern joint (Fig. 62.2).

Free-ranging animals should be blindfolded to decrease stimulation during light anesthesia or physical restraint. It is important to take care around the legs and horns of lightly anesthetized animals as they may kick and stab. The animal should be placed on a soft surface to avoid pressure points, and they should be supported in sternal recumbency for recovery, following anesthesia.

Drug Delivery

Helicopter darting and free-range stalking of animals are the major methods used to facilitate drug delivery in wild sheep and goats. Helicopter darting, which is generally not available in Europe outside Scandinavia, has been associated with increased mortality in bighorn sheep and mountain goats (Jessup 1999; Kock et al.

1987a). Free-range stalking and ground-based drug delivery can also be used to facilitate drug delivery (Caulkett et al. 2012; Festa-Bianchet & Jorgenson 1985; Merwin et al. 2000; Shury & Caulkett 2006). Stalking is strenuous and time-consuming, but is used routinely in the Alps to capture chamois and ibex. On average, it requires 25 hours of stalking per captured chamois in an alpine protected area (Walzer et al. 1998). The recovery of darted animals can be problematic in the high-strung chamois, and the use of radio-telemetry darts may be indicated. Ground-based stalking tends to be associated with less stress related complications compared with helicopter darting (Fig. 62.3).

Pharmacological Considerations for Anesthesia of Wild Sheep and Goats

Drug Combinations for Induction of Immobilization Many different drug combinations have been used to facilitate capture of wild sheep and goats. All of these combinations have advantages and disadvantages. In this chapter, individual combinations will be discussed by species. The chapter will focus on currently used combinations. There are some general principles that are worthy of discussion. Alpha-2 agonist-dissociative anesthetic combinations may be associated with less excitement during the induction period, compared with narcotic-based protocols. This may decrease the risk of losing track of a darted animal due to excitement during the induction period. The administration of alpha-2 agonists tends to be associated with hypoxemia. Supplemental oxygen should be carried to offset hypoxemia encountered during immobilization. As a general rule, yohimbine may not be an effective antagonist for alpha-2 agonists in bighorn sheep (Jessup 1999). We have had good results with atipamezole, in a variety of sheep species immobilized with xylazine and medetomidine-based protocols. An appropriate

Figure 62.2. Volatile anesthesia of a Stone's sheep. Note placement of the indirect blood pressure cuff on the left forelimb.

Figure 62.3. Ground-stalking bighorn sheep in British Columbia, Canada.

choice of immobilizing drugs should be based on current literature, experience with the drugs, and drug availability.

Volatile Anesthesia

Volatile anesthesia may be used to facilitate maintenance of anesthesia for surgery, imaging or prolonged procedures. We typically use isoflurane or sevoflurane for maintenance of anesthesia. The sheep or goat is induced to anesthesia with xylazine-telazol or medetomidine-ketamine. Once the animal is recumbent, its depth of anesthesia is assessed. If airway protective reflexes are intact, either diazepam-ketamine or propofol is administered IV to obtund airway protective reflexes and facilitate intubation. We typically use a dose of 0.1 mg/kg of diazepam, combined with 2 mg/kg of ketamine, administered to effect. Propofol is administered at 1–2 mg/kg. Commonly encountered side effects of volatile anesthesia are respiratory depression and hypotension. Respiratory depression is typically treated with intermittent positive pressure ventilation, and hypotension often responds to a lightening of the anesthetic plane or fluid therapy. Body temperature should be closely monitored as hypothermia may be encountered, particularly in smaller animals.

Once the procedure is complete, it is advisable to antagonize residual alpha-2 agonist drugs; otherwise prolonged recoveries may be encountered.

Species Specific Considerations

Bighorn Sheep (*Ovis canadensis canadensis*) and Dall or Stone's Sheep (*Ovis dalli*) Narcotic-based anesthesia with carfentanil-xylazine or etorphine-xylazine has been used for helicopter-based capture of bighorn sheep. Etorphine has been used at a dose of 3.5 mg, combined with 50 mg of xylazine. Carfentanil has been used at 0.044 mg/kg in combination with 0.2 mg/kg of xylazine (Jessup 1999). Both of these combinations can be used to successfully capture sheep. Complications tend to occur with partial dosing or trauma during induction. This may reflect the method of capture (helicopter darting) more than an actual drug effect.

Xylazine-ketamine combinations have been used for capture of bighorns (Festa-Bianchet & Jorgenson 1985). Xylazine-ketamine solutions must be delivered in relatively high volumes; therefore, this mixture has been largely replaced by xylazine-Telazol®. Xylazine-Telazol has been used to effectively capture human habituated bighorn sheep. It has been advocated at a dose of 4.2 mg/kg of Telazol combined with 0.5 mg/kg of xylazine (Merwin et al. 2000). A major drawback of this mixture is that recoveries tend to be prolonged following antagonism of the xylazine; this is probably the result of residual Telazol. In order to address this concern, we have recently started using a mixture of xylazine, Telazol and hydromorphone (Shury &

Caulkett 2006). This mixture is administered at a dose of 1.64 mg/kg of Telazol, combined with 1.1 mg/kg of xylazine and 0.22 mg/kg of hydromorphone. The mixture proved to be suitable for capture of human habituated sheep. Recovery was relatively rapid (10.3 minutes) following the administration of 0.11 mg/kg of atipamezole and 0.18 mg/kg of naltrexone.

We have also used 0.06–0.08 mg/kg of medetomidine, combined with 2 mg/kg of ketamine, to induce anesthesia in captive bighorn sheep. This combination is readily reversed with atipamezole at three times the medetomidine dose. Free-ranging bighorns require a significantly greater dose. We have been using 0.16 ± 0.04 mg/kg of medetomidine, combined with 4.2 ± 1.6 mg/kg of ketamine, to induce anesthesia of wild bighorns that have been stalked on foot (Caulkett et al. 2012).

In our experience, Dall and Stone's sheep are very similar to bighorn sheep. We have used 1 mg/kg of xylazine combined with 2 mg/kg of Telazol for induction, prior to administration of volatile anesthetics in captive Stone's sheep. We have also used 0.06–0.08 mg/kg of medetomidine, combined with 2 mg/kg of ketamine in captive Dall and Stone's sheep.

Mountain Goat (*Oreamnos americanus*) Free-ranging mountain goats have typically been anesthetized with potent narcotics. Carfentanil has been advocated, as the sole agent, at a dose of 0.035 mg/kg (Jessup 1999). Etorphine has also been used at a dose of 4–5 mg per animal (Jessup 1999). We have anesthetized captive mountain goats with 0.06–0.08 mg/kg of medetomidine, combined with 2 mg/kg. This dose will produce light anesthesia for restraint or as a premedication for general anesthesia. The medetomidine is readily antagonized with atipamezole administered at three times the medetomidine dose.

Markhor (*Capra falconeri megaceros*) A detailed study exists that compares the efficacy and safety of medetomidine-ketamine and etorphine-acepromazine in captive Markhors (Jalanka 1989). This study compared a mean dose of 63 µg/kg of medetomidine, combined with 1.6 mg/kg of ketamine against 56 µg/kg of etorphine, combined with 0.25 mg/kg of acepromazine. Both of these combinations were readily reversible. Atipamezole was used at a mean dose of 282 µg/kg, and diprenorphine was administered at a dose of 76 µg/kg.

Both combinations induced moderate hypoxemia. Medetomidine-ketamine induced slightly more respiratory depression evidenced by a significantly greater PaCO₂, compared with etorphine-acepromazine. Medetomidine-ketamine produced better myorelaxation and a more complete immobilization than etorphine-acepromazine (Jalanka 1989). Medetomidine-

ketamine has become a commonly recommended combination for anesthesia of sheep and goats.

Chamois (*Rupicapra rupicapra*) Various methods to chemically immobilize chamois have been described. In the German-speaking areas of Europe, the Hellabrunner mix (125-mg xylazine + 100-mg ketamine per mL) was until recently the method of choice. It is important to note that the required dose (0.27-mg/kg ketamine + 0.34-mg/kg xylazine) for chamois is extremely low when compared with other mountain ungulates (Wiesner & von Hegel 1990). The advantage of this combination is that very low dart volumes (0.04–0.08 mL) are possible. The combination of medetomidine and ketamine has proven to be a superior choice. In captive chamois, 60–100 µg/kg medetomidine with 1.5 mg/kg ketamine are recommended. (Jalanka & Roeken 1990; Walzer et al. 1996). In wild chamois, it is recommended to use 80–100 µg/kg of medetomidine with 1.5–2 mg/kg of ketamine in order to reduce the time to recumbency. Medetomidine is reversed with atipamezole at 0.4 mg/kg. Other combinations that have been used among others are xylazine at 1.4–4.8 mg/kg (Dematteis et al. 2008) and tiletamine-zolazepam (Chaduc et al. 1993).

Alpine Ibex (*Capra ibex*) Similar to other goat and sheep species, a combination of medetomidine and ketamine is recommended for the chemical capture of the ibex. For captive animals, 80–140 µg/kg of medetomidine, combined with 1.5 mg/kg of ketamine, has been recommended (Jalanka & Roeken 1990). Alternatively, 190–270 µg/kg of medetomidine plus 1.4–2 mg/kg of ketamine and 6.8 mg/kg of tiletamine-zolazepam have also been used (Santiago-Moreno et al. 2011). In free-ranging animals, various combinations have been used: 100–120 µg/kg of medetomidine and 3 mg/kg of ketamine for the Iberian ibex; 80–100 µg/kg of medetomidine and 1.5 mg/kg of ketamine and 1.4–2.4 mg/kg of xylazine and 1.5–2.9 mg/kg of ketamine for the alpine ibex have been reported (Casas-Díaz et al. 2011; C. Walzer, unpubl.).

Argali Sheep (*Ovis ammon*) Wild argali with an estimated weight of 90 kg, have been captured using a combination of 4-mg carfentanil, 50-mg xylazine, and 100-mg ketamine. Anesthesia was reversed with a combination of 500-mg naltrexone and 15-mg yohimbine (Kenny et al. 2008).

Barbary Sheep (*Ammotragus lervia*), Himalayan Tahr (*Hemitragus jemlahicus*), and Mouflon (*Ovis musimon*) All of these sheep and goat species can be effectively immobilized with medetomidine-ketamine. The following doses have been used in captive animals (Jalanka & Roeken 1990). Barbary sheep: 100–140 µg/kg of medetomidine, combined with 1.5 mg/kg of ketamine.

Himalayan tahr: 80–100 µg/kg of medetomidine, combined with 1.5 mg/kg of ketamine. Mouflon: 125 µg/kg of medetomidine, combined with 2.5 mg/kg of ketamine.

All of the earlier-mentioned doses were used in captive animals. It may be necessary to increase the dose in free-ranging animals. It is important to allow adequate time for induction with medetomidine-based protocols as animals may rouse and flee if they are approached too early. Typically, the animal can be approached approximately 5 minutes post induction.

Muskox (*Ovibos moschatus*) Muskox anesthesia can be somewhat more challenging than anesthesia of the smaller sheep and goat species. Their head is relatively large and they have a small oral cavity; this can make intubation a challenge. We typically use a mouth gag to open the mouth, and use a long flat laryngoscope blade to visualize the glottis. It is important to induce good muscle relaxation to facilitate intubation. We have used 0.05–0.1 mg/kg of diazepam or 5% guaifenesin, given to effect, to induce muscle relaxation. Manual intubation may be attempted in large muskox. The endotracheal tube is guided into the trachea manually by placing a hand dorsally over the end of the tube and advancing the hand into the pharynx. Once the operator's hand is in the pharynx, the epiglottis is reflected ventrally and the tube is advanced into the trachea (Fig. 62.4).

Free-ranging adult muskox have been immobilized with 2 mg of etorphine, combined with 30 mg of xylazine and 200 IU of hyaluronidase (Clausen et al. 1984). Recently, a dose of 0.05 mg/kg etorphine and 0.15 mg/kg xylazine has been reported on in 133 wild musk ox

Figure 62.4. Intubation of muskox can be difficult it may be attempted by palpation in large animals, a long laryngoscope blade is required in smaller animals (photo courtesy of Jessica Paterson).

immobilization procedures (Blix et al. 2011). We have used 50–60 µg/kg of medetomidine, combined with 1.5 mg/kg of ketamine for short-term anesthesia of muskox. We have also used 0.5–1 mg/kg of xylazine alone, or combined with 1–2 mg/kg of ketamine for deep sedation of captive muskox. These animals were relatively tame and human habituated, and these doses should not be extrapolated to wild muskox.

Nondomestic Cattle

Julie Napier and Douglas L. Armstrong

INTRODUCTION

Wild cattle are a part of the family Bovidae in the order Artiodactyla. Genus *Bubalus* includes Asian water buffalo (*Bubalus bubalis*), tamaraw (*Bubalus mindorensis*), lowland anoa (*Bubalus depressicornis*), and mountain anoa (*Bubalus quarlesi*). Tamaraw are rare in captivity. Genus *Syncerus* is comprised of a single species, the African buffalo (*Syncerus caffer*). Genus *Bos* is the largest group of animals and contains five species: aurochs (*Bos taurus*), banteng (*Bos javanicus*), gaur or seladang (*Bos gaurus*), kouprey (*Bos sauveli*), and yak (*Bos grunniens*). Wild aurochs are the ancestors of domestic cattle and gave rise to numerous breeds, including the Ankoli cattle or watusi and the zebu.

The family Bovidae are true ruminants and are physiologically very similar to domestic cattle. They have a four-compartment stomach with the size of these compartments varying by species. They are browsers and grazers and live in a variety of climates and geographic areas. Wild cattle generally do very well in captivity (Nowak, 1991).

PHYSICAL RESTRAINT

Exotic ruminants vary greatly in behavior, temperament, and size (Table 63.1). These animals can be formidable and aggressive in nature. Most wild cattle have large horns and hooves and a strong fight or flight response when approached. Careful planning is necessary when considering any kind of restraint, handling, or procedure. The primary concern should always be human and animal safety. Animals designated for a procedure should be separated from the group and held in a smaller enclosure or holding area whenever possible. Ideally, this area would be quiet and free of unnecessary stimulation.

Should physical rather than chemical restraint be utilized, there are several methods that can be used with wild cattle. Behavioral conditioning using positive reinforcement, such as food reward, can be used to move animals through walkways in buildings or to crate train. Manual restraint is possible with smaller exotic bovids and calves, but should not be attempted in animals in excess of 70 kg. Exceptional skill and experience, as well as the appropriate protective equipment, would be necessary to handle some of the larger species, especially in a noncontrolled environment. Any animal under manual restraint should be monitored for stress and hyperthermia. Blindfolds will calm some but not all individuals (Citino 2003).

For most adult wild cattle, some type of mechanical or physical restraint device is required for minor procedures, such as trimming horns, tuberculin testing, venipuncture, administering medications, rectal and vaginal examinations, or brief physical exams. Restraint chutes, including box chutes with or without a head gate and drop-floor types, have become more typical in zoo settings (Boever 1986; Fowler 1995).

