Authorization to photocopy items for internal or personal use, or the internal or personal use of specific clients, is granted by Blackwell Publishing, provided that the base fee is paid directly to the Copyright Clearance Center, 222 Rosewood Drive, Danvers, MA 01923. For those organizations that have been granted a photocopy license by CCC, a separate system of payments has been arranged. The fee codes for users of the Transactional Reporting Service are ISBN-13: 978-0-8138-1183-3/2014.

Designations used by companies to distinguish their products are often claimed as trademarks. All brand names and product names used in this book are trade names, service marks, trademarks or registered trademarks of their respective owners. The publisher is not associated with any product or vendor mentioned in this book.

The contents of this work are intended to further general scientific research, understanding, and discussion only and are not intended and should not be relied upon as recommending or promoting a specific method, diagnosis, or treatment by health science practitioners for any particular patient. The publisher and the author make no representations or warranties with respect to the accuracy or completeness of the contents of this work and specifically disclaim all warranties, including without limitation any implied warranties of fitness for a particular purpose. In view of ongoing research, equipment modifications, changes in governmental regulations, and the constant flow of information relating to the use of medicines, equipment, and devices, the reader is urged to review and evaluate the information provided in the package insert or instructions for each medicine, equipment, or device for, among other things, any changes in the instructions or indication of usage and for added warnings and precautions. Readers should consult with a specialist where appropriate. The fact that an organization or Website is referred to in this work as a citation and/or a potential source of further information does not mean that the author or the publisher endorses the information the organization or Website may provide or recommendations it may make. Further, readers should be aware that Internet Websites listed in this work may have changed or disappeared between when this work was written and when it is read. No warranty may be created or extended by any promotional statements for this work. Neither the publisher nor the author shall be liable for any damages arising herefrom.

Dedication

The second edition of *Zoo Animal and Wildlife Immobilization and Anesthesia* is dedicated to our dear friend and colleague, Dr. Greg Fleming (March 13, 1966–March 9, 2013).

How miserably things seem to be arranged in this world. If we have no friends, we have no pleasure; and if we have them, we are sure to lose them, and be doubly pained by the loss.

—Abraham Lincoln

Contents

Contributors	xi	13. Human Safety during Wildlife Capture	181
Preface	xvii	<i>Nigel Caulkett and Todd Shury</i>	
I. General		II. Invertebrates, Fish, Reptiles, and Amphibians	
1. Clinical Pharmacology	5	14. Invertebrates	191
<i>Leigh A. Lamont and Kurt A. Grimm</i>		<i>Cornelia I. Mosley and Gregory A. Lewbart</i>	
2. Monitoring	43	15. Bony Fish (Lungfish, Sturgeon, and Teleosts)	209
<i>Larissa Ozeki and Nigel Caulkett</i>		<i>Natalie D. Mylniczenko, Donald L. Neiffer, and Tonya M. Clauss</i>	
3. Airway Management	53	16. Elasmobranchs and Holocephalans	261
<i>Jonathan Cracknell</i>		<i>Natalie D. Mylniczenko, Tonya M. Clauss, and M. Andrew Stamper</i>	
4. Thermoregulation	65	17. Amphibians	303
<i>Jeff C. Ko and Rebecca A. Krimins</i>		<i>Eric Baitchman and Mark Stetter</i>	
5. Oxygen Therapy	69	18. Crocodilian Capture and Restraint	313
<i>Åsa Fahlman</i>		<i>Kent A. Vliet</i>	
6. Analgesia	83	19. Crocodilians (Crocodiles, Alligators, Caiman, and Gharial)	325
<i>Douglas P. Whiteside</i>		<i>Gregory J. Fleming</i>	
7. Physical Capture and Restraint	109	20. Venomous Reptile Restraint and Handling	337
<i>Todd Shury</i>		<i>Frederick B. Antonio</i>	
8. Zoo and Wildlife CPR	125	21. Squamates (Snakes and Lizards)	351
<i>Søren Boysen</i>		<i>Mads F. Bertelsen</i>	
9. Field Emergencies and Complications	139	22. Chelonia (Tortoises, Turtles, and Terrapins)	365
<i>Jon M. Arnemo, Alina L. Evans, Åsa Fahlman, and Nigel Caulkett</i>		<i>Alessio Vigani</i>	
10. Euthanasia	149	III. Bird Anesthesia	
<i>Murray Woodbury</i>		23. Avian Anatomy and Physiology	391
11. Remote Drug Delivery	155	<i>Ashley M. Zehnder, Michelle G. Hawkins, and Peter J. Pascoe</i>	
<i>Ramiro Isaza</i>			
12. Capture Myopathy	171		
<i>Jessica Paterson</i>			

viii CONTENTS

24. Cagebirds	399	42. Procyonids and Mustelids	607
<i>Michelle G. Hawkins, Ashley M. Zehnder, and Peter J. Pascoe</i>		<i>George V. Kollias and Noha Abou-Madi</i>	
25. Penguins	435	43. Viverrids	619
<i>Kate Bodley and Todd L. Schmitt</i>		<i>Anneke Moresco and R. Scott Larsen</i>	
26. Ratites	445	44. Hyenidae	627
<i>Jessica Siegal-Willott</i>		<i>Nina Hahn, John M. Parker, Gregory Timmel, Mary L. Weldele, and Wm. Kirk Suedmeyer</i>	
27. Raptors	459	45. Felids	635
<i>Patrick T. Redig, Michelle Willette, and Julia Ponder</i>		<i>Edward C. Ramsay</i>	
28. Galliformes and Columbiformes	473	46. Phocid Seals	647
<i>Darryl Heard</i>		<i>Michael Lynch and Kate Bodley</i>	
29. Free-Living Waterfowl and Shorebirds	481	47. Otariid Seals	661
<i>Daniel M. Mulcahy</i>		<i>Martin Haulena</i>	
30. Birds: Miscellaneous	507	48. Walrus	673
<i>Darryl Heard</i>		<i>David B. Brunson</i>	
IV. Mammal Anesthesia		49. Cetaceans	679
31. Monotremes (Echidnas and Platypus)	517	<i>Christopher Dold and Sam Ridgway</i>	
<i>Peter Holz</i>		50. Sirenians (Manatees and Dugongs)	693
32. Marsupials	521	<i>Elizabeth C. Nolan and Michael T. Walsh</i>	
<i>Peter Holz</i>		51. Elephants	703
33. Insectivores (Hedgehogs, Moles, and Tenrecs)	529	<i>William A. Horne and Michael R. Loomis</i>	
<i>Darryl Heard</i>		52. Nondomestic Equids	719
34. Edentata (Xenartha)	533	<i>Chris Walzer</i>	
<i>Gary West, Tracy Carter, and Jim Shaw</i>		53. Tapirs	729
35. Tubulidentata and Pholidota	539	<i>Sonia M. Hernandez, James Bailey, and Luis R. Padilla</i>	
<i>Jennifer N. Langan</i>		54. Rhinoceroses	741
36. Chiropterans (Bats)	543	<i>Robin W. Radcliffe and Peter vdB. Morkel</i>	
<i>Darryl Heard</i>		55. Nondomestic Suids	773
37. Prosimians	551	<i>Luis R. Padilla and Jeff C. Ko</i>	
<i>Cathy V. Williams and Randall E. Junge</i>		56. Hippopotamidae	787
38. Monkeys and Gibbons	561	<i>Michele Miller, Gregory J. Fleming, Scott B. Citino, and Markus Hofmeyr</i>	
<i>Rolf-Arne Ølberg and Melissa Sinclair</i>		57. Camelids	797
39. Great Apes	573	<i>Khursheed R. Mama and Chris Walzer</i>	
<i>Shannon Cerveny and Jonathan Sleeman</i>		58. Giraffidae	809
40. Canids	585	<i>Scott B. Citino and Mitchell Bush</i>	
<i>R. Scott Larsen and Terry J. Kreeger</i>		59. Cervids (Deer)	823
41. Ursids (Bears)	599	<i>Nigel Caulkett and Jon M. Arnemo</i>	
<i>Nigel Caulkett and Åsa Fahlman</i>			

60. Antelope	831	64. Bison	873
<i>Ray L. Ball and Markus Hofmeyr</i>		<i>Nigel Caulkett</i>	
61. Gazelle and Small Antelope	843	65. Lagomorphs (Rabbits, Hares, and Pikas)	879
<i>An Pas</i>		<i>Darryl Heard</i>	
62. Wild Sheep and Goats	857	66. Rodents	893
<i>Nigel Caulkett and Chris Walzer</i>		<i>Darryl Heard</i>	
63. Nondomestic Cattle	863	Index	905
<i>Julie Napier and Douglas L. Armstrong</i>

Preface

Welcome to the second edition of *Zoo Animal and Wildlife Immobilization and Anesthesia*. The publication of this edition occurs at a time when continual advances in wildlife anesthesia are being made. Increasingly, veterinarians, biologists, veterinary technicians, and others are challenged to provide exemplary care to threatened or endangered species. To meet these challenges, we continually strive to ensure the highest level of patient safety. The goal of this book is to provide an efficient method to access knowledge about wildlife anesthesia.

We wish to express our appreciation to all of our contributing authors. Their hard work, willingness to share their expertise, and their dedication to this field allow us to produce a high quality and clinically useful publication.

There is still much to learn about the anesthetic and analgesic management of our wildlife patients. We hope that this book can help augment educational experiences for veterinarians and veterinary students and provide important information about anesthesia in some of the most challenging species that veterinarians work with.

We recognize the monumental effort of Susan Engelken at Wiley for helping us organize the production of this book. Without her extraordinary effort and guidance, this book would not be possible.

We are very proud of our final product and feel that we have produced another excellent piece of work.

Gary West, Darryl Heard, and Nigel Caulkett

ZOO ANIMAL AND WILDLIFE IMMOBILIZATION AND ANESTHESIA

Second Edition

Section I

General

1

Clinical Pharmacology

Leigh A. Lamont and Kurt A. Grimm

INTRODUCTION

Pharmacology is the study of drugs and their interactions with organisms (Page & Maddison 2002). Pharmacology incorporates aspects of statistics, biochemistry, biology, pathology, and medicine. Failure to interpret the description of drugs' pharmacological properties in the context of the clinical picture (i.e., clinical pharmacology) can result in unintended outcomes.

The pharmacological data available for most drugs are mean values derived from a relatively small number of individuals (usually healthy individuals). While this approach provides a starting point for clinical use of drugs, individual responses can vary greatly due to disease states, body condition, environment, genetics, coadministered drugs, and many other factors. When the toxic dose is close to the therapeutic dose (as is often the case with drugs used for immobilization and anesthesia), careful titration of dose and patient monitoring are required. However, the nature of working with wildlife and captive nondomestic species often precludes baseline health assessment, individualization of dosing, and intensive patient monitoring. This is one factor associated with increased risk of adverse outcomes when capturing or anesthetizing nondomestic species. It should also be appreciated that advances in drug safety will likely result in only limited improvement of the safety of anesthesia and immobilization. Management of other risk factors through airway management, reduction of stress, and improvements in supportive care will also be beneficial.

PHARMACOKINETICS

Pharmacokinetics (PK) can be generally defined as what an organism does to a drug. Absorption, distribution, biotransformation, and elimination are processes that

determine the concentration of the drug at the site of action (i.e., biophase). Pharmacokinetic parameters are estimates of these processes in the group of animals studied. These estimates can be used to predict or understand the way a drug interacts with an organism. It is important to understand that pharmacokinetic parameters can vary between individual animals and can be influenced by many different drug- and organism-related factors. Additionally, pharmacokinetic parameters are derived using mathematical models selected by the investigator. There is usually no correlation between model components and anatomical structures.

PHARMACODYNAMICS

Pharmacodynamics (PD) can be generally defined as what a drug does to an organism. PD includes intended drug effects, as well as adverse drug actions. Drugs such as opioids, alpha-2 adrenergic agonists, and antimuscarinics act by binding to relatively well-characterized receptor complexes located on cellular membranes. Nonsteroidal anti-inflammatory drugs (NSAIDs) inhibit prostaglandin production by binding to cyclooxygenase enzyme isoforms. Relating plasma drug concentrations to observed NSAIDs actions can be complex in comparison with other drugs (e.g., opioids) due to the different nature of their action. Preexisting prostaglandins, as well as their slower process of inhibiting an enzyme system, confound the relationship between drug concentration and effect. The molecular actions of inhalant anesthetics have not been completely characterized, even though their clinical use has been well described (Steffey & Mama 2007).

Pharmacodynamic effects are predictable for most clinically used drugs. However, individual animal

responses can vary considerably. Additionally, the nature of capture of free-ranging and captive wildlife often makes accurate dosing and drug delivery difficult or impossible. Therefore, close monitoring of patient response and preparation for supportive care are paramount to safe immobilization and anesthesia.

INHALANT ANESTHETICS

Inhalant anesthetics are commonly used in companion animal veterinary practice. Their use under field conditions is limited due to the requirement for specialized delivery devices and a supply of delivery gas (e.g., oxygen). However, inhalant anesthetics are used commonly in controlled settings, such as zoological parks and research laboratories, because of the ease of titration of anesthetic depth and rapidity of recovery. Inhalant anesthetics should be delivered by a well-maintained anesthetic machine and properly trained individuals. While inhalant anesthetics are relatively safe, their low therapeutic index mandates frequent and careful monitoring of anesthetic depth.

Physics of Gases and Vapors

An understanding of the processes that influence the uptake and delivery of inhalant anesthetics allows the anesthetist to predict and respond to individual circumstances.

Brief Review of Molecular Theory Molecules in a liquid state have more vibrational energy than when in a solid state, and each molecule can move through the liquid. If heat is added to a liquid, each molecule gains more kinetic energy and eventually some overcome the forces exerted by their neighbors and are able to escape into the space above the liquid. This state is that of a gas or a vapor. A gas is a phase of matter that expands indefinitely to fill a containment vessel. A vapor is the gaseous state of a material below its boiling point.

A vapor is in equilibrium with the liquid beneath it. Because both gaseous and liquid molecules have kinetic energy, they are in constant motion. The molecules in the vapor phase are striking the liquid–gas interface and returning to the liquid while liquid molecules are leaving the interface to become vapor. The relationship between these two phases depends mainly on the physicochemical properties of the molecules and the temperature of the system.

Vapor Pressure Molecules in a gaseous state possess kinetic energy and collide with the walls of the containment vessel. These collisions produce a force on the walls. This force is spread over a surface area and therefore is a pressure (Pressure = Force/Area). This pressure is called the vapor pressure. Since kinetic energy increases directly with temperature, vapor pressure must always be given with reference to the temperature

Table 1.1. Anesthetic agent vapor pressures at 20 and 24°C

Anesthetic Agent	Vapor Pressure at 20°C in mmHg	Vapor Pressure at 24°C in mmHg
Methoxyflurane	23	28
Sevoflurane	160	
Enflurane	172	207
Isoflurane	240	286
Halothane	243	288
Nitrous oxide	Gas	Gas

it was measured at (e.g., vapor pressure of water is 47 mmHg at 37°C).

When many gases are present in a mixture, such as with atmospheric air or during delivery of inhalant anesthetics, each gas has a vapor pressure that is independent of the other gases (Dalton's law of partial pressures). It is convention to refer to vapor pressure as partial pressure under these conditions. Partial pressure of an anesthetic agent is analogous to the concept of "free drug" and is important for determining the effect of the anesthetic (e.g., the level of CNS depression correlates directly with the partial pressure of isoflurane within the brain) (see Table 1.1) (Steffey & Mama 2007).

Vapor Concentration Vapor (i.e., partial) pressure is important for the observed pharmacological effect of inhalant anesthetics. However, almost all anesthesiologists refer to the amount of anesthetic delivered in units of volumes % (said as volumes-percent), or just percent, which is a concentration. The fundamental difference between anesthetic partial pressure and anesthetic concentration is partial pressure relates to the absolute number of molecules and their kinetic energy whereas concentration refers to the number of molecules of anesthetic relative to the total number of molecules present.

Critical Temperature The critical temperature is the temperature above which a substance cannot be liquefied no matter how much pressure is applied. The critical temperature of nitrous oxide is 36.5°C. Consequently, nitrous oxide can be (and is) a liquid below this temperature, but is a gas at greater temperatures. Placing a nitrous oxide tank near a heat source will result in volatilization of liquid nitrous oxide, resulting in a high tank pressure and danger of explosion or tank venting.

The critical temperature of oxygen is –119°C. Therefore, at room temperature, oxygen cannot be liquefied. All compressed cylinders of medical oxygen contain only gas. There are liquid oxygen tanks, but the internal tank temperature is below –119°C.

Table 1.2. Selected partition coefficients of commonly used anesthetic agents

Anesthetic	Blood:Gas Partition Coefficient	Brain:Blood Partition Coefficient
Nitrous oxide	0.47	1.1
Desflurane	0.42	1.3
Enflurane	1.4	1.4
Sevoflurane	0.69	1.7
Methoxyflurane	12.0	2.0
Isoflurane	2.6	2.7
Halothane	2.9	2.9

Inhalation anesthetics. In: *Lumb and Jones' Veterinary Anesthesia*, 4th ed. (WJ Tranquilli, JT Thurmon, KA Grimm, eds.). Ames: Blackwell.

Henry's Law Henry's law states the solubility of a gas in a liquid is proportional to the pressure of the gas over the solution. It describes the solubility of an anesthetic in body fluids or other liquids. From it you can derive the following formula: $c = k \cdot P$; where c is the molar concentration (mol/L) of the dissolved gas and P is the pressure (in atmospheres) of the gas over the solution. For a given gas, k is the Henry's law constant and is dependent on temperature.

Partition Coefficient A partition coefficient is the ratio of the concentration of a substance in one medium relative to another at equilibrium. It is related to the solubility of an agent. At equilibrium, the partial pressure is the same throughout the body, including the alveolar gas, but the concentration of total drug may be very different due to partitioning into tissues or body fluids (Table 1.2) (Steffey & Mama 2007). Partition coefficients are not absolute constants for an anesthetic agent. Tissue composition may change as a function of age, sex, body condition, and so on, and these changes may influence partitioning.

Mechanism of Action of Inhaled Anesthetics The specific mechanism of action of most anesthetics remains unknown. Volatile anesthetics appear to share some common cellular actions with other sedative, hypnotic, or analgesic drugs. A sound theory of anesthetic action should provide an explanation for the observed correlation of potency with the oil/gas partition coefficient, the observation that a large number of diverse chemical structures can cause anesthesia, and explain why the agents produce side effects. Experimental work has implicated a protein "target" on a diverse population of ionophores that is required for anesthetic action (Franks & Lieb 2004). The alteration in ionophore conductance may be related to direct action of the anesthetic at a two amino acid sequence within the transmembrane spanning domains.

The protein receptor hypothesis postulates that protein receptors in the central nervous system are

responsible for the mechanism of action of inhaled anesthetics. This theory is supported by the steep dose-response curve for inhaled anesthetics. However, it remains unclear if inhaled agents disrupt ion flow through membrane channels by an indirect action on the lipid membrane, via a second messenger, or by direct and specific binding to channel proteins. Another theory describes the activation of gamma-aminobutyric acid (GABA) receptors by the inhalation anesthetics. Volatile agents may activate or facilitate GABA channels, resulting in hyperpolarized cell membranes. In addition, they may inhibit certain calcium channels, preventing the release of neurotransmitters and inhibit glutamate channels.

Evidence for the protein receptor theory includes the observation made by Franks and Lieb that a broad range of inhalant anesthetics inhibited the water-soluble enzyme firefly luciferase (Franks & Lieb 1984). This enzyme hydrolyzes luciferin to create light and is often a model for anesthetic action because the rank orders of potency of the anesthetics in animals parallels that of luciferase inhibition. Franks and Lieb studied the enzyme in a lipid free environment, with only the enzyme present, and observed the enzyme could be completely inhibited. This suggests the site of action is within the protein structure and is not strictly dependent on lipid. Franks and Lieb also noted that some anesthetics exist as stereoisomers and that the effects of these isomers can differ. However, when the stereoisomers are introduced into a lipid substrate, the physical effects on the lipid are identical. This is further evidence that the anesthetic is acting at a stereoselective "receptor" and would implicate a protein as the site of action.

Following up on the work by Franks and Lieb, Harrison, Harris, Mihic, and colleagues attempted to reconcile the apparent problem of the nonspecific action of anesthetics on a wide range of protein channels including glycine, glutamate, GABA, and other neurotransmitter activated channels (Mihic et al. 1997). For the anesthetic to act on all of these channels, one would expect a target amino acid sequence would be conserved among all channels or the anesthetic would be altering receptor function by distorting the surrounding environment. In their experiments, this group began making chimeric DNA encoding the c-terminal human GABA rho receptor subunit, which is an anesthetic insensitive receptor, and the N-terminal glycine-binding part of the human glycine alpha-receptor subunit that is situated in the transmembrane spanning domain. They expressed the cDNA in *Xenopus* oocytes and measured resulting chloride conductance. They determined the site of anesthetic action was within the N-terminal sequence of the third transmembrane spanning domain. The researchers then began to construct cDNA containing point mutations within this region and created receptors that were insensitive

to enflurane. They ultimately found two amino acids in the glycine receptor that abolished enflurane sensitivity when mutated. Changing the corresponding amino acids on the GABA receptor also abolished enflurane sensitivity. However, these mutations did not reduce the receptor's sensitivity to the injectable anesthetic propofol.

Inhalant Anesthetic Pharmacokinetics

Anesthetic Uptake and Distribution A series of partial pressure gradients, beginning at the vaporizer, continuing in the anesthetic breathing circuit, the airways, alveoli, blood, and ending in the tissues, will drive the movement of an anesthetic gas. The movement of that gas will continue until equal partial pressures are present throughout the system. Since the lung is the point of entry and exit to the body, the alveolar partial pressure governs the partial pressure of the anesthetic in all body tissues. Therefore, it is most important to understand how to influence the alveolar partial pressure. Increasing alveolar minute ventilation, flow rates at the level of the vaporizer, and inspired anesthetic concentration, can speed the delivery of anesthetic and increase the rate of rise of alveolar anesthetic partial pressure. Solubility, cardiac output, and the alveolar-to-venous anesthetic gradient are factors that determine the uptake of the anesthetic from the alveoli into the blood. Solubility describes the affinity of the gas for a medium such as blood or adipose tissue and is reported as a partition coefficient. The blood/gas partition coefficient describes how the gas will partition itself between the two phases (blood and alveolar gas) after equilibrium has been reached. Isoflurane for example has a blood/gas partition coefficient of approximately 1.4 (Steffey & Mama 2007). This means that if the gas partial pressures are in equilibrium, the concentration in blood will be 1.4 times greater than the concentration in the alveoli. A higher blood/gas partition coefficient means a greater uptake of the gas into the blood, therefore, a slower rate of rise of alveolar and blood partial pressure. Since the blood partial pressure rise is slower, it takes longer for the brain partial pressure of the gas to increase resulting in a longer induction time.

Increased cardiac output exposes the alveoli to more blood per unit time. The greater volume of blood removes more inhalant anesthetic from the alveoli, therefore lowering the alveolar partial pressure. The agent might be distributed faster within the body, but the partial pressure in the arterial blood is lower. It will take longer for the gas to reach equilibrium between the alveoli and the brain. Therefore, a high cardiac output usually prolongs induction time. The alveolar to venous partial pressure difference reflects tissue uptake of the inhaled anesthetic. A large difference is caused by increased uptake of the gas by the tissues during the induction phase.

Transfer of the gas from the arterial blood into tissues such as the brain will depend on perfusion and the relative solubility of the gas in the different tissues. The brain/blood coefficient describes how the gas will partition itself between the two phases after equilibrium has been reached. Isoflurane has a brain/blood coefficient of 2.7; therefore, when the system is at equilibrium the concentration in the brain will be 2.7 times greater than the concentration in the blood (Steffey & Mama 2007). All contemporary inhalation anesthetics have high adipose/blood partition coefficients. This means that most of the gas will accumulate in adipose tissue as time goes by. The partial pressure of the gas in adipose tissue will rise very slowly since this tissue has a high capacity (as indicated by the high adipose/blood partition coefficient). Inhalation anesthetics stored in obese patients may delay awakening at the end of long periods of anesthesia. Fortunately, adipose tissue has a relatively low blood flow and does not accumulate significant amounts of anesthetic during the short periods of anesthesia commonly encountered in veterinary medicine.