Many of the current devices were designed for cattle- or the game-farming business and have been successfully modified for use with exotic bovids. Some of the restraint devices available include manual squeeze chutes (Heavy-Duty Squeeze Chute, Powder River Livestock Equipment, Provo, UT) (Read et al. 1989), drop-floor chutes (The Tamer and Tamer, Jr., Fauna Research, Red Hook, NY), and hydraulic squeeze chutes (Hydraulic Tamer, Fauna Research) (Blumer & DeMaar 1993; Citino 2003). When an animal is in a drop-floor chute, the floor can be dropped or lowered, leaving the animal wedged in a v-shaped trough, suspended with the feet off the ground. Many animals will cease struggling once they have lost their footing. Most

Table 63.1. Average body weights of adult exotic cattle^a

Species	Body Weight (kg)
African buffalo	400–900
Ankole (Watusi)	400–725
Anoa (both species)	150–300
Asian water buffalo	700–1000
Banteng	400–900
Gaur (Seladang)	600–1000
Yak	400–1000
Zebu	300–600

^aFor both females (lower end of the range) and males (higher end of the range).

Figure 63.1. Jugular venipuncture in an adult gaur bull (*Bos gaurus*).

devices available have a variety of access panels and a mechanism to release the animal quickly should that become necessary.

VASCULAR ACCESS AND URINE COLLECTION

The most commonly used vascular access site in wild cattle is the jugular vein. Other common sites for blood collection include the cephalic, medial and lateral saphenous, tail (coccygeal), and auricular veins. In larger ungulates, the jugular can be hard to palpate. Holding off the vein with the knee and using the fingertips to bounce along the neck to locate the vein when the animal is in sternal or lateral recumbency can be useful, as is following the line of the caudal ramus of the mandible to locate the jugular (Fig. 63.1).

Catheter placement can be done in the jugular, cephalic, or auricular vein. Alcohol applied topically to the ear in addition to pressure at the base of the ear can help the auricular vein be more easily visualized. Supplemental anesthesia, antagonists to anesthetic

Figure 63.2. Obtaining a sample for blood gas values from the medial digital artery.

drugs, fluids, emergency drugs, or other medications are administered most commonly in the jugular or auricular veins. Blood gas values require a smaller volume of blood and can be obtained from the medial or caudal digital artery just proximal to the fetlock (Fig. 63.2) or the auricular artery.

Urine can be collected via urethral catheterization in females, but is generally not successful in males due to the sigmoid flexure of the penis. Ultrasound-guided cystocentesis is the easiest method for urine collection in most exotic bovids.

CHEMICAL RESTRAINT AND CAPTURE

In many situations, physical restraint is not an option (i.e., field procedures, excessively long procedures, and surgeries). There are a variety of chemical agents available for use in wild cattle. Personal preference and experience, size, temperament and physiology of the species and the environmental setting will help to determine what chemical restraint should be utilized.

PRE-ANESTHETIC CONSIDERATIONS

Ruminants are prone to ruminal tympany and regurgitation, which can lead to aspiration and subsequent pneumonia, especially in recumbent anesthesia. A rumen tube should be part of the standard equipment to help prevent or treat ruminal tympany. Animals should be fasted for a period of 18–36 hours prior to induction. Water access should be discontinued 8–12 hours prior. Maintaining the animal in sternal recumbency can reduce the possibility of rumen regurgitation, especially in field conditions, when the animal cannot be fasted. When sternal recumbency is not possible, as in an electroejaculation or surgical procedure,

when access to the ventrum is necessary, the head should be positioned or propped so the mouth and nose are pointed in a downwards direction. This will allow flow from the oral cavity of any rumen contents, reducing the chances of aspiration. In either lateral or sternal recumbency, the head and neck should be extended to maintain a patent airway. To greatly reduce the occurrence of aspiration of regurgitated rumen contents, an animal can be intubated with an endotracheal tube, as described.

ANESTHETIC MONITORING

The same monitoring standards and equipment that are used in other mammals under anesthesia can be used in wild cattle. Depth of anesthesia can be assessed by several methods. Although most animals will go into sternal recumbency on their own, some animals will head press against a wall or remain standing with the legs positioned in a wide stance. Through manual manipulation, they can be moved into sternal recumbency after placing a towel or cloth over the eyes. (Fig. 63.3).

Other animals, such as the gaur, will maintain a dog-sitting position prior to sternal recumbency (Fig. 63.4 and Fig. 63.5). Once in sternal recumbency, depth of anesthesia can be monitored by response to the ear pinch, response to tactile stimuli in the extremities or most accurately by manipulating the globe of the eye. The eye rotates ventromedially during a light plane of anesthesia. In deep anesthesia, it will rotate back to a central position (Reibold et al. 1982).

Normal heart and respiratory rates can vary greatly among wild cattle, depending on species, size, age, and the level of excitement attained prior to immobilization. Heart rate can be obtained using a stethoscope. Pulses can be palpated at the base of the tail and the facial artery in younger and smaller species, as well as the caudal auricular artery and the common digital arteries. To assess cardiovascular function and

Figure 63.3. Field immobilization of an African buffalo (*Syncerus caffer*), moved into sternal recumbency with a blindfold placed over the eyes.

peripheral perfusion, capillary refill time (CRT) can be utilized. This involves blanching the gums of the oral mucosa for several seconds then releasing and monitoring refill time, which should not exceed 2 seconds. The cardiovascular system should be monitored at regular intervals throughout anesthesia.

A pulse oximetry probe can be placed on the tongue, ear, or vulvar or preputial skin folds. (Fig. 63.6) Many pulse oximetry units will measure pulse rate as well as oxygen saturation of hemoglobin (SaO_2), providing another set of data for anesthetic monitoring. The color of the oral mucus membranes can also be utilized as an indicator of oxygenation. If hypoxemia is present, the intranasal route is an easy way to administer supplemental oxygen. Respiratory rate is generally monitored visually by watching the movement of the thorax and abdomen.

Figure 63.4. Gaur bull (*Bos gaurus*) in typical dog-sitting position prior to going into sternal recumbency.

Figure 63.5. Gaur bull (*Bos gaurus*) in sternal recumbency.

Figure 63.6. Pulse oximeter probe placed on the tongue to assess oxygen saturation of hemoglobin (SaO_2) as well as pulse rate.

Figure 63.7. Obtaining indirect systemic blood pressure values by placing an oscillometric cuff just proximal to the fetlock.

Hyperthermia is common in immobilized wild cattle especially if the animal goes into a hyperexcited state due to under dosing. Excessive running, high-stepping, or pacing occurring prior to induction can lead to very elevated body temperatures (Citino 2003). Normal wild cattle body temperatures range from 37 to 39°C (99 to 102°F). If temperatures exceed this range, topical application of cold water or cold-water enemas are quite useful in bringing down the body temperature, although enemas will initially preclude accurate follow-up rectal thermometer temperature readings.

Indirect systemic blood pressure values can be acquired by placing an oscillometric cuff just proximal to the fetlock on most species or at the base of the tail in some smaller species (Fig. 63.7). The bladder

of the cuff should be positioned on the medial aspect of the leg and on the ventral aspect of the tail for accurate measurements. Direct measurement requires catheterization, usually of the caudal auricular artery.

ENDOTRACHEAL INTUBATION

For prolonged procedures or in animals that are prone to aspiration of regurgitated rumen contents, inhalation anesthesia via an endotracheal tube (ET) may be required. Tubes used in exotic cattle should have an inflatable cuff. Wild cattle can be intubated in lateral or sternal recumbency. Younger animals and smaller species should be intubated in sternal recumbency for easier elevation of the head. Endotracheal intubation can be accomplished by direct visualization via a laryngoscope or digital palpation. The tongue should be extended rostrally and to the side for easy insertion of the laryngoscope or the ET tube. Using either approach, the ET tube is guided through the oral cavity to the epiglottis, which is deviated ventrally to feed the tube into the trachea.

SEDATION AND TRANQUILIZATION

There are short- and long-acting sedatives available for exotic bovids. Commonly used short-term sedatives include the α_2 -adrenergic agents: xylazine, detomidine and medetomidine (Short 1992). The α_2 -agents can produce a calming state that can be overridden in a highly excited animal. In cattle, standing sedation has been attained with intravenous (IV) xylazine (0.02 mg/kg) or detomidine (0.01 mg/kg). The duration of effect can be extended with the addition of butorphanol to the protocol at a dose of 0.05 mg/kg (Lin & Riddell 2003). Another combination that has been used in cattle is xylazine administered IV or intramuscularly (IM) at 0.05–0.2 mg/kg with detomidine at 0.0025–0.01 mg/kg IV (Caulkett 2003). In domestic cattle, IM detomidine can induce standing sedation at dosages of 0.04 mg/kg. Detomidine has been used to sedate domestic calves at doses of 0.01 mg/kg for lighter sedation and 0.02–0.04 mg/kg for deeper sedation. (Peshin et al. 1991). Calves have also been successfully sedated using xylazine at dosages of 0.025–0.05 IV or 0.1–0.2 IM (Caulkett 2003). Sedation has been achieved in free-ranging Norwegian cattle using xylazine (0.37–0.73 mg/kg) or medetomidine (0.029–0.049 mg/kg) (Arnemo & Soli 1993). In yaks, medetomidine at 0.07 mg/kg produces deep sedation, whereas detomidine at 0.025 mg/kg produces light sedation (Sharma et al. 1998, 2001).

An intermediate-acting phenothiazine, acepromazine, has been used on its own and in combination with other drugs for anesthesia in domestic cattle. When used alone, IM doses of 0.05–0.10 mg/kg can produce a sedation effect in 10–20 minutes. The effect

can last between 4 and 8 hours, with potential residual effect up to 12 hours in duration (Blumer 1991; Swan 1993).

Haloperidol has been used in a variety of ungulates. It has an onset of around 10 minutes and duration of effect can last from 6 to 18 hours (Blumer 1991). Twenty to 40 mg of haloperidol in combination with 50- to 350-mg perphenazine enanthate can induce longer periods of tranquilization (Ebedes & Raath 1999). Perphenazine administered IM has been used in gaur to reduce stress-induced self-trauma and in African buffalo in quarantine. The sedation effect has an onset of 12–16 hours and can last as long as 7 days (Blumer 1991; Citino 2003; Ebedes & Raath 1995, 1999; Swan 1993). Extrapyramidal effects and anorexia have been noted in some animals after administration of haloperidol. It should be used with caution in very young or geriatric animals because the effect can be unpredictable (Ebedes & Raath 1999).

Azaperone at a dosage of 0.1 mg/kg had been used to successfully sedate African buffalo (Ebedes & Raath 1999). It can be combined with zuclopenthixol acetate at 1 mg/kg for a tranquilization effect. When administered IM, the onset of effect is 60 minutes with a duration lasting up to 3 days (Citino 2003; Ebedes & Raath 1995; Swan 1993). Zuclopenthixol and perphenazine may be used concurrently to get the initial effects of the zuclopenthixol and the longer-lasting effects of the perphenazine. Pipotiazine palmate has an onset of 48–72 hours with a duration of up to 30 days when given IM and can be used concurrently with zuclopenthixol as well (Blumer 1991; Citino 2003; Ebedes & Raath 1995; Swan 1993). Extrapyramidal effects such as torticollis, tremors, muscle rigidity, head swaying, and akinesia can be seen with overdoses of perphenazine, azaperone, and zuclopenthixol. Administration of diazepam (10–20 mg) or xylazine (5–10 mg) have been used to control these symptoms (Quandt & Ebedes 1998). Newer antipsychotic drugs (APD) are also becoming more available to treat the extrapyramidal symptoms of neuroleptics. These include risperidone, olanzapine, ziprasidone, and olanzapine. These drugs are available in injectable form and can be administered at human doses as a starting point. There is no published information on the use of these agents in bovids, but they have been used successfully in cervids and rhino (Zuba & Oosterhuis 2007).

Benzodiazepine use for sedation has been reported in domestic and exotic bovids. Midazolam is more commonly used in combination with other drugs for general anesthesia. Diazepam has been used in domestic calves at 0.2 mg/kg in combination with other drugs for sedation and induction of anesthesia (Caulkett 2003). Diazepam should not be used alone in yak as it has been known to produce very rough inductions, paddling of the limbs, and the inability to rise after falling (Kumar et al. 1999).

GENERAL ANESTHESIA

There are a variety of techniques and chemical agents that have been used for general anesthesia in wild cattle. (Table 63.2) The drug classes most commonly used include opioids, α_2 -adrenoreceptor agents, and dissociatives. Most general anesthesia is administered IM. In close quarters, a pole syringe can be utilized. Injection via a remote darting system is the most common route of administration. Young animals, under the appropriate restraint, may be induced with inhalant anesthesia using a face mask. Commonly used inhalant anesthetics include isoflurane and sevoflurane. An African buffalo calf was induced with midazolam and ketamine prior to intubation for maintenance on an inhalant anesthetic (Stegmann 2004). Short-term anesthesia can be produced in adult cattle with xylazine as a preanesthetic, ketamine for induction, and a mixture of guaifenesin and ketamine for maintenance (Caulkett 2003).

Where available, opioids are the most common group of drugs used to produce general anesthesia in wild cattle. They provide a smooth induction and a short recovery period. Carfentanil and etorphine are the most widely used; however, use of thiafentanil (A3080) is becoming increasingly common. It has been studied in various hoofstock (Citino et al. 2002; Janssen et al. 1991; Napier et al. 2011). Doses for etorphine range from 0.005 to 0.050 mg/kg. Doses for carfentanil range from 0.005 to 0.015 mg/kg. Thiafentanil doses range from 0.007 to 0.018 mg/kg. Inductions generally take longer with etorphine and are shortest with thiafentanil. In some species, such as gaur, induction times are quite similar with carfentanil and thiafentanil (1–4 vs. 1–6 minutes, respectively) (Napier et al. 2011). Hyaluronidase increases the rate of absorption of the opioid and may decrease induction times. Opioids are frequently used in conjunction with α_2 -agents, including xylazine, medetomidine, and detomidine. They are also used in combination with acetylpromazine, a phenothiazine. These combinations reduce the amount of opioid needed to produce the desired anesthetic effect and can increase muscle relaxation. They can be given with the opioid in a single injection or 15–20 minutes prior to the opioid. African buffalo have routinely been immobilized with etorphine (0.01 mg/kg) and azaperone (0.015–0.2 mg/kg) (Puffer et al. 2001). A combination of thiafentanil, medetomidine, and ketamine has been used successfully in bovids. This combination provided rapid onset and good muscle relaxation in field conditions (Citino et al. 2002). Gaur may be effectively immobilized with xylazine (0.08–0.10 mg/kg) and carfentanil (0.005–0.10 mg/kg) (Armstrong 1989; Napier et al. 2011; Wilson et al. 1993). The combination of thiafentanil (0.012 mg/kg) and medetomidine (0.02 mg/kg) was also used successfully in multiple electroejaculation procedures of gaur (Napier et al. 2011).

Table 63.2. Recommended anesthetic agents and protocols for wild cattle

Species	Anesthetic Agent(s) (mg/kg)	Antagonist(s) (mg/kg)	Desired Effect

Notes: The dosages and protocols presented in this table are a compilation of information from the listed references, personal experience, and personal communication with staff from the following institutions: Denver Zoo, Denver, CO, USA; Disney's Animal Kingdom, Lake Buena Vista, FL, USA; Exotic Animal Service, Edinburgh University, Edinburgh, UK; Marwell Preservation Trust, Winchester, UK; Royal Zoological Society of Antwerp, Antwerp, Belgium; Omaha's Henry Doorly Zoo, Omaha, NE, USA; Soffolk Wildlife Park, Edinburgh, UK; St. Louis Zoo, St. Louis, MO, USA; Whipsnade Wild Animal Park, Bedfordshire, UK; Zoological Society of London, London, UK.

^aNaltrexone in Gaur can be administered 30–50% IV and 50–70% IM or 25% IV and 75% SQ which may reduce renarcitization.

If the initial immobilizing opioid dose is insufficient for adequate anesthesia, another IM dose of half of the initial dose can be given.

Because of their extreme potency in relation to morphine, exetorphine, carfentanil, and thiafentanil are classified as ultra-potent opioids. Thiafentanil is still investigational in the United States, but will most likely be a schedule II drug like etorphine and carfentanil. It is imperative to take appropriate precautions when using these opioids. An emergency procedure should be in place in the event human exposure occurs with any of these substances. At the very least, personal protective equipment should include eye protection and impermeable gloves. It is advisable to have antagonists ready for injection prior to the preparation and use of these ultra-potent opioids. Accurate record keeping for all controlled substances is required by government and regulatory agencies.

When opioids are not available, dissociatives in combination with α_2 -agents or benzodiazepines are commonly used (Barnett & Lewis 1990). Ketamine and the combination of tiletamine and zolazepam (Telazol and Zolatil) have been used. Adding an α_2 -agent reduces the dose of the dissociative as it does with opioids. Medetomidine generally provides smoother inductions and recoveries compared with xylazine. Detomidine combined with tiletamine and zolazepam has been used successfully to immobilize wild banteng (Bradshaw et al. 2005). The quality of Telazol inductions and immobilizations is poor in gaur (Wilson et al. 1993). A detomidine (0.01 mg/kg), diazepam (0.01 mg/kg), and ketamine (3.0 mg/kg) combination has been used in Asian buffalo calves (Pawde et al. 2000). As with opioids, if the initial immobilization doses do not achieve the necessary level of anesthetic depth, lesser doses of these drugs can be given intravenously or intramuscularly.

In the majority of situations, intramuscular administration is the only route available for administering anesthetic agents; consequently, barbituates are not commonly used in wild cattle. This is also the case with glycerol guaiacolate, which is often combined with dissociatives and barbituates in IV administrations in domestic cattle. If venous access is available, these drugs can be given using domestic cattle doses. Propofol may also be used for IV induction at doses of 2.0–4.0 mg/kg (Jalanka et al. 1992).

If procedures are going to last in excess of an hour, inhalant anesthetic can be utilized. Sevoflurane and isoflurane can be administered following protocols used in domestic cattle.

ANALGESIA

In any situation where an animal may be expected to experience pain, analgesia administration should be considered. These agents include opioids, α_2 -adrenergic agents, and nonsteroidal anti-inflammatories (NSAIDs).

Opioids and α_2 -agents, which have already been discussed as common agents used for sedation and general anesthesia, provide analgesia during those periods. Detomidine has demonstrated analgesia comparable with epidural administration in domestic cattle when given IM at 0.04 mg/kg (Prado et al. 1999). Unless animals are going to be held in some kind of enclosure, opioids and α_2 -agents are not generally used outside of anesthesia due to their potent sedative effects.

NSAIDs produce analgesia without the complication of sedation. There are no recent publications on the effectiveness of these drugs in wild cattle, but there are numerous publications on the effect of NSAIDs in domestic bovids. Ketoprofen given at 3.0 mg/kg IV produces analgesia in calves undergoing horn debudding and domestic bulls undergoing castration (Faulkner & Weary 2000; Ting et al. 2003). Ketoprofen is used less frequently in domestic cattle as it does not offer an advantage over drugs that are labeled for use in bovids or are less expensive (Smith et al. 2008). Phenylbutazone has been used in domestic cattle at doses of 10–20 mg/kg orally, then 2.5–5 mg/kg every 24 hours or 10 mg/kg every 48 hours (Jenkins 1987), and oral doses of 9 mg/kg with maintenance doses of 4.5 mg/kg administered every 48 hours (Eberhardson et al. 1979). Flunixin meglumine has been given IV, IM, and orally to dairy cows and beef cattle at doses of 1.1–2.2 mg/kg (Anderson et al. 1986; Smith et al. 2008).

Numerous studies have been conducted using meloxicam alone or in combination with other drugs in domestic cattle. Gabapentin capsules or powder, given orally at 10 mg/kg with meloxicam at 0.5 mg/kg, has been used for management of neuropathic pain in cattle (Coetzee et al. 2010). Meloxicam alone, at a dose of 0.5 mg/kg, has demonstrated nonimmunosuppressive and anti-inflammatory benefits in cattle with respiratory disease and in calves that have been dehorned (Heinrich et al. 2010; Smith et al. 2008).

RECOVERY

One of the advantages of using opioids for immobilizations is the ability to reverse the drugs and provide a safe, smooth, and rapid recovery. Naltrexone is the preferred antagonist for both carfentanil and thiafentanil. For carfentanil, the dosage of naltrexone is 100 mg per 1-mg carfentanil given. For thiafentanil, a dose as low as 10 mg per 1 mg thiafentanil can be given. The dose for naltrexone is usually split between IV, IM, and subcutaneous (SC) administration. The recommended label dose is one-fourth IV and three-fourths SC. A study was done that did not find any advantage to splitting the dose when reversing carfentanil (Mutlow et al. 2004).

Reversals for α_2 -agonists include yohimbine for the reversal of xylazine and detomidine and atipamezole for medetomidine. Atipamezole can be used

to reverse xylazine and detomidine if yohimbine is not available.

If supplemental drugs have been given during the procedure, such as ketamine, antagonists should not be given for at least 20 minutes after the ketamine has been administered to allow for a smooth recovery.

If an animal has been intubated, the endotracheal tube should not be removed until there is evidence of pharyngeal activity. It is not necessary to completely deflate the cuff of the tube in order to remove it. Keeping the cuff partially inflated will help clear the mouth of any oral secretions or regurgitated material that may have accumulated during the procedure.

In a herd situation, animals should be returned to the group as soon as possible if conspecifics do not pose an immediate threat to the recovering individual.

COMPLICATIONS

Hypoxemia occurs frequently with the use of potent opioids and should be treated with ventilation and intubation, if necessary. If the animal is not intubated, nasal oxygen can be given. Hyperthermia can occur in immobilized animals and can be treated as previously discussed.

Excess gas in the rumen can lead to tympany. A stomach tube should be passed in an attempt to reduce the gas. This problem can be seen in animals that have not been fasted but is infrequent in animals that were fasted previous to the procedure.

Capture or exertional myopathy has been reported in numerous bovid species. Since this condition is difficult to treat, especially in a free-ranging setting, it is important to keep preimmobilization stress and activity to a minimum. This can be accomplished by selecting drugs and doses that will facilitate a rapid induction, limiting chases under free-ranging conditions and removing anything that might contribute to stress, such as excess personnel and loud noises. (Schumacher 2008). Pressure myopathy should be considered with heavy-bodied cattle under anesthesia for extended periods of time.

Renarcotization has also been reported in numerous cases in animals immobilized with potent opioids, particularly with carfentanil citrate (Allen 1989; Schumacher 2008). Studies have shown some species are more prone to this phenomenon than others and animals given a lower dose of reversal will have a greater tendency to experience renarcotization (Allen 1989; Haigh & Gates 1995; Mutlow et al. 2004; Wilson et al. 1993). Wild cattle that have been immobilized with potent opioids should be monitored for 72 hours post procedure. Clinical signs usually occur around 12–24 hours after the administration of the reversal and include circling, high stepping, agitation or mild excitement, recumbency paddling, and dulled menta-

tion. IM administration of 50% of the initial antagonist dose should be given if any of these signs are noted. Repeated doses may be needed if the clinical signs of renarcotization do not subside.

Bison

Nigel Caulkett

INTRODUCTION

Bison can be extremely difficult to anesthetize. Major complications of anesthesia can include: hypoxemia, bloat, and regurgitation. Bison are also predisposed to the development of capture myopathy, which can occur during or after anesthesia.

Two subspecies of bison can be found in North America. The plains bison (*Bison bison bison*) is most commonly encountered in free-ranging and captive herds. The wood bison (*Bison bison athabasca*) is confined to a few free-ranging herds in northern Canada, and some captive animals. Response to anesthesia is similar in both subspecies and this discussion applies equally to both. There are wild populations of the European bison (*Bison bonasus*) in Poland, Russia, Belarus, Ukraine, and the western Caucasus. The focus of this paper is on North American bison, but it should also be applicable to European bison.

SPECIES-SPECIFIC PHYSIOLOGY

Bison are similar to domestic cattle in many respects; anesthesia of an animal with a full rumen pack typically results in bloat or regurgitation. Xylazine or general anesthesia with volatile agents will lead to decreased rumen motility, bloat, and regurgitation. These can be fatal complications and tend to be more severe in large, mature animals (Caulkett et al. 2000).

Bison are prone to hypoxemia during general anesthesia. Positioning in dorsal or lateral recumbency will exacerbate hypoxemia (Caulkett et al. 2000). Alpha-2 agonist drugs such as xylazine or medetomidine will also exacerbate hypoxemia (Caulkett et al. 2000).

Bison stress very quickly. Stressed animals tend to override the sedative effects of alpha-2 agonist drugs necessitating the use of relatively high dosages of these

agents to produce immobilization. Stressed animals are prone to capture myopathy, the acute form of which is a shock-like syndrome that can result in death within hours. The subacute form often results in muscle damage, myoglobinuria, and potentially kidney failure. The chronic form is characterized by severe muscle fibrosis, chronic progressive renal failure, and the possibility of muscle rupture in already weakened tissues (Spraker 1993). Rupture of the gastrocnemius muscles is a common manifestation of exertional myopathy in bison. It can occur acutely or may manifest in the chronic form. It is extremely important to keep chase times to a minimum, and try to avoid excitement prior to induction. (Fig. 64.1).

Hyperthermia increases metabolic oxygen demand and increases the risk of capture myopathy. If immobilization is anticipated, it should be planned for the cool hours of the day. Trauma during induction of anesthesia is not uncommon. It is particularly important to control the rest of the herd during induction as other members of the herd may traumatize the drugged animal. There is no information concerning the abortogenic effects of xylazine in bison cows. The risk of abortion in the last third of pregnancy may be increased with this drug.

PHYSICAL CAPTURE AND RESTRAINT

Captive bison may be handled in facilities that are relatively similar to cattle handling facilities. Bison are very powerful and it is vital that the chute system and squeeze is built from material that can accommodate rough handling. Ideally, the chute system should be enclosed, and there should be no right angle turns, as the animal may run directly into the wall and injure itself. Typically, a hydraulic squeeze is used to capture

Figure 64.1. Aerial darting of wood bison; pursuit times should be limited to less than 2 minutes whenever possible.

and restrain the animal, it is not uncommon to include a crash gate at the end of the squeeze as the animal may enter the squeeze very rapidly and a physical barrier is required to stop the animal at the end of the squeeze. Restraint time must be kept to a minimum in order to decrease the risk of stress-related complications. Physical capture of free-ranging bison is typically achieved with a net gun. An experienced crew can potentially capture and handle cows and calves with this method. Mature bulls are more challenging, and typically chemical immobilization is required.

CHEMICAL RESTRAINT AND ANESTHESIA

Vascular Access

The two most common sites for vascular access are the jugular vein and the coccygeal vein. The coccygeal vein can be used to obtain small volume blood samples and to top-up anesthetic or immobilizing drugs; it is not a good location to place an indwelling catheter. The jugular vein is a good location to obtain large volume blood samples or to place indwelling catheters, but it can be challenging to locate in large males. The size of the head will also make it difficult to manipulate the head and neck in sternally recumbent animals. Catheter selection is similar to domestic bovids, either over the needle or through the needle catheters may be used, a typical gauge is 10–14, with a typical length of 10 cm. A small, full thickness incision of the skin overlying the vein will facilitate catheter placement. In the laterally recumbent animal, the lateral saphenous may also be used. Caution should be exercised as lightly anesthetized bison may suddenly kick with their hind limbs. Arterial samples may be obtained from the coccygeal artery or the femoral artery, auricular arteries are typically difficult to locate.

Figure 64.2. Plains bison positioned in sternal recumbency.

Endotracheal Intubation

Intubation is not typically performed in field settings, but it is recommended if the bison is to be maintained on volatile anesthesia. The technique is the same as for cattle. The bison is maintained in sternal recumbency. A mouth gag is placed, prior to intubation. The tongue is pulled forward and the distal end of the tube is held. The person performing the intubation will advance their arm into the oral cavity and guide the tube to the epiglottis. The epiglottis is displaced ventrally with a finger, and the tube is advanced into the glottis. A mature bison will require a size 24–30 endotracheal tube. The head will need to be elevated to facilitate intubation; this can be difficult in large, mature animals, as the head can be heavy.

Monitoring and Supportive Care

Pulmonary Function Hypoxemia can be severe during anesthesia. Hypoxemia, in the face of hyperthermia, is a particularly serious situation, as hyperthermia increases tissue oxygen demand. This can increase the risk of capture myopathy or result in acute mortality. Hypoxemia can be prevented or treated in the field. Animals should be positioned in sternal recumbency (Fig. 64.2).

The head and neck should be extended to maintain a patent airway. The animal should be monitored for hypoxemia, ideally with a pulse oximeter. A multi-site sensor applied to the tongue generally provides a good signal. Normal hemoglobin saturation should be 95–98%, and a saturation below 85% is considered hypoxic. If a pulse oximeter is not available, the mucous membranes should be monitored for cyanosis. Severely hypoxic animals are often tachycardic. Heart rates above 150 in bison may result from a stress response due to hypoxemia, hypercarbia, pain, or hypotension. Tachycardia, followed by severe bradycar-

Figure 64.3. Collection of an arterial blood sample from the coccygeal artery of a sternally recumbent bison.

dia ($HR < 30$), is often a warning sign that the degree of hypoxemia is critical and the heart may fail. Supplemental inspired oxygen should be considered in hypoxic animals (Caulkett et al. 2000). Portable equipment is available to facilitate oxygen delivery. An ambulance type regulator and aluminum D-cylinder is lightweight, portable, and sturdy. It can provide a 10L/min flow for up to 30 minutes. An E-cylinder will provide this flow for an hour or more. A nasal catheter is a simple method to provide supplemental inspired oxygen. The catheter should be threaded as far as the medial canthus of the eye. A flow rate of 10–15L/min is required in bison.

Arterial blood gas analysis will provide the most accurate means of assessing oxygenation. The femoral artery may be used in laterally recumbent animals. It is prudent to exercise caution when working near the legs of anaesthetized bison, as they may spontaneously kick. The coccygeal artery can be used to facilitate arterial blood sampling in sternally recumbent bison (Fig. 64.3).

Cardiovascular System Heart rate and pulse quality should be monitored every 5 minutes. The auricular pulse is difficult to palpate in bison. The facial artery or the femoral artery may be used. Bison anesthetized with xylazine-telazol or medetomidine-telazol have an average heart rate of approximately 60 beats/min (Caulkett et al. 2000). Bison anesthetized with carfentanil-xylazine have a slightly higher heart rate. An average heart rate of 75 beats/min has been reported with carfentanil-xylazine (Haigh & Gates 1995; Kock & Berger 1987).