Elimination of Inhaled Anesthetics The rate of induction and recovery from anesthesia with inhalant anesthetics differs between agents due to differences in tissue solubility; however, general statements can be made. During induction, all tissue partial pressures are zero. During recovery, different tissues in the body have different partial pressures of anesthetic which is governed by the tissue anesthetic content and not the alveolar partial pressure. Recovery is not as controllable as induction of anesthesia. During recovery from anesthesia, elimination occurs due to exhalation and biotransformation.

Enzymes responsible for inhalant anesthetic metabolism are mainly located in liver and kidneys. Anesthetic elimination via metabolism is approximately 50% for methoxyflurane, 10–20% for halothane, 5–8% for sevoflurane, 2.5% for enflurane, about 0.2% for isoflurane, 0.001% for desflurane, and nearly zero for nitrous oxide (Steffey & Mama 2007). The amount of anesthetic eliminated from the body during anesthesia due to metabolism is small compared with the amount exhaled. However, anesthetic metabolism accounts for a larger proportion of the anesthetic clearance after anesthetic delivery ceases. The low, but prolonged, blood partial pressure of the anesthetic found after terminating delivery is no longer overwhelming the enzyme systems (enzymes become saturated above ~1 MAC), so metabolism accounts for a larger proportion of clearance than it did during exposure to high partial pressures.

Elimination of the anesthetic via the lungs can be complex. The first point to consider is what effect an increase in alveolar minute ventilation will have on recovery. During recovery, increasing minute ventila-

tion will decrease alveolar anesthetic partial pressure and increase the gradient for diffusion from the blood to the alveoli. This increases elimination, especially for most anesthetic agents with high blood/gas partition coefficients.

Another situation to consider is what effect a change in cardiac output will have on the rate of decrease of partial pressure of the inhalant anesthetic. During induction, high cardiac output will increase the rate at which anesthetic is removed from the lung, slowing the rate of rise of anesthetic partial pressure, slowing induction. When cardiac output is reduced (e.g., cardiogenic shock), there is a slower removal of anesthetic and subsequently a faster rate of rise of alveolar partial pressure and induction occurs. During recovery, a high cardiac output will increase the rate at which anesthetic is returned to the lung for excretion. Since the partial pressure of anesthetic in the blood is determined by the tissues, the higher blood flow will shorten recovery. During low cardiac output situations, there will be a slower recovery due to the decreased rate at which tissue anesthetic partial pressure decreases.

The last major influence on the rate of induction and recovery is the solubility of the anesthetic agent. Agents with high blood/gas solubility will be partitioned into the blood to a greater extent than agents with low blood/gas solubility. The blood acts as a depot for agent maintaining anesthetic partial pressure. Agents with low blood/gas solubility do not partition into the blood to the extent of highly soluble agents, thus the decrease in partial pressure is faster and recovery time is reduced. Highly soluble agents have high blood concentrations, and it will take longer for the partial pressure to decrease if all other factors are equal. In summary, elimination of a volatile anesthetic depends on ventilation, cardiac output, and solubility of the gas in blood and tissue.

Control of the Partial Pressure of Delivered Anesthetic

Inhalant anesthetics can be classified as either gaseous (nitrous oxide and xenon) or volatile (isoflurane, sevoflurane, halothane, methoxyflurane, and desflurane). Gaseous anesthetics are usually delivered to the anesthesia machine under pressure, and their rate of delivery to the breathing circuit is controlled by a flow meter. Volatile anesthetics are liquids at room temperature and pressure, and are usually delivered by a specialized apparatus that controls the volatilization of the liquid, and proportioning of the vapor in the fresh gas delivered to the patient. A vaporizer can be as simple as a piece of cotton soaked with agent held near the nose (not recommended), or can be as complex as the Tec 6 vaporizer for desflurane.

The Breathing System With most modern anesthetic machines, the outflow gas from the vaporizer will be

delivered to the patient through a set of tubes and machinery collectively called a breathing system. There are many styles of breathing systems, each with a multitude of uses. It is important that the anesthetist understands how the type of breathing circuit used will impact the rate at which the anesthetic concentration can be changed and the relationship between the vaporizer setting and inspired concentration.

Waste Anesthetic Gases The health effects of chronic exposure to waste anesthetic gases are not completely known. The frequency of inhalant anesthetic use and the lack of significant associations between exposure, and most types of chronic toxicities (e.g., cancer, infertility, birth defects, etc.) would suggest there is only a very low risk (if any) associated with chronic exposure. However, certain individuals are highly susceptible to potentially life-threatening reactions, even with trace level exposure (e.g., malignant hyperthermia). In light of this, and with the admission that we do not completely understand all the risks associated with chronic exposure, it is generally agreed that the exposure of personnel be kept as low as reasonably acceptable (ALARA). In the United States, the Occupational Safety and Health Administration (OSHA) requires veterinary hospitals to maintain a system to prevent waste gases from building up in the area of use and can enforce exposure limits that are consistent with recommendations offered by the National Institute of Occupational Safety and Health (NIOSH). The NIOSH recommends that the maximum time-weighted average concentration of volatile halogenated anesthetics should not exceed 2 ppm when used alone or 0.5 ppm when used with nitrous oxide, and that nitrous oxide concentration should not exceed 25 ppm (American College of Veterinary Anesthesiologists 1996).

Minimum Alveolar Concentration (MAC)

The measurement of the dose of an inhalant anesthetic is the minimum alveolar concentration (MAC) multiple. It is defined as the minimum alveolar concentration at 1 atm, required to prevent gross purposeful movement in 50% of the subjects tested, following a 60-second application of a supramaximal stimulus (Steffey & Mama 2007). One MAC is by definition the EC_{50} (i.e., effective concentration in 50% of patients) for that agent. Animals awaken from anesthesia at approximately 0.5 MAC, surgical anesthesia occurs at approximately 1.3 MAC, and severe autonomic nervous system depression occurs around 2 MAC. Birds and many reptiles do not have true alveoli so the concept of MAC has been modified or redefined to be the minimum anesthetic concentration. It is not identical to MAC from other species, but closely approximates it in many ways.

Physiological and Pharmacological Factors that Alter MAC Minimum alveolar concentration is age dependent,

being lowest in newborns, reaching a peak in infants, and then decreasing progressively with increasing age (Lerman et al. 1983, 1994; Taylor & Lerman 1991). Increases in MAC can also occur from hyperthermia and hypernatremia, and decreases in MAC can result from hypothermia, hyponatremia, pregnancy, hypotension, and drugs, such as lithium, lidocaine, opioids, and α_2 -adrenergic agonists.

General Pharmacological Actions of Inhalant Anesthetics

Inhalant anesthetic agents have more similarities than differences with respect to their effects on vital organ systems. The differences are primarily related to the speed and magnitude with which the changes occur. There are a few classic differences that have been included in the following synopsis.

Central Nervous System All inhalant general anesthetics alter consciousness, memory, and pain perception by acting on the central nervous system. Most inhalant anesthetics cause a mild to moderate decrease in the cerebral metabolic requirement for oxygen (CMRO₂), and they usually have minimal effects on cerebral blood flow autoregulation at low MAC multiples (Mielck et al. 1998, 1999). Patients with intracranial hypertension should not be anesthetized, with nitrous oxide because it may cause an increase in CMRO₂ (Algotsson et al. 1992; Hoffman et al. 1995; Roald et al. 1991). Halothane is also a poor choice because of its significant effects on cerebral blood flow autoregulation (Steffey & Mama 2007). Isoflurane, sevoflurane, and desflurane are the inhalants of choice at this time.

Cardiovascular System Most inhalant anesthetic agents cause direct myocardial depression. Halothane is the most depressant on contractility; however, it generally has the fewest effects on vascular resistance (Steffey & Mama 2007). Isoflurane, enflurane, sevoflurane, and desflurane cause some degree of vasodilatation, which tends to improve forward blood flow and maintain tissue perfusion. The reduction in afterload also tends to offset some of the direct myocardial depressant effects and may result in a net improvement in cardiac output. Nitrous oxide is a sympathomimetic and can improve contractility, blood pressure, and heart rate at light levels of anesthesia. Rapid changes in anesthetic concentration (especially with desflurane) may result in a sympathetic response and temporarily increase cardiac work.

Respiratory System All anesthetics tend to depress the chemoreceptor response to carbon dioxide leading to an accumulation of carbon dioxide and a respiratory acidosis unless ventilation is assisted or controlled. The ether derivatives tend to be the most depressant; however, all agents may cause significant depression.

Most inhalant agents may interfere with hypoxic pulmonary vasoconstriction and may worsen ventilation-perfusion matching in the lung. This is most dramatic in larger animals where significant pulmonary shunting is often observed.

Genital–Renal Systems Most anesthetics cause a decrease in renal perfusion and an increase in antidiuretic hormone (ADH) secretion. Inhalant anesthetics may be the safest anesthetic techniques in anuric renal failure since pulmonary excretion is not dependent upon renal function.

Inhalant anesthetics may cause an increase in postpartum uterine bleeding. This is a bigger consideration in primate anesthesia due to placentation characteristics. Isoflurane, sevoflurane, desflurane, and nitrous oxide have been advocated for use during Caesarian section because of the rapid onset and termination of effect, and the transient effects on the delivered fetuses. Methoxyflurane and halothane are less desirable due to their greater solubility and slower elimination.

Clinically Useful Inhalant Anesthetics

Nitrous Oxide Nitrous oxide is commonly used in combination with a primary inhalant or injectable anesthetic drug. The reason it is not useful in veterinary anesthesia as a solo anesthetic is because of its low potency. Nitrous oxide's MAC value has been estimated to be near 100% for humans and closer to 200% for veterinary patients. It is obvious that 200% nitrous oxide cannot be delivered; in fact, no more than 79% nitrous oxide can be safely delivered without creating a hypoxic gas mixture. In practice, it is common to use a 50% nitrous oxide mixture with the balance of the mix being oxygen. If 50% nitrous oxide is delivered to an animal, it is only providing approximately 0.25 MAC of anesthesia. A potent volatile anesthetic, injectable agent, or other sedative/analgesic drug must supply the remaining 0.75 MAC. Because of this limited anesthetic effect, nitrous oxide use for anesthetic maintenance is not widespread in veterinary medicine. Nitrous oxide is used by some anesthetists during induction of anesthesia for the *second gas effect*. Since nitrous oxide is present in the inspired gas mixture in a relatively high concentration and it rapidly diffuses into the body from the alveoli, the rate of rise of partial pressure of a second coadministered inhalant anesthetic is increased, and induction time can be shortened.

Nitrous oxide has a low blood/gas partition coefficient and has a rapid onset and recovery. The gas can diffuse out of the blood so rapidly that if nitrous oxide delivery is suddenly halted and supplemental oxygen is not administered, a situation known as *diffusion hypoxia* may result. Diffusion hypoxia happens when the mass movement of nitrous oxide down its partial pressure gradient results in high alveolar nitrous oxide

partial pressure at the expense of oxygen and nitrogen partial pressures. Since breathing room air will result in an alveolar oxygen partial pressure of approximately 100mmHg under ideal circumstances, any displacement of oxygen by nitrous oxide will result in alveolar hypoxia. Diffusion hypoxia can be minimized or prevented by continuing the administration of oxygen enriched gas for 5–10 minutes following the discontinuation of nitrous oxide. This helps because during normal breathing, 100% oxygen should result in an alveolar oxygen partial pressure close to 500mmHg. The partial pressure of oxygen can drop a lot further before hypoxia develops.

Nitrous oxide is contraindicated in animals with pneumothorax, gastric dilatation/rumen tympany, gas embolism, and other conditions that are exacerbated by accumulation of gas inside a closed space. This effect is caused by diffusion of nitrous oxide out of the blood into the preexisting gas space in an attempt to establish equilibrium. Nitrous oxide is also contraindicated in animals with gas diffusion impairment, such as interstitial pneumonia. These animals typically have low arterial oxygen partial pressure when breathing oxygen-rich mixtures. The dilution of oxygen by nitrous oxide will lower the inspired oxygen partial pressure and may worsen hypoxemia.

Halothane Halothane was a major advancement in inhalant anesthesia in its day. It was introduced in the late 1950s and was potent, nonirritating, and nonflammable. Chemically, it is classified as a halogenated hydrocarbon, and it is not chemically related to the ethers. Halothane was used widely in human anesthesia until it became apparent there were potentially fatal adverse effects associated with its use. Human patients developed a syndrome known as *halothane hepatitis* (Daghfous et al. 2003; Neuberger 1998). This rare, but life-threatening, complication is still somewhat of a mystery, although an immunological etiology is implicated. The disease appears as a fulminant hepatitis, similar to that seen with viral hepatitis, which develops after a short period of apparent recovery. A second more common form of hepatitis is less severe and is characterized by a reversible elevation in liver enzymes. The etiology of this second form is thought to be anesthetic related hepatic hypoxia and does not appear to be immune related. Diagnosis of the correct form is important since a repeated exposure to halothane, or any of the volatile agents producing trifluoroacetic acid, is more likely to trigger the immunologically mediated form and result in high morbidity and mortality. Both forms are not commonly documented in veterinary patients; however, transient elevation of liver enzymes may occur postoperatively in some patients. A thorough diagnostic workup is required due to the nonspecific and multifactorial etiology of elevated liver enzymes.

A second complication associated with halothane anesthesia is the development of arrhythmias. Halogenated hydrocarbon anesthetics, especially halothane, can sensitize the myocardium to the arrhythmogenic effects of epinephrine. Halothane is generally contraindicated in patients that are predisposed to ventricular arrhythmias (e.g., hypoxia, trauma, or myocardial disease) (Steffey & Mama 2007). Arrhythmias that develop during halothane anesthesia may resolve when the anesthetic agent is switched to isoflurane or sevoflurane. Other causes of perianesthetic arrhythmias should also be ruled out.

Halothane undergoes extensive hepatic metabolism (~20%) and is not chemically stable (Steffey & Mama 2007). Commercially available halothane contains thymol, a preservative, that does not volatilize to the same degree as halothane. This results in a sticky residue inside the vaporizer that should be cleaned out during periodic maintenance. Veterinary use of halothane is declining due to the increasing popularity of isoflurane, and sevoflurane and its limited availability worldwide.

Isoflurane Isoflurane is arguably the most widely used veterinary inhalant anesthetic in the world today. Isoflurane is stable, potent, and undergoes little metabolism. Isoflurane can be irritating to airway tissues at high inspired concentrations and its use for induction in people has been limited because of patient complaints and complications. However, in veterinary medicine, isoflurane mask induction is still common. Isoflurane is a potent agent (MAC ~1.3% in dogs) and has a high saturated vapor pressure (~240mmHg at room temperature) (Steffey & Mama 2007). These characteristics, coupled with the fact that it is possible to cause rapid partial pressure changes in the brain, would suggest that only precision vaporizers located outside the circuit (VOC) should be used to deliver the agent. However, several reports of the use of modified VIC vaporizers suggest that this type of anesthetic system can be used to safely administer the agent (Bednarski et al. 1993; Laredo et al. 1998).

Isoflurane metabolism is minimal (less than 1%) and fluoride induced nephrotoxicity is uncommon. Isoflurane and many of the ether-derivative volatile agents are excellent vasodilators and can cause or worsen hypotension. Administration of fluids and/or sympathomimetic agents can usually counteract the observed hypotension. Likewise, administering pre-anesthetic drugs (e.g., opioids) that reduce the amount of inhalant required will also reduce the degree of vasodilation.

Desflurane Desflurane use in veterinary medicine is limited to academic institutions and a very limited number of private practices. The main disadvantage to desflurane use is cost associated with the agent and

the cost associated with a specialized vaporizer that is required to deliver the drug. Desflurane is extremely insoluble and is capable of producing extremely rapid inductions and recoveries (Barter et al. 2004; Clarke 1999). Its main market is for human outpatient anesthesia where rapid recovery is a large cost savings. It is highly fluorinated, has a very low potency (MAC ~ 9%), and has a high saturated vapor pressure (~670 mmHg at room temperature) (Steffey & Mama 2007). Desflurane boils at 23°C and must be handled using a specialized apparatus for vaporizer filling. The vaporizer is specific for desflurane and is electrically heated to boil the desflurane so that a reliable vapor pressure will be produced. Then, sophisticated differential pressure transducers and electronic circuits calculate an injection ratio for delivery of the desired anesthetic concentration. Desflurane is very stable and undergoes almost no metabolism.

Sevoflurane Sevoflurane is the newest volatile inhalant anesthetic approved for veterinary use. Sevoflurane has a low blood/gas partition coefficient (~0.7) that is greater than desflurane and nitrous oxide, but about half of that of isoflurane. Extensive pulmonary elimination of sevoflurane minimizes the amount available for metabolism. Up to 3–8% of the sevoflurane dose is metabolized and appears in the urine as inorganic fluoride (Steffey & Mama 2007). This fluoride exposure does not appear to be clinically significant, although serum levels of fluoride can approach those previously reported to be nephrotoxic for methoxyflurane. Factors other than peak serum fluoride concentrations appear important for predicting the incidence of nephrotoxicity (Driessen et al. 2002).

Sevoflurane represents a deviation from the methyl ethyl ether structural theme present in other contemporary volatile anesthetics. Sevoflurane is chemically related to methyl-isopropyl ethers. The structure is significant because an important metabolite of most methyl-ethyl ether volatile anesthetic agents (trifluoroacetic acid) is a suspected trigger of halothane hepatitis. Sevoflurane cannot be metabolized to form this compound. This is not a major consideration in veterinary medicine, but is important in human anesthesia. Sevoflurane is also pleasant and non-irritating when used for mask induction and many pediatric anesthesiologists suggest this agent is the drug of choice for pediatric induction via mask. Sevoflurane is less potent than isoflurane (MAC ~2.3% for dogs and horses). When used for induction of anesthesia it is common to use 7–9% sevoflurane.

An early subject of controversy surrounding sevoflurane anesthesia was the production of compound A. Compound A is a degradation product produced when sevoflurane reacts with the carbon dioxide absorbent. Early toxicology studies performed in rats suggested that proximal tubular renal damage could result from

Table 1.3. Structure and characteristics of inhalation anesthetics

Agent	Year Introduced	Structure	Type
Halothane	1956	CF ₃ -CHClBr	Alkane
Isoflurane	1981	CF ₃ CHCl-O-CHF ₂	Ether
Enflurane	1972	CHClF-CF ₂ -O-CHF ₂	Ether
Methoxyflurane	1960	CHCl ₂ -CF ₂ -O-CH ₃	Ether
Desflurane	1992	CF ₃ CHF-O-CHF ₂	Ether

clinically relevant exposure to compound A. This led to the suggestion that sevoflurane should not be used in closed circuit anesthesia or with fresh gas flow rates lower than 2L per min. However, since that time, little clinical evidence of renal damage in humans and dogs has emerged, even with very low fresh gas flows. Some have suggested that rats have a 10–100 times higher level of the enzyme beta-lyase that is believed to convert the intermediate compounds of Compound A metabolism to a nephrotoxic molecule (Kharasch et al. 2005; Sheffels et al. 2004). Humans and dogs do not appear to have the same level of enzyme conversion and are therefore less susceptible to Compound A toxicity. Safety studies in most other rodents and exotic animals are not published and caution should be used when administering sevoflurane via a breathing system using a carbon dioxide absorbant until further safety data is available (Table 1.3).

INJECTABLE ANESTHETICS

Injectable anesthetics are an important family of compounds used for immobilization and anesthesia of wildlife. The dissociative anesthetics in particular are commonly combined with other adjunctive drugs, such as alpha-2 adrenergic agonists and opioids, to improve reliability and speed of onset of action.

Barbiturates

Barbiturates can be classified in several ways. One is by chemical structure. Oxybarbiturates are historically important, but not commonly used today due to their slower onset of action, long recovery characteristics, and relatively small margin of safety. Pentobarbital is the prototypical oxybarbiturate. It has been combined with several adjunctive drugs for anesthesia. The thio (i.e., sulfur substituted) analog of pentobarbital, thiopental, is still used by intravenous administration for induction of anesthesia in domestic animals. However, perivascular injection can result in tissue necrosis, and its use in nondomestic species is limited due to the inability to obtain reliable intravenous access prior to anesthetic induction and current availability problems.

Barbiturates cause anesthesia through global depression of CNS activity. This is accomplished through interference with nervous system impulse conduction. Like many other anesthetics, other excitable tissues can be affected, resulting in commonly encountered side effects, including depression of cardiorespiratory function. Barbiturates decrease cerebral blood flow (CBF) and cerebral metabolic requirement for oxygen (CMRO₂). Cerebral metabolic requirement for oxygen decreases progressively until electroencephalographic activity becomes isoelectric (Branson 2007).

Propofol

Propofol (2,6-diisopropylphenol) is commonly used for sedation, induction, and maintenance of anesthesia in humans and domestic species. Propofol is supplied as a milky white liquid for intravenous injection. It is insoluble in aqueous solution; therefore, it is usually formulated as an emulsion of 10% soybean oil, 2.25% glycerol, and 1.2% egg phosphatide. Some formulations of propofol (e.g., Diprivan[®], Propoflo[™]) do not contain preservative and will support bacterial and fungal growth should the drug become contaminated. This has led to the label recommendation of discarding unused drug at the end of the procedure or within 6 hours of opening a vial. A newer formulation has been available in some European countries (PropoClear[®]) which uses a different carrier solution than the traditional soybean emulsion. The inhibition of bacterial growth allowed a 28-day shelf life. However, there have been reports of tissue irritation following injection, and the product is being reevaluated. Some formulations have additives, such as benzyl alcohol (e.g., Propoflo28[®]), to improve stability or reduce the potential of contamination with storage. Species-sensitivities to these additives should be investigated before their use (Davidson 2001).

Propofol is classified as an ultrashort-acting injectable anesthetic agent. Duration of effect is typically 5–10 minutes in dogs and 5–20 minutes in cats. Its rapid recovery characteristics are maintained in most species following prolonged infusions. Recovery times may be prolonged in the cat (and other species that have reduced capacity for glucuronidation of drugs) following repeated doses or continuous rate infusions.

Propofol has been used in dogs, cats, horses, pigs, goats, sheep, and even birds. Wild turkeys, mallard ducks, pigeons, and chickens have been anesthetized with propofol, but there is significant cardiorespiratory depression in ducks and chickens, indicating birds may need ventilatory support during anesthesia (Machin & Caulkett 1998). Apnea and respiratory depression are the best known side effects of propofol administration. The incidence of apnea may be reduced by administering the drug over 60–90 seconds (Muir & Gadawski 1998). It would be prudent to be prepared to intubate

and support ventilation if apnea occurs. Pain is reported on propofol injection by some people. Muscle fasciculations and spontaneous twitching can occur in some animals.

Dissociative Anesthetics

Ketamine Most veterinary formulations of ketamine are a racemic mixture consisting of two optical enantiomers. However, in many countries, (*S*)-ketamine is available as a human or veterinary product. The *S* enantiomer is less cardiodepressant and has a fourfold greater affinity for the phencyclidine site in the NMDA (N-methyl-D-aspartate) receptor. Serotonin transport is inhibited twofold by the *R* form. Some of ketamine's effects are not stereoselective. Norepinephrine release is equivalent from the *S* and *R* forms (Kohrs & Durieux 1998).

Ketamine can be administered intramuscularly to anesthetize animals which are not easily given drugs intravenously. Intramuscular administration will produce a longer duration of anesthesia than intravenous administration, but the recovery is usually longer and can be accompanied by more dysphoria. Recovery from ketamine appears to be due to redistribution and metabolism similar to the thiobarbiturates. Hepatic biotransformation to norketamine (a.k.a. metabolite I) and dehydronorketamine (aka metabolite II) is the major route of metabolism in most species studied. It was thought ketamine was excreted unchanged in the urine of cats, however this originated from one paper published in 1978 by Gaskell et al. and since that time it has been shown by Waterman that biotransformation is an important route of elimination in domestic cats (Waterman 1983). Norketamine is about one-third to one-fifth as potent as the parent compound but may contribute to the prolonged analgesic effects of ketamine (Kohrs & Durieux 1998).

Ketamine produces a form of anesthesia that is different from other hypnotic drugs. In general terms, ketamine induces anesthesia and amnesia by functional disruption (dissociation) of the CNS through marked CNS stimulation resulting in catalepsy, immobility, amnesia, and marked analgesia. Electroencephalographic analysis indicates that depression of the thalamocortical system occurs in conjunction with activation of the limbic system. Awakening from ketamine anesthesia in people is frequently characterized by disagreeable dreams and hallucinations. Sometimes, these unpleasant occurrences may recur days or weeks later. Almost half of adults over the age 30 exhibit delirium or excitement, or experience visual disturbances. The occurrence of adverse psychological experiences is much lower in children. The incidence of adverse psychological experiences in animals is unknown; however, a significant number of animals transiently vocalize and have motor disturbances during recovery.