Body Temperature Rectal temperature should be monitored every 5–10 minutes. Bison are prone to hyperthermia, particularly following a long pursuit. Rectal temperatures greater than 40°C are cause for concern,

and attempts should be made to cool the animal, cold water sprayed on the animal or snow packed into the inguinal and axillary regions may help. Rectal temperature in excess of 41°C is an emergency and should be treated aggressively. It is difficult to actively cool large animals, and often the best option with severe hyperthermia is to antagonize the immobilizing agents and allow the animal to recover. Hyperthermia greatly increases metabolic oxygen demand. Hyperthermia, in the face of hypoxemia, is a particularly serious complication. Hyperthermic animals should receive supplemental inspired oxygen to offset hypoxemia.

Supportive Care Maintenance in sternal recumbency will help to prevent the development of rumenal tympany. If rumenal tympany is a problem, the animal may be rocked gently to stimulate eructation. A rumen tube can be used, but may predispose to regurgitation and aspiration. Generally, if rumenal tympany is severe, it is advisable to finish the procedure quickly and antagonize the anesthetic agents. If alpha-2 agonists have been used, the administration of tolazoline or atipamezole will stimulate rumenal activity and relieve rumenal tympany.

Sedation and Anesthesia of Captive Bison

Bison restrained in a head gate and squeeze can be sedated with intravenous xylazine. The coccygeal vein is useful for the injection of small volumes. Xylazine can be used as the sole agent at a dose of 0.1–0.2 mg/kg IV for standing sedation. Sedation may be enhanced by the addition of 0.05 mg/kg of acepromazine or 0.05 mg/kg of butorphanol administered IV. All three drugs may also be combined to produce deep sedation, and possibly recumbency. If short-term general anesthesia is desired, 0.2–0.5 mg/kg of xylazine can be administered IV, via the tail vein, to produce recumbency. This is followed by 2 mg/kg of ketamine, via the jugular vein. If the jugular vein is used the head must be adequately restrained to avoid injury to handlers.

Anesthesia may be prolonged with 5% guaifenasin and additional 1 mg/kg boluses of ketamine administered to effect. Use guaifenasin cautiously as we have observed guaifenasin toxicity in two bison, at what appeared to be a relatively low dose. It would be premature to say these animals are overly sensitive to the drug, but it should be used cautiously until more information is available. Guaifenasin must be administered via a jugular catheter, as it will cause severe tissue irritation and damage if it is administered perivascularly.

Xylazine should be antagonized at the end of the procedure. If IV ketamine has been used, the antagonist should not be administered for 10–15 minutes to avoid undesirable effects of the ketamine.

Bison calves can be induced to anesthesia with IV ketamine 2–4 mg/kg plus diazepam 0.2 mg/kg. This combination will give 5–10 minutes of light anesthesia.

In depressed calves, diazepam 0.2 mg/kg + 0.1 mg/kg of butorphanol can be used IV for sedation. If the calf is difficult to work with, 0.1–0.2 mg/kg of xylazine + 0.1 mg/kg of butorphanol can be administered IM prior to induction with ketamine-valium.

Immobilization of Free-Ranging Bison

Bison may require immobilization for a variety of reasons. Remote delivery of immobilizing agents necessitates the use of potent agents that can be delivered in relatively small volumes.

Carfentanil-Xylazine This combination has been used for capture of free-ranging wood and plains bison (Haigh & Gates 1995; Kock & Berger 1987). Carfentanil is administered at a dose of 4–8 µg/kg; this is combined with xylazine, at a dose of 0.05–0.1 mg/kg. Bison, like other ungulates, will demonstrate increased activity and excitement during induction. If the animal demonstrates head and/or limb movement when approached after becoming recumbent an additional 0.05–0.1 mg/kg of xylazine may be administered IV to improve muscle relaxation. Following the procedure, carfentanil should be antagonized with naltrexone at a ratio of at least 100-mg naltrexone per 1 mg of carfentanil. Naltrexone has been shown to be the drug of choice for antagonism of carfentanil in bison. Antagonism of carfentanil, with naloxone, has resulted in a high incidence of mortality from renarcotization. Naltrexone has a long half-life and the incidence of re-narcotization is very low.

Complications of immobilization can include the following: hypoxemia, hypoventilation, regurgitation, and hyperthermia. Renarcotization is not usually a problem if naltrexone is used to antagonize carfentanil.

The major advantage of this combination is that it can be administered in very small volumes and will produce reliable immobilization. It is a particularly attractive combination for wild animals, as decreased volume requirements will improve the accuracy of dart placement and decrease tissue trauma.

Xylazine-Telazol A dose range of 0.75–1.5 mg/kg of xylazine, combined with 1.5–3 mg/kg of telazol is generally effective to immobilize bison (Caulkett et al. 2000). The low end of the dose is often effective in calm animals. The high end of the dose range may be required in fractious or wild animals. A 400-kg cow could require a dose volume of up to 7 mL, which can decrease dart accuracy and increase tissue trauma. Large volume requirements decrease the utility of this mixture for wild animals, but it is still very useful in captive or game-farmed animals.

The mixture will produce approximately 1 hour of anesthesia, and will provide adequate analgesia for minor procedures. The major complications that can

be encountered with this combination are hypoxemia, bloat and/or regurgitation, and hyperthermia.

Xylazine should be antagonized following the procedure. Since the telazol dose is relatively low recoveries are generally smooth. Rougher recoveries may be noted if a high dose of telazol was used for induction. Tolazoline or atipamezole should be used to antagonize xylazine in bovids. Tolazoline can be administered at a dose of 2–3 mg/kg. This dose may be split between IV and IM administration. Yohimbine will not effectively antagonize xylazine-induced sedation in bovids and should not be used as the reversal agent (Klein & Klide 1989).

Medetomidine-Telazol The immobilization characteristics of this combination are similar to those of xylazine-telazol (Caulkett et al. 2000). The major advantage of medetomidine-telazol is that it can be administered at approximately half the volume of xylazine-telazol. This quality greatly increases its utility in free-ranging animals. Another major advantage is that a lower dose of telazol is required and arousal from sedation is significantly faster than recovery following antagonism of the xylazine in the xylazine-telazol mixture.

A dosage of 60 µg/kg of medetomidine + 1.2 mg/kg of telazol can be used to immobilize in captive and free-ranging bison. Medetomidine can be antagonized with 180–300 mg/kg of atipamezole. Caution should be observed following antagonism of the medetomidine, as arousal from anesthesia can be very rapid, and IV administration of atipamezole should be avoided unless the condition of the animal is seriously compromised.

Complications are similar to those of xylazine-telazol and include hypoxemia, hypercarbia, and rumenal tympany. Steps should be taken to prevent or treat these complications.

Medetomidine-Ketamine

This combination has been used for immobilization of captive European bison. The effective dose is 2.5 mg/kg of ketamine plus 0.08 mg/kg of medetomidine. (Jalanka & Roeken 1990).

Xylazine-Hydromorphone-Telazol

This combination will address some of the adverse effects of xylazine-telazol alone. The addition of hydromorphone to this combination decreases the telazol and xylazine requirements. The mean dosage administered to plains bison was 1.98 mg/kg of telazol, 0.26 mg/kg of hydromorphone, and 1.32 mg/kg of xylazine. Reversal of sedation was achieved with 4 mg/kg of tolazoline and 0.09 mg/kg of naltrexone (Shury & Caulkett 2006). Preliminary results indicate that this mixture induces less hypoxemia than xylazine-telazol

alone and that reversal of sedation is more rapid following the administration of antagonists. This combination is promising in bison and other ungulates.

Volatile Anesthesia Volatile anesthesia may be used for prolonged procedures. Isoflurane is preferable to halothane as it is less arrhythmogenic. Induction can be achieved with IV xylazine-ketamine or xylazine-guaifenesin-ketamine in restrained animals, or IM xylazine-telazol in unrestrained animals. It is very important to fast animals for 24–48 hours prior to general anesthesia as bovids are particularly prone to bloat and regurgitation during volatile anesthesia. Animals under 150 kg can be anesthetized with a small animal machine. Animals over 150 kg require a large animal circuit.

65 Lagomorphs (Rabbits, Hares, and Pikas)

Darryl Heard

INTRODUCTION

The order Lagomorpha includes 91 living species distributed among two families: Leporidae (rabbits and hares) and Ochotonidae (pikas) (Wilson & Reeder 2005). Lagomorphs are herbivores, closely related to rodents (Nowak 1999). Adults have two pairs of upper incisors; the smaller second is located directly behind the first. Pikas are small (125–400 g) with short ears and legs, and no visible tail (Nowak 1999). Rabbits and hares have elongated ears and legs, and rely on speed to escape predators. Pikas are found in northern Eurasia and western North America. The sexes are equal in size, and their fur is long and dense (Nowak 1999). Despite enduring severe winters, they do not appear to hibernate.

The term “hare” is restricted to animals of the genus *Lepus* (Nowak 1999), all other leporids are rabbits. Hares are usually larger and have black ear tips. Young rabbits are born blind, naked and helpless in a fur-lined nest. In contrast, hares are born fully furred in the open with eyes open and capable of running in a few minutes (Nowak 1999). Leporids weigh 400–7000 g; females are usually larger than males (Nowak 1999). Frightened or captured rabbits may emit loud, shrill screams.

The literature is dominated by parenteral anesthetic regimens for research rabbits (and rodents). Great care must be taken in selecting regimens for clinical cases or free-living animals based on this information. This is because the goals of research anesthesia are often not the same (i.e., prolonged immobility and not necessarily recovery). Similarly, anesthetic regimens have improved in safety, analgesia, and efficacy as new drugs have become available; older anesthetic references must be critically interpreted. Conversely, the benefit of rabbits being used as research animals is there is a lot of controlled studies on the physiologic effects and pharmacokinetics of analgesic and anesthetic drugs.

The European rabbit (*Oryctolagus cuniculus*) is a popular pet, as well as food and fur animal, and one of the most common research mammals. Consequently, the following discussion emphasizes this species. Pikas are similar to rodents in form and size, and anesthesia is the same (see Chapter 66).

PHYSICAL RESTRAINT

Domestic rabbits are not aggressive. However, some animals, particularly those used in research, will bite and scratch. Rabbits and hares have long legs for leaping and running, and will explosively kick when restrained. The kick force is sufficient to fracture the lower thoracolumbar vertebrae. Distal tibial fractures are common if a rabbit falls. Leg fractures also occur in wire bottom cages when a toe or leg is caught. Leporids must not be held by the ears. They can be grasped by the nape for short periods, but it is important to support the rump at the same time. When carrying for a distance, they are either placed in a transport cage or cradled in one arm with their head tucked into the body of the handler.

Physical restraint devices (e.g., rabbit squeezeboxes and cat bags) are a useful adjunct to anesthesia, particularly in the induction period. Restrained rabbits quickly develop hyperthermia, however, especially when environmental temperatures are high. Physical restraint of free-living rabbits and hares should be minimal. Chemical immobilization or inhalation anesthesia is recommended for examination and sample collection.

VASCULAR ACCESS

Blood can be collected from either the external jugular, cephalic, or saphenous vein. This author also collects

Figure 65.1. (a) The ear of a domestic rabbit showing the relationship of the auricular artery (the large central vessel) and veins (the vessels along the edge of the ear). (b) Care should be taken to prevent injury of the auricular artery, which may lead to thrombosis and ischemic necrosis.

Figure 65.2. (a and b) The marginal ear veins can be catheterized with either 22- or 24-gauge over-the-needle catheters. A roll of gauze inside the ear can be used to facilitate securing the catheter with tape.

blood from the auricular artery (Fig. 65.1a). After clipping over the artery, a bleb of local anesthetic is infiltrated over the site on the artery where blood will be collected. This will prevent reflex vasospasm and cause vasodilation. A 25-gauge needle and either 1- or 3-mL syringe are used to collect an appropriate volume. Once the sample is collected, care is taken to ensure hemostasis and the vessel is open. This author will also use this vessel for collection of large volumes of blood quickly for transfusion. A 22-gauge over-the-needle catheter can be carefully placed, then removed after the blood has been collected.

Catheters can also be placed in either the cephalic or marginal ear (Fig. 65.1a and Fig. 65.2a,b) vein for fluid administration. For cephalic vein catheterization, this author uses 22- to 24-gauge over-the-needle catheters. The cephalic vein is found on the forearm in the same position as in other domestic animals. Care must be taken when removing hair to use clippers appropriate for the dense hair of rabbits and to not tear the skin. Rabbit skin is also easily burned by clippers and susceptible to irritation from iodine solutions and alcohol.

The auricular veins are located on the edge of the ears and are usually relatively small (Fig. 65.1a); a 22- to

24-gauge over-the-needle catheter is used by this author. To facilitate catheterization, a bleb of local anesthetic can be infused around the vessel, or applied topically. This provides the dual benefits of analgesia and vessel dilation. Massaging the ear will help to dilate the vessels. Gauze rolled into a tube and placed on the inside of the ear aids in taping the catheter in place (Fig. 65.2a,b). In an awake rabbit, the ears can be taped together. This maintains them in an upright position for continuous fluid administrations using a fluid pump. Care must be taken to prevent ischemic necrosis caused by too-tight bandaging (Fig. 65.1b).

In small patients, intraosseous catheterization can be used as an alternative route to attain vascular access. Catheters can be placed in the proximal tibia, humerus, or femur. Spinal needles (18–22 gauge) are used for intraosseous catheters.

PREANESTHETIC PREPARATION

Assessment of patency of the nares and nasopharynx is essential, especially when an inhalant anesthetic mask is used. Lagomorphs are primary or obligate nasal breathers, and upper respiratory disease is common (e.g., snuffles). The thorax of rabbits is very small relative to abdominal volume (Fig. 65.3). Obesity is also very common in captive animals and can contribute to hypoventilation during anesthesia.

This author does not recommend fasting since leporids do not regurgitate or vomit. Fasting has also been recommended to reduce gastrointestinal volume and, thereby, diaphragmatic and lung compression (Fig. 65.3). It is unlikely, however, to significantly reduce volume in an herbivore and may cause perioperative ileus.

PREMEDICATION

Premedication always includes an analgesic plan; recommended premedication dosages are given in Table 65.1.

Figure 65.3. Lateral radiograph of a domestic rabbit. Note the small thoracic cavity relative to the large abdomen. The trachea is also relatively short compared with body length, and single bronchial intubation is common. Note also the angle of the oral cavity in relation to the trachea emphasizing the need to hyperextend the head and neck to facilitate intubation.

Routine use of parasympatholytics is unnecessary and will alter gastrointestinal motility. Many, but not all rabbits have circulating levels of atropinesterases. Atropinesterase was found in 62% of New Zealand white rabbits (Liebenberg & Linn 1980). More males possessed the enzyme, and there were significant differences in atropinesterase levels between winter and summer (Liebenberg & Linn 1980). Higher atropine dosages in animals lacking these enzymes increase the likelihood of toxicosis. In rabbits, atropine sulfate (0.2–2.0 mg/kg) only briefly induced a moderate tachycardia, but glycopyrrolate (0.1 mg/kg) elevated heart rate for ≥ 50 minutes (Olson et al. 1994).

Acepromazine has similar effects as in other domestic mammals. It is used only in healthy hemodynamically stable animals. Peak effect is not attained for 30–45 minutes, even when administered IV. Tranquilization is inversely related to the amount of environmental stimulation. Acepromazine decreases tear production in rabbits and may, therefore, contribute to corneal injury (Ghaffari et al. 2009).

Benzodiazepines provide good sedation and relaxation. They are a useful adjunct to induction of debilitated patients because of their minimal cardiopulmonary effects, and they can be reversed with flumazenil. The alpha-2-adrenergic agonists xylazine, detomidine, and medetomidine are usually not used alone for sedation.

ANALGESIA

The principles and techniques for small mammal analgesia are well reviewed by Flecknell (2001), Robertson (2001), as well as in Chapter 7. Recommended rabbit dosages are given in Table 65.2. Although a study of the pharmacokinetics of tramadol (11 mg/kg PO) showed levels of its active metabolite O-desmethyltramadol insufficient to produce

Table 65.1. Drug dosages (mg/kg, IM, SC or IV) for premedication and sedation of rabbits

Drug	Dosage	Comments
Acepromazine	0.1–1.0	Healthy, hemodynamically stable animals—will produce hypotension. Peak effect may take ≥ 45 minutes.
Diazepam	1.0–5.0	
Midazolam	0.5–2.0	
Xylazine	1.0–5.0	Higher dosages associated with marked cardiopulmonary depression and bradyarrhythmias.
Atropine	0.04–1.0	Use in emergencies to effect, not recommended for routine premedication. Many but not all rabbits have high circulating levels of atropinase.
Glycopyrrolate	0.01–0.02

IM, intramuscular; SC, subcutaneous; PO = oral.

analgesia in humans (Souza et al. 2008), this author has subjectively observed positive results in rabbits with degenerative joint disease at much lower dosages (1–4 mg/kg every 12–24 hours).

LOCAL AND REGIONAL ANESTHESIA

Rabbits are models for epidural and intrathecal administration of local anesthetics and analgesics (Hughes et al. 1993; Pang et al. 1999; Taguchi et al. 1996). Local and epidural anesthesia are used for minor and occasionally major (e.g., Cesarean section) procedures, respectively. Recommended epidural volume administered by the lumbosacral space is 0.2 mL/kg. Using this dosage, the rank order for onset of action and duration of effect was 2% lignocaine, 2% lignocaine with epinephrine (1:200,000), and 0.5% bupivacaine (Hughes et al. 1993).

Some long-acting local anesthetics have a low therapeutic index (e.g., bupivacaine), and commercial preparations contain concentrations appropriate to humans. Consequently, care must be taken to calculate and prepare appropriate volumes for infiltration. For example, if the toxic dose of lidocaine is 10–20 mg/kg, the equivalent volume of a 2% lidocaine solution would be ≤ 0.5 to 1.0 mL/kg.

PARENTERAL ANESTHESIA

Rabbits, and other lagomorphs, have evolved the ability to detoxify many ingested plant chemicals. For example, circulating atropine esterases in many breeds are capable of inactivating belladonna alkaloids. A high metabolic rate also implies rapid metabolism and excretion of parenteral drugs. Consequently, they generally have a shorter duration of effect than comparable doses in larger mammals.

Drug Administration

Injection routes include subcutaneous, intramuscular, intraperitoneal, intravenous, and intraosseous. This

Figure 65.4. The foot of a rabbit self-mutilated in response to irritation from cephalic catheter. Self-mutilation can occur in response to pain from peripheral injection of irritant solutions, such as xylazine/ketamine or enrofloxacin. The likelihood of it occurring can be reduced by administering injections into large proximal muscle groups (e.g., quadriceps), and with the use of analgesics.

author prefers intramuscular injections be given in the quadriceps muscle. The rabbit is held on a table with its head tucked into the arm of the holder. The muscle is held with one hand and the other hand makes the injection from the front.

Potentially irritant solutions (e.g., high or low pH solutions) are not administered SC or IM because of the risk of self-mutilation (Beyers et al. 1991) (Fig. 65.4). This can be reduced by diluting the solution, avoiding large volume injections, and injecting in the large proximal leg muscles. The author recommends IP, rather than IM or SC, injections in pikas because of their small size.

Intranasal administration of some analgesics, sedatives, and anesthetics is an effective and rapid route in rabbits (Lindhardt et al. 2001; Robertson & Eberhart 1994).

Drugs

Ketamine has a very short duration of clinical effect due, in part, to redistribution and renal elimination (Bjorkman & Redke 2000). Consequently, renal impairment will markedly prolong recovery. Xylazine and other alpha-2 adrenergic agonists are frequently combined with ketamine for short-term immobilization and surgical anesthesia. These combinations, particularly at the higher dosage levels, produce mild to severe

dose-dependent hypotension, bradyarrhythmias, and respiratory depression, with associated hypercapnia, acidemia, and hypoxemia. As with all parenteral anesthetic regimens, some form of oxygen supplementation and assisted ventilation is recommended. Ketamine/benzodiazepine combinations produce less cardiopulmonary depression and analgesia, but good muscle relaxation.

In Dutch belted rabbits, multiple anesthetic episodes with ketamine/xylazine (50/10mg/kg IM) were associated with myocardial necrosis and fibrosis (Marini et al. 1999). Similarly, in New Zealand white rabbits, detomidine, alone and in combination with ketamine or diazepam, produced the same injury (Hurley et al. 1994). The postulated mechanism was decreased coronary blood flow. However, other causes (e.g., hypovitaminosis E, excessive anesthetic dosage, and hypoxemia) were not ruled out.

Tiletamine/zolazepam is not recommended for use. This combination requires very high dosages (32–64 mg/kg) to produce immobility to noxious stimuli (Brammer et al. 1991). These dosages also produce dose-dependent renal tubular necrosis within 7 days of injection (Brammer et al. 1991).

Propofol is used for induction and maintenance. Its effects are similar to those described in domestic animals (Aeschbacher & Webb 1993a, 1993b). The total induction dose is dependent upon administration rate. Propofol alone produces inadequate analgesia for painful procedures, and anesthetic maintenance with infusions is not recommended unless cardiopulmonary support is provided. It is indicated for induction of healthy animals in which vascular access can be attained prior to anesthesia. A slow infusion can also be used for sedation to facilitate mask induction. Animals should be intubated and ventilated as soon as possible after induction.

Alfaxalone (3 mg/kg IV, IM?) can be used to induce anesthesia in rabbits (Gil et al. 2012). In comparison to propofol (10 mg/kg IV) both anesthetics induced a comparable decrease in heart and respiratory rates, while propofol affected adrenocortical function less (Gil et al. 2012).

INHALATION ANESTHESIA

Inhalation anesthesia with either isoflurane or sevoflurane is the primary component of most anesthetic regimens. It allows rapid induction, recovery, and control of anesthetic depth, while adverse effects are dose-dependent and reversible.

Immediately after induction, rabbits often have shallow rapid respirations and decreased alveolar ventilation. This delays attainment of maintenance alveolar anesthetic levels, and may explain the need for high isoflurane vaporizer settings (4–5%) in spontaneously

breathing rabbits. Premedication and assisted endotracheal intubation ameliorates this. Intubation allows assisted ventilation, improved alveolar ventilation, and thus better control of anesthesia.

Induction

Inhalant anesthesia is used either alone or as an adjunct to induction. The anesthetic is administered into an induction chamber or through a mask. The advantage of a chamber is the animal is not physically restrained during the involuntary excitement phase of induction. This reduces the risk of injury to both handler and patient. Disadvantages include environmental contamination and difficult monitoring.

Mask induction of restrained unpremedicated animals is not recommended. Anesthetic chambers and masks are clear to see the patient (Fig. 65.5). The chamber top is secured to prevent the animal escaping. Inhalant anesthetic is introduced through one opening and waste gas removed from another. The vaporizer is set at maximum concentration and oxygen flow rate at 2 to 4 L/min. Once the animal loses its righting response (usually 5 to 10 minutes), it is removed from the chamber and a mask placed over its nose and mouth. The chamber is placed outside or closed to allow waste gases to be safely voided. The animal is either maintained with a mask or intubated.

When using a mask, the animal's head and neck is kept in extension to prevent obstruction to breathing (Fig. 65.6). Respiratory pattern, rate and noise are assessed. If there appears to be difficulty in breathing the head and neck are moved to correct the obstruction. If not, a cotton-tipped applicator is used to clear the oropharynx and nares. If this fails to relieve the problem, the animal is intubated or awakened.

Figure 65.5. Induction of a premedicated rabbit with an inhalant anesthetic administered in oxygen. Note the clear chamber to allow visualization of the animal, and the scavenging system. Once the animal loses its righting reflex, it is removed from the chamber and maintained with a mask until intubated.

Figure 65.6. Mask induction is recommended only in animals that have been premedicated to prevent struggling. Note the extension of the head and neck to reduce the possibility of airway obstruction.

Endotracheal Intubation

In clinical practice intubation of rabbits should be a routine standard of care, especially for complex and prolonged procedures. Maintenance with a mask allows more inhalant anesthetic gas contamination of the environment, and does not allow assisted ventilation. Pediatric laryngeal mask airways are easier to position, but may be associated with increased waste gas exposure and stomach inflation during ventilation (Smith et al. 2004).

Endotracheal tube size ranges from 2- to 4.5-mm ID. They are preferably clear to see condensation or occlusion with mucous and blood. In rabbits, it is essential the animal's head and neck is moderately hyperextended to align the larynx and trachea with the oropharynx (Fig. 65.7). The epiglottis must be displaced ventral to the soft palate for visualization of the glottis through the oropharynx (Fig. 65.8). Regardless of technique, the rabbit is relaxed before intubation. This is indicated by absence of a response to either an ear or toe pinch.

There are two techniques: blind and direct visualization. An additional technique, not recommended because of laryngeal and tracheal trauma, uses retrograde placement of a guide wire or catheter through the larynx and out through the mouth. The endotracheal tube is then passed over the wire into the larynx. This technique is indicated for respiratory arrest when direct visualization fails.

This author prefers the blind technique for routine intubation. However, it requires breathing to guide endotracheal tube placement. The rabbit is placed in sternal recumbency on a table at a height comfortable for the anesthetist (Fig. 65.7). If you are right handed,

Figure 65.7. For endotracheal intubation, it is necessary to alter the normal angle between the oral cavity and trachea (Fig. 65.2). Regardless of technique used, the head and neck need to be hyperextended. This author prefers the animal be in sternal recumbency for this positioning. Alternatively, the animal can be placed in dorsal recumbency.

Figure 65.8. Endoscopic view of the glottal opening in an eastern cottontail rabbit (*Sylvilagus floridanus*). Lagomorphs are obligate nasal breathers. The soft palate has been displaced, allowing a view of the simple flat epiglottis and the arytenoid cartilages.

stand on the right side of the animal and grasp the head with the left hand. The head is grasped from above and behind with the thumb and little finger under the mandibular ramus. Alternatively, some find aligning the head and neck horizontal and parallel to the table in the dorsally recumbent rabbit also allows intubation. Although this author has used this position, it makes it awkward to listen and manipulate the tube.

Figure 65.9. For blind intubation, it is unnecessary to open the jaws. Once the rabbit is fully unconscious and relaxed, the endotracheal tube is introduced through the space between the incisors and first premolars, and passed over the base of the tongue.

The endotracheal tube is inserted between the incisors and first premolar, and passed over the tongue base (Fig. 65.9). The head and neck are lifted into hyperextension, and the anesthetist places her/his ear to the tube (Fig. 65.10). The tube is advanced towards the glottis until respiratory noise is loudest. No or gurgling sound indicate the tube is in the esophagus. The tube is repetitively and gently advanced to the glottis until it enters the trachea. At the point of peak noise it helps to rotate the endotracheal tube 180° to displace the epiglottis (Fig. 65.8). Local anesthetic, both as a gel applied to the end of the tube or a liquid poured down the tube, desensitizes the glottis and facilitate intubation. The rabbit may forcefully cough the tube out. Do not persist in intubation attempts for more than a few minutes, or when there is evidence of either laryngeal edema or hemorrhage.

The direct visualization technique is similar. An assistant opens the animal's jaws using gauze tape placed around the upper and lower incisors (Fig. 65.11). The tongue is grasped by gauze square and pulled up and to the side. A cotton-tipped applicator may assist grabbing the tongue. A laryngoscope with a pediatric straight blade (Miller # 0 or 1) is inserted into the oropharynx, the head and neck are hyperextended, and the epiglottis displaced. The endotracheal tube is passed down the laryngoscope blade and through the glottis; sight of the glottis is usually lost as the endotracheal

Figure 65.10. Blind intubation requires listening for respiratory noise to identify positioning of the endotracheal tube. The loudest noise indicates the tube is aligned and close to the laryngeal opening. If the noise goes away during positioning, it indicates the tube is in the esophagus, and it should be gently pulled back until respiratory sounds are again identified.

tube occludes the oropharynx. Alternatively, a small-diameter catheter is placed as a guide for the tube.

Alternatively, the endotracheal tube can also be placed over a rigid endoscope used to visualize the glottis (Tran et al. 2001). If a 2.7-mm outside-diameter endoscope is used, the tubes are limited to ≥ 3.0 mm internal diameter. The other disadvantage of using an endoscope is the potential for fracturing of the glass from flexion or chewing by a semi-awake rabbit. Alternatively, a small diameter (1.9-mm ID) fiberoptic scope can be used (Fig. 65.11b). These scopes allow some flexion and smaller-diameter tubes appropriate to small rabbits, and are relatively less expensive. A problem with using this technique in the warm humid environment of the mouth is fogging of the endoscope. This can be reduced or avoided by using antifogging solutions used to clear scuba masks, or similar liquids. Once in place, the tube is advanced into the glottis. Placing the rabbit in dorsal recumbency may facilitate glottal visualization.

If unsure the tube is in the correct place, remove it and reassess placement. A pulse oximeter is invaluable for monitoring potential oxygenation problems due to airway obstruction. Correct tube placement is determined by either: (1) seeing condensation on the inside of the tube (Fig. 65.12a) or on a metal surface placed at the end of the tube or (Fig. 65.12b); (2) detecting air

Figure 65.11. (a) Direct visualization techniques require the head and neck to be hyperextended, as for the blind technique. In this animal, a small pediatric straight laryngoscope is being used to visualize the glottis. (b) An alternative direct visualization technique for endotracheal intubation uses an endoscope. The endotracheal tube is placed on the outside of the endoscope, then guided into the larynx once the glottis is visualized. This is an example of an inexpensive semi-flexible 1.9-mm scope.

Figure 65.12. (a) Assessment of correct positioning of the endotracheal tube in the trachea can be done by visualizing condensation within the clear tube on exhalation, or with the use of a capnograph. (b) Assessment of correct positioning of the endotracheal tube in the trachea can also be done by observing condensation on a metal surface, such as the bottom of a laryngoscope.

Figure 65.13. The position of the eye changes with increasing depth of inhalation anesthesia. A medial eye position suggests light surgical anesthesia.

movement with hair placed in front of the tube; (3) watching the nonbreathing bag; (4) the response to intubation (coughing, etc.); or (5) detection of exhaled carbon dioxide on a capnograph (Fig. 65.12a). To insure the tube has not been placed into a single bronchus (Fig. 65.3), premeasure the tube before use, and auscultate both lung fields for respiratory sounds after intubation.

PERIOPERATIVE MONITORING

Anesthetic Depth

In rabbits anesthetized with isoflurane, the eyelid aperture increased in a predictable dose-dependent manner (Imai et al. 1999) (Fig. 65.13). This response cannot be evaluated in the clinical patient because the cornea is protected with either a lubricant or the eyelids are taped closed. The eyeball rotates medially (Fig. 65.13), then either dorsally or ventrally at 0.8 isoflurane MAC before becoming centrally fixed at >1.5 MAC (Imai et al. 1999). Palpebral and corneal reflexes are observed at 0.8 MAC, but are abolished at >2.0 MAC. A fixed dilated pupil, unresponsive to light and with no corneal reflex, is a cross-species indicator of either excessive anesthetic depth or brain stem hypoperfusion and ischemia. Anal tone is usually retained until deep anesthesia.