Ketamine's neuropharmacology is complex. The compound interacts with N-methyl-D-aspartate and non-NMDA glutamate receptors, nicotinic, muscarinic cholinergic, monoaminergic, and opioid receptors. In addition, there are interactions with voltage-dependent ion channels, such as Na⁺ and L-type Ca²⁺ channels. It is believed that the NMDA receptor antagonism accounts for most of the analgesic, amnestic, psychomimetic, and neuroprotective effects of the compound, but the exact mechanism of its anesthetic action is not known. NMDA receptor activation is believed to play a role in the "memory" of the central nervous system, which is involved in the "wind-up," hyperalgesia, and allodynia seen in certain pain syndromes (Kohrs & Durieux 1998).

Ketamine can increase the CMRO₂ due to increased metabolic activity associated with increased activity in certain areas of the brain. Intracranial pressure (ICP) also increases, possibly because of two mechanisms: (1) Ketamine can increase mean arterial blood pressure so cerebral blood flow (CBF) can increase and ICP passively increase in patients with altered autoregulation, and (2) Ketamine can depress respiration increasing P_aCO₂. The brain responds to elevations in P_aCO₂ by increasing CBF which will increase ICP. Ventilation may reduce the increase in CBF. Current clinical dogma dictates avoiding ketamine in patients with suspected head trauma.

Ketamine causes a characteristic breathing pattern termed *apneustic breathing*, characterized by prolonged inspiratory duration and relatively short expiratory time. When ketamine is administered by itself, it typically causes minimal respiratory depression that is short-lived. Hypoxic and hypercapnic respiratory regulation appears to remain intact. However, ketamine is seldom given alone. It is often combined with benzodiazepines, acepromazine, opioids, or alpha-2 adrenergic agonists. The combined effect of these drugs is usually decreased minute ventilation, increased P_aCO₂, and mild respiratory acidosis.

Ketamine, when given to animals with functioning sympathetic nervous systems, generally increases heart rate and arterial blood pressure. Cardiac output will usually stay the same or slightly increase. Ketamine is seldom given alone to healthy animals. The use of adjunctive drugs, such as benzodiazepines, acepromazine, or alpha-2 adrenergic agonists, tends to blunt the sympathomimetic effect of ketamine and will tend to decrease cardiac function and decrease arterial blood pressure.

Tiletamine/Zolazepam Tiletamine/zolazepam combinations are available in a fixed ratio. Telazol[®] is a non-narcotic, nonbarbiturate, injectable anesthetic agent. Chemically, Telazol[®] is a combination of equal parts by weight of tiletamine hydrochloride (2-[ethylamino]-2-[2-thienyl]-cyclohexanone hydrochloride), an aryl-

aminocycloalkanone dissociative anesthetic, and zolazepam hydrochloride (4-[o-fluorophenyl]-6,8-dihydro-1,3,8-trimethylpyrazolo[3,4-e][1,4]diazepin-7[1H]-1-hydrochloride), a benzodiazepine having minor tranquilizing properties. The product is supplied sterile in vials, each containing a total of 500 mg of active drug as free base equivalents and 288.5 mg mannitol. The addition of 5-mL diluent produces a solution containing the equivalent of 50-mg tiletamine base, 50-mg zolazepam base, and 57.7-mg mannitol per milliliter. The resulting solution has a pH of 2–3.5. Zoletil[®] is available in many countries outside North America and is commonly marketed as a mixture containing 25 mg/mL each of zolazepam and tiletamine (Zoletil 50) or 50 mg/mL each (Zoletil 100).

Duration of effect is dependent upon route of administration and amount of drug given. When used intravenously, it lasts approximately 15–20 minutes. When given intramuscularly, it may last 30–45 minutes. It is commonly used in place of ketamine and its duration is typically longer.

Tiletamine induces dissociative anesthesia similar to ketamine. It has the potential to cause seizure activity; however when combined with zolazepam, the incidence of seizures is greatly reduced. Its effects on CBF and ICP are similar to those of ketamine. Nephrotoxicity in New Zealand white rabbits has been reported following Telazol administration (Doerning et al. 1992). Anecdotally, tigers do not appear to recover well after Tiletamine/zolazepam, therefore its use is generally contraindicated. Tiletamine/zolazepam can be combined with other drugs to improve its analgesic and recovery characteristics.

Miscellaneous Anesthetics

Etomidate Etomidate has been used extensively as a hypnotic agent for the induction of anesthesia in man, but less commonly in other species. Etomidate is a rapidly acting, ultrashort acting imidazole derivative. The duration of effect following intravenous bolus administration is typically 5–10 minutes. Etomidate causes dose dependent CNS depression, leading to sedation, hypnosis, and finally an isoelectric electroencephalogram.

Etomidate, in contrast to almost all other induction agents, does not seem to cause significant depression of cardiac contractility and has minimal effects on heart rate, cardiac output, and arterial blood pressure. Elimination of etomidate occurs by ester-hydrolysis in plasma and in the liver at approximately equal rates. Metabolism of etomidate in the liver is a capacity-limited Michaelis–Menten process. Hepatic hydrolysis results in the corresponding inactive carboxylic acid. Etomidate will temporarily reduce steroidogenesis (Boidin 1985; Moon 1997). Steroid synthesis usually increases with the stress of anesthesia so the net effect may be little or no change (Dodam et al. 1990). It is

not a clinical contraindication except for animals with hypoadrenocorticism (Addison's disease.) Intravenous administration of etomidate may induce excitement, myoclonus, pain on injection, vomiting, and apnea during induction of anesthesia. Some animals may have purposeless myoclonic muscle movements during recovery from anesthesia. The frequency and severity of the side effects can be attenuated or eliminated by the administration adjunctive drugs, such as diazepam, acepromazine, or opioids prior to etomidate administration. A constant rate infusion of etomidate may result in hemolysis (Moon 1994; Van de Wiele et al. 1995). This is thought to be due to the propylene glycol carrier and the very high osmolality of available products (Doenicke et al. 1997).

Alphaxalone/Alphadolone

Saffan® Alphaxalone is a steroid anesthetic with a relatively wide margin of safety, little cardiovascular or respiratory depression, and minimal induction and recovery excitement. Alphaxalone is poorly soluble in water so to improve solubility, it is formulated with another steroid, alphadolone acetate, which also has anesthetic activity. The addition of alphadolone increases the water solubility of alphaxalone by threefold. One commercially available formulation, **Saffan®**, is a mixture of alphadolone, alphaxalone, and cremophor EL®. The cremophor is a nonionic surfactant, which makes the aqueous solution possible; however, cremaphor can cause histamine release and severe cardiovascular adverse events in some species (e.g., domestic dog). The main route of elimination is by biotransformation in the liver and secretion in the bile.

Alfaxan CD® Alphaxalone is available as a novel formulation that uses cyclodextran in water as a solvent rather than cremophor EL. The resulting compound lacks the histamine-releasing properties of **Saffan**, yet retains the therapeutic index and efficacy of alphaxalone.

OPIOIDS

All drugs classified as "opioids" are chemically related to a group of compounds that have been purified from the juice of a particular species of poppy, *Papaverum somniferum*. The unrefined extract from the poppy is called opium and contains approximately 20 naturally occurring pharmacologically active compounds, including morphine and codeine. In addition, numerous semisynthetic and synthetic analogs of these natural compounds have been developed for clinical use. The word opioid is typically used to encompass all chemical derivatives of the compounds purified from opium and will be the term used to describe this class of analgesics throughout this section.

The opioids are a versatile group of drugs with extensive applications related to the management of pain in companion animal veterinary medicine. In the past, their use in wild and exotic species has been largely limited to the ultra-potent agents utilized in remote capture techniques. However, with the rapid evolution of zoo animal medicine and surgery, the opioids are being used increasingly as analgesics for the management of surgical pain in a wide variety of species. Though there are few pharmacokinetic or pharmacodynamic studies involving opioids in wild and exotic animals, a general discussion of opioid pharmacology is relevant and may facilitate extrapolation from companion animal species.

Opioid Receptors

It is well known that exogenously administered opioids, such as morphine or heroin, exert their effects by interacting with specific opioid receptors and mimicking naturally occurring molecules known as endogenous opioid peptides. Based on work carried out over the past 20 years, it is now accepted that there are three well-defined types of opioid receptors, most commonly known by their Greek letter designations as μ (mu), δ (delta), and κ (kappa) (Harrison et al. 1998; Inturrisi 2002; Janecka et al. 2004; Kieffer 1999). This classic system of nomenclature has been under reconsideration for a number of years and during this time several alternative naming systems have been proposed leading to considerable confusion. In addition, a fourth type of opioid receptor, the nociceptin receptor (also known as the orphanin FQ receptor) has been characterized (Moran et al. 2000; Smith & Moran 2001). According to the most recent recommendations of the International Union of Pharmacology subcommittee on nomenclature, variations based on the Greek letters remain acceptable. Thus, mu, μ or MOP (for "mu opioid peptide"); delta, δ or DOP (for "delta opioid peptide"); kappa, κ or KOP (for "kappa opioid peptide"); and NOP (for "nociceptin opioid peptide") are considered interchangeable abbreviations. Distinct cDNA sequences have been cloned for all four opioid receptor types, and each type appears to have a unique distribution in the brain, spinal cord, and periphery (Smith & Lee 2003).

The diversity of opioid receptors is further extended by the existence of several subtypes of μ , δ , and κ receptors. Based on pharmacologic studies, there are thought to be at least three μ receptor subtypes, μ_1 , μ_2 , and μ_3 ; two δ receptor subtypes, δ_1 , and δ_2 ; and perhaps as many as four κ receptor subtypes, κ_{1a} , κ_{1b} , κ_2 , and κ_3 (Smith & Lee 2003). The discovery of opioid receptor subtypes generated great enthusiasm among researchers and introduced the possibility of developing subtype-specific therapeutic agents with favorable side effect profiles. At this point, however, the functional significance of these receptor subtypes remains unclear,

and distinct cDNA sequences corresponding to these subtypes have not yet been identified (Smith & Lee 2003).

In general, it appears that the μ receptor mediates most of the clinically relevant analgesic effects, as well as most of the adverse side effects associated with opioid administration (Kieffer 1999). Drugs acting at the δ receptor tend to be poor analgesics, but may modify μ receptor-mediated antinociception under certain circumstances and mediate opioid receptor "cross-talk." The κ receptor mediates analgesia in several specific locations in the central nervous system and the periphery; however, distinguishing μ - and κ -mediated analgesic effects has proven to be difficult (Kieffer 1999; Smith & Lee 2003). In contrast to the classic opioid receptors, the nociceptin receptor does not mediate typical opioid analgesia, but instead produces antiopioid (pronociceptive) effects (Inturrisi 2002; Janecka et al. 2004; Moran et al. 2000; Smith & Moran 2001). Due to the considerable structural homology between the three classically described opioid receptors, it is likely that there are significant interactions between these receptors in different tissues, and the loosely defined physiologic roles ascribed to each receptor type still require further clarification.

Endogenous Opioid Receptor Ligands

The opioid receptors discussed earlier are part of an extensive opioid system that includes a large number of endogenous opioid peptide ligands. Endogenous opioid peptides are small molecules that are naturally produced in the central nervous system and in various glands throughout the body, such as the pituitary and the adrenal (Janecka et al. 2004). Three classical families of endogenous opioid peptides have been identified: the enkephalins, the dynorphins, and β -endorphin. Each of these is derived from a distinct precursor polypeptide, pro-enkephalin, pro-dynorphin, and pro-opiomelanocortin, respectively (Janecka et al. 2004). These classical endogenous opioid peptides are expressed throughout the central nervous system, and their presence has more recently been confirmed in peripheral tissues as well (Janecka et al. 2004). There are considerable structural similarities between these three groups of peptides, and each family demonstrates variable affinities for μ , δ , and κ receptors. None of them bind exclusively to a single opioid receptor and none of them have any significant affinity for the nociceptin receptor. The physiological roles of these peptides are not completely understood at this time. They appear to function as neurotransmitters, neuromodulators and, in some cases, as neurohormones. They mediate some forms of stress-induced analgesia and also play a role in analgesia induced by electrical stimulation of discrete regions in the brain, such as the periaqueductal gray of the mesencephalon (Inturrisi 2002).

Nociceptin (also known as orphanin FQ) is the endogenous ligand for the more recently discovered nociceptin receptor. Nociceptin is derived from pro-nociceptin, and its amino acid sequence is closely related to that of the classical endogenous opioid peptides discussed earlier (Janecka et al. 2004; Moran et al. 2000). Despite this homology, nociceptin binding is specific for the nociceptin-receptor and the peptide does not appear to interact with μ , δ , or κ receptors. Furthermore, the physiologic effects of nociceptin are in direct contrast to the actions of the classical endogenous opioid peptides, with nociceptin producing a distinctly pro-nociceptive effect (Janecka et al. 2004; Moran et al. 2000; Smith & Moran 2001). The functional significance of nociceptin and its receptor remain to be elucidated, but additional insight into this novel opioid peptide may have substantial implications in future therapeutic drug development.

In addition to the enkephalins, dynorphins, β -endorphin, and nociceptin, there are now two other recently discovered endogenous opioid peptides called endomorphin-1 and endomorphin-2 (Zadina et al. 1999). These peptides are putative products of an, as yet, unidentified precursor, and have been proposed to be the highly selective endogenous ligands for the μ receptor (Janecka et al. 2004; Zadina et al. 1999). The endomorphins are small tetrapeptides that are structurally unrelated to the classical endogenous opioid peptides (Zadina et al. 1999). Their identification has heralded a new era in research of the μ opioid system, which may contribute to our understanding of the neurobiology of opioids, and provide new avenues for therapeutic interventions.

Opioid Receptor Signaling and Mechanisms of Analgesia

Binding of an opioid agonist to a neuronal opioid receptor, regardless of whether the agonist is endogenous or exogenous, typically leads to several events that serve to inhibit the activation of the neuron. Opioid receptors are part of a large superfamily of membrane-bound receptors that are coupled to G-proteins (Smith & Lee 2003). As such, they are structurally and functionally related to receptors for many neurotransmitters and other neuropeptides, which act to modulate the activity of nerve cells. Opioid receptor binding, via activation of various types of G-proteins, may lead to inhibition of adenylyl cyclase (cAMP) activity, activation of receptor-operated K^+ currents, and suppression of voltage-gated Ca^{2+} currents (Inturrisi 2002).

At the presynaptic level, decreased Ca^{2+} influx will result in reduced release of transmitter substances, such as substance P, from primary afferent fibers in the spinal cord dorsal horn, thereby inhibiting synaptic transmission of nociceptive input (Inturrisi 2002). Postsynaptically, enhanced K^+ efflux will result in

neuronal hyperpolarization of spinal cord projection neurons and inhibition of ascending nociceptive pathways. A third potential mode of opioid action involves upregulation of supraspinal descending antinociceptive pathways in the periaqueductal gray. It is now known that this system is subject to tonic inhibition mediated by GABAergic neurons, and opioid receptor activation has been shown to suppress this inhibitory influence and augment descending antinociceptive transmission (Christie et al. 2000; Inturrisi 2002). The proposed cellular basis for this involves μ receptors present on presynaptic GABAergic nerve terminals, which activate voltage-dependent K^+ currents and thereby inhibit GABA release into the synaptic cleft (Christie et al. 2000). It is important to note that while our collective understanding of opioid receptor-mediated signaling has increased dramatically in recent years, the relationship of such subcellular events to clinical analgesia at the level of the organism requires further clarification.

Opioid Receptor Distribution and Therapeutic Implications

While cellular and molecular studies of opioid receptors and ligands are invaluable in understanding their function, it is critical to place them in their anatomical and physiological context to fully appreciate the opioid system and its relevance to pain management. It has long been a principle tenet of opioid analgesia that these agents are centrally acting, and this understanding has shaped the way we use opioid analgesics clinically. It has been well established that the analgesic effects of opioids arise from their ability to directly inhibit the ascending transmission of nociceptive information from the spinal cord dorsal horn, and to activate pain control circuits that descend from the midbrain via the rostral ventromedial medulla to the spinal cord. Within the central nervous system, evidence of μ , δ , and κ opioid receptor mRNA and/or opioid peptide binding has been demonstrated in supraspinal sites including the mesencephalic periaqueductal gray, the mesencephalic reticular formation, various nuclei of the rostral ventromedial medulla, forebrain regions including the nucleus accumbens, as well as spinally within the dorsal horn (Gutstein & Akil 2001; Yaksh 1998). The interactions between groups of opioid receptors at various spinal and supraspinal locations, as well as interactions between different receptor types within a given location, are complex and incompletely understood at this time.

Systemic administration of opioid analgesics via intravenous, intramuscular, or subcutaneous injection will result in a relatively rapid onset of action via interaction with these central nervous system receptors. Oral, transdermal, rectal, or buccal mucosal administration of opioids will result in variable systemic absorption, depending on the characteristics of the particular

agent, with analgesic effects being mediated largely by the same receptors within the central nervous system. In addition, neuraxial administration, either into the subarachnoid or epidural space, is a particularly efficacious route of administration. Small doses of opioids introduced via these routes readily penetrate the spinal cord and interact with spinal and/or supraspinal opioid receptors to produce profound and potentially long-lasting analgesia, the characteristics of which will depend on the particular drug utilized.

Despite the fact that opioids have long been considered the prototype of centrally acting analgesics, a body of evidence has emerged over the past decade, which clearly indicates that opioids can produce potent and clinically measurable analgesia by activation of opioid receptors in the peripheral nervous system (Stein et al. 2001). Opioid receptors of all three major types have been identified on the processes of sensory neurons, and they respond to peripherally applied opioids and locally released endogenous opioid peptides when upregulated during inflammatory pain states (Fields et al. 1980; Stein 1993; Stein et al. 1993, 2001, 2003). Furthermore, sympathetic neurons and immune cells have also been shown to express opioid receptors, but their functional role remains unclear (Stein et al. 2003). While the binding characteristics of peripheral and central opioid receptors are similar, the molecular mass of peripheral and central μ opioid receptors appears to be different, suggesting that selective ligands for these peripheral receptors could be developed, which would produce opioid analgesia without the potential to induce centrally mediated adverse side effects (Stein 1995; Stein & Yassouridis 1997; Stein et al. 1996, 2001, 2003).

Adverse Effects of Clinically Used Opioids

While opioids are used clinically primarily for their pain relieving properties, they also produce a host of other effects on a variety of body systems. This is not surprising in light of the wide distribution of endogenous opioid peptides and their receptors in supraspinal, spinal and peripheral locations. Since information regarding opioid side effects in most wild and exotic animals is lacking, reference is made to common domestic species, where appropriate.

Central Nervous System

Level of Arousal There are considerable species differences in the central nervous system response to opioid analgesics that cannot be attributed to pharmacokinetic variations alone. Central nervous system depression (i.e., sedation) is typically seen in the dog, monkey, and human, while central nervous system stimulation (i.e., excitement and/or spontaneous locomotor activity) may be elicited in the cat, horse, goat, sheep, pig, and cow following systemic administration of various opioids, most notably morphine (Branson et al. 2001).

Reasons for these different responses are not entirely clear at this time, but are presumably related to differing concentrations and distributions of μ , δ , and κ receptors in various regions of the brain in these species (Hellyer et al. 2003). Details regarding the central nervous system responses of specific wild and exotic species to opioids are not known at this time. Regardless of the species, however, there are numerous factors which may play a role, including the temperament or condition of the animal, the presence or absence of pain in the animal, the dose, route and timing of drug administration, and the specific opioid administered.

Thermoregulatory Center The hypothalamic thermoregulatory system is also affected by opioid administration. Hypothermia tends to be the most common response, particularly when opioids are used during the perioperative period in the presence of other central nervous system depressant drugs (Branson et al. 2001; Gutstein & Akil 2001). Under some clinical circumstances, however, hyperthermia is observed in cats, horses, swine, and ruminants following opioid administration (Niedfeldt & Robertson 2006; Posner et al. 2007, 2010). Part of this increase in body temperature may be attributed to an increase in muscle activity associated with central nervous system excitation in these species; however, a specific central hypothalamic mechanism has also been implicated but remains poorly understood (Branson et al. 2001).

Emetic Center Nausea and vomiting associated with opioid administration are a result of direct stimulation of the chemoreceptor trigger zone for emesis located in the area postrema of the medulla (Gutstein & Akil 2001; Stoelting 1999). As with the other centrally mediated side effects, species plays a role in determining an individual's tendency to vomit after an opioid is administered. Horses, rabbits, ruminants, and swine do not vomit with opioid administration. Cats may vomit, but usually at doses that are greater than those which stimulate vomiting in dogs. Dogs will commonly vomit following opioid administration, especially with morphine.

Cough Center Opioids have variable efficacy in depressing the cough reflex, at least in part by a direct effect on a cough center located in the medulla (Gutstein & Akil 2001). Certain opioids are more effective antitussives than others, including drugs such as codeine, hydrocodone, and butorphanol.

Pupillary Diameter As a general rule, opioids tend to produce mydriasis in those species that exhibit central nervous system excitation, and miosis in those that become sedated following opioid administration (Branson et al. 2001; Stephan et al. 2003; Lee & Wang 1975; Wallenstein & Wang 1979). Miosis is due to an

excitatory action of opioids on neuronal firing in the oculomotor nucleus (Lee & Wang 1975; Stoelting 1999; Wallenstein & Wang 1979). In the cat, and presumably in other species that exhibit mydriasis, this increase in activity in the oculomotor nuclear complex still occurs, but the miotic effect is masked by increased release of catecholamines, which results in mydriasis (Wallenstein & Wang 1979).

Respiratory System Opioids produce dose-dependent depression of ventilation, primarily mediated by μ_2 receptors leading to a direct depressant effect on brainstem respiratory centers (Gutstein & Akil 2001; Stoelting 1999). This effect is characterized by decreased responsiveness of these centers to carbon dioxide and is reflected in an increased resting PaCO₂ and displacement of the carbon dioxide response curve to the right. This effect is compounded by the coadministration of sedative and/or anesthetic agents, meaning that significant respiratory depression and hypercapnia are much more likely to occur in anesthetized patients that receive opioids versus those that are conscious. It should be noted that, in general, humans tend to be more sensitive to the respiratory depressant effects of opioids when compared with most veterinary species. However, respiratory support and/or specific opioid antagonists should be immediately available anytime very high doses, or very potent opioids, are used.

Cardiovascular System Most opioids have minimal effects on cardiac output, cardiac rhythm, and arterial blood pressure when clinically relevant analgesic doses are administered. Bradycardia may occur as a result of opioid-induced medullary vagal stimulation and will respond readily to anticholinergic treatment if warranted. Particular opioids (morphine and meperidine) can cause release of histamine, especially after rapid intravenous administration, which may lead to vasodilation and hypotension (Branson et al. 2001; Smith et al. 2001). Due to their relatively benign effects on cardiovascular function, opioids commonly form the basis of anesthetic protocols for human patients or animals with preexisting cardiovascular disease.

Gastrointestinal System The gastrointestinal effects of the opioids are mediated by μ and δ receptors located in the myenteric plexus of the gastrointestinal tract (Branson et al. 2001; Gutstein & Akil 2001). Opioid administration may stimulate defecation in certain species. Following this initial response, spasm of gastrointestinal smooth muscle predisposes to ileus and constipation. Horses and ruminants in particular may be predisposed to gastrointestinal complications associated with opioid administration, such as colic and ruminal tympany, respectively. Chronic opioid use may predispose to gastrointestinal stasis in other species.

In human patients, opioids (most notably fentanyl and morphine) have been shown to increase bile duct pressure through constriction of the sphincter of Oddi (Radnay et al. 1984). The incidence of this side effect in humans is, however, quite low (Jones et al. 1981). The incidence of increased bile duct pressure secondary to opioid administration in various animal species, and its potential clinical significance, is unknown at this time.

Genitourinary System Opioids, particularly when administered neuraxially, may cause urinary retention through dose-dependent suppression of detrusor contractility and decreased sensation of urge (el Bimary & Abu el-Nasr 2001; Kuipers et al. 2004). Urine volume may also be affected by opioids, and the mechanism of this effect appears to be multifactorial. Mu agonists tend to produce oliguria in the clinical setting, and this is in part a result of increased antidiuretic hormone release, leading to altered renal tubular function (Mercadante & Arcuri 2004; Stoelting 1999). Elevations in circulating plasma atrial natriuretic peptide may also play a role in morphine-induced antidiuresis (Mercadante & Arcuri 2004). Conversely, κ agonists tend to produce a diuretic effect, possibly through inhibition of antidiuretic hormone secretion (Mercadante & Arcuri 2004; Stoelting 1999). Other peripheral mechanisms involving stimulation of renal alpha-2 adrenergic receptors may also contribute to this κ agonist effect (Mercadante & Arcuri 2004).

Opioid Agonists

Almost all clinically useful opioids exert their analgesic and immobilizing effects by acting as agonists at μ receptors. While there are a few opioids that act as κ agonists, these drugs also tend to have antagonist or partial agonist effects at μ and/or δ receptors and are thus not classified as *pure* agonists. Pure or full opioid agonists are capable of eliciting maximal activation of the receptor when they bind it and the subsequent downstream processes result in a maximal analgesic effect (Fig. 1.1). Clinically, the full μ agonists are superior analgesics, and they are the drugs of choice for pain of moderate to severe intensity in many veterinary species. The following section contains brief descriptions of full μ agonists currently used in veterinary medicine. Specific details regarding μ agonist clinical pharmacology in various wild and exotic species is lacking.

Morphine (Morphine Sulfate) Morphine is the prototypical opioid analgesic and acts as a full agonist not only at μ receptors, but also at δ and κ receptors (Gutstein & Akil 2001). Despite the development of numerous synthetic opioids, many of which are more potent than morphine and may have other characteristics that make them desirable alternatives to morphine in

Figure 1.1. Effects of opioid agonists.

certain circumstances, it is worth noting that no other drug has been shown to be more efficacious than morphine at relieving pain in humans. Compared with the synthetic opioid agonists, morphine is relatively hydrophilic in nature and crosses the blood-brain barrier more slowly than fentanyl or oxycodone, thereby delaying the peak effect somewhat even after intravenous administration (Gutstein & Akil 2001; Stoelting 1999). Clinically, this lag is not likely to be significant under most circumstances, with the onset of analgesia occurring reasonably promptly after a single dose of morphine and typically lasting 3–4 hours (Barnhart et al. 2000; Taylor et al. 2001). Morphine's poor lipid solubility means that it can produce long-lasting analgesia when administered into the epidural or subarachnoid space, with effects persisting for 12–24 hours. The first-pass effect is significant after oral administration and the bioavailability of oral morphine preparations is only in the range of 25%.

In most species, the primary metabolic pathway for morphine involves conjugation with glucuronic acid leading to the formation of two major metabolites, morphine-6-glucuronide and morphine-3-glucuronide (Faura et al. 1998; Gutstein & Akil 2001). Despite the low levels of glucuronyl transferase in the cat, the PK of morphine in this species seem to be broadly comparable with the dog and human, though clearance rates may be marginally slower (Barnhart et al. 2000; Faura et al. 1998; Taylor et al. 2001). This suggests that morphine must undergo a different type of conjugation reaction in this species. Morphine-6-glucuronide has pharmacological activities that are indistinguishable

from those of morphine in animal models and in human beings, while morphine-3-glucuronide appears to have little affinity for opioid receptors, but may contribute to the excitatory effects of morphine in some situations (Gutstein & Akil 2001; Smith 2000). With chronic morphine administration, it is likely that the active metabolite, morphine-6-glucuronide, contributes significantly to clinical analgesia.

Very little morphine is excreted unchanged in the urine. The major metabolites, morphine-3-glucuronide and, to a lesser extent, morphine-6-glucuronide, are eliminated almost entirely via glomerular filtration. In human patients, renal failure may lead to accumulation of morphine-6-glucuronide and persistent clinical effects, while liver dysfunction seems to have minimal impact on morphine clearance (Gutstein & Akil 2001; Stoelting 1999).

The side effects associated with morphine administration are typical of most opioid agonists and have been discussed previously in this chapter. In particular, the increased incidence of vomiting after morphine administration, as well as its potential to cause histamine release after intravenous administration, distinguish morphine from other full opioid agonists.

Oxymorphone Oxymorphone is a synthetic opioid that acts as a full agonist at μ receptors and is comparable with morphine in its analgesic efficacy and duration of action. It is a more lipid-soluble drug than morphine and is readily absorbed after intramuscular or subcutaneous administration. Oxymorphone is not available as an oral formulation.

When compared with morphine, oxymorphone may be less likely to cause vomiting and tends to produce more sedation when administered to domestic species. Its respiratory depressant effects are similar to those induced by morphine, but oxymorphone seems more likely to cause panting in dogs. It does not produce histamine release, even when administered intravenously (Smith et al. 2001). Oxymorphone's other side effects are typical of other full μ agonist opioids and have been discussed previously.

Hydromorphone Hydromorphone is a synthetic opioid that acts as a full agonist at μ receptors and is used in both human and veterinary medicine. Clinically, hydromorphone and oxymorphone have similar efficacy, potency, duration of analgesic action, and side effect profiles, but hydromorphone remains significantly less expensive. Like oxymorphone, hydromorphone is not associated with histamine release so bolus intravenous administration is considered safe (Smith et al. 2001).

Meperidine Meperidine is a synthetic opioid that exerts its analgesic effects through agonism at μ receptors. Interestingly, it also appears able to bind other types of

receptors, which may contribute to some of its clinical effects other than analgesia. Meperidine is capable of blocking sodium channels and inhibiting activity in dorsal horn neurons in a manner analogous to local anesthetics (Wagner et al. 1999; Wolff et al. 2004). It has also recently been shown that meperidine exerts agonist activity at alpha-2 receptors, specifically the alpha_{2B} subtype, suggesting that it may possess some alpha-2 agonist-like properties (Takada et al. 1999, 2002).

Meperidine has a considerably shorter duration of analgesic action compared to morphine, oxymorphone, or hydromorphone, typically not extending beyond 1 hour (Branson et al. 2001). Metabolic pathways vary among different species but, in general, most of the drug is demethylated to normeperidine in the liver and then undergoes further hydrolysis and ultimately renal excretion (Branson et al. 2001; Taylor et al. 2001; Yeh et al. 1981). Normeperidine is an active metabolite and possesses approximately one-half the analgesic efficacy of meperidine (Branson et al. 2001; Gutstein & Akil 2001). Normeperidine has produced toxic neurologic side effects in human patients receiving meperidine for prolonged periods of time, especially in the presence of impaired renal function (Stoelting 1999; Stone et al. 1993).

Unlike most of the other opioids in clinical use, meperidine has been shown to produce significant negative inotropic effects when administered alone to conscious dogs (Priano & Vatner 1981). Also, due to its modest atropine-like effects, meperidine tends to increase heart rate rather than predispose to bradycardia, as is often seen with other opioids (Branson et al. 2001; Stoelting 1999). The clinical significance of these cardiovascular effects in the perianesthetic period has never been clearly ascertained. Like morphine, meperidine also causes histamine release when administered intravenously (Branson et al. 2001).

A rare but life-threatening drug interaction has been reported in human patients receiving meperidine that may have relevance in veterinary medicine. The combination of meperidine (and perhaps other opioids) with a monoamine oxidase inhibitor may lead to "serotonin syndrome," which is characterized by a constellation of symptoms, including confusion, fever, shivering, diaphoresis, ataxia, hyperreflexia, myoclonus, and diarrhea (Bowdle 1998; Heinonen & Myllyla 1998; Sporer 1995; Tissot 2003). A monoamine oxidase inhibitor, selegiline (Deprenyl[®]), has been used in dogs to treat pituitary-dependent hyperadrenocorticism or to modify behavior in patients with canine cognitive dysfunction. Though there have not, to date, been any reports of adverse meperidine-selegiline interactions in dogs, the veterinarian must be aware of the potential for complications if analgesia is required in patients receiving monoamine oxidase inhibitors. A recent study has evaluated the effects of other opioids (oxy-

morphine and butorphanol) in selegiline-treated dogs and did not identify any specific adverse drug interactions in these animals (Dodam et al. 2004).

Fentanyl Fentanyl is a highly lipid soluble, short-acting synthetic μ opioid agonist. A single dose of fentanyl administered intravenously has a more rapid onset and a shorter duration of action than morphine. Peak analgesic effects occur in about 5 minutes and last approximately 30 minutes (Gutstein & Akil 2001; Stoelting 1999). Rapid redistribution of the drug to inactive tissue sites, such as fat and skeletal muscle, leads to a decrease in plasma concentration and is responsible for the prompt termination of clinical effects. In most veterinary species the elimination half-time after a single bolus or a brief infusion is in the range of 2–3 hours (Carroll et al. 1999; Lee et al. 2000; Maxwell et al. 2003). Administration of very large doses or prolonged infusions may result in saturation of inactive tissues with termination of clinical effects becoming dependent on hepatic metabolism and renal excretion (Gutstein & Akil 2001; Stoelting 1999). Thus, the context-sensitive half-time of fentanyl increases significantly with the duration of the infusion, and clinical effects may persist for an extended period following termination of a long-term intravenous infusion.

Side effects associated with fentanyl administration are similar to those of the other full μ agonist opioids. In general, cardiovascular stability is excellent with fentanyl, and intravenous administration is not associated with histamine release (Gutstein & Akil 2001; Stoelting 1999). Bradycardia may be significant with bolus doses but readily responds to anticholinergics if treatment is warranted (Branson et al. 2001; Gutstein & Akil 2001). In human patients, muscle rigidity, especially of the chest wall, has been noted after administration of fentanyl or one of its congeners (Bowdle 1998; Fahrenstich et al. 2000; Muller & Vogtman 2000). The potential significance of this adverse effect in animal patients is not clear at this time, and the risk is considered minimal if large rapid bolus administrations are avoided.

Clinically, fentanyl is used most frequently in dogs and cats, but it is also a potentially useful analgesic in other species, including the horse, cow, sheep, goat, and pig. Historically, fentanyl was available in combination with the butyrophenone tranquilizer, droperidol, in a product called Innovar-Vet, which was typically administered in the preanesthetic period to provide sedation and analgesia. This product is no longer available, and systemic administration of fentanyl today is usually via the intravenous route.

The development of novel less invasive routes of opioid administration for use in human patients led to the marketing of transdermal fentanyl patches (Duragesic®). The patches are designed to release a constant amount of fentanyl per hour, which is then absorbed across the skin and taken up systemically. Fentanyl

patches are designed for human skin and body temperature, however, their use has been evaluated in a number of domestic veterinary species (Carroll et al. 1999; Egger et al. 1998, 2003; Franks et al. 2000; Gellasch et al. 2002; Gilberto et al. 2003; Maxwell et al. 2003; Robinson et al. 1999; Wilkinson et al. 2001). Substantial variations in plasma drug concentrations have been documented, and significant lag times after patch placement are common prior to onset of analgesia (Carroll et al. 1999; Egger et al. 1998, 2003; Lee et al. 2000). Furthermore, changes in body temperature have been shown to significantly affect fentanyl absorption in anesthetized cats, and it is likely that other factors associated with skin preparation and patch placement have the potential to substantially alter plasma fentanyl levels and analgesic efficacy (Pettifer & Hosgood 2003). Fentanyl patch safety and efficacy in most species is unknown at this time.

Alfentanil, Sufentanil, and Remifentanil Alfentanil, sufentanil, and remifentanil are all structural analogues of fentanyl that were developed for use in humans in an effort to create analgesics with a more rapid onset of action and predictable termination of opioid effects. All three are similar with regard to onset, and all have context-sensitive half-times that are shorter than that of fentanyl after prolonged infusions (Stoelting 1999). Remifentanil is unique among opioids because it is metabolized by nonspecific plasma esterases to inactive metabolites (Chism & Rickert 1996; Hoke et al. 1997). Thus, hepatic or renal dysfunction will have little impact on drug clearance and this, in combination with the robust nature of the esterase metabolic system, contributes to the predictability associated with infusion of remifentanil (Gutstein & Akil 2001; Stoelting 1999).

All three of these drugs are used during general anesthesia for procedures requiring intense analgesia and/or blunting of the sympathetic nervous system response to noxious stimulation. As yet, they have limited applications for postoperative or chronic pain management. Like fentanyl, they can be administered at relatively low infusion rates as adjuncts to general anesthetic protocols based on volatile inhalant or other injectable agents, or they can be administered at higher rates as the primary agent for total intravenous anesthesia. The minimum alveolar anesthetic concentration-sparing properties of these agents have been demonstrated in both the dog and cat (Hoke et al. 1997; Ilkiw et al. 1997; Mendes & Selmi 2003; Michelsen et al. 1996; Pascoe et al. 1997). In the horse, systemic infusions of alfentanil did not have significant effects on minimum alveolar concentrations of inhalant anesthetics and when administered to conscious horses were associated with increases in locomotor activity (Pascoe & Taylor 2003; Pascoe et al. 1991, 1993). There is little evidence to suggest that any of the

fentanyl analogues offer advantages over morphine when administered into the epidural space for analgesia (Natalini & Robinson 2000).

Methadone Methadone is a synthetic μ opioid agonist with pharmacologic properties qualitatively similar to those of morphine, but possessing additional affinity for N-methyl-D-aspartate receptors (Gorman et al. 1997; Ripamonti & Dickerson 2001). Methadone's unique clinical characteristics include excellent absorption following oral administration, no known active metabolites, high potency, and an extended duration of action (Branson et al. 2001; Gutstein & Akil 2001; Ripamonti & Dickerson 2001). In human patients, the drug has been used primarily in the treatment of opioid abstinence syndromes, but is being used increasingly for the management of chronic pain. Though there are reports of intramuscular or intravenous administration of methadone in the perioperative period in dogs, cats, and horses, the drug is not commonly used in this setting in North America at this time (Dobromylskyj 1996; Fisher 1984; Kramer et al. 1996).

Codeine Codeine is the result of substitution of a methyl group onto morphine, which acts to limit first-pass hepatic metabolism and accounts for codeine's high oral bioavailability (Gutstein & Akil 2001; Stoelting 1999). Codeine is well known for its excellent anti-tussive properties and is often combined in an oral formulation with a non-opioid analgesic, such as acetaminophen (Tylenol 3[®]), for the management of mild to moderate pain in human patients.

Oxycodone and Hydrocodone Oxycodone and hydrocodone are opioids that are typically administered orally for the treatment of pain in human patients. Though oxycodone is available as a single-drug continuous-release formulation (Oxycontin[®]), these drugs are most often prepared in combination with nonopioid analgesics, such as aspirin and acetaminophen (Percocet[®], Percodan[®], Lorcet[®], Vicodan[®], etc.). Little has been published regarding the use of these opioids in veterinary species.

Etorphine and Carfentanil (M-99[®] and Wildnil[®], Respectively) These two opioids are discussed together because they are both used exclusively for the restraint and capture of wild animals, rather than as analgesic agents. They are extremely potent opioids, and the immediate availability of a suitable antagonist is mandatory before these drugs are to be used, not only to reverse drug effects in animal patients, but also as a safety precaution in the event of accidental human injection. Though etorphine and carfentanil are most often injected intramuscularly (usually using a remote drug delivery technique), recent studies suggest that carfentanil is useful when administered orally in a

variety of species, including the brown bear, the Brazilian tapir, and the chimpanzee (Kearns et al. 2000; Mama et al. 2000; Mortenson & Bechert 2001; Pollock & Ramsay 2003). A number of different drugs have been used in combination with etorphine or carfentanil to enhance muscle relaxation, including acepromazine, xylazine, and medetomidine (Caulkett et al. 2000; Miller et al. 2003; Ramdohr et al. 2001; Roffe et al. 2001).

Thiafentanil Thiafentanil is an opioid agonist that has been utilized to facilitate capture of several species of birds and mammals (Borkowski et al. 2009; Cushing & McClean 2010; Grobler et al. 2001; Kilgallon et al. 2010). It is pharmacologically classified as a synthetic opioid that has a relatively short duration of action. The shorter duration of action in combination with its reversibility with the opioid antagonist naltrexone make it an attractive agent when long periods of narcotization are not desirable.

Opioid Agonist–Antagonists and Partial Agonists

This group includes drugs that have varying opioid receptor binding profiles, but which have one thing in common: they all occupy μ opioid receptors, but do not initiate a maximal clinical response. Drugs such as butorphanol and nalbuphine are classified as agonist–antagonists. They are competitive μ receptor antagonists, but exert their analgesic actions by acting as agonists at κ receptors (Fig. 1.2). Buprenorphine, on the other hand, is classified as a partial agonist and binds

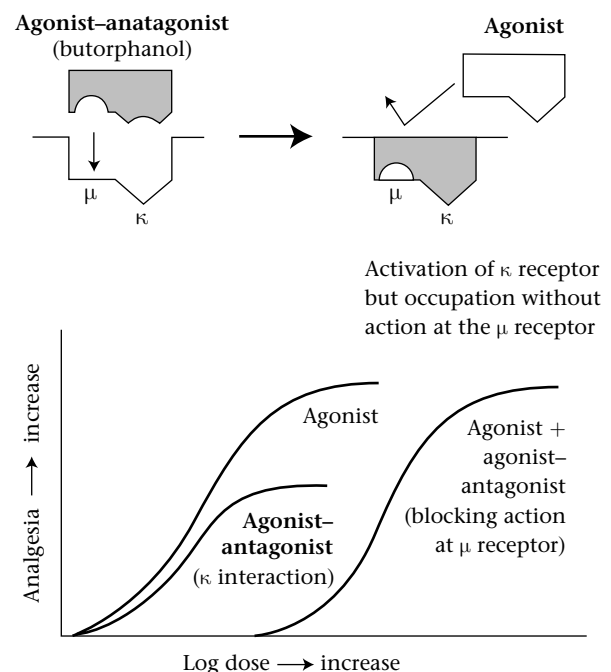

Figure 1.2. Activation of κ receptor, but occupation without action at the μ receptor.

Figure 1.3. Partial activation of μ receptor.

μ receptors but produces only a limited clinical effect (Fig. 1.3). These mixed agonist–antagonist drugs were developed for the human market in an attempt to create analgesics with less respiratory depression and addictive potential. Due to their opioid receptor-binding affinities, the side effects associated with these drugs demonstrate a so-called ceiling effect, whereby increasing doses do not produce additional adverse responses. Unfortunately, the benefits of this ceiling effect on ventilatory depression come at the expense of limited analgesic efficacy and only a modest ability to decrease anesthetic requirements.

The coadministration of opioids with differing receptor binding profiles is currently an active area of research that deserves further attention. The interactions in this setting are complex and it appears that opioid coadministration has the potential to produce additive, synergistic, or antagonistic analgesic effects depending on the particular species, dosage, drugs, and pain model being evaluated. The following section contains brief descriptions of opioid agonist–antagonists and partial agonists that are currently used in veterinary medicine.

Butorphanol Butorphanol is a synthetic agonist–antagonist opioid and has been used extensively in a wide variety of veterinary species. The drug was originally labeled as an antitussive agent in dogs and, even now, is approved as an analgesic in the cat and horse only (Branson et al. 2001). Butorphanol exerts its relevant clinical effects through its interactions at κ receptors and acts as an antagonist at μ receptors. The duration of butorphanol's analgesic effects remains

somewhat debatable and likely varies with species, type and intensity of pain, dosage, and route of administration (Sawyer et al. 1991; Robertson et al. 2003a; Sellon et al. 2001). In general, its effects are shorter lived than those of morphine and are probably in the range of 1–3 hours. Butorphanol does not induce histamine release when administered intravenously and has minimal effects on cardiopulmonary function. There is conflicting evidence regarding the effects of butorphanol on inhalant anesthetic requirements in the dog, cat, and horse. Earlier studies failed to demonstrate a significant sparing effect on minimum alveolar concentration when butorphanol was co-administered with halothane in dogs and ponies (Doherty et al. 1997; Matthews & Lindsay 1990; Quandt et al. 1994). More recently, isoflurane MAC reductions have been documented after administration of clinically relevant doses of butorphanol in both dogs and cats (Ilkiw et al. 2002; Ko et al. 2000). Reasons for these discrepancies are probably related to differences in study techniques and, in the dog and cat specifically, it seems that butorphanol is capable of inducing at least modest reductions in inhalant anesthetic requirements.

Traditionally, it was thought that the simultaneous or sequential administration of butorphanol with a pure μ opioid agonist, such as morphine or hydromorphone, would be counterproductive from an analgesic standpoint because butorphanol's ability to antagonize μ receptors could inhibit or even reverse the effects of the agonist drug. Certainly, it has been clearly demonstrated that excessive sedation associated with a pure μ agonist can be partially reversed by the administration of low doses of butorphanol, and it was presumed that butorphanol would similarly reverse the μ -mediated analgesic effects as well. It would now appear that the potential interactions between butorphanol and full μ opioid agonists are more complex than originally believed. One study demonstrated that coadministration of butorphanol and oxymorphone to cats subjected to a visceral noxious stimulus resulted in enhanced analgesic effects (Briggs et al. 1998). A more recent feline study, however, evaluated the combination of butorphanol and hydromorphone in a thermal threshold pain model and failed to demonstrate enhanced analgesia and suggested that butorphanol did, in fact, inhibit hydromorphone's analgesic effects (Lascelles & Robertson 2004). These contradictory findings illustrate that we still have much to learn about coadministration of opioid agents with differing receptor-binding profiles and the clinical effects produced by such co-administration likely depend on many factors, including species, type of pain, dose, and the specific drugs involved.

Nalbuphine and Pentazocine Nalbuphine and pentazocine are classified as agonist–antagonist opioids and are clinically similar to butorphanol. They induce mild

analgesia accompanied by minimal sedation, respiratory depression, or adverse cardiovascular effects. Like butorphanol, nalbuphine is occasionally used to partially reverse the effects of a full μ agonist opioid while maintaining some residual analgesia.

Buprenorphine Buprenorphine is a semisynthetic, highly lipophilic opioid derived from thebaine. Unlike other opioids in this category, buprenorphine is considered to be a partial agonist at μ opioid receptors. The drug binds avidly to and dissociates slowly from μ receptors, but is not capable of eliciting a maximal clinical response. Due to its receptor-binding characteristics, buprenorphine has a delayed onset of action and takes at least 60 minutes to attain peak effect after intramuscular administration. It also has a relatively long duration of action with clinical analgesic effects persisting for 6–12 hours in most species. Also, its high affinity for the μ receptor means that it may be difficult to antagonize its effects with a drug, such as naloxone. Buprenorphine has most often been administered intravenously or intramuscularly; however, due to the long lag time before clinical effects are achieved after intramuscular administration, the intravenous route is preferred. Comparable plasma drug levels and analgesic efficacy with oral transmucosal administration versus intravenous administration has been demonstrated in cats (Robertson et al. 2003b). Compounded versions of buprenorphine are widely available and include higher concentrations for convenient dosing to larger animals and sustained release formulations for increased duration of action. If sustained release preparations are used, there should be a plan for supportive care should significant adverse effects occur since complete reversal of buprenorphine with conventional antagonists is often unsuccessful.

Opioid Antagonists

These drugs have high affinities for the opioid receptors and are able to displace opioid agonists from μ and κ receptors. After this displacement, the pure antagonists bind to and occupy opioid receptors, but do not activate them (Fig. 1.4). Under ordinary circumstances, in patients that have not received exogenous agonist opioids, the opioid antagonists have few clinical effects when administered at clinically relevant dosages (Gutstein & Akil 2001). It is important to recognize that these drugs will rapidly reverse all opioid-induced clinical effects including analgesia.

Naloxone This pure opioid antagonist is capable of reversing all opioid agonist effects, producing increased alertness, responsiveness, coordination and, potentially, increased perception of pain. Naloxone's duration of action is shorter than many of the opioid agonists, with recommended intravenous doses lasting between 30 and 60 minutes. Consequently, animals

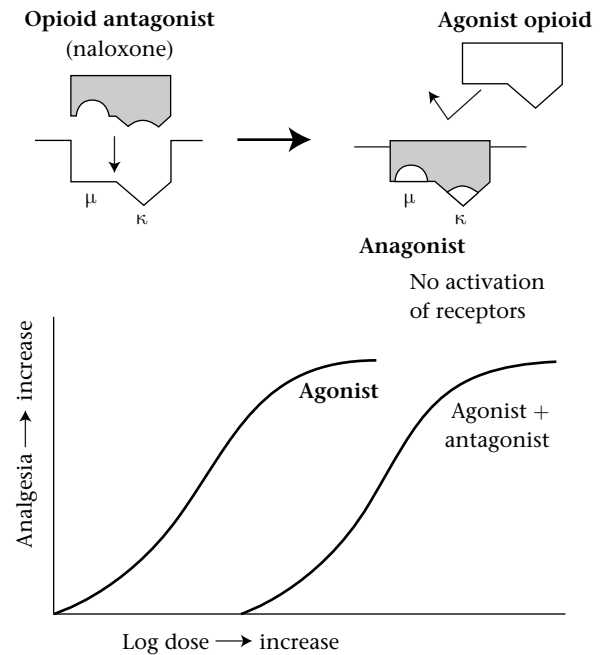

Figure 1.4. No activation of receptors.

need to be closely monitored for reanarcotization after a dose of naloxone. Occasionally, excitement or anxiety may be seen after naloxone reversal of an opioid agonist. Premature ventricular contractions have also been documented after reversal, but are not a common occurrence and seem to be more likely if there are high levels of circulating catecholamines. This drug is sometimes administered sublingually to neonatal patients exhibiting respiratory depression that have been delivered by cesarean section after maternal administration of an opioid agonist.