Evaluating physiologic and muscular response to a painful stimulus assesses pain and nociceptor response. This can be a toe, ear, and/or tail pinch, or a skin incision. Increasing depth toward a surgical plane of anesthesia is assumed when muscle tone (e.g., jaw muscle and anal sphincter) decreases, palpebral and corneal reflexes are obtunded, and respiration pattern becomes regular and even. Sudden tachycardia, hypertension,

Figure 65.14. A Doppler flow probe can be placed over the auricular artery for monitoring blood flow.

and tachypnea in response to stimuli are indicative of inadequate anesthetic depth or analgesia.

Cardiovascular

An esophageal stethoscope can be used to monitor heart rate in the intubated anesthetized patient. Alternatively, a quality pediatric stethoscope is used. The electrocardiograph should have a multichannel oscilloscope with nonfade tracing and freeze capabilities. Additionally, it must be able to record at speeds of 100 mm/s and amplify the signal to at least 1 mV equal to 1 cm. Standard lead positions are used.

Placement sites for the Doppler flow probe include the ventral aspect of the tail base, the carotid, femoral, and auricular arteries, and directly over the heart (Fig. 65.14). Sites for indirect blood pressure measurement include the legs, forearms, tail, and ears. The forelimb cuff oscillometric method is accurate for evaluation of arterial blood pressure at low and normal pressure ranges (Ypsilantis et al. 2005). Direct arterial blood pressure can be measured using a 22- to 24-gauge over-the-needle catheter placed in the auricular artery in the center of the pinna (Ypsilantis et al. 2005).

Respiratory

Respiration rate (RR) is inversely related to bodyweight and is determined by evaluating either thoracic wall or reservoir bag movement. As with cardiac auscultation, evaluation requires a good quality stethoscope with appropriate head and length of tubing, and an experienced ear. The esophageal stethoscope can be used to evaluate respiratory noise. However, there is more

likely to be artifactual noise that must be distinguished from true respiratory noise. Arterial blood gas samples are obtained from any palpable artery: the femoral, metatarsal, and auricular arteries. Infiltration of the periarterial area with 1% lidocaine without epinephrine may prevent reflex vasoconstriction.

Pulse oximetry has been evaluated in rabbits and appears accurate at hemoglobin saturation levels greater than 85% (Vegfors et al. 1991). Potential sites for placement of transmission pulse oximeter sensors include the ear, tongue, buccal mucosa, paw, vulva, prepuce, and proximal tail. Surprisingly, in rabbits, the tail base and the paws appear more effective than the ears. This may be due to excessive compression of the aural vasculature by the clamp holding the probe. A reflectance pulse oximeter sensor is used in either the esophagus, rectum, or applied to the skin surface on the ventral neck overlying the carotid artery.

Thermoregulatory

Hypothermia is common; body temperature measurement is a standard of care during all procedures. It is preferably measured continuously. For measurement of core body temperature, it is necessary to use a temperature probe attached to an esophageal stethoscope.

PERIOPERATIVE SUPPORTIVE CARE

The eyes of rabbits and hares are prominent and care must be taken to prevent corneal injury during positioning. It is important to place ophthalmic ointment at the beginning and during a procedure, and make sure the eyelids are closed.

Cardiovascular

Vascular access is established in physiologically unstable patients and those likely to decompensate from hemorrhage, endotoxemia, and so on, during the peri-anesthetic period. Catheter placement sites and technique are described above. Catheters should not be placed in the central auricular artery (except for blood pressure monitoring) because of the risk of thrombosis and ischemic necrosis of the ear. Subcutaneous fluid administration is the least appropriate route for correction of deficits or replacement from hemorrhage.

Respiratory

General anesthetics produce ventilatory depression. This effect may be either additive or synergistic with underlying disease, resulting in marked hypercapnia and/or ventilatory arrest. High-inspired oxygen concentrations also decrease ventilatory drive. Ventilation is also affected by body position and compression of the respiratory exchange tissues by distended viscera and/or obesity. Inadvertent compression of the chest by surgeons is common in small patients. Developing good hand position techniques, an attentive anesthe-

tist, and the use of clear plastic drapes helps prevent this. Rabbits have very small chest cavities relative to body size and have a high prevalence of respiratory disease (Fig. 65.2). Additionally, they will often develop tachypnea under anesthesia with a normal to decreased alveolar ventilation.

Adequacy of ventilation is most accurately assessed using $P_a\text{CO}_2$. Visualization of chest wall movement is a deceptive guide to adequacy of ventilation. Consequently, the author recommends either assisted or controlled ventilation of intubated patients under general anesthesia. Capnography is appropriate for indirectly monitoring PaCO_2 , but the sensor increases mechanical dead space in the breathing system (Fig. 65.11). Doxapram is not recommended for use in hypoventilating patients unless anesthetic reversal, or intubation and mechanical ventilation are impossible or contraindicated.

Thermoregulatory

Minimizing anesthesia time and the use of warm surgical preparation solutions, wrapping the body, increasing the room temperature, and the use external heat sources (i.e., circulating warm water blankets and forced air warmers) reduces hypothermia. Electric heat blankets are not used because they have the potential to cause severe burns. Similarly, heated fluid bags placed in contact with the skin may cause burns.

RECOVERY

Recovery is a critical period during which the patient is placed in a warm, quiet environment and monitored. Supportive care established during anesthesia is continued until the patient is fully alert and stable. In particular, vascular access is maintained to allow emergency administration of drugs and fluids.

The anesthetic drugs used, duration of procedure, and the magnitude of physiologic dysfunction incurred determine duration and quality of recovery. Prolonged recovery is usually due to hypothermia, hypoglycemia, and anesthetic overdose or impaired drug elimination. Care is taken when rewarming an animal that is possibly hypovolemic and/or hypoglycemic, because warming will result in dilation of vasoconstricted peripheral vessels, as well as increase metabolic demand for glucose.

RECOMMENDED ANESTHETIC REGIMENS FOR DOMESTIC RABBITS

Drug dosages for premedication, analgesia, and anesthesia are given in Table 65.1, Table 65.2, and Table 65.3, respectively.

Unpremedicated rabbits can be induced in an anesthetic box with an inhalant (isoflurane or sevoflurane) in oxygen. This technique, however, has been shown

Table 65.3. Drugs used for induction and maintenance of anesthesia in rabbits (and hares)

Drug or Drug Combination	Dosage	Route	Comments	References
Parenteral				
Acepromazine/ ketamine	0.25–1.0/25–40 mg/kg	IM, IV		
Xylazine/ketamine	3–5/20–40 mg/kg	IM, IV	Sometimes marked cardiopulmonary depression. Duration of effect decreased with yohimbine (0.2 mg/kg IV).	Borkowski et al. (1990); Henke et al. (2005); Hobbs et al. (1991); Lipman et al. (1987, 1990); Sanford and Colby (1980)
Diazepam/ketamine	1–5/20–40 mg/kg	IM, IV		
Midazolam/ketamine	1/20–40 mg/kg	IM, IV		
Zolazepam/ tiletamine	5–25 mg/kg	IM, IV	This dosage does not provide complete immobility or surgical anesthesia. Very high dosages associated with nephrotoxicity.	Brammer et al. (1991)
Xylazine/zolazepam/ tiletamine	5/15 mg/kg	IM	Cardiopulmonary depression, surgical anesthesia, prolonged duration of effect.	Popilskis et al. (1991)
Medetomidine/ ketamine	0.5/35 mg/kg	IM, IV	Combined with buprenorphine 0.03 mg/kg, animals intubated, ventilated, and maintained with isoflurane.	Difilippo et al. (2004); Orr et al. (2005)
Propofol	3–6	IV	Produces cardiopulmonary depression depending on rate of administration.	Aeschbacher and Webb (1993a,b)
Alfaxolone	3–6	IV, IM?		
Inhalant				
Halothane	Induction 5%, maintenance 1–2%			
Isoflurane	Induction 5%, maintenance 2–3%			
Sevoflurane	Induction 7–8%, maintenance 3–4%			

to be stressful and to induce moderate hypercapnia and acidemia due to breath holding (Flecknell et al. 1999). Similarly, mask induction of unpremedicated rabbits is not recommended because of struggling. Although sevoflurane is reported to be less noxious in humans, it produced a similar adverse effect as isoflurane in rabbits (Flecknell et al. 1999). It is, therefore, recommended that all rabbits be premedicated before induction. The benzodiazepine midazolam (0.2–0.5 mg/kg IM) provides good sedation and muscle relaxation given 10–15 minutes before induction. For painful procedures, an analgesic is added to midazolam. This author prefers buprenorphine (0.02–0.04 mg/kg IM) because of its duration of effect. Midazolam and buprenorphine together may still not provide adequate immobilization to allow mask induction. Low dose ketamine (5–10 mg/kg) added to other premedication will facilitate handling for mask induction and potentially be additive for analgesia. A nonsteroidal analgesic (e.g., meloxicam) can be added to the premedication when pain is anticipated.

Alternatively, an alpha-2 adrenergic agonist (i.e., xylazine, medetomidine, and dexmedetomidine) can be administered with ketamine for induction. If intra-

venous access is available, propofol can be given to effect (Aeschbacher & Webb 1993a, 1993b). Since it does not produce analgesia, a nonsteroidal anti-inflammatory or opioid should be included in the premedication for painful procedures. Propofol (4–6 mg/kg IV) or alfaxolone (4–6 mg/kg IV) can produce marked respiratory depression depending on rate of administration; the rabbit should be intubated after induction, and respiratory support may be required. Anesthesia can then be maintained with an inhalant such as isoflurane in oxygen.

RECOMMENDED ANESTHETIC REGIMENS FOR FREE-LIVING LAGOMORPHS

Inhalation anesthesia is recommended for wild lagomorphs because of rapid induction and recovery. Capture and placement into an induction chamber is relatively easy. Alternatively, the trap can be placed in the chamber or a plastic bag for inhalant anesthetic administration. Where inhalant anesthesia is not feasible, parenteral drug combinations are administered IM or IP (Table 65.3). Drug combinations that include either alpha adrenergic agonists or benzodiazepines are

potentially reversible (Table 65.3). In European brown hares (*Lepus europaeus*), medetomidine (0.2 mg/kg IM), combined with either ketamine (30 mg/kg IM) or S(+)-ketamine (15 mg/kg IM), showed only minor advantages to using the latter (Gerritsmann et al. 2012). Surgical anesthesia was not achieved reliably with either protocol and hypoxemia was identified.

The formulation of alfaxalone 2-hydropropyl-beta-cyclodextrin (Alfaxan-CD RTU) (5 mg/kg IM) was used in combination with medetomidine (0.25 mg/kg IM) to induce anesthesia in wild European rabbits (*Oryctolagus cuniculus*) in Australia for surgical implantation of body temperature loggers (Marsh et al. 2009). Anesthesia was maintained with 1.5–3% isoflurane.

Rodents

Darryl Heard

INTRODUCTION

Rodentia includes the most living mammalian species, 2277 (Wilson & Reeder 2005). Although usually small (≤ 200 gms), several are very large (e.g., marmots, *Marmota*; giant squirrels, *Ratufa*; pacas, *Agouti*; maras, *Dolichotis*; capybara, *Hydrochaeris hydrochaeris*; beaver, *Castor*; and porcupines, *Hystrix*). Rodents are common pets and research animals, including the house mouse (*Mus musculus*), rat (*Rattus norvegicus*), chinchilla (*Chinchilla laniger*), Syrian and Siberian hamsters, guinea pig (*Cavia porcellus*), and gerbil. Rodents have four incisors, no canines, and there is a gap between the incisors and the cheek teeth (Nowak 1999). Some have cheek pouches, internal or external, that open near the angle of the mouth (Nowak 1999). During anesthesia, these pouches can be a source of aspirated food material.

CONSEQUENCES OF SMALL BODY SIZE

Schmidt-Nielsen (1984) describes the relationship between body size and vertebrate physiology. As small animals, rodents have high metabolic and oxygen consumption rates, and, therefore, low tolerance to even brief hypoxemia. Irreversible CNS injury occurs within ≤ 30 seconds of respiratory arrest. Increased oxygen uptake requires increased alveolar ventilation, resulting in more rapid inhalant anesthetic uptake and excretion. High metabolic rates increase the speed of elimination of parenteral drugs. In herbivores, this is enhanced by adaptations for detoxification of chemicals in their food. Consequently, drugs generally have shorter duration of effect than in larger mammals and require higher dosages.

High metabolic rates and small glycogen reserves predispose to hypoglycemia. A small body has a large surface area to volume ratio, and often higher tempera-

ture. Convective heat loss is rapid and hypothermia assured unless supplemental heat is provided. Loss of even small amounts of blood may lead to hemorrhagic shock and death. Airway resistance is inversely related to radius⁴; slight changes in diameter (e.g., from edema and mucous accumulation) will have a dramatic effect on respiratory work.

ZOONOTIC DISEASES

Many species harbor pathogens that infect humans (Padovan 2006). For example, deer mice (*Peromyscus maniculatus*) are the reservoir for the virus that causes Hantavirus pulmonary syndrome in people in the southwestern United States (Elliott et al. 1994). *Giardia* are present in beavers (*Castor* spp.) and capybaras (Thompson 2004). Handling rodents awake is minimized to prevent bites and scratches. The use of physical barriers (i.e., gloves, breathing masks, and biological hazard suits) is based upon the predetermined risk, species, and the procedure.

PHYSICAL RESTRAINT

All rodents bite, including many kept as pets. In an animal of unknown temperament, inhalant anesthesia is an acceptable alternative for physical examination. Care is taken with small rodents to avoid physical restraint in place of adequate analgesia and anesthesia. Large rodents are restrained in squeeze cages (Chapter 8) or remotely injected for drug administration (Chapter 12).

Pet rodents can often be gently picked up in the palm of the hand. Guinea pigs and similar sized rodents are supported under the rump while being held (Fig. 66.1). Some rodents may be grasped at the tail base for

Figure 66.1. Tame rodents, such as this guinea pig, can be held, but should be supported below the rump.

Figure 66.2. Some rodents (e.g., Siberian hamster) can be restrained by grasping the skin at the nape of the neck. Sufficient skin, however, must be grasped to prevent the animal turning and biting the handler.

transfer from cage to cage. This technique, however, is avoided in animals that shed their tails in response to a threat (e.g., spiny-tailed mice) or are able to turn and bite (Nowak 1999).

Grasping the nape is used to restrain some small rodents. Hamsters and others with loose skin require a very tight grasp to prevent them turning and biting (Fig. 66.2). Small- to medium-sized rodents are

Figure 66.3. A restraint cage for Southern African crested porcupines developed at the Central Florida Zoo. The cage is metal to prevent the animal chewing. One side has large openings that cause the legs to fall through when the cage is turned. This allows an unprotected leg to be grasped and injected with immobilization drugs. Care must be taken in this species to prevent skin tearing.

restrained with a hand around the neck and the thumb positioned under the jaw to prevent biting. In laboratory animal facilities, mice and other small rodents can be transferred from cage to cage using soft forceps. This technique is also used for small free-living rodents caught in traps. Leather or chain-mail gloves can be used to handle aggressive rodents, but they limit feel and the former do not protect against a direct bite.