Nalmefene and Naltrexone Both of these drugs are pure opioid antagonists with clinical effects that last approximately twice as long as naloxone (Veng-Pedersen et al. 1995). Though little is published about the use of these drugs in veterinary patients, they may be advantageous in preventing reanarcotization when used to antagonize the effects of a long-acting opioid.

NONSTEROIDAL ANTI-INFLAMMATORIES

The nonsteroidal antiinflammatory drugs (NSAIDs) relieve mild to moderately severe pain and have been used extensively in a wide variety of domestic animals for many years. While pharmacokinetic and pharmacodynamic studies involving NSAIDs in wild and exotic animals are lacking, their use in such species continues to increase.

This class of drugs dates back thousands of years with the salicylates being among the oldest and still

most commonly used analgesics (Vane & Botting 2003). Salicylate is a naturally occurring substance found in willow bark and was used for centuries to manage pain associated with rheumatism prior to production of the synthetic compound. In 1878, Felix Hoffman working at the Bayer company in Germany made the acetylated form of salicylic acid which has come to be known as aspirin (Vane & Botting 2003). While aspirin (acetylsalicylic acid or ASA) has been found to be effective in the management of acute and chronic mild discomfort, the newer injectable NSAIDs appear to have comparable efficacy to the pure μ agonist opioids in controlling moderate to severe soft tissue and orthopedic pain. The NSAIDs appear to confer synergism when used in combination with opioids and may demonstrate an opioid sparing effect should lower dosages of opioid be required. Their extended duration of action, in addition to their analgesic efficacy make the NSAIDs ideal for treating acute and chronic pain in veterinary species. Careful patient and drug selection is critical, however, due to their potential for harmful side effects.

The Cyclooxygenases and Prostaglandin Synthesis

In 1971, Vane discovered the mechanism by which aspirin exerts its antiinflammatory, analgesic and antipyretic actions. He proved that aspirin and other NSAIDs inhibited the activity of a cyclooxygenase (COX) enzyme, which produced prostaglandins (PGs) involved in the pathogenesis of inflammation, swelling, pain, and fever (Vane 1971). Twenty years later, the discovery of a second COX enzyme was made, and more recently, a newly identified COX-3 (Botting 2000, 2003; Chandrasekharan et al. 2002). Cyclooxygenase (previously termed prostaglandin synthase) oxidizes arachidonic acid (previously termed eicosatetraenoic acid) to various eicosanoids (including PGs and other related compounds) (Fig. 1.5) (Livingston 2000). Oxidation of arachidonic acid by 5-lipoxygenase (5-LOX), the most biologically important of the mammalian oxygenases, results in the series of eicosanoids termed leukotrienes (Fig. 1.5). The release of arachidonic acid from membrane phospholipid is catalyzed by the

Figure 1.5. Eicosanoid synthesis.

enzyme phospholipase A₂ and is the rate-limiting step in PG and leukotriene synthesis. Prostaglandin G₂ is the initial prostenoid formed, followed by prostaglandin H₂, which serves as a substrate for prostaglandin E-synthetase, prostaglandin D-isomerase, prostaglandin F-reductase, prostacyclin synthetase, and thromboxane synthetase for conversion to a variety of other prostenoids ubiquitous throughout cells and tissues in the body (Livingston 2000). These include the PGs PGE₂, PGD₂, PGF₂, and PGI₂ (prostacyclin), and the thromboxanes TXA₂ and TXB₂, all with diverse functions (Vane & Botting 1995). The PGs are not stored but are synthesized at a constant rate. They have short half-lives of 4–6 minutes at 37°C, and act locally at the site of production.

The PGs produced by both COX-1 and COX-2 are ubiquitous throughout the body and serve to facilitate many normal physiologic functions during both health and illness. Consequently, the clinical use of NSAIDs has the potential to disrupt these functions with the possibility of significant organ dysfunction. Thus, in addition to their role as analgesics, the effects of NSAIDs on the constitutive functions of the PGs must always be considered. There are several key points to note: (1) COX-1 generates PGs that are responsible for “mucosal defense” (i.e., secretion of bicarbonate and mucus, mucosal blood vessel attenuation of constriction, and mucosal epithelial regeneration), as well as thromboxane A₂, which is necessary for platelet function; (2) COX-2 produces PGs, which function in the prevention and promotion of healing of mucosal erosions, exert antiinflammatory effects by inhibiting leukocyte adherence, as well as play a role in renal protection and maturation; and (3) COX-3 produces PGs, which exert a protective function by initiating fever (Botting 2003; Vane & Botting 1995).

Thus, depending on the NSAID selected, primary plug formation of platelets, modulation of vascular tone in the kidney and gastric mucosa, cytoprotective functions within the gastric mucosa, smooth muscle contraction, and regulation of body temperature will all be affected (Vane & Botting 1995). However, in this regard, not all NSAIDs are created equal. As noted above, the COX-1, COX-2, and COX-3 enzymes make variable contributions to these functions, and individual NSAIDs inhibit each of these enzymes differently. Some NSAIDs inhibit both COX-1 and COX-2, (i.e., aspirin, phenylbutazone, ketoprofen/Anafen[®], ketorolac/Toradol[®], and flunixin meglumine/Banamine[®]); other NSAIDs preferentially inhibit COX-2 with only weak inhibition of COX-1 (i.e., meloxicam/Metacam[®], carprofen/Rimadyl[®], etodolac/Etogesic[®], vedaprofen/Quadrisol-5[®], and tolfenamic acid/Tolfedine[®]); others inhibit COX-2 exclusively (i.e., deracoxib/Deramax[®], firocoxib/Prevacox[®], Robenacoxib/Onsior[®], and mavicoxib/Trocoxil[®]); while still another drug, acetaminophen, only weakly inhibits both COX-1

and COX-2, but is able to inhibit COX-3 activity preferentially (Botting 2000).

Several *in vitro* studies investigating NSAID selective inhibition of the COX-1 and COX-2 isoenzymes have been published; however, these are very difficult to interpret due to inconsistencies in the assays used (Kay-Mugford et al. 2000). Clinically, this information is confusing as it does not consider the PK of particular drugs and their concentrations in various tissues (Bertolini et al. 2001). Most NSAIDs that inhibit COX have been shown to result in diversion of arachidonate to the 5-LOX pathway. The 5-LOX is principally found in polymorphonuclear cells, mast cells, monocytes, basophils, and B lymphocytes that are recruited during inflammatory and immune reactions (Bertolini et al. 2001). This enzyme catalyzes the initial step in leukotriene biosynthesis, which subsequently produces various eicosanoids, with LTB₄ being the most notable potent mediator of inflammation. The excessive production of leukotrienes has been implicated in the creation of NSAID-induced ulcers (Hudson et al. 1993; Rainsford 1992). As always, however, the biological system is not clear-cut. While the LOX pathway is pro-inflammatory, there is also an anti-inflammatory pathway, which is discussed in more detail later (Serhan & Chiang 2004).

The contribution of the leukotrienes to the inflammatory process would seem to suggest that inhibition of both the COX and 5-LOX pathways by a therapeutic agent would result in an enhanced safety profile and may confer even greater analgesic efficacy due to broader anti-inflammatory and anti-nociceptive effects (Kirchner et al. 1997b). Data available show that dual-acting compounds are effective in arthritic models, where they also retain anti-thrombotic activity, produce little or no gastrointestinal damage, and do not adversely affect the asthmatic state (Bertolini et al. 2001). A recently approved dual COX/5-LOX inhibitor (tepoxalin/Zubrin[®]) has undergone clinical trials and is now approved for veterinary use (Kirchner et al. 1997b; Argentieri et al. 1994). Tepoxalin has demonstrated gastrointestinal antiinflammatory activity in mice, supporting the theory that 5-LOX inhibition has the potential to play a vital role in the prevention of NSAID-induced gastric inflammation (Kirchner et al. 1997a).

The NSAIDs and Mechanisms of Analgesia

Prostaglandins, notably PGE₂ and prostacyclin, are potent mediators of inflammation and pain. These molecules exert hyperalgesic effects and enhance nociception produced by other mediators, such as bradykinin. The NSAIDs' analgesic mechanism of action is through inhibition of COX-1, COX-2, and COX-3, activity with subsequent prevention of PG synthesis.

The antinociceptive effects of the NSAIDs are exerted both peripherally and centrally (Chopra et al. 2000).

The NSAIDs penetrate inflamed tissues where they have a local effect, which makes them excellent analgesic choices for injuries with associated inflammation, as well as conditions such as synovitis, arthritis, cystitis, and dermatitis (Chopra et al. 2000). The central action is at both the spinal and supraspinal levels, with contributions from both COX-1 and COX-2 (Chopra et al. 2000; McCormack 1994; Malmberg & Yaksh 1992; Yaksh et al. 1998). This central effect may account for the overall well-being and improved appetite that is often observed in patients receiving parenterally administered NSAIDs for relief of acute pain.

The rational use of NSAIDs as analgesics should be based on an understanding of pain physiology and pathophysiology. Nociceptive pathways may involve either the COX-1 or COX-2 gene, and these genes are expressed in different locations and under different circumstances. The COX-2 isoenzyme is known as the inducible isoform because it is upregulated in inflammatory states and is known to play a key role in nociception. While the COX-1 gene has traditionally been thought of as being expressed constitutively, this isoenzyme also plays an integral role in the pain experience (Chandrasekharan et al. 2002). The COX-1 selective NSAIDs are superior to COX-2 selective NSAIDs at inhibiting visceronociception caused by chemical pain stimulators in a mouse peritoneal model (Ochi et al. 2000). This has been confirmed by visceronociception being greatly reduced in COX-1 but not COX-2 knockout mice (Ballou et al. 2000). These studies concluded that peripheral COX-1 mediates nociception in slowly developing pain in mice, such as in visceral pain, and central COX-1 may be involved in rapidly transmitted, nonvisceral pain, such as that caused by thermal stimulation (Ballou et al. 2000). Visceral pain may be mediated, at least in part, by stimulation of intraperitoneal receptors located on sensory fibers by COX-1-produced prostacyclin (Botting 2003). Interestingly, there may be gender differences, as in Ballou's mouse model, which demonstrated that spinal COX-2 did in fact contribute to visceral nociception, but only in female mice (Ballou et al. 2000). The analgesic potency of a range of NSAIDs in relieving tooth extraction pain in humans correlates closely with increasing selectivity toward COX-1 rather than COX-2. These findings highlight the importance of both COX-1 and COX-2 contributions to pain and the selective efficacy of the NSAIDs in treating various painful conditions.

The COX-2 or inducible isoenzyme can potentially increase by 20-fold over baseline in the presence of tissue injury and inflammation (Malmberg & Yaksh 1992). Pro-inflammatory cytokines and mitogens, such as interleukin-1-beta, (IL- β), interferon gamma, and tumor necrosis factor-alpha (TNF- α), induce COX-2 expression in macrophages, as can platelet-activating factor (PAF), and PGE₂ (Bertolini et al. 2001). These events may also occur in chondrocytes, osteoblasts and

synovial microvessel endothelial cells. The higher COX levels increase prostenoid production, where these compounds serve as amplifiers of nociceptive input and transmission in both the peripheral and central nervous systems (Malmberg & Yaksh 1992). The COX-2 selective NSAIDs have been shown to be clinically useful in managing inflammatory pain in humans and animals. This has been a focus of the pharmaceutical industry, as a selective COX-2 inhibitor may potentially show efficacy in alleviating pain and hyperalgesia while sparing COX-1 constitutive activity and potential adverse effects associated with NSAID administration. Unfortunately, the biological system is not as simple as first envisioned. While COX-2 is induced during inflammation, it has also been shown to be induced during resolution of the inflammatory response where the antiinflammatory PGs (PGD₂ and PGF_{2 α}), but not pro-inflammatory PGE₂, are produced. Potentially, inhibition of COX-2 during this phase may actually prolong inflammation (Bertolini et al. 2001). As is the case for COX-1, it now appears that the COX-2 isoenzyme also has important constitutive functions. Studies indicate there may be a protective role for COX-2 in maintenance of gastrointestinal integrity, ulcer healing, and in experimental colitis in rats (DuBois et al. 1998; Reuter et al. 1996; Schmassmann et al. 1998). In addition, the COX-2 isoenzyme appears to have constitutive functions associated with nerve, brain, ovarian and uterine function, and bone metabolism (DuBois et al. 1998). Therefore, the potential for NSAID associated side effects with these systems is of concern. Of major importance are the COX-2 constitutive functions within the kidney which differ from those of COX-1 in hypotensive and hypovolemic states (Imig 2000). Also, COX-2 appears to be important in nephron maturation (Harris 2000). The canine kidney is not fully mature until three weeks after birth, and administration of a NSAID during this time, or to the bitch prior to birth, may cause a permanent nephropathy (Horster et al. 1971). In fact, in COX-2 null mice which lack the gene for COX-2, all animals die before 8 weeks of age from renal failure (Morham et al. 1995). This does not occur in COX-1 null mice, and interestingly, these mice did not develop gastric pathology (Morham et al. 1995).

When considering the COX selectivity of a particular NSAID, the concentration (i.e., dose) of the NSAID may also influence its actions. A drug may function as a competitive, nonpreferential, or selective COX inhibitor (COX-1 or COX-2) at higher concentrations, and as a COX-2 selective inhibitor at lower concentrations (Lipsky et al. 2000). The significance of this is the potential for inhibition of COX-1 with administration of an allegedly COX-2 selective NSAID. The COX selectivity may be present *in vitro*, however, at the dosing required to achieve analgesia, such selectivity may be lost. Cloning studies comparing canine COX isoenzymes with human COX isoenzymes found that they

are highly homologous (Gierse et al. 2002). Canine COX-1 and COX-2 had a 96% and 93% DNA sequence homology, respectively, with their human counterparts. This suggests that they would be similarly affected by pharmaceuticals, such as NSAIDs designed to inhibit their function. However, the distribution of the COX enzymes may differ among species. When summarizing the common adverse effects noted in veterinary patients following administration of NSAIDs (ie. gastrointestinal ulceration, renal perturbations, and hemorrhage), hemorrhage is the only one that appears to be spared with COX-2 selective NSAIDs in animals with normal platelet numbers and function.

Cyclooxygenase-2 is reduced following administration of glucocorticoids, which may partially explain the antiinflammatory and analgesic effects of this class of medications. Of interest, in addition to the COX-2 role in inflammation, aberrantly upregulated COX-2 expression is increasingly implicated in the pathogenesis of a number of epithelial cell-origin carcinomas, including colon, esophagus, breast, and skin, and in Alzheimer's disease and other neurological conditions (Fosslien 2000; Lipsky 1999; Smalley & DuBois 1997). The COX-2 inhibitors are being researched as potential anti-carcinogenic agents (FitzGerald & Patrono 2001).

Dissecting out the details of the derivation and specific actions of COX-1 and COX-2 continues to provide important insight into the management of pain with NSAIDs. The picture, however, remains incomplete, as some NSAIDs do not significantly inhibit these enzymes. This finding stimulated the search for a potential COX-3 isoenzyme. Based on studies using canine cortex, a COX-3 isoenzyme was discovered that was derived from the same gene as COX-1 (Chandrasekharan et al. 2002). The COX-3 isoenzyme is also present in human brain and heart tissues. It is distinct from COX-1 and -2, as demonstrated in studies using common analgesic/antipyretic NSAIDs in suppressing COX production. Acetaminophen inhibited COX-3 activity, but not COX-1 and -2, as did dipyron (Chandrasekharan et al. 2002). Both of these agents are frequently used to reduce fever in animals. Other analgesic/antipyretic NSAIDs found to be effective COX-3 inhibitors are diclofenac (the most potent), and aspirin and ibuprofen (which preferentially inhibit COX-3 over COX-1 and -2). The overall conclusion of this particular study was that COX-3 possesses COX activity that differs pharmacologically from both COX-1 and -2, but is more similar to COX-1 (Chandrasekharan et al. 2002). This study also reported that the COX-3 isoenzyme is more susceptible to inhibition by drugs that are analgesic and antipyretic but which lack anti-inflammatory activity. This observation again emphasizes the potential utility of administering NSAIDs with different COX selectivities for managing pain of different etiologies. As the COX-3 isoenzyme

genetic profile is derived from the COX-1 gene, it appears that the COX-1 gene plays an integral role in pain and/or fever, depending on the physiologic context (Chandrasekharan et al. 2002). This has been confirmed by the studies mentioned earlier (Ballou et al. 2000; Botting 2003; Ochi et al. 2000). The COX-1 selective NSAIDs used in veterinary and human patients with poor central nervous system penetration (i.e., ketoprofen and ketorolac) may, in fact, reach sufficient concentrations in the brain to inhibit COX-3 (Warner et al. 1999). It is also recognized that the analgesic effects of these NSAIDs frequently occur at lower dosages than those required to inhibit inflammation.

The NSAIDs and Fever

Just as the relationship between pain and the various activities of the COX system is complex, so too is the association between fever and the COX isoenzymes. The mechanisms leading to the generation of fever vary depending on the inciting factor that may be peripheral (i.e., endotoxin) or central (i.e., endogenous pyrogens, such as IL-1). Interspecies variation is also substantial, and the definitive role of the COXs in pyresis remains to be clearly elucidated. Evidence suggests that COX-2 plays a role in endotoxin pyrexia while, based on the antipyretic effects of acetaminophen and aspirin, COX-1 and COX-3 appear to function in endogenous pyrexia (Botting 2000, 2003; Chandrasekharan et al. 2002).

The NSAIDs and Endogenous Antiinflammatory Mechanisms

Endogenously generated small chemical mediators, or autacoids, play a key role in controlling inflammation by inhibiting polymorphonuclear cell recruitment and enhancing monocyte activity in a nonphlogistic manner (Rainsford 1992). Arachadonic acid-derived lipoxins (LX), particularly LXA4, have been identified as anti-inflammatory mediators, indicating that the LOX pathway has a dual proinflammatory and anti-inflammatory function.

The NSAIDs may amplify or decrease this endogenous anti-inflammatory system. Aspirin is more COX-1 selective and can impair many components of mucosal defense and enhance leukocyte adherence within the gastric and mesenteric microcirculation (Wallace & Fiorucci 2003). However, with chronic use of aspirin, there is an adaptation of the gastric mucosa that is associated with a marked upregulation of COX-2 expression and lipoxin production. This lipoxin is specifically termed aspirin-triggered lipoxin (ATL). Aspirin is unique among current therapies because it acetylates COX-2, thereby enabling the biosynthesis of 15(R)-hydroxyeicosatetraenoic acid (15(R)-HETE) from arachidonic acid, which is subsequently converted to ATL by 5-LOX. Inhibition of either the COX-2 or 5-LOX enzymes results in blockade of ATL synthesis (Wallace

& Fiorucci 2003). Lipoxin A4 and ATL (a carbon-15 epimer of LX) attenuate aspirin-induced leukocyte adherence, whereas administration of selective COX-2 inhibitors blocks ATL synthesis and has been shown to augment aspirin-induced damage and leukocyte adherence to the endothelium of mesenteric venules in rats (Wallace & Fiorucci 2003).

In addition to the lipoxins, aspirin-induced COX-2 acetylation results in the generation of numerous other endogenous autacoids derived from dietary omega-3 fatty acids (Serhan et al. 2002). Some of these local autacoids are potent inhibitors of neutrophil recruitment, thereby limiting the role of these cells during the resolution phase of inflammation, and thus are referred to as “resolvins” (Serhan et al. 2002). The identification of both the lipoxins and the resolvins has introduced new potential therapeutic avenues for the treatment of inflammation, cardiovascular disease, and cancer.

Other Pharmacologic Considerations for NSAID Use

Because of their high protein binding, NSAIDs can displace other drugs from their plasma protein binding sites and potentially increase their plasma concentration. This is rarely a concern unless administered to animals with organ dysfunction or in those receiving other highly protein bound medications with a narrow therapeutic index. Interference with the metabolism and excretion of certain coadministered drugs may occur; therefore, verifying the safety of combination therapy is always mandatory.

Some NSAIDs may induce the syndrome of inappropriate secretion of antidiuretic hormone (ADH). Renal water reabsorption depends on the action of ADH mediated by cyclic adenosine monophosphate (cAMP). As PGs exert a controlled negative feedback action on cAMP production, inhibition of PG synthesis results in above-normal levels of cAMP with potential for enhanced ADH activity. In addition, the administration of a COX-2 selective NSAID may enhance sodium and water reabsorption. Clinically, both mechanisms may result in high specific gravity urine with dilutional hyponatremia. Urine volume may be decreased through this mechanism but without renal injury (Dunn & Buckley 1986; Petersson et al. 1987).

Contraindications for NSAIDs

NSAIDs should not be administered to animals with acute renal insufficiency, hepatic insufficiency, dehydration, hypotension, conditions associated with low “effective circulating volume” (i.e., congestive heart failure and ascites), coagulopathies (i.e., factor deficiencies, thrombocytopenia, and von Willebrand’s disease), or evidence of gastric ulceration (i.e., vomiting with or without the presence of “coffee ground material,” and melena). Administration of NSAIDs following gastrointestinal surgery must be determined by the health of

this organ at the time of surgery. As the COX-2 isoenzyme is important for healing, intuitively, NSAIDs would be contraindicated where compromised bowel is noted. Concurrent use of other NSAIDs (i.e., aspirin) or corticosteroids is not recommended. The COX-1 preferential NSAIDs are contraindicated in animals with spinal injury (including herniated intervertebral disc) due to the potential for hemorrhage and neurologic deterioration, and due to excessive bleeding at the surgical site should surgical treatment be pursued. The NSAIDs should never be administered to animals in shock, trauma cases at the time of presentation, or animals with evidence of hemorrhage (i.e., epistaxis, hemangiosarcoma, and head trauma). Animals with severe or poorly controlled asthma, or other types of moderate to severe pulmonary disease, may deteriorate with NSAID administration. Aspirin has been documented to exacerbate asthma in human patients; however, COX-2 specific NSAIDs did not result in worsening of clinical signs (West & Fernandez 2003). It is not known whether animals may be affected in this way. Although administration of NSAIDs in head trauma, pulmonary diseases, or thrombocytopenia is generally contraindicated, COX-2 preferential NSAIDs (i.e., meloxicam, etodolac, carprofen, tolfenamic acid, and deracoxib) may prove to be safe with further study. Due to inhibition of PG activity, the NSAIDs may be detrimental to reproductive function. Indomethacin may block prostaglandin activity in pregnant women, resulting in cessation of labor, premature closure of the ductus arteriosus in the fetus, and disruption of fetal circulation (DuBois et al. 1998). These effects may occur in animals; therefore, NSAIDs should not be administered during pregnancy. As COX-2 induction is necessary for ovulation and subsequent implantation of the embryo (DuBois et al. 1998), NSAIDs should also be avoided in breeding females during this stage of the reproductive cycle. As previously mentioned, the COX-2 isoenzyme is required for maturation of the embryological kidney so administration to lactating mothers should be avoided.

NSAIDs used in Veterinary Medicine

There is little data regarding clinical pharmacology of NSAIDs in exotic species, thus care must be taken when extrapolating from common domestic species.

Meloxicam Meloxicam is a COX-2 preferential NSAID approved for use in dogs in Australasia, Europe, and North America. The parenteral formulation is approved for cats in the United States and Australasia. Its use in cats in Canada is under investigation with completed studies indicating safety and efficacy. Its use in horses is also under investigation, with pharmacokinetic studies indicating that the half-life is shorter and clearance greater than in the dog, suggesting that dosing more than once a day may be necessary (Sinclair et al. 2003).