Porcupines offer a unique challenge. Although they do not “shoot” their sharp quills, they will back rapidly and with great force into a threat. The quills of New World porcupines have barbs that make their removal very difficult. Additionally, the quills of porcupines may be covered in potentially pathogenic bacteria. They also make remote injection difficult. The author uses a purpose-built restraint box at the Central Florida Zoo to allow drug injection into the leg muscles of Southern African crested porcupines (*Hystrix africaeaustralis*) (Fig. 66.3). The metal box has one side of wire with spaces sufficient to allow legs to drop through when the cage is turned. A leg is then grabbed and injected with a parenteral anesthetic. This porcupine, however, has skin that tears very easily.

PREANESTHETIC PREPARATION

Rodents are primary or obligate nasal breathers and upper respiratory disease is common (e.g., pseudodontoma in prairie dogs and mycoplasmosis in rats). The nares are assessed for patency before induction with an inhalant anesthetic and mask. This author does not routinely remove food or water prior to anesthesia. Fasting exhausts glycogen stores. It may also contribute to ileus and pregnancy ketosis in guinea pigs and other herbivores.

PREMEDICATION

Recommended dosages are given in Table 66.1. In rats, atropine sulfate (0.05 mg/kg) and glycopyrrolate (0.5 mg/kg) increased heart rate for 30 and 240 minutes, respectively (Olson et al. 1994). Although both reduce bradycardia in rodents anesthetized with ketamine/alpha-2 adrenergic agonist combinations, glycopyrrolate is more effective in maintaining heart rate within normal range (Olson et al. 1994). Neither glycopyrrolate nor atropine influences respiration rate, core body temperature, or systolic blood pressure alone or combined with injectable anesthetics.

Benzodiazepines provide good sedation and relaxation and are a useful for induction of debilitated patients because of their minimal cardiopulmonary effects. Xylazine, medetomidine, or dexmedetomidine are combined with ketamine to improve muscle relaxation, analgesia, and duration of effect. However, they produce respiratory depression and bradycardia. Interestingly, midazolam may ameliorate the adverse cardiovascular effects of dexmedetomidine in rats (Cornelis et al. 2000). Alpha2-adrenergic agonists are reversed with yohimbine, tolazoline, or atipamezole. Tolazoline (10–50 mg/kg), when compared with yohimbine (1 mg/kg), appeared most effective and safe for the reversal of xylazine/ketamine anesthesia in rats (Komulainen &

Olson 1991). In rats, yohimbine (20 mg/kg IP) produced a high (22%) mortality.

ANALGESIA

The principles and techniques for rodent analgesia are reviewed by Machin (Chapter 7), Flecknell (2001) and Robertson (2001). The two main groups of analgesic premedicants, opioids and nonsteroidal anti-inflammatory drugs (NSAIDs), are combined or used alone. Even low dosage ketamine provides analgesia and is worthwhile including, for this reason, in some anesthetic regimens (Robertson 2001). Local and regional anesthesia (see below) also has the potential to further enhance analgesia. Tramadol is an additional analgesic that can be used in the perianesthetic period, but only oral or compounded formulations are available in North America. Effective drug dosages are still to be determined for many species. Recommended dosages for analgesics are given in Table 66.2.

LOCAL AND REGIONAL ANESTHESIA

Many large captive species (e.g., guinea pig) are amenable to local and epidural anesthesia for minor and occasionally major (e.g., Cesarean section) procedures,

Table 66.1. Drugs used for premedication in rodents

Drug	Rat	Mouse	Gerbil	Hamster	Guinea Pig, Chinchilla, and Prairie Dog	Beaver, Capybara, and Porcupine
Acepromazine	0.5–2.5 IM IP	0.5–2.5 IP	Not recommended	0.5–2.5 IM IP	0.5–2.5 IM	0.1 IM
Diazepam	3–5 IP PO	3–5 IM IP PO	3–5 IP PO	3–5 IP PO	1–2.5 IM IP PO	0.1–1.0 IM PO
Midazolam	1–2 IP	1–2 IM IP	1–2 IP	1–2 IP	1–2 IM IP	0.1–0.5 IM
Xylazine	10–15 IP	10–15 IP	5–10 IP	5–10 IP	5–10 IP SC	1–5 IM SC
Atropine	0.05 SC IM	0.05 SC IM	0.05 SC IM	0.05 SC IM	0.05 SC IM	0.03 SC IM
Glycopyrrolate	0.01–0.02 SC IM	0.01–0.02 SC IM	0.01–0.02 SC IM	0.01–0.02 SC IM	0.01–0.02 SC IM	0.01 SC IM

Notes: Use lower dosages for debilitated, geriatric, or obese animals and for those that are relatively large for the species.

Acepromazine is not recommended for use in gerbils because it may lower the seizure threshold.

respectively (Eisele et al. 1994). Most local anesthetics have a low therapeutic index (particularly the long-acting drugs, such as bupivacaine) and commercial preparations usually contain drug concentrations suitable for humans. Consequently, great care must be taken to calculate and prepare appropriate volumes of local anesthetic for infiltration.

PARENTERAL ANESTHESIA

Small- to medium-sized rodents are preferably induced and maintained with an inhalant anesthetic (see later). Parenteral anesthetic regimens are used where inhalant anesthesia is not available (e.g., for field immobilizations), to reduce inhalant anesthetic pollution, to enhance analgesia, to facilitate mask induction with an inhalant, and for convenience in research facilities. Representative parenteral anesthetic regimens and dosages are described in Table 66.3.

Most published anesthetic regimens are designed for research animals. Unfortunately, the dosages and drugs are often not compatible with clinical practice or fieldwork. They also assume animals are young and healthy. Conversely, there are many excellent studies of the effects of parenteral anesthetics in rodent models.

Drug Administration

Injection routes include subcutaneous (SC), intramuscular (IM), intraperitoneal (IP), intravenous (IV), and intraosseous (IO). Potentially irritant solutions (e.g., high or low pH solutions) should not be administered SC or IM, because of the risk of self-mutilation (Gaertner et al. 1987; Leash et al. 1973). Diluting the solution, avoiding large volume injections, and injecting in the proximal muscles of the legs reduce the risk of developing this adverse effect. Alternatively, drugs are administered by IP injection. Large rodents are enclosed in squeeze cages (Fig. 66.3) or administered drugs using a remote injection system.

Vascular Access

Small size makes venous and intraosseous catheterization difficult, but practice and attention to technique enable attainment of these essential skills. Potential catheterization sites include the cephalic, saphenous, and auricular veins. The lateral coccygeal veins can be accessed in rats with small-gauge needles. Penetration of the skin before placement, with either a hypodermic needle or scalpel blade, is done to prevent catheter buckling. Intraosseous catheterization using 18- to 22-gauge spinal needles can be performed at the proximal femur (via the trochanteric fossa), tibia (tibial crest), and humerus.

Venipuncture and Blood Collection

Depending on size and species, blood samples can be collected in clinical cases from the jugular, cephalic, saphenous (Hem et al. 1998), femoral, perineal (agoutis and related species), and lateral coccygeal veins. The cranial vena cava, femoral artery, and ventral coccygeal vessels are alternative sites in some species. The heart and retro-bulbar sinus are used in research species, but are not recommended for clinical patients.

For collection of blood from the saphenous vein, the rodent can be placed head first into a plastic tube for restraint (Hem et al. 1998). The hair over the proximal tarsus is gently clipped to allow visualization of the vessel, and microhematocrit tubes are used to collect blood from small rodents (Hem et al. 1998).

The restraint tube can also be used to facilitate blood collection from lateral coccygeal veins in rats. The major problem with the use of these vessels is ensuring an adequate blood flow (Conybeare et al. 1988). One technique is to briefly warm the tail by immersion in a water bath (up to 45°C). This causes a local vasodilation. Prolonged vasodilatation can be achieved by using a heating lamp placed above the rodent cage, but a major disadvantage is the lack of temperature control and the danger of burns. Instead, controlled warming of the total environment of the rat or mouse to temperatures around 40°C, a large blood

flow through the tail makes it possible to collect blood from the lateral caudal vein (Conybeare et al. 1988).

Parenteral Anesthetics

Some rodents (e.g., guinea pigs) have limb movement at ketamine or tiletamine/zolazepam dosages expected to produce surgical anesthesia. Ketamine (44 mg/kg) takes 8–10 minutes for induction and has a very short duration of effect (15–20 minutes) (Weisbroth & Fudens 1972). Ketamine and ketamine/xylazine may be associated with self-mutilation (Gaertner et al. 1987).

Xylazine and other alpha-2 adrenergic agonists are frequently combined with ketamine for short-term immobilization and surgical anesthesia. These combinations, however, produce mild to severe dose-dependent hypotension, bradyarrhythmias and respiratory depression (Hart et al. 1984; Wixson et al. 1987). Oxygen supplementation and assisted ventilation is recommended. Ketamine/benzodiazepine combinations produce less cardiopulmonary depression and analgesia, but good muscle relaxation.

In rats and mice, acute reversible lens opacity has been observed with xylazine and xylazine/ketamine (Calderone et al. 1986). These “cataracts” were associated to a varying degree with proptosis, obtunded blink response, corneal surface drying, and mydriasis. Reversible lens opacity due to dehydration has been observed by this author.

Although moderately effective for minor surgery in rats and gerbils, very high tiletamine/zolazepam dosages are required to prevent response to noxious stimuli in other species (i.e., mice, hamsters, and guinea pigs) (Silverman et al. 1983).

Propofol is used for induction and maintenance of anesthesia when administered as a continuous IV infusion or intermittent bolus. The propofol can be diluted with saline for injection in very small patients. Apnea is related to dose, rate of injection, and the presence of other drugs. The induction dose is dependent upon rate of administration (Larsson & Wahlström 1994). In rats, both fast (20 mg/kg/min) and slow (2.5 mg/kg/min) rates result in larger doses than those at an intermediate rate (10 mg/kg/min). Propofol is a poor analgesic. It is indicated for induction of healthy rodents in which vascular access can be attained.

Alfaxalone is a potent steroid hypnotic agent whose poor water solubility prompted the development of a 2-hydroxypropyl- β -cyclodextrin (HP β CD) formulation. It is similar to propofol, but can also be given intramuscularly. Large injection volume and cost usually precludes its use by the latter route in larger rodents. Alfaxalone is more readily eliminated from males than female due to differential clearance (Brewster et al. 1996). This can result in faster recovery for males. In rats, alfaxalone (10 mg/kg IP) was not analgesic and did not potentiate the antinociception of opioids (Winter et al. 2003).

INHALATION ANESTHESIA

Inhalation anesthesia is the primary component of most, if not all, clinical anesthetic regimens.

Inhalant Anesthetics

Isoflurane is associated with rapid induction and recovery, and rapid control of anesthetic depth. It produces a dose-dependent cardiopulmonary depression, does not sensitize the myocardium to catecholamine-induced arrhythmias, and is a poor analgesic (Imai et al. 1999). Sevoflurane is similar to isoflurane, except it produces even more rapid induction and recovery.

Inhalant Induction

For induction, inhalant anesthesia is used alone or as an adjunct to parenteral drugs. The anesthetic is administered into a chamber or through a mask. The advantage of an induction chamber is the animal is not manually restrained during the involuntary excitement phase of induction. This reduces injury to handler and patient. The disadvantages include greater potential for environmental contamination with inhalation anesthetic and difficulty in monitoring.

Mask induction of manually restrained animals, without premedication and supplemental injectable anesthesia, is not recommended. Anesthetic chambers and masks are opaque to allow visualization of the patient. Chambers can be made from commercial plastic containers and sized to the animal (Fig. 66.4). The chamber top should be able to be secured to prevent the animal forcibly opening it and escaping. For induction of an awake or lightly sedated animal, inhalant anesthetic is introduced into the container through one opening, and waste gas removed from another opening. The vaporizer is set at maximum

Figure 66.4. Small- to medium-sized rodents (e.g., agouti) can be induced with inhalant anesthetics administered into a chamber. These induction chambers can be made from commercially available plastic boxes that should be opaque and have a secure top.

concentration, and oxygen flow rate set at 2–4L/min depending upon the size of the container. It will take a period of time for the concentration in the induction chamber to equilibrate with the vaporizer setting. The animal loses its righting response in 5–10 minutes and is removed from the chamber. A mask is placed over its nose and mouth, and the chamber is removed outside or closed to allow waste gases to be safely voided to the atmosphere. The animal is then either maintained using the mask or intubated when it is sufficiently relaxed.

When maintaining anesthesia with a mask, it is important to have the animal's head and neck in extension to facilitate air movement. Respiratory pattern, rate, and noise should also be assessed to ensure minimum resistance to breathing. If the animal appears to be having respiratory difficulty, move the head and neck to see whether the obstruction can be corrected. If not, use cotton tipped applicators to clear the oropharynx and nares. If this fails to relieve the problem, intubate or wake the animal and cancel the procedure.

Equipment

Small size is an indication for a nonbreathing system for administration of inhalant anesthetics. T-piece breathing systems are recommended for the smallest. Rebreathing bags can be constructed from small balloons to facilitate visualization of respiratory movement. Fresh gas flow rate for nonbreathing systems is about 200 mL/kg/min.

Inhalation anesthesia is often maintained with a mask connected to the breathing system. Systems have been developed for small rodents that also allow concurrent scavenging of waste anesthetic gases (Levy et al. 1980; Mauderly 1975). These usually include the fresh gas line entering the mask and an exit line for removal of waste gases.

Endotracheal Intubation

Respiratory obstruction and hypoventilation are common limitations to diagnostic and surgical procedures. With practice and the use of appropriate technique and equipment, intubation should be a routine standard of care in some rodents.

There are a variety of commercially available endotracheal tubes; the smallest cuffed and uncuffed tubes have a 3- and 1-mm internal diameter (ID), respectively. Guidelines for endotracheal tube size are given in Table 66.4. Endotracheal tubes are preferably opaque for visualization of condensation or occlusion with mucous or blood. For the smallest patients, endotracheal tubes are constructed from over-the-needle catheters or urinary catheters.

Guinea pigs present many obstacles to routine intubation. Their cheek pouches frequently contain stored food and they readily regurgitate if the oropharynx is

Table 66.4. Guidelines for endotracheal tube size selection in rodents

Species	Endotracheal tube internal diameter (mm)
Rat	16- to 18-gauge over-the-needle catheter
Guinea pig, chinchilla	14- to 16-gauge over-the-needle catheter, ≤ 2
Hamster	16-gauge over-the-needle catheter
Eastern Gray Squirrel	≤ 2
Prairie dog	2.0–2.5
Capybara	6.0

stimulated. They produce profuse salivary secretions that can be controlled, in part, by glycopyrrolate. The soft tissue at the base of the tongue is readily traumatized by a laryngoscope blade resulting in profuse hemorrhage. The soft palate is fused to the base of the tongue, and entry to the glottis is through the small opening of the palatal ostium (Timm et al. 1987). The palatal ostium is also present in chinchillas and capybaras, and probably other hystericomorph rodents. The glottis is also very small relative to the size of the animal. For these reasons, this author rarely intubates guinea pigs, but has had success using a blind technique. However, other authors describe intubation of dorsally recumbent animals using direct visualization techniques with modified pediatric # 0 blades and 14-gauge over-the-needle catheters (Kujime & Natelson 1981).

Rat intubation usually involves direct visualization of the glottis. It requires magnification and a focused light source (e.g., rigid endoscope). One technique describes transillumination with a high intensity light source in contact with the skin surface in front of the neck near the pharyngoepiglottic region (Yasaki & Dyck 1991). This author uses a rigid endoscope or an otoscope attached to a # 2 ear speculum that has had the distal two-thirds of the tip along the right side removed (Tran & Lawson 1986). The rat is positioned in dorsal recumbency on a board. An elastic band is then affixed to the upper incisors and fastened to the board to extend the head and neck. The tongue is pulled forward and to the side, and a cotton-tipped applicator is used to clear any secretions from around the glottis. Topical application of local anesthetic on the glottis will reduce laryngospasm. A slight pressure exerted on the ventral surface of the neck may further facilitate visualization of the glottis. A blind technique, similar to that described above for other rodents, has also been reported (Stark et al. 1981).

Endotracheal tubes for rats are constructed from 14- to 16-gauge over-the-needle catheters. The needle stylette is cut to the same length as the catheter, and the end is then filed smooth so that the smoothed needle is approximately 1-mm shorter than the cath-

eter (Stark et al. 1981). Alternatively, a 70-mm length of malleable 20-gauge wire is used as a stylette (Tran & Lawson 1986). At 1.5 cm from the end of the catheter, the stylette is bent at a 30° angle. A surgical suture can be tied to the catheter at a point 4.5 cm from its end to prevent excessive insertion of the catheter into the trachea. Mucous obstruction is common and changing the tube may be necessary. This technique can also be used for hamsters.

Prairie dogs, chinchillas, squirrels, and other medium to moderately large rodents (e.g., African pouched rats, and maras) can routinely be intubated for inhalation anesthesia using a blind technique. The anesthetized rodent is laid in lateral recumbency, with the head and neck moderately extended. The tube is then passed in a similar manner to that described for the rabbit (Chapter 65). Alternatively, an endotracheal tube can be placed with the assistance of an endoscope. The tube is placed over the scope or alongside it (Fig. 66.5 and Fig. 66.6).

When in doubt, remove the endotracheal tube and reassess placement. The use of a pulse oximeter is invaluable for determining potential oxygenation problems due to airway obstruction. Correct endotracheal tube placement is determined by: (1) visualizing condensation on either the inside of the endotracheal tube or a metal surface placed at the end of the tube; (2) detecting air movement with hair placed in front of the tube; (3) watching the nonbreathing bag; (4) the response to intubation (coughing etc.); and (5) the

detection of exhaled carbon dioxide on a capnograph. To insure the tube has not been placed into a single bronchus, premeasure the tube before use, and auscultate both lung fields for respiratory sounds after intubation.

MONITORING

Monitoring is described in Chapter 3. It is recommended that a trained person be assigned as anesthetist for each patient. This facilitates monitoring, recording, and supportive care, and saves time when intervention is required.

Unconsciousness is based on anesthetic dose and vaporizer setting, muscle relaxation, decreased reflex activity, and absence of limb and body movement. Palpebral and corneal reflexes are observed at 0.8 minimum alveolar concentration (MAC), but are abolished at >2.0 MAC (Imai et al. 1999). The corneal reflex, however, is a poor guide to anesthetic depth (Imai et al. 1999). A fixed dilated pupil, unresponsive to light, is a cross-species indicator of excessive depth. Anal tone is retained until deep anesthetic levels, but is difficult to assess in small rodents.

Pain and nociceptor responses are assessed with a toe, ear, and tail pinch, or a skin incision. Increasing depth is assumed when muscle tone (e.g., jaw muscle and anal sphincter) decreases, palpebral and corneal reflexes are obtunded, and respiration pattern becomes regular and even. Sudden tachycardia, hypertension, or

Figure 66.5. For endotracheal intubation of chinchillas and other medium to large rodents the glottis can be visualized with an endoscope.

Figure 66.6. Although large, capybaras are difficult to intubate. In this animal, an endoscope is being placed directly into the glottis of an anesthetized animal, and the endotracheal tube is then slid off the endoscope.

tachypnea in response to stimuli is indicative of inadequate anesthetic depth or analgesia.

Rodent heart rates are determined by temperature, size, metabolism, respiratory state, and the presence or absence of painful stimuli. Heart rate is inversely related to body size. The resting heart rate for mammals is calculated from the allometric equation $241 \times M_b^{-0.25}$, where M_b = bodyweight (kg) (Schmidt-Nielsen 1984). A heart rate 20% above or below the calculated rate for an individual is considered either tachycardic or bradycardic, respectively.

The esophageal stethoscope is not practical to use in small rodents, and it may induce regurgitation in guinea pigs. Alternatively, a quality pediatric stethoscope is used. The electrocardiograph should have a multichannel oscilloscope with nonfade tracing and freeze capabilities. Additionally, it must be able to record at speeds of 100 mm/s and amplify the signal to at least 1 mV equal to 1 cm. Standard lead positions are used.

The Doppler flow detector is used anywhere there are major arteries close to the skin. These include the ventral aspect of the tail base, the carotid, femoral, and auricular arteries, and directly over the heart. Potential sites for indirect blood pressure measurement include the legs, forearms, tail, and ears. Indirect blood pressure measurement techniques have been designed and validated for use in rats (e.g., Ibrahim et al. 2006; Widdop & Li 1997).

As with cardiac auscultation, evaluation of the respiratory system requires a good quality stethoscope with appropriate head and length of tubing, and an experienced ear. Pulse oximetry has been evaluated in rats, and appears accurate at hemoglobin saturation levels greater than 70% (Decker et al. 1989). Potential sites for placement of transmission pulse oximeter sensors include the ear, tongue, buccal mucosa, paw, vulva, prepuce, and proximal tail (Decker et al. 1989). A reflectance pulse oximeter sensor is used in either the esophagus or the rectum or applied to the skin/fur surface on the ventral aspect of neck overlying the carotid artery (rat).

Hypothermia is common in anesthetized rodents because of the large surface area-to-volume ratio. Additionally, many anesthetics suppress normal thermoregulatory mechanisms. Further, anesthetic gases are of low humidity and temperature. Body temperature is preferably measured continuously, and the thermometer should be sufficiently small to be used in small patients. For measurement of core body temperature, it is necessary to use a temperature probe attached to an esophageal stethoscope.

SUPPORTIVE CARE

Vascular access is discussed earlier. The cephalic vein is able to be catheterized in medium to large rodents (Fig.

Figure 66.7. An anesthetized fox squirrel. The animal was intubated with an uncuffed 2-mm ID tube using a blind technique. A capnograph is used to assess correct placement. A 24-gauge over-the-needle has been placed in the cephalic vein for fluid administration. A pediatric stethoscope is being used to monitor heart rate.

66.7). Small volume infusors are essential for accurate fluid infusion in small patients. Some can be preprogrammed to flow rates for emergency and other drugs, so that all that is necessary for administration is to enter the bodyweight of the animal. They also allow a continuous infusion, which is preferable to bolus injection.

General anesthetics usually produce a dose-dependent ventilatory depression. This effect may be either additive or synergistic, with underlying disease resulting in marked hypercapnia and/or ventilatory arrest. High-inspired oxygen concentrations also decrease ventilatory drive. Ventilation is also affected by body position and compression of the respiratory exchange tissues by distended viscera and/or obesity. Inadvertent compression of the chest by surgeons is common in small exotic patients. Developing good hand position techniques, an attentive anesthetist, and the use of clear plastic drapes helps prevent this cause of hypoventilation.

Guinea pigs have relatively small-diameter tracheas, and are prone to airway obstruction because of regurgitation and profuse salivary secretions. Adequacy of ventilation is most accurately assessed using $P_a\text{CO}_2$. Capnography provides an indirect estimate of $P_a\text{CO}_2$ (Fig. 66.6), but is too inaccurate in most small exotic patients to be used for anything other than validation of successful endotracheal intubation. Visualization of chest wall movement is a deceptive guide to adequacy of ventilation. Consequently, the author recommends either assisted or controlled ventilation of intubated patients under general anesthesia. Doxapram is not recommended for use in hypoventilating patients unless intubation and mechanical ventilation is impossible or contraindicated.

Ventilation is either assisted or controlled by positive pressure either manually or mechanically. Many of the ventilators used in small animal anesthesia can be modified to ventilate rodents. A commercially available combination ventilator and anesthesia machine (Anesthesia WorkStation, Halowell EMC, Pittsfield, MA) has been designed for research rodents. It is both a circle system for delivery of inhalant anesthetic and an optional ventilator with an adjustable pressure safety limit. The advantage of mechanical ventilation is that it frees the anesthetist to concentrate on other tasks. The disadvantages are that mechanical ventilators require a thorough theoretical and technical understanding for their safe use, they require endotracheal intubation, and they produce positive intrathoracic pressures that interfere with venous return to the heart and may cause lung trauma.

Manual ventilation provides the advantage, with a skilled anesthetist, of rapidly adjusting ventilatory pressures and volumes, and responsiveness to the surgeon who may require brief irregular periods of ventilatory arrest to safely complete a procedure. Further research is necessary to evaluate the efficacy and appropriateness of ventilation techniques in small mammal practice. There may be situations where some hypoventilation is preferable to the adverse effects of positive pressure ventilation.

Administration of elevated inspired oxygen concentrations (>40%) will often overcome mild to moderate hypoxemia, assuming no major pulmonary shunting is present. Although mammals are susceptible to pulmonary oxygen toxicity, this syndrome is unlikely to be observed in patients maintained on high-inspired oxygen concentrations for 24 hours.

Minimizing anesthesia time and the use of warm surgical preparation solutions, wrapping the body, increasing the room temperature, and the use external heat sources (i.e., circulating warm water blankets and forced air warmers) reduces hypothermia. Electric heat blankets are not used because they have the potential to cause severe burns. Similarly, heated fluid bags placed in contact with the skin may cause burns. If endotracheal intubation is not possible, an indirect ventilation technique using a bulb inflator placed over the nose has been used in small rodents (Ingall & Hasenpusch 1966).

RECOVERY

The patient is placed in a warm, quiet environment and monitored. Supportive care is continued until the patient is fully alert and physiologically stable. Vascular access is maintained to allow emergency administration of drugs and fluids. Drugs, procedure duration, and the magnitude of physiologic dysfunction incurred determine duration and quality of recovery. Prolonged recovery is usually due to hypothermia, hypoglycemia,

and anesthetic overdose and/or impaired drug elimination. Rewarming will exacerbate underlying hypovolemia and hypoglycemia.

ANESTHETIC REGIMENS FOR SMALL DOMESTIC RODENTS

Drug dosages are given in Table 66.1, Table 66.2, and Table 66.3. Most anesthetic regimens for clinical patients are based around an inhalant anesthetic (i.e., isoflurane or sevoflurane). Endotracheal intubation, as discussed previously, is difficult in many pet rodent species. Premedication with glycopyrrolate is recommended in guinea pigs and other rodents that have profuse salivary secretions. Although small rodents can be induced either in an anesthetic induction box or by mask using an inhalant, it is recommended the animals be premedicated.

The benzodiazepines (i.e., midazolam and diazepam) are relatively safe, reduce response to handling, provide muscle relaxation, and decrease inhalant and other anesthetic requirements. They do not, however, provide any analgesia. Midazolam can be combined with a relatively low dose ketamine. The ketamine provides some analgesia. Alpha-2-adrenergic agonists (i.e., xylazine, medetomidine, dexmedetomidine, and detomidine) have the advantage of being able to be reversed by yohimbine, tolazoline, or atipamezole, as well as improved analgesia, but also produce more to sometimes severe cardiopulmonary depression.

Analgesics should always be included for painful procedures. Assuming good hydration, this author will combine an NSAID (i.e., meloxicam) in the initial premedication, as well as an opioid. Analgesics work best when given before the onset of nociception and pain. Although only a partial μ -opioid agonist, buprenorphine has a relatively prolonged duration of effect. Morphine or hydromorphone can also be used for severe pain. Tramadol and meloxicam be administered orally before and after a procedure, as well as at home.

ANESTHETIC REGIMENS FOR FREE-LIVING RODENTS

Capture techniques for free-living, primarily small rodents are well described by Barnett and Dutton (1995). The anesthetic techniques described for small captive rodents based on inhalant anesthetics will also work for the wild species. Where inhalant anesthetics are not available or impractical, then parenteral anesthetic protocols are required (Table 66.3).

Capybara

The largest living rodent, the capybara, weighs approximately 35–65 kg. Their large size and robust incisors make them difficult and dangerous to immobilize. They are also well adapted to aquatic systems, and will

retreat to water when threatened. They can hide immersed with just their nares breaking the surface under floating vegetation. It is imperative, therefore, to capture free-living animals away from water, and prevent their escape. Capybaras have been captured by lassoing, as well as darting, from horseback (Salas et al. 2004). Alternatively, they can be trapped in baited traps or corrals. Both techniques require dry area for capture.

In one study in capybaras, ketamine (10.0 mg/kg) and xylazine (0.5 mg/kg) provided the best immobilization and analgesia in comparison with tiletamine-zolazepam (5.0 mg/kg), and tiletamine-zolazepam (5.0 mg/kg) and levomepromazine (0.5 mg/kg) (Nishiyama et al. 2006). Drugs were administered intramuscularly using darts delivered by a blowgun. The tiletamine-zolazepam combination allowed approximately 1 hour immobilization for procedures where intense analgesia is not necessary. The addition of levomepromazine improved analgesia and muscular relaxation, as well as the duration of anesthesia and recovery time.

In another study in capybaras, an intramuscular combination of tiletamine:zolazepam (1.5 mg/kg), medetomidine (0.0075 mg/kg), and butorphanol (0.075 mg/kg) was preferable to tiletamine:zolazepam alone or combined with medetomidine (King et al. 2010) for immobilization. This combination provided adequate analgesia for intraperitoneal implantation of radio transmitters.

Beaver

The Eurasian (*Castor fiber*) and North American (*Castor canadensis*) beavers are the second largest rodents. Similar to capybaras, they are robust and potentially dangerous, and agile in water. Consequently, some form of physical or chemical immobilization is required for safe handling of these species.

Ketamine alone (10–15 mg/kg IM) successfully immobilized beaver for handling (Lancia et al. 1978). Inhalant anesthesia (halothane) following immobilization with a combination of ketamine (25 mg/kg IM) and diazepam (0.1 mg/kg IM) was safe and effective for handling and surgery for intraperitoneal implantation of radio transmitters in North American beavers (Greene et al. 1991). Anesthesia was maintained with halothane in oxygen via a semiclosed circle anesthetic circuit. Throughout the surgical procedure, all beavers had mean arterial pressure less than 60 mmHg and esophageal temperature less than 35°C. Respiratory acidemia was observed in spontaneously ventilating beavers, but not in beavers maintained with controlled ventilation.

In another study comparing anesthetic regimens for intraperitoneal implantation of radio transmitters in European beavers (*Cas. fiber*), a combination of medetomidine (0.05 mg/kg), ketamine (5 mg/kg), butorphanol (0.1 mg/kg), and midazolam (0.25 mg/kg) was preferred (Ranheim et al. 2004).

Alternatively, isoflurane or sevoflurane alone was used for surgical anesthesia in North American beavers (Breck & Gaynor 2003). After placement in a burlap bag, a mask was placed over the nose of the beaver through the bag and the inhalant anesthetic administered at the highest vaporizer setting until the animals became relaxed. The animals were not intubated.