Studies indicate no renal or hepatic abnormalities with acute administration and minimal to no anti-thromboxane activity, suggesting hemostasis in normal animals may not be a problem (Mathews et al. 1999; Poulsen Nautrep & Justus 1999). Few adverse reactions have been documented, and most involve the gastrointestinal tract. A recent study showed no difference in gastric erosions over saline placebo when meloxicam was administered at 0.1 mg/kg for 3 days postelectrical stimulation (i.e., surgical simulation) under anesthesia. However, corticosteroids plus meloxicam in this study resulted in significant gastric erosions (Boston et al. 2003). A case report of combination aspirin and meloxicam in a dog resulted in duodenal perforation (Reed 2002). This case illustrates the importance of COX-2 in intestinal protection when aspirin is coadministered, and reinforces that different NSAIDs should not be administered concurrently. Analgesia is excellent when meloxicam is combined with an opioid.

Carprofen Although classified as a NSAID, carprofen administration to beagle dogs did not inhibit PGE₂, 12-hydroxyeicosatetrenoic acid or thromboxane B₂ synthesis in an experimental study utilizing subcutaneous tissue cage fluids (McKellar et al. 1994a). It was concluded that the principle mode of action of carprofen must be by mechanisms other than cyclooxygenase or 12-lipoxygenase inhibition. However, more recent studies indicate that it is a COX-2 preferential NSAID (Kay-Mugford et al. 2000; Ricketts et al. 1998). Carprofen is approved for perioperative and chronic pain management in dogs in Australasia, Europe, and North America. Carprofen is approved for single dose, perioperative use in cats in Europe, and is licensed for use in horses in the United Kingdom. In sheep, carprofen (0.7 mg/kg, IV) resulted in plasma concentrations of 1.5 µg/mL, similar to those required to confer analgesia in horses, for up to 48 hours (Welsh et al. 1992). However, analgesia was not assessed in this sheep study (Welsh et al. 1992). Antithromboxane activity is minimal, suggesting that induced coagulopathy may not be a problem in animals with intact hemostatic mechanisms (McKellar et al. 1990; Poulsen Nautrep & Justus 1999).

Ketoprofen Ketoprofen is approved for postoperative and chronic pain in both dogs and cats in Europe and Canada. Ketoprofen is also approved for use in horses and ruminants. As ketoprofen is an inhibitor of both COX-1 and COX-2, adverse effects are a potential problem requiring careful patient selection. Although several studies using ketoprofen preoperatively indicate its effectiveness in controlling postoperative pain, a general consensus among veterinarians has restricted its use primarily to the postoperative period to reduce the potential for hemorrhage (Lobetti & Joubert 2000; Mathews et al. 1999; Pibarot et al. 1997). Ketoprofen

should not be administered to patients with risk factors for hemorrhage. It is often administered to animals immediately after orthopedic procedures (i.e., fracture repair, cruciate repair, and onychectomy).

Etodolac Etodolac is COX-2 preferential and is approved in the United States for use in dogs for the management of pain and inflammation associated with osteoarthritis, but is also useful in other painful conditions (Budenberg et al. 1999; Glaser et al. 1995). The adverse effects appear to be restricted to the gastrointestinal tract.

Deracoxib Deracoxib is a COX-2 specific inhibitor. Deracoxib is approved in the United States and Canada for control of postoperative pain and inflammation associated with orthopedic surgery in dogs. The incidence of vomiting and diarrhea were similar in dogs receiving deracoxib compared with dogs receiving placebo in a perioperative field trial, and overall the drug was well tolerated and effective (Novartis Animal Health USA 2004). It was also shown to be effective in attenuating lameness in dogs with urate crystal-induced synovitis after prophylactic and therapeutic administration (McCann et al. 2004; Millis et al. 2002). This group of NSAIDs appeared to be gastroprotective in human patients when compared with the less COX-2 specific NSAIDs, when used for 8 days to 3 months (Silverstein et al. 2000). However, more recent studies in humans indicate these NSAIDs cannot guarantee gastroprotection with chronic use. Furthermore, in a recent canine study comparing the gastrointestinal safety profile of licoferone (a dual inhibitor) to rofecoxib (another specific COX-2 inhibitor), rofecoxib was found to induce significant gastric and gastroduodenal lesions (Moreau et al. 2005).

Diclofenac Diclofenac is available worldwide as several different human and veterinary formulations. It is a useful antiinflammatory and analgesic drug and has been studied for antimicrobial activity (Dutta et al. 2007). Diclofenac has been observed to cause severe hepatic and nephrotoxicity in many species of birds and its use, or accidentally ingestion from carcasses should be avoided (Hussain et al. 2008; Jain et al. 2009; Jayakumar et al. 2010; Naidoo et al. 2009; Oaks et al. 2004; Taggart et al. 2007).

Firocoxib Firocoxib is available as an oral paste and injectable for horses and as an oral formulation for dogs. The efficacy and adverse events appear similar to other coxib-class NSAIDs (Food and Drug Administration: Center for Veterinary Medicine [FDA-CVM], 2011).

Robenacoxib Robenacoxib is available (currently outside the United States) as an oral and injectable formulation for treatment of pain and inflammation in

both dogs and cats. The efficacy and adverse events appear similar to other coxib-class NSAIDs.

Mavicoxib Mavicoxib is a long-acting NSAID approved outside the United States for use in dogs. The dosing interval is usually 2 weeks between doses 1 and 2, the 4 weeks between subsequent doses. The elimination half-life in healthy dogs is approximately 2 weeks (range 7.9–38.8 days) (Cox et al. 2010). Significant individual and breed associated differences have been observed, but effects on drug safety and effectiveness have yet to be determined (Cox et al. 2011).

Tepoxalin Tepoxalin is a COX-1, COX-2, and LOX inhibitor of varying degrees with efficacy comparable with meloxicam or carprofen and safety comparable with placebo (FDA-CVM 2005). Tepoxalin has been approved for management of osteoarthritic pain in dogs. The safety profile of tepoxalin showed no difference from placebo when administered prior to a 30-minute anesthesia period and a minor surgical procedure in dogs (Kay-Mugford et al. 2004).

Tolfenamic Acid Tolfenamic acid is approved for use in cats and dogs in Europe and Canada for controlling acute postoperative and chronic pain. The dosing schedule is 3 days on and 4 days off that must be strictly adhered to. Reported adverse effects are diarrhea and occasional vomiting. Tolfenamic acid has significant anti-inflammatory and antithromboxane activity; therefore, posttraumatic and surgical hemostasis may be compromised during active bleeding after administration of this NSAID (McKellar et al. 1994b).

Flunixin Meglumine Flunixin meglumine is a COX-1 and COX-2 inhibitor and is approved for use in dogs in Europe but not North America. It is also approved for use in ruminants and horses and is commonly used for equine colic pain.

Phenylbutazone Phenylbutazone is approved for use in horses, cattle, and dogs in North America. Since safer NSAIDs are approved for dogs, phenylbutazone is not recommended for this species. In horses, there is high risk of gastric ulceration and nephrotoxicity, where signs of toxicity may progress from inappetence and depression to colic, gastrointestinal ulceration, and weight loss (Collins & Tyler 1984; MacAllister et al. 1993; Snow et al. 1981). Phenylbutazone has a prolonged elimination half-life in cattle, ranging from 30 to 82 hours (Arifah & Lees 2002; DeBacker et al. 1980).

Aspirin Aspirin is primarily a COX-1 inhibitor. It has been most commonly used as an analgesic for osteoarthritic pain in dogs. It is also available in proprietary combinations with various opioids (aspirin plus codeine or aspirin plus oxycodone) to achieve a synergistic

effect for the treatment of moderate pain. It is also used as an antipyretic and anticoagulant in dogs and cats. Aspirin has also been recommended in cattle (Gingrich et al. 1975).

NSAIDs Not Approved for Use in Veterinary Medicine (Off-Label Use)

Ketorolac Ketorolac is a COX-1 and COX-2 inhibitor and is included for the benefit of those working in the research setting associated with human hospitals where the availability of ketorolac is more likely than other NSAIDs. Adverse gastrointestinal effects are common.

Acetaminophen Acetaminophen is a COX-3 inhibitor with minimal COX-1 and COX-2 effects. It should not be administered to feline species due to deficient glucuronidation of acetaminophen in these species (Court & Greenblatt 1997).

Dipyrone Dipyrone is a COX-3 inhibitor and is approved for use in cats and dogs in Europe and Canada. Dipyrone should be given intravenously to avoid the irritation experienced when given intramuscularly. The analgesia produced is not usually adequate for moderate to severe postoperative pain, and dipyrone is reserved for use as an antipyretic in cases where other NSAIDs are contraindicated. Dipyrone induces blood dyscrasias in humans; however, this has not been reported in animals.

ALPHA-2 ADRENERGIC RECEPTOR AGONISTS AND ANTAGONISTS

Introduction

The use of alpha-2 adrenergic agonists in veterinary medicine began following the synthesis of xylazine in 1962. Early reports of the sedative and anesthetic sparing qualities of xylazine predated the elucidation of its mechanism of action in 1981. Alpha-2 adrenoreceptors have been identified in the CNS, cardiovascular, respiratory, renal, endocrine, gastrointestinal, and hemotologic systems, resulting in widespread drug effects (Aantaa et al. 1995). Most FDA-CVM approved alpha-2 agonists carry label indications as sedatives and analgesics.

Alpha-2 adrenoceptors are linked to Gi-protein second messengers (Aantaa et al. 1995). These are similar to those used by many opioid receptor subtypes and in fact, opioid and alpha-2 agonists usually have additive or synergistic effects (Maze & Tranquilli 1991). Alpha-2 adrenoreceptors are classically described as being located presynaptically at noradrenergic neurons exerting an inhibitory feed-back role on the release of subsequent norepinephrine (NE) (Maze & Tranquilli 1991). This results in decreased sympathetic nervous system efferent activity and probably is related to the decreased vigilance, decreased anesthetic requirements,

and decreased heart rate and blood pressure observed following administration of these drugs to most species. Alpha-2 adrenoreceptors are also found in the vascular smooth muscle (a nonpresynaptic site) and when activated result in vasoconstriction. This results in increased vascular resistance and will result in increased baroreceptor-mediated vagal tone. The result is slowing of heart rate and decreasing cardiac output, but blood pressure remains within physiologic normal values. Confusion often exists about the clinical effect of alpha-2 agonist administration (e.g., hypertension [postsynaptic] vs. hypotension [presynaptic]) expected in a patient. The net clinical result will vary with route of administration, dose, species, and the duration of time following the administration.

Alpha-2 agonist doses vary at least 10-fold across species. Pigs tend to have the highest requirements, followed by cats, dogs, horses, and finally ruminants. Breed and sex differences also exist within cattle that should be appreciated.

Alpha-2 Adrenergic Agonist Effects

Central Nervous System Alpha-2 adrenergic agonists exert many of their inhibitory effects on central nervous system (CNS) function through inhibiting NE release from sympathetic neurons (Maze & Tranquilli 1991). Inhibition of intraneuronal transmission is also responsible for muscle relaxation observed following alpha-2 adrenergic agonist administration. Analgesia is mediated by spinal and supraspinal alpha-2 adrenergic receptors. Agonist binding modulates afferent activity at a spinal level and increases the diffuse noxious inhibitory control system activity. The net result is sedation, reduced anesthetic requirements, reduced stress responses, and analgesia. It should be noted that alpha-2 agonists, like all sedatives and tranquilizers, are not anesthetics. Although animals can appear in a sleep-like state, they may become aroused by noxious stimulation and may become defensive. Additionally, on rare occasions, paradoxical behavior (aggression rather than sedation) may be noted. Accidental intracarotid injection of alpha-2 adrenergic agonists will induce seizure-like activity and must be avoided.

Emetic Center Alpha-2 agonists are predictable emetics in cats and dogs, especially at high doses. This is due to activation of the chemoreceptor trigger zone of the area postrema (Hikasa et al. 1992). Dopaminergic blocking agents do not prevent alpha-2-induced emesis.

Thermoregulation Alpha-2 agonists will often cause changes in thermoregulation. The effect is usually a decrease; however, increases can be seen when animals are placed in warm environments. This is especially a concern when alpha-2 agonists are used for capture of cattle or other hoof-stock. If possible, body temperature should be monitored for 12–24 hours following

sedation or administration of an alpha-2 adrenergic antagonist should be considered. In smaller animals, hypothermia is more common and may be due to decreased metabolic activity accompanying sedation as well as decreased thermoregulatory control. It is usually not a life-threatening problem if managed appropriately.

Eye Alpha-2 agonists generally cause mild miosis to little change in pupil diameter and a mild decrease in intraocular pressure (IOP) (Verbruggen et al. 2000). The class of drugs is relatively contraindicated with increases in intraocular pressure or corneal lacerations because of the probability of inducing vomiting (which causes further increases in IOP) in those species that can vomit.

Respiratory System Most alpha-2 adrenergic receptor agonists can cause decreased responsiveness to CO₂, especially in higher doses. This effect is compounded by the coadministration of opioids or anesthetic agents and is of concern during anesthesia. In some species, alpha-2 agonists do not normally depress respiration to the point of creating hypoxia and cyanosis. In fact, arterial blood gas values for PaO₂ are usually normal. The bluish color of the mucous membranes that may be noticed on occasion is usually due to slowed venous blood flow accompanying vasoconstriction. As the capillary transit time increase, oxygen extraction increases, and notable hemoglobin desaturation will appear as a blue(ish) color. Oxygen therapy will often resolve this condition. However, in sheep and possibly some other species, xylazine administration has been shown to result in central hypoxemia related to pulmonary changes (Celly et al. 1997, 1999).

Cardiovascular System Intravenous administration of alpha-2 adrenergic agonists typically results in rapid and pronounced vasoconstriction (Pypendop & Versteegen 1998). If heart rate and cardiac output do not decrease (as can be seen with atropine administration), blood pressure would increase impressively (Alibhai et al. 1996; Short 1991). However, normal baroreceptor reflexes attempt to maintain blood pressure within physiologic limits by increasing vagal tone and slowing heart rate. Heart rate may decrease by 50–75% in some individuals. The cardiac rhythm is often a slow sinus rhythm characterized by two or three sequential beats followed by a long sinus pause. Occasionally, second-degree atrioventricular blockade will be seen. Both rhythms are often responsive to antimuscarinic administration (block the vagal reflex) and high heart rates (and blood pressures) will result. Intramuscular or oral administration tends to decrease the incidence of profound bradycardia.

After the initial direct vasoconstriction occurs, vasodilation and reduction in blood pressure may be seen.

This is more prominent in primate species. The alpha-2 adrenergic receptor agonists decrease sympathetic nervous system efferent activity, which results in decreased vasomotor tone and heart rate. Alpha-2 adrenergic agonists have historically been used in humans as antihypertensive agents because they reduce vasomotor tone and block the reflex increase in heart rate that can accompany alpha-1 antagonists.

Most of the contraindications to alpha-2 adrenergic receptor agonist administration are related to their cardiovascular side effects. As a general rule, this class of drugs should not be administered to animals that do not have normal healthy cardiovascular systems and/or are exercise intolerant. There are some exceptions, but a thorough understanding of the underlying disease is required and appropriate monitoring necessary.

Urinary Tract Alpha-2 adrenergic receptor agonists increase urine output by increasing production of dilute urine (Grimm et al. 2001; Saleh et al. 2005). This is primarily related to inhibition of antidiuretic hormone (ADH) release and/or synthesis, as well as changes in renal hemodynamics (Saleh et al. 2005).

Gastrointestinal Tract Animals may have complications associated with decreased propulsive activity, including colic and bloat, although this is unusual in most species (Thompson et al. 1991). Longer-acting drugs are more likely to result in a problem. Patients should be observed following alpha-2 adrenergic receptor agonist administration for signs of abdominal distension.

Endocrine A classic neuroendocrine response is hyperglycemia following alpha-2 agonist administration (Abdel el Motal & Sharp 1985; Osman & Nicholson 1991). This is due to a decrease in insulin release. It is usually transient and not clinically significant, although alpha-2 agonists should not be used to sedate animals for glucose curves.

Since alpha-2 agonists reduce sympathetic activity and inhibit the stress response, neuroendocrine markers of the stress response should be affected. Cortisol levels are usually decreased following alpha-2 agonist administration and may not be reliable as indicators of stress or pain (Brearley et al. 1990; Sanhoury et al. 1992).

Specific Drugs

Several alpha-2 adrenergic receptor agonists are approved for veterinary use. Generally, their pharmacologic actions will be similar, but the duration of action and species compatibility will vary. All alpha-2 agonists are potent and potentially dangerous following accidental human ingestion or injection. Care should be taken when handling syringes loaded with these drugs and medical help should be sought immediately if exposure occurs.

Xylazine Xylazine is the prototypical veterinary alpha-2 adrenergic receptor agonist. Another alpha-2 agonist, clonidine, has been used in humans as an antihypertensive agent and is often used as the prototypical drug in research applications. Xylazine has been administered to many different species, both domestic and exotic. It is readily available and relatively inexpensive.

Xylazine has a shorter duration of action than many of the other drugs. Typical doses will result in muscle relaxation and sedation of horses for 45–60 minutes. This can be advantageous when performing field anesthesia/sedation when a rapid recovery is desired. Xylazine is often combined with opioids like butorphanol to enhance sedative and analgesic qualities.

Detomidine Detomidine is a longer acting alpha-2 agonist approved for use in horses as a sedative. It is commonly administered when profound, long-lasting sedation is needed. When used in high doses as a pre-anesthetic, low respiratory rates may accompany induction. Detomidine is not used in small animals and has not been widely evaluated in exotic species.

Medetomidine Medetomidine is approved for use as a sedative/analgesic in dogs. The drug has also been extensively evaluated in all domestic species and many exotic and zoological species. It is extremely selective for the alpha-2 receptor and binds it avidly. Atipamezole was developed as the specific antagonist for medetomidine for this reason.

Romifidine Romifidine is an alpha-2 adrenergic receptor agonist that is approved for use in horses. It has been evaluated in other species and appears to be relatively safe, but offers few advantages over other approved products. Some equine clinicians believe it is a good sedative without causing excessive ataxia.

Dexmedetomidine Dexmedetomidine is the newest of the alpha-2 adrenergic agonists to be marketed to veterinarians. Unlike medetomidine, which is a racemic mixture of two stereoisomers, dexmedetomidine contains only the pure dextrorotatory enantiomer, which appears to be responsible for all of the clinically relevant properties of the drug. Due to the absence of the inactive levorotatory enantiomer, dexmedetomidine is twice as potent as medetomidine. It is currently marketed as a solution with half the strength of medetomidine, meaning that equivalent doses of dexmedetomidine and medetomidine have the same volume. The sedative, analgesic, and anesthetic-sparing effects of both drugs appear to be similar when administered at equivalent doses in dogs and cats (Ansah et al. 1998; Granholm et al. 2006, 2007; Kuusela et al. 2000). Hemodynamic side effects also appear similar. While it has been proposed that recoveries from dexmedetomidine

may be faster compared with medetomidine due to the additional metabolic burden imposed by levomedetomidine, there is no current evidence to support this claim.

Alpha-2 Adrenergic Receptor Antagonists

One big advantage alpha-2 adrenoreceptor agonists have over other sedative/tranquilizers like acepromazine is reversibility. It is possible to administer an antagonist and within minutes animals will regain function and be able to be released. Antagonist administration will usually result in opposite hemodynamic effects (e.g., acute vasodilation and tachycardia), and they should not be administered in a cavalier fashion. Many of the difficulties (including some deaths) occur with reversal. Also, alpha-2 agonist-mediated analgesia is reversed, necessitating administration of other analgesic classes to animals in pain. Some species (e.g., domestic horses) are not routinely reversed because of the potential for uncontrollable activity and possible self-trauma.

Yohimbine Yohimbine is a plant-derived compound that has been used by humans for centuries because of its performance enhancing properties. It is relatively effective for reversing xylazine in horses, dogs, and cats, but is less effective in ruminants. Additionally, yohimbine has some stimulant actions that may result in excitation upon recovery. Yohimbine has not been effective at reversing newer agents like medetomidine.

Tolazoline Tolazoline was originally used as a therapy for human infants suffering from pulmonary hypertension. It is a relatively nonselective alpha-receptor blocker and is useful for reducing pulmonary vascular resistance. It is also effective at antagonizing xylazine sedation. It is most commonly used for equine and ruminant species. It appears more effective in ruminant species than yohimbine.

Atipamezole Atipamezole is the marketed antagonist for medetomidine and dexmedetomidine. It is effective at reversing all available alpha-2 adrenoreceptor agonists and its use is limited only by cost. It is relatively selective for alpha-2 adrenergic receptors and usually does not cause excessive stimulation, although excitation may occur. Atipamezole is approved for use in dogs; however, it is used in other species commonly. Under most circumstances, it is best given by the IM route except in emergency situations.

PHENOTHIAZINES AND BUTYROPHENONES

Introduction

The phenothiazines and butyrophenones produce an array of behavioral, autonomic, and endocrine effects

and have been used clinically in numerous domestic and wild species. Their tranquilizing effects are mediated by antagonism of dopamine receptors (primarily the D2 subtype) located in the cerebral cortex, basal ganglia, and limbic system. In addition, other antidopamine effects are noted in the hypothalamus (increased prolactin secretion and impaired thermoregulation), brainstem (impaired vasomotor reflexes), and chemoreceptor trigger zone of the medulla (antiemesis). Both drug classes also have varying antagonistic effects at adrenergic (alpha-1 and alpha-2), serotonergic (5HT), muscarinic (M1), and histaminergic (H1) receptor systems. It is important to note that they do not possess any inherent analgesic properties and their effects are not reversible.

Acepromazine Acepromazine is the most widely used phenothiazine tranquilizer in veterinary medicine. In dogs and cats it is commonly combined with an opioid to produce a state historically referred to as “neurolept-analgesia.” Such combinations are suitable to provide chemical restraint for short, noninvasive procedures or as preanesthetic medication prior to induction of general anesthesia. Acepromazine administration in the preanesthetic period will cause dose-dependent reductions in both injectable and inhalant anesthetic requirements in these species. In horses and cattle, the drug is used primarily for its antianxiety effects. In susceptible pigs, acepromazine has been shown to prevent or reduce the onset of halothane-induced malignant hyperthermia. In certain wild and exotic species, the combination of acepromazine and the potent opioid etorphine (Large Animal Immobilon) has been used for immobilization and anesthesia.

Cardiovascular effects of acepromazine include decreases in mean arterial blood pressure in the range of 20–30% accompanied by dose-dependent reductions in stroke volume and cardiac output. Isoflurane, due to its potent vasodilatory effects, appears to potentiate acepromazine-induced hypotension. At clinically relevant doses, heart rate may not change appreciably or may increase slightly. At very high doses, bradycardia and sinoatrial block may occur. Acepromazine has also been shown to reduce the arrhythmogenic effects of epinephrine and halothane.

In general, effects on pulmonary function (i.e., oxygenation and ventilation) tend to be minimal in conscious animals, though respiratory rate may decrease somewhat. Acepromazine has been shown to dose-dependently decrease hematocrit by as much as 20–50% in dogs and horses due to splenic sequestration. This effect occurs within 30 minutes and appears to persist for at least 2 hours. The drug also decreases platelet aggregation but the clinical hemostatic significance of this appears minimal.

Regarding the gastrointestinal system, acepromazine has been shown to have antiemetic effects when

administered 15 minutes prior to morphine, hydromorphone, or oxymorphone. Lower esophageal sphincter tone is reduced, which may lead to an increased risk of gastric reflux, though this has not been proven. Decreased gastrointestinal motility and delayed gastric emptying have been demonstrated in horses.

Renal blood flow and glomerular filtration rate appear to be well maintained in dogs receiving acepromazine and isoflurane. In cats under halothane anesthesia, urethral pressure has been shown to decrease by 20% with acepromazine administration. There are anecdotal reports of penile prolapse/priapism in stallions. The magnitude and duration of the protrusion appear to be dose-dependent, and this side effect appears to be mediated by alpha adrenergic antagonism. Also, because of its antihistaminergic effects, acepromazine is not suitable for allergic skin-testing.

Azaperone Azaperone is classified as a butyrophenone and its only approved indication is for control of aggression associated with mixing or regrouping of swine. It is also used as a preanesthetic agent in pigs and has clinical properties and side effects similar to acepromazine. In various wild and exotic species, azaperone is used in combination with potent opioids, such as etorphine or carfentanil, to produce immobilization or anesthesia.

Monitoring

Larissa Ozeki and Nigel Caulkett

INTRODUCTION

The anesthetist must serve as the patient's advocate from the time of induction until it is fully recovered. To serve in this role, it is vital that the anesthetist is constantly aware of the patient's physiological status. There have been many advances in monitoring technology over the past 20 years, and portable, sturdy monitors are available for use in the field and remote situations. Zoo and wild animals can be particularly challenging to monitor as their diversity in physiology may result in a lack of normal values for commonly monitored parameters. Much of the monitoring equipment we use was designed for human patients, and diversity in size can introduce a challenge when these monitors are applied to very large or very small patients.

As with any patient, it is important to monitor cardiovascular and respiratory function; ideally, there should be constant monitoring of these systems. It is also vital to monitor thermoregulation. Hyperthermia is a common complication during wildlife capture that may lead to acute death or possibly contribute to capture myopathy. Since animals are often anesthetized outdoors, hypothermia may occur more rapidly in small patients. Body temperature should be monitored frequently in anesthetized wildlife.

This chapter will discuss an approach to monitoring anesthetized zoo and wild animals. It will discuss the utility of commonly used monitoring techniques and their application in a variety of species. The chapter will start with the basic requirements of monitoring and will be expanded to discuss monitoring by body system. The focus will be on the monitoring technology with specific normals and application of these techniques being discussed in the species-specific chapters.

MONITORING BASICS

Before any anesthetic procedure, it is important to devise an anesthetic and a monitoring plan. The monitoring plan must take into account the anesthetic risk, the procedure the patient is about to undergo, the environment where the procedure will take place, and any anticipated complications. With anesthesia of free-ranging wildlife, there are often limitations in the amount of equipment that can be carried or the number of personnel available to monitor the patient, as even if a veterinarian is present, they may often be involved in sampling or surgical procedures.

Frequency of monitoring is an important consideration. Ideally, cardiovascular and respiratory function should be monitored continuously, with depth of anesthesia and body temperature being monitored intermittently. If continuous monitoring is not available, frequency of monitoring will probably be dependent on the availability of personnel who can devote their time to monitoring. Ideally, monitoring should be performed continuously with specific values recorded every 5–10 minutes.

Appropriate monitoring always requires an anesthetic record. During anesthesia, trends in physiological status are as important as absolute values. A well-designed record allows for the visual observation of trends. The record should contain patient information, including age, species, sex, and temperament. It should contain any hematological information and physical condition. It should include information regarding the procedures being performed and the ambient conditions (with field procedures). The record should contain information regarding capture technique and drugs administered (including number of darts). Typically, a time to sternal recumbancy and

head down is also recorded. Any therapeutic interventions should be recorded, for example, oxygen therapy, and monitoring modalities should also be recorded. A section is devoted to a record of physiological values over time. The record should include dose and administration time of any antagonist drugs and time to head up and walking. A section should also be included for comments to include any additional information that may be pertinent to the procedure.

Why Is Monitoring Important?

There have been many improvements in wildlife capture and handling over the years, and the efficacy and safety of anesthetic techniques has increased greatly, but we still encounter many complications, even in healthy animals. Some of these complications, such as hypoxemia in ungulates, are predictable, but others, such as hyperthermia, acidosis, and capture myopathy, may result from the capture event itself. With capture of free-ranging wildlife or dangerous zoo animals we cannot perform a pre-anesthetic exam and although we often assume that we are dealing with healthy animals we cannot determine the health status until the animal is under anesthesia. In some situations, anesthesia can result in decompensation and emergent situations. With anesthesia of domestic animals, it is often possible to titrate induction drugs to minimize side effects. During anesthesia of wildlife, we will often deliver drugs at the higher end of the dose range in an attempt to induce anesthesia rapidly, without repeated dart administration and prolonged pursuit. Anesthesia of zoo and wild animals is further complicated by the massive variety of species and varied physiology between species. There is often a paucity of information in the scientific literature concerning anesthetic techniques of many of these species, and we are often forced to extrapolate from other closely related species. Free-ranging wildlife are subject to the environmental conditions in which they live, and may be exposed to extremes of temperature and physical hazards during induction and recovery. Anesthesia of zoo and wildlife patients is arguably one of the most challenging aspects of veterinary anesthesia. Given the potential risks involved, it is vital to initiate monitoring procedures as soon as the animal has been approached and to continue monitoring throughout the procedure.

What Should be Monitored?

Neglecting to monitor depth of anesthesia can have very adverse consequences for capture personnel during anesthesia of potentially dangerous wildlife. It is vital to take the time to monitor anesthetic depth on a routine basis. Anesthetic drugs have many side effects and the choice of monitoring techniques will often depend on the drugs that are being used, the species being anesthetized, and the availability of equipment.

In an ideal world, it would be best to use a monitor that would ensure that blood flow is preserved to vital organs and that oxygen delivery to the tissues is adequate to meet the tissue oxygen demand. Monitors are available to provide this information, but unfortunately they are not practical in routine clinical situations. For this reason, we typically use monitors that will indirectly allow us to determine that we are adequately perfusing organs and meeting the body's oxygen demand.

Global oxygen delivery (DO_2) is the product of cardiac output \times arterial oxygen content (CaO_2) and is represented by the following equation:

$$DO_2 = \text{Cardiac output} \times 0.003 (\text{PaO}_2) + 1.39 (\text{SaO}_2 \times \text{Hb}).$$

From the above equation, it is apparent that to maximize global oxygen delivery, it is important to ensure an adequate cardiac output, maximize percent hemoglobin saturation, and ensure an adequate hemoglobin concentration (or hematocrit). We have the ability to measure PaO_2 , SaO_2 , and Hb concentration, it is difficult to measure cardiac output under field conditions; therefore we must rely on indirect measurements such as blood pressure and heart rate. It is also apparent that appropriate monitoring should evaluate cardiovascular and respiratory function. Hyperthermia will increase metabolic oxygen demand, necessitating an increase in oxygen delivery to meet the increased oxygen demand. If this increased demand is not met, tissue hypoxia may result. Frequent measurement of body temperature is vital during wildlife capture and handling.

MONITORING THE RESPIRATORY SYSTEM

The most basic monitoring of the respiratory system consists of visualization of chest excursions to determine rate and subjectively determine depth of respiration. Respiratory rate should be monitored every 5 minutes at minimum. To effectively monitor the respiratory system, it is important to determine oxygenation, and ventilation. A crude method to determine oxygenation is to visualize mucous membranes, and determine if cyanosis is present. This can be extremely subjective. The pulse oximeter can be used to determine percent hemoglobin concentration, which will assist with a diagnosis of hypoxemia. The pulse oximeter will not determine if ventilation is adequate. Capnography can be used to assess the adequacy of ventilation in field situations; it will quantify end-tidal carbon dioxide, and this value can be analyzed to determine if hypoventilation or hyperventilation is present. Both of these techniques will provide an indirect measure of respiratory function and are very useful tools, but both techniques are subject to considerable error during wildlife anesthesia. Arterial blood gas analysis is the gold standard to determine oxygenation and

ventilation; it will provide a direct measurement of PaO_2 and PaCO_2 , which can be used to effectively diagnose hypoxemia, hypoventilation, or hyperventilation. These techniques are discussed below.

Pulse Oximetry

The pulse oximeter is a simple, noninvasive monitor that provides real-time values of hemoglobin saturation and pulse rate; therefore, it enables the anesthetist to detect hypoxemia in the patient before other clinical signs develop (Dorsch & Dorsch 2008; Sinex 1999). It is ideal for perioperative monitoring because it is an automatic, continuous, and audible monitor. The pulse oximeter's portability, ease of operation, and wide availability make it a useful tool to monitor anesthesia in field situations.

The pulse oximeter estimates the oxygen percentage linked to hemoglobin in arterial blood by measuring light absorption characteristics. The main principle of this spectral analysis is the Beer-Lambert law, which states that an absorbing substance's concentration can be determined by the intensity of light transmitted through it, given the transmission path length, the absorbance characteristic of that substance at that specific wavelength, and the intensity and wavelength of incident light (Sinex 1999).

Two light-emitting diodes (LEDs) in the pulse oximeter's probe emit two wavelengths (660nm—red and 940nm—infrared) through the vascular bed of a tissue, such as the tongue (Fig. 2.1). Opposite the LED, a pho-

todiode detects the intensity of the transmitted light and converts it into an electrical signal (Sinex 1999). The two different wavelengths allow the differentiation between reduced hemoglobin and oxyhemoglobin, due to the fact that the reduced hemoglobin absorbs more light in the red band and the oxyhemoglobin in the infrared band (Dorsch & Dorsch 2008). A ratio between these two signals is calculated and related to the arterial O_2 saturation (SaO_2) via an empiric algorithm. The algorithm was created by measuring the ratio in volunteers and comparing it with simultaneous blood gas analysis (Sinex 1999).

To determine the value of the oxygen saturation (SpO_2) correctly, the equipment must isolate absorbance of arterial hemoglobin from other absorbents such as venous blood, connective tissues, non-pulsatile arterial blood and skin pigment (Haskins 2007). To isolate these confounders, the pulse oximeter exploits the pulsatile nature of arterial blood (Dorsch & Dorsch 2008; Sinex 1999). Vender and Hand (Vender et al. 1995) evaluated the reliability of the pulse oximetry comparing it to blood gas analysis in rats. They concluded that the device could predict the SaO_2 93–98% of the time. However, the accuracy and reliability of the pulse oximetry can be affected by hemoglobin concentration, placement of the probe close to large vessels, motion artifacts, ambient light, vasoconstriction, and vasodilation (Barton et al. 1996; McEwen et al. 2010). In white-tailed deer, SpO_2 generally overestimated the SaO_2 , and with $\text{SaO}_2 < 80\%$, the agreement between pulse oximetry and blood gas analysis could not be considered sufficient (Muller et al. 2012). This is especially important to be considered in species that are more susceptible to develop hypoxemia, as ungulates.

Correlation (and not the agreement) between SaO_2 and SpO_2 was calculated for rabbits, dogs, sheep, goats and pigs (Erhardt et al. 1990). The results demonstrated that in all species, SpO_2 was always higher; and the lower the SaO_2 was, the greater was the difference between them.

Vasoconstriction and vasodilation cause inaccurate SpO_2 readings (McEwen et al. 2010). In wild animals, vasoconstriction is commonly associated with use of alpha-2 agonists in immobilization protocols for either captive or free-ranging animals (Arnemo 2010; Fenati et al. 2008; King et al. 2010; Shilo et al. 2010; Sontakke et al. 2009; Wolfe et al. 2008). Patients presenting with low blood pressure may also have a less accurate pulse oximetry reading, as the animal may respond to the low pressure by redirecting the blood flow to vital organs via peripheral vasoconstriction (Barton et al. 1996).

Knowing that so many factors can influence the reliability of the pulse oximeter readings, the anesthetist should verify the quality of the pletysmographic waveform and/or the signal strength indicator (which

Figure 2.1. Pulse oximeter placement on the tongue of a brown bear.

should reach at least three-quarters of the total length). It is also important to compare the heart rate shown by the oximeter and that produced by the electrocardiograph or auscultation (Dorsch & Dorsch 2008). Evaluation of the quality of the information produced by the device associated with clinical observations and knowledge of pharmacodynamics can insure a better interpretation of the values displayed by the pulse oximeter.

It is worth mentioning that these devices are calibrated for mammals and do not have the same consistency in avian species or reptiles as their hemoglobin has different absorption characteristics and SpO₂ values may not accurately reflect SaO₂ (Longley 2008; Schmitt et al. 1998).

Capnography

Capnometry is a noninvasive method of monitoring the partial pressure of CO₂ from airway gasses. The device displays the value of ETCO₂ (end tidal CO₂), which is the maximum value of carbon dioxide obtained at the end of the expiration (Dorsch & Dorsch 2008; Nagler & Krauss 2008). Analysis of the capnograph waveform is a useful method to evaluate the animal's respiratory status. The "capnogram" enables the anesthetist to verify the validity of the measured ETCO₂ and provides more detailed information regarding physiological and pathological conditions (Dorsch & Dorsch 2008). The capnogram also provides the respiratory rate, and permits the anesthetist to evaluate the adequacy of ventilation, correct placement of the endotracheal tube, and airway patency by utilization of waveform analysis. Capnography was shown to recognize changes in 70% of human patients who had an acute respiratory event, 4 minutes before any unusual clinical observations, or an observable decrease in pulse oximetry values (Burton et al. 2006).

Capnography is based on infrared spectroscopy. A beam of infrared radiation is sent, through an air sample, from a light source to a photometer. CO₂ absorbs at a wavelength of 4.26 μm; the amount transmitted is measured by the photometer and CO₂ concentration is calculated (Nagler & Krauss 2008). There are two main types of capnograph, the *mainstream* and the *sidestream* analyzer. This classification depends on the location of the sensor. The mainstream has the sensor directly on the hub of the endotracheal tube and the sidestream aspirates airway gas continuously, via a section of microtubing, to a sensor located inside the monitor (Fig. 2.2) (Nagler & Krauss 2008).

The mainstream capnograph should be used only in intubated patients, and the sidestream may be used in both intubated and nonintubated patients. The sidestream analyzer is not reliable with small respiratory volumes; it has a slower response time and the sample line can be contaminated or blocked by mucous or moisture. Standard flow sidestream capnographs can be

Figure 2.2. Sidestream capnography on a cockatoo.

Figure 2.3. Mainstream capnograph placed between the anesthetic circuit and the endotracheal tube of a toucan.

inaccurate for ETCO₂ monitoring in animals with small tidal volumes and high respiratory rates, such as birds and small rodents. To help alleviate this problem, low aspiration flow rate sidestream capnographs have been developed (Desmarchelier et al. 2007). Mainstream monitors may have the sensor contaminated by mucous or moisture. They function better than sidestream with smaller volumes, and have a faster response time, but they are also heavy and can dislodge the endotracheal tube (Fox et al. 2009). Mainstream capnographs typically provide more accurate readings; however, in species that have small tidal volumes, such as birds and small rodents, the dead space added by its sensor makes the use of this device problematic (Fig. 2.3).

ETCO₂ reflects PaCO₂ values but usually underestimates PaCO₂ by 2–5 mmHg (Nagler & Krauss 2008).

There are some important situations where the difference between ETCO_2 and PaCO_2 can increase. The most important one is immediately prior to systemic circulatory collapse or cardiac arrest. As cardiac output drops, so will pulmonary blood flow and CO_2 elimination will be impaired. Typically, a large acute drop in the ETCO_2 value is observed, while arterial CO_2 increases. This may be observed before any change in blood pressure values. The capnograph is a useful monitor to predict circulatory collapse (Dorsch & Dorsch 2008; Fox et al. 2009).

MONITORING THE CARDIOVASCULAR SYSTEM

The simplest method of monitoring the cardiovascular system consists of determination of heart rate and rhythm. This can be determined by auscultation with a stethoscope or by palpation of a pulse. Ideally, heart rate should be monitored continuously, and many modern monitors will enable this. If intermittent monitoring is the only technique available, it should be performed every 5–10 minutes at minimum. In an ideal world, it would be useful to be able to measure cardiac output continuously. There have been major advances in the measurement of cardiac output, but monitors are still not available in a form that would prove useful for field situations. Blood pressure is dependent on cardiac output and systemic vascular resistance. An increase in blood pressure may result from an increase in cardiac output or an increase in systemic vascular resistance. Hypertension is commonly encountered in wildlife anesthetized with high dosages of alpha-2 agonists. This increase in blood pressure results from vasoconstriction, and cardiac output may decrease considerably from baseline values (Caulkett et al. 1996). It is always important to consider the cardiovascular effects of the anesthetic technique when blood pressure values are interpreted.

Blood Pressure

Blood pressure is an important determinant of the heart's work and is commonly performed to assess cardiovascular performance. By itself, it is not the best indicator of tissue perfusion, but a low blood pressure can lead to a blood flow decrease and impaired oxygenation of major organs (Shih et al. 2010). Anesthesia, especially inhalant anesthesia, can cause a significant decrease in blood pressure. Hypotension is usually diagnosed at a mean arterial pressure (MAP) lower than 60 mmHg in small animals (Shih et al. 2010). There are several ways to measure blood pressure. They can be divided into *invasive*, or *direct*, and *noninvasive*, or *indirect*.

Invasive Blood Pressure Direct blood pressure measurement is accepted as the gold standard for determin-

Figure 2.4. Invasive blood pressure measurement in a reindeer.

ing the systolic (SAP), diastolic (DAP), and mean arterial pressures (MAP). It requires an arterial catheter placement, which can be challenging in small or hypovolemic patients. Typical locations for catheter placement are the auricular artery in ungulates, or the femoral or pedal artery in carnivores (Fig. 2.4). The artery is connected to a transducer, via noncompliant, fluid-filled tubing. The transducer connects to the monitor and translates the mechanical signal into an electrical signal. This technique is considered to be the most accurate method of measuring blood pressure, and it should be the technique of choice in research procedures.

Noninvasive Blood Pressure Monitors Noninvasive methods (NIBP) simplify monitoring and do not require special skills for their placement. The two most common NIBP devices are the *Oscillometric* and the *Doppler ultrasound*. The most clinically important blood pressure is the mean, because it represents the mean driving pressure for organ perfusion. The systolic pressure has a variable relationship with the mean so the anesthetist should be aware of it when measuring only systolic pressure (Haskins 2007). To decrease this margin of error with NIBP methods is important to maintain the cuff width: limb circumference ratio at approximately 40% (Haskins 2007).

The oscillometric monitor utilizes an automatically inflating blood pressure cuff to detect oscillations produced by blood flow and uses these oscillations to determine arterial pressure (Dorsch & Dorsch 2008). (Fig. 2.5) The Doppler also utilizes a cuff, but the operator must

Figure 2.5. Oscillometric cuff placed over the distal limb of a tiger.

Figure 2.6. Ultrasonic Doppler flow probe being used to monitor heart rate.

inflate it, and determine the systolic arterial pressure (SAP) by listening for the return of the pulse signal on deflation of the cuff.

A major advantage of the ultrasonic Doppler is the ability to continuously monitor heart rate. This is especially important in species with small body size, such as rodents, birds, and reptiles. In these animals, the doppler probe can be placed over an artery or the heart, and the blood flow will generate a sound that allows real-time monitoring of heart rate (Fig. 2.6). However, noninvasive techniques have been shown to be unreliable in some avian species, such as parrots and ducks (Acierno et al. 2008; Lichtenberger 2005).

A high rate of error has been observed when oscillometric monitors were assessed in red-tailed hawks. In the same study, the Doppler NIBP measurement tended to underestimate the SAP at all sites of cuff placement, but doppler was a good predictor of the MAP (Zehnder et al. 2009). Many factors can affect the accuracy of NIBP measurements, including the monitor itself, the site of the cuff placement, the cuff size, and the blood pressure itself (Dorsch & Dorsch 2008).

Electrocardiography Electrocardiography can be used to assess heart rate, and to diagnose arrhythmias and some electrolyte disorders. It is not a first-line monitor, but it can be used to provide important additional information required to diagnose and treat cardiac complications. Drugs used in wildlife capture can often induce arrhythmias. Bradyarrhythmias are common with alpha-2 agonists. Ventricular ectopic arrhythmias have been noted during immobilization with potent narcotics. Hypoxemia, hypercarbia, and catecholamine release can also be associated with arrhythmias. Since the treatment of arrhythmias varies greatly, it is important to make an accurate diagnosis of the rhythm prior to treatment.

Blood Gas Analysis Blood gas analyses is an important part of anesthetic monitoring in wild and zoo animal medicine (Kilgallon et al. 2008). When the results are correctly interpreted, they can show an overview of the respiratory and metabolic status in the anesthetized patient (Proulx 1999).

The blood gas analyzer is the only monitor that provides real values of pH, partial pressure of oxygen, and carbon dioxide in arterial or venous blood. Another advantage of the blood gas analyzer is the fact that it utilizes whole blood and the results can be provided in few minutes (Fauquier et al. 2004).

Free-ranging or captive wild hoof stock occasionally develop acute or delayed capture myopathy associated with lactic acidosis, electrolyte imbalance, circulatory compromise, hyperthermia, and free-radical production. This syndrome can be compounded by drug-induced respiratory depression and a negative balance in ventilation-perfusion ratio; only blood-gas and acid-base analysis enables early detection and constant monitoring of these derangements (Kilgallon et al. 2008).

Large animals such as rhinoceros can regularly develop hypoxemia and hypercapnia especially when they are immobilized with protocols that utilize very potent opioids, such as etorphine. This depression is dose-dependent and can be made worse due to the rigidity of the thoracic musculature of these species (Wenger et al. 2007).

Oxygenation is best assessed with arterial samples. It is crucial to preheparinize the syringe and the needle

to avoid blood coagulation (Proulx 1999). It is also important to avoid air bubbles in the syringe, as they interfere with the analysis. Ambient air PO_2 is 160 mmHg at sea level; if the arterial blood has a PaO_2 higher than ambient air, a bubble will cause it to drop over time, and the opposite will occur if the PaO_2 in the blood is lower than 160 mmHg (Hasan 2008). The PCO_2 in the ambient air is virtually zero so no matter which $PaCO_2$ the blood has, it will change towards zero; and as the $PaCO_2$ falls, the pH will rise (Hasan 2008).

The blood gas analyzer has electrodes comprised of two half-cells each. Each half-cell is immersed in an electrolyte solution and an external ammeter completes the circuit (Hasan 2008). Blood gas analyzers usually contain at least three electrodes: O_2 , CO_2 , and pH. The O_2 electrode works through polarography. A silver anode and a platinum cathode are immersed in a KCl solution and a semipermeable membrane separates it from the blood sample. When the O_2 molecules in the sample diffuses into the half-cell and react with the cathode, this reaction produces an amount of electrons that is proportional to the PaO_2 (Hasan 2008). The CO_2 electrode is immersed in a bicarbonate buffer solution, which is separated from the blood sample also by a membrane. Similarly, the CO_2 diffuses through the membrane and changes the buffer's pH. The concentration of H^+ is measured by a modified pH cell and the difference in the electrical potential creates a current (Hasan 2008). The pH electrode is the most complex of the three and has a special hygroscopic membrane that separates the blood from the electrolyte solution. In contact with the blood, the hydrogen ions dissociate from the membrane producing a flow of electrons and creating a current depending upon the difference in the electrical charges on either side (Hasan 2008). After obtaining the results, the first parameter to be interpreted is the pH and the nature of the imbalance should be defined as metabolic, respiratory, or mixed. After this, the treatment can be defined (Muir & de Moraes 2007). Portable clinical blood-gas and acid-base analyzers have allowed the anesthetist to perform this type of monitoring in settings where it was previously impossible (Fauquier et al. 2004).

Body Temperature Hypothermia during anesthesia can be related to drug-induced depression of muscular activity, metabolism, or hypothalamic thermostatic mechanisms (Haskins 2007). During wildlife capture, *hyperthermia* is commonly observed. Root causes are high ambient temperature, increased muscular activity during pursuit, and alpha-2 agonist-induced impairment of thermoregulation (Caulkett & Arnemo 2007).

Hyperthermia can be treated with cold water enemas or cold intravenous crystalloids. Reversal of alpha-2 agonist drugs may also be considered (Caulkett & Arnemo 2007; Haskins 2007). Hyperthermic animals may benefit from supplemental oxygen as increased

metabolism increases the oxygen demand for major organs.

Hypothermia can be treated by passive or active rewarming. Passive rewarming involves minimizing heat loss and enabling the patient to warm themselves metabolically, it can only be performed in animals with core temperatures between 36 and 34°C. Active rewarming is achieved by providing a source of heat to the patient. Convective warming works particularly well in these situations.

The most common devices used for temperature monitoring are esophageal or rectal thermistors attached to a thermometer, or handheld digital thermometers (Spelman et al. 1997). Telemetric temperature monitoring devices have been recently developed and show promise in this area.

Anesthetic Depth Monitoring the anesthetic depth during wildlife capture is fundamental for the safety of the animals and also of the staff. A light plane of anesthesia represents a threat for the people involved in the procedure and a very deep plane represents a risk for the animal, since vital organ functions may be compromised.

Parameters most commonly monitored are: *palpebral reflex* (lateral and medial), *corneal reflex*, *jaw tone*, and *ocular globe positioning*. The palpebral reflexes can be present or absent depending on the protocol used. The corneal reflex should be present in most species, as its loss characterizes a very deep anesthetic plan. Jaw tone varies depending on the anesthetic protocol used, as some drugs promote better muscle relaxation than others.

The ocular globe position varies among species. Mammals, in general, rotate the globe medially and ventrally in a surgical plane of volatile anesthesia. A centralized globe may represent a shallow plane when palpebral reflexes are present; or a very deep plane, when the palpebral reflexes are absent. Avian species and reptiles do not rotate the ocular globe, but they do generally prolapse the nictitating membrane during a surgical plane.

Dissociative drugs, when used alone, maintain all reflexes and increase muscular tone (Ramsden et al. 1976). Most protocols combine dissociative drugs with agents that induce muscle relaxation, such as alpha-2 agonists or benzodiazepines (Atkinson et al. 2002; Citino et al. 2001; Jalanka 1989; Smith et al. 2006). It is crucial to know what to expect in a given species when using these combinations, as combinations of dissociatives and sedatives are arguably the most utilized drug combinations to immobilize wildlife.

When anesthetized with combinations of dissociative drugs and benzodiazepines, especially tiletamine and zolazepam, some animals can demonstrate some somatic movement during the procedure, even when well immobilized. When these drugs are used at lower

doses and combined with alpha-2 agonists, head movement is a sign of very light anesthesia, and the potential for sudden arousal.

Heart rate, respiratory rate, and arterial blood pressure should be evaluated and interpreted along with reflexes, degree of muscle relaxation, and eye position. Typically, the lighter the anesthetic plan, the higher the sympathetic activity. Clinically, this presents as: increases heart rate, respiratory rate, and arterial blood pressure. Assessment of anesthetic depth has always been a challenge for the anesthetist; given the breadth of species covered in this text, it is important to consult individual chapters and experts in the field to determine how to appropriately monitor depth of anesthesia in a given species, with a particular anesthetic protocol.

Airway Management

Jonathan Cracknell

INTRODUCTION

Induction of general anesthesia or sedation tends to result in hypoxia as a result of airway obstruction, respiratory depression, and decreased cardiac output. Airway management consists of the management of a patent airway, the effective delivery of oxygen rich anesthetic gases, and the safe elimination of waste gases, such as carbon dioxide, from the patient. Often, this is the management of gases in the case of the terrestrial species but can also be considered to be water management in the aquatic species.

The upper airway represents an area where patency can be reduced through obstruction by normal anatomical features, pathology, or foreign bodies. During anesthesia, normal anatomical structures can reduce, or even obstruct, the passage of oxygen, air, or anesthetic gases on inspiration or the loss of waste gases on expiration. Suitable positioning, preferably combined with airway management devices, is essential for optimal homeostasis during anesthesia and the prevention of hypoxia and hypercapnoea. In some cases, respiration ceases and the anesthetist must maintain a patent airway and ensure adequate ventilation occurs. This is only possible with the placement of a suitable airway device. It is essential to ensure that the airway remains patent and is managed appropriately: serious problems are rare if suitable planning and preparation is taken for each individual anesthetic.

GENERAL PRINCIPLES OF AIRWAY MANAGEMENT

While there is a considerable variety of patient size, anatomy, respiratory physiology, and environmental requirements, there are general principles that can be followed when approaching any airway management

case. Calder and Pearce (2007) highlights these general principles to airway management as follows: Preparation is paramount including selection of suitable equipment, resources, and staffing for the procedure. Preoxygenation gives valuable time for establishment of a patent airway.

Good monitoring equipment certainly reduces the frequency of complications.

Signs of Airway Obstruction

- An obstructed upper airway results in an increase in negative intrathoracic pressure during inspiration, this is noted as the thorax sinking and the abdomen rising (the opposite of normal) (Cook 2007). Turbulent flow may occur in the upper airway, resulting in noise that is worse on inspiration. Auscultation of the larynx and trachea is useful to assess airway patency. It should be noted that lack of sounds can occur with narrowed or obstructed airways. Secretions or foreign bodies may cause obstruction; this includes the anesthetic circuits and airway devices. Normal values of pulse oximetry or PaO₂ are not reliable indicators of airway patency. The airway should be expected to become less patent when the consciousness level declines. Capnometry is extremely useful for assessing airway patency and changes that may occur during anesthesia. In general, there are fewer problems with the airway when an animal is deeply anesthetized, but aspiration of material into lungs becomes a possibility as the conscious level declines

APPROACHES TO AIRWAY MANAGEMENT

There are a variety of different methods in managing the airway:

- *Airway Unsupported*: This is commonly practiced, especially in the field. An animal spontaneously ventilates through an unaltered airway. Often, this is the only viable option; however, it is associated with an increased risk of obstruction or aspiration, and as such, positioning and continual assessment is essential.
- *Supraglottic Airway Devices (SAD)*: Airway management is achieved with a variety of devices that sit at the level of the glottis or above. This allows supplementation with oxygen or volatile agents and, depending on the system employed, ventilation to occur. While aspiration and obstruction are possible, this method of airway management has a lower risk of these occurring when compared with unsupported airways, depending on the device employed.
- *Tracheal Intubation*: Considered by many to be the gold standard of airway management, this method employs the use of a tube inserted directly into the trachea, often with an inflated cuff. This offers the greatest degree of protection against aspiration and allows optimal airway management and control of respiration.

Unsupported Airway

Following induction, there is a period where an animal relies on the patency of its own airway. In some cases, an animal may not be intubated for a procedure and the anesthetist must maintain a patent airway using that animal's own anatomical features. Often not a problem on expiration, airway patency can be compromised on inspiration due to critical instability of oral structures, such as partial posterior displacement of the tongue, soft palate, pharyngeal fat, pharyngeal neoplasia, or foreign bodies (Farmery 2007). The neck should be extended, the tongue pulled forward and laterally, and patency assessed through either physical assessment of airway movement on respiration or on auscultation of the laryngeal or thoracic area. If any concerns are noted, then the animal should be repositioned or the anesthetist intervenes with an airway device, such as a tracheal tube or supraglottic device.

Consideration should be given to aspiration. While the airway should never be considered protected with any method of airway device, having no airway management in place poses the highest risk of aspiration. This is especially so in ruminants but can occur in any animals, especially if the procedure requires dental or oral surgery. The rostrum should be positioned lower than the larynx, reducing gastrointestinal fluids passing up the esophagus but also allowing passive drainage from the oral cavity. Suction is useful in reducing any fluids found within the oral or pharyngeal cavity during or at the end of surgery. Manual and active suction systems are available and should be considered as part of the basic anesthetic kit.

The position of the animal must be considered, for instance, large mammals in dorsal recumbency are likely to have abdominal viscera pressing on the diaphragm resulting in a reduction in ventilation. Equally, animals that are being moved in stretchers or have their neck flexed for cerebrospinal fluid taps may be at risk of decreased airway patency, and intubation or armored tubes should be considered. It is essential that airway patency is monitored and maintained throughout a procedure, whether intubated or not.

Awake Intubation

“Awake” intubation is relatively common in human anesthesia. The logistical challenges in zoo and wildlife anesthesia make this unsuitable for most patients; however, it is a useful technique in reptiles and avian patients with existing airsac cannulae. It is described in sedated foals (Bednarski 2009) and could potentially be employed under sedation, if indicated.

Snakes, where intravenous or intramuscular inductions are contraindicated or simply not preferred due to the nature of the procedure, may be restrained and intubated consciously with or without sedation (Redrobe 2004). The animal must often be ventilated and can be induced using a volatile agent, leaving the tracheal tube in place for management throughout anesthesia (Fig. 3.1).

Avian patients with previously placed airsac cannulae can be connected to the anesthetic machine while gently restrained and induced via the caudal airsacs (Hawkins & Pascoe 2007).

Intubation Following Induction

Intubation following induction is the most common route for intubation in both domestic and wildlife patients. Induction can be achieved through the use of inhalation, intramuscular, or intravenous agents depending on the species and the choice of anesthetic

Figure 3.1. Cave racer (*Elaphe taeniura ridleyi*) consciously intubated with a Cole tube prior to being induced with isoflurane.

agent. Inhalation induction can be achieved with the direct application of a facemask, the use of an induction chamber, or through conscious intubation. Muscle relaxants are not often employed in veterinary medicine yet are a useful aid to augment intubation; these do require the use of manual or mechanical ventilation, and rapid intubation must be ensured to prevent hypoxia. Once the patient is anesthetized, the oral cavity can be opened and intubation should be relatively straightforward, depending on the species and the implementation of the airway management plan (Hartsfield 2007).

Planning Airway Management

The American Society of Anesthesiologists (Hasan 2010) has five basic steps in airway management (Calder & Pearce 2007):

- Evaluation of the airway
- Preparation of the airway
- Airway strategy at the start of anesthesia
- Airway management at the end of anesthesia
- Follow-up.

The same principles apply to airway management in zoo animals and wildlife. Evaluation of the airway seeks to establish which airway device will provide the appropriate level of protection and maintenance for the proposed procedure. It requires a basic level of knowledge regarding the patient's anatomy, physiology, and any risks that may occur during anesthesia. In some cases, airway devices maybe ruled out due to being incompatible with the species, for example, cuffed tubes must be used with care in species with complete tracheal rings, or is the tracheal tube selected long enough to reach the thoracic larynx of the giant anteater (*Myrmecophaga tridactyla*) The inherent risk of each device must also be considered, especially when utilizing a new technique for the first time.

Selection is based upon:

- Species suitability
- Experience of the anesthetist
- Size of the patient
- Perceived risk of aspiration
- The nature of the surgery
- Whether positive pressure ventilation is required
- Requirement for surgical access to the head or neck
- Whether the surgery is likely to interfere with the airway
- Availability.

Evaluation is often difficult, especially when anesthetizing a new species for the first time. Anatomical variation is considerable across the taxonomic groups and as such the clinician should endeavor to gain as much insight into the idiosyncrasies of their patient's anatomy

prior to induction, or at a minimum have a wide variety of options available when planning and implementing the airway strategy.

An airway strategy simply considers the default plan for intubation and having a plan B if plan A fails, and potentially a plan C if plan B fails (Calder & Pearce 2007). It is important to consider common eventualities and have support through colleagues and alternative airway management devices during intubation. Intubation is often a simple, hassle free exercise but when it goes wrong it can be extremely stressful and have a major impact on the patient. Difficulty in intubation can occur in a variety of causes depending on who you are, where you are, what equipment and drugs you have, who you have to help you, and what the patient is like. Patient causes of difficult airway management include normal but poorly assessed anatomy, poorly positioned patient, unwanted reflexes, stiffness or deformity of the head or peripharyngeal anatomy, swelling, foreign bodies, and airway pathology. It can be extremely useful to have a difficult airway algorithm. Examples can be found on the ASA and Difficult Airway Society (DAS) websites (<http://www.asahq.org> or <http://www.das.uk.com>, respectively).

It is important that the process of the airway strategy is documented on the anesthetic chart and in the subsequent medical records. This should include, as a basic minimum, any specific notes on the anatomy that pertain to intubation, the airway device used, the size of the device and any problems noted during anesthesia, and any comments on the act of intubation itself. This information is useful for follow-up audits or subsequent anesthetics for that individual or the species as a whole, which may benefit the anesthetist and their colleagues.

MAINTENANCE OF THE AIRWAY DURING ANESTHESIA

Patient Positioning

The position of the patient is often dictated by the needs of the surgery but must take into consideration the impact on ventilation and subsequent alteration of respiratory mechanics and physiology.

The upper airway should remain patent prior to intubation or during the procedure if intubation is not performed. For most species, this simply consists of extending the neck, pulling the tongue rostrally, and placing the head with the rostrum lower than the larynx to protect against aspiration: this applies to obligate nasal breathers and oral breathers. It is important to make sure that no environmental structures can obstruct the nares or mouth during anesthesia, for example, if an animal is anesthetized in a deep straw bed.

Positioning of the body is extremely variable depending on the individual species and the need of

the procedure. In general terms, sternal recumbency is preferred but often impractical; lateral recumbency is most common and for short periods has minimal impact on respiratory function; with dorsal often having the greatest impact on respiratory function due to the abdominal viscera pressing on the diaphragm, airsacs or lungs. It should be noted though that species variation is considerable and positioning needs to take into account the anatomy of the species concerned for example, sternal recumbency is considered to be contraindicated, except in extreme circumstances, in elephants due to their unique pulmonary anatomy (Steffey 2006).

Supraglottic Airway Devices

The term *supraglottic* refers to the area situated or occurring above the glottis, this encompasses the epiglottis and anything rostral to the vocal cords. As soon as an airway device enters the larynx, passing the vocal cords, it is classed as an *infraglottic* device or simply endotracheal. Some authors utilize an alternative classification with the supraglottic airway devices (SAD) separated into simple airway adjuncts and SAD, which includes the various laryngeal mask airways only (Cook 2012). The former classification will be used here. Subglottic devices are found below the larynx, for example, tracheostomy tubes.

There are many supraglottic airway devices and these include:

- Oropharyngeal airway
- Nasopharyngeal airway
- Facemasks
- Laryngeal mask airway (LMA).

Oropharyngeal (Guedel) Airways This is a simple device that ensures patency of the supraglottic airway by pushing the tongue and epiglottis from the posterior pharyngeal wall. Commonly used in human anaesthesia, their use is limited in zoo and wildlife species due to more useful alternatives such as tracheal intubation. Their use in zoo and wildlife medicine is questionable, but homemade variants can be used as bite blocks or to augment preoxygenation following induction, in an emergency prior to intubation proper.

Nasopharyngeal Airways These are passed through the nares, along the ventral nasal meatus to sit in the oropharynx above the epiglottis. They are useful as they can bypass nasal, soft palate and tongue obstructions and allow delivery of oxygen and volatile agents (Fig. 3.2). Nasopharyngeal airways are commonly used in equine anaesthesia during recovery, especially when the horse has been in dorsal recumbency for a prolonged period (Taylor & Clarke 2008). If there are any concerns regarding airway patency, then nasopharyngeal tubes are a simple preventative method that can

Figure 3.2. White rhinoceros (*Ceratotherium simum*) with a nasopharyngeal tube in place that was later used as a nasotracheal tube. Nasopharyngeal tubes can be useful in recovery where nasal edema may lead to obstruction or restricted upper airways in nasal obligate breathers.

easily be passed by most species soon after recovery. Placement of nasopharyngeal tubes can be extended to nasotracheal intubation simply by advancing the tube through the glottis (Bednarski 2009).

Facemasks Face masks are designed to fit over the nose and mouth of patients with a low pressure seal. The facemask consists of three parts: the mount, the body, and the edge. Facemasks are commonly used in zoo and wildlife medicine for induction of smaller, manually restrained mammals or birds. Larger animals require sedation prior to facemask induction. In some cases, they are used for maintenance as well, although this is not recommended for anything more than the shortest of procedures or where intubation is impossible or contraindicated. Facemasks can be a useful tool for augmenting or preoxygenating patients. In some cases, intermittent positive pressure ventilation is possible but carries the risk of gastric tympany.

Facemasks are either opaque or transparent. Opaque masks are useful during induction as they eliminate any visual stimulation to the animal. However, transparent masks have an advantage during maintenance as signs of regurgitation and expiration fogging can be seen through the mask's body. Choice is down to the individual anaesthetist.

When selecting the facemask size, consideration must be given to the volume of the mask. Large volumes

result in increased apparatus dead space, which can have considerable impact on smaller patients due to rebreathing expired gases. It is preferable to have the smallest volume within the mask possible: this can be achieved with snug fitting masks or by reducing the space by packing the mask with cotton wool or similar materials. Placing the whole head in the mask reduces this space, also but care must be taken to ensure that the edge does not compress the skin of the muzzle, trachea or even the thorax (Dorsch & Dorsch 2008a). In practice, increased flow rates of carrier gas can eliminate the risk of rebreathing, and clinicians are more likely to have flow rates that exceed the requirement intended for selected patient-circuit combinations.

Facemasks can be commercially produced or homemade. Often, commercially made masks do not meet the variety of our patient head and nares sizes. Homemade masks are often easy to produce, can be made cheaply and even disposable depending on the type. This author often uses the neoprene from old wet suits for the edge and a variety of tubs and drain pipes as the body of his facemasks, using standard endotracheal tube mounts attached at the circuit end. Latex gloves can also be used as an effective edge, requiring disposal afterwards. These homemade masks are safe and often very effective. Consideration should be given to the type of facemask used, a small mask is just as effective and may have smaller apparatus dead space than a larger one (Fig. 3.3).

Facemasks do not prevent supraglottic obstruction, and the patient must always be monitored for signs of airway obstruction. Equally, they do not provide any protection against aspiration. While commonly used on their own, this cannot be recommended due to their inability to ensure a patent airway (Bateman et al. 2005).

Figure 3.3. A homemade facemask being used for maintenance in a giant anteater (*Myrmecophaga tridactyla*): such a large apparatus dead space requires high flow rates to prevent rebreathing when compared to a smaller facemask.

Laryngeal Mask Airways (LMA) These are a relatively new method of airway management introduced in the late 1980s in human anesthesia, with subsequent trials in the 1990s in veterinary patients and the first commercial veterinary LMAs becoming available in 2010 (Dorsch & Dorsch 2008b). They have been used in a variety of species, varying from great apes to swine to small mammals including rabbits (Bateman et al. 2005; Cassu et al. 2004; Fulkerson & Gustafson 2007). Currently, commercial LMAs are only available for rabbits and cats, with six sizes being available for each species (Crotaz 2010). LMAs can be considered as a bridge between the ease of use of simple airway adjuncts and the technical and sometimes challenging aspects of tracheal intubation. The LMA consists of an inflatable cuff that sits over or above the level of the larynx, overlying a bowl, similar to a small facemask, joined to a stem that extends out of the oral cavity where it is attached to the anesthetic circuit. The LMA sits over the larynx, directly above the glottis in most cases: the limitation being quality of the seal is dependent on the variation in laryngeal anatomy across the species and the requirement for the LMA to be compatible with species-specific anatomical variation. This major limitation has been overcome with the development of the commercial veterinary LMAs.

LMAs are fitted in a variety of methods depending on the type (there are currently more than 40). In general, the LMA is a reusable device and must undergo sufficient checks prior to use, including: does the cuff leak, is there eccentric inflation of the cuff, or failure of the inflation valve, is the lumen clear? The cuff is then deflated, with the cuff retracting behind the level of the bowl. This is then lubricated with a water-based gel. The LMA is typically advanced along the hard palate, then the soft palate to be guided into place until resistance is felt. The cuff is then inflated with air. Each has a maximum volume and inflation should be achieved with a lower, optimal volume; overinflation can increase cuff pressures, reduce the seal and increase the risk of aspiration. In humans the success rate using the blind technique is extremely high (>95%) (Cook 2012). Checks for correct placement are described as follows: on inflation, the mask tip rises 0.5–2 cm, the anterior neck of the patient is seen to slightly fill and the midline on the tube should remain anatomically in midline: if any of these do not occur then the LMA should be refitted. In the case of the commercial veterinary LMAs, the devices have a shoulder that catches on the palatine arch providing confirmation of correct placement. These lack an inflatable cuff and rely on a tight fit locally to effect the seal and have features specific to the individual species that ensure the seal occurs.

The advantage of the LMAs include the maintenance of a patent upper airway, improved airway maintenance compared with other supraglottic devices, they

are useful in species that are difficult to intubate, reduce risk of endotracheal or laryngeal damage, ease of application, and they are well tolerated by patients, especially in recovery. However, they do not guarantee tracheal isolation from aspiration; ventilation is dependent on a tight seal, which is species-LMA brand dependent, and gastric tympany is possible if the seal is not tight or ventilation pressures are high. In humans, complications include failures, displacements, airway obstruction, sore throats, pharyngeal trauma and nerve injuries from pressure effects: with the main concern being that of aspiration (Cook 2012). A similar picture is likely in animals. There are several different LMAs and readers are advised to utilize species-specific veterinary LMAs or alternatively follow manufacturer's guidelines and seek advice for individual species prior to the use of human LMAs in wild animal patients.

Infraglottic Devices

Tracheal Tubes Tracheal, orotracheal, or endotracheal tubes are considered to provide the highest level of airway maintenance and protection as well as providing the most suitable route for airway ventilation. They are unlikely to be dislodged, provide protection from inhalation of foreign material, glottis reflexes are bypassed, and they allow good intraoral surgical access, which is needed in zoo and wildlife patients with dental work being a part of standard health checks. This is a common method of airway maintenance and is familiar to most veterinarians. However, it is not a benign methodology, and an understanding of the anatomy of the endotracheal tube is essential.

The generic tracheal tube consists of a beveled end, often with a murphy eye, a cuff, the tube itself, a self-sealing valve, and a 15-mm connector (with larger ones found on large animal tubes). Additional features include markings for the length of the tube, a radio-opaque line, and the internal diameter of the tube in millimetres (Cook 2012). Tracheal tubes can be straight but are usually curved with some, such as RAE tubes, having a 180° curve in them. The bevel assists in insertion through the glottis, with the murphy eye preventing obstruction if the bevel were to become occluded against the tracheal wall or blocked with foreign material. The tracheal tube is often made of either transparent soft silicone or more rigid plastics, such as PVC or polyurethane. Older, but still available, "red rubber" tubes may also be seen, which are made of mineralized rubber. The "red rubber" tube's disadvantage being that they are opaque and risk not being adequately cleaned, and the rubber tends to crack over time leading to further hygiene concerns. Armoured tubes are also available, which have a steel spiral running the length of the tube: these are kink resistant but not kink proof. They are particularly useful if moving animals in stretchers where the neck may become kinked

leading to airway obstruction. Tracheal tubes come in a large variety of sizes and shapes that meet the need of most of the species that may be met in a zoo or wild setting.

When choosing the type of tracheal tube, the cuff design is an important consideration. There are two basic types: low volume–high pressure (LVHP) and high volume–low pressure (HVLP) (Mitchell & Patel 2007). LVHP cuffs are uncommon but can still be seen on the "red rubber" type tracheal tubes. They have several disadvantages when compared with the HVLP types: the high pressure needed to inflate the cuff can result in excessive transluminal pressures resulting in tracheal ischemia, scarring, and stenosis; the cuff inflates in a circular manner and does not conform to the tracheal shape: and as the rubber cuff ages, it has the potential to deteriorate with weaknesses appearing, resulting in balloons forming that could herniate over the end of the tube leading to obstruction. The HVLP cuffs in comparison have a much larger volume and a lower pressure is required to effect a seal of the airway. This minimizes the transluminal pressures and reduces the impact on the tracheal mucosa; however, the cuff does develop folds through which liquids can pass and be aspirated (Cook 2012). Therefore, the concept of tracheal tubes protecting the airway should be challenged as this protection is incomplete. In practice, however, the benefits of the HVLP may be theoretical as their contact is over a larger area than the LVHP with the potential for low level damage to the tracheal mucosa over a larger area, as such the cost–benefit is likely to be similar when all aspects are considered.

All cuffs should be inflated to the pressure needed to create a seal, not to a predetermined volume. Excessive pressures can lead to tracheal pathology as noted previously. Cuff pressure always exceeds lateral wall pressure and it is advisable, although rarely performed, to measure cuff pressures with an intracuff pressure monitor (Mitchell & Patel 2007). Cuff pressures vary throughout a procedure: in the case of nitrous oxide, the gas can diffuse into the cuff and inflate the cuff, or in the case of positive pressure ventilation, as airway pressure increases the cuff becomes compressed, raising the internal cuff pressure. Cuff pressures are also not uniform within the same cuff, with variation across a cuff being considerable. Tracheal tubes close to tracheal lumen diameter will have a greater tracheal mucosal pressure if a similar volume is used for insufflation of a smaller diameter tube. This may seem obvious, but often clinicians insufflate with a standard volume, whatever the size of the patient. The recommended insufflation pressure is 20–34 cm H₂O, any higher than 40 cm H₂O will potentially result in tracheal ischemia and its subsequent sequelae (Dorsch & Dorsch 2008c; Hartsfield 2007). Any lower than the risk of aspiration is increased. Overinflation can also result in occlusion of the tracheal tube itself. The use of an intracuff pres-

Figure 3.4. An intracuff pressure monitoring device allows accurate selection of cuff pressure and a reduction in risks associated with excessive cuff pressures.

sure monitor device is strongly recommended but these are rarely seen in clinical practice (Fig. 3.4).

Some tracheal tubes do not have a cuff. There is a variety of choices, the most common being the uncuffed tube and the Cole tube. The Cole tube has a patient end that is smaller than the rest of the shaft. This is commonly used in avian and reptilian patients with the shoulder placed against the larynx to form a seal. This is a misuse of this type of tube and the shoulder should not come into contact with the laryngeal structures as it may result in their damage. The Cole tube is designed to have less resistance to flow than a tube with a narrower consistent internal diameter for its entire length (Dorsch & Dorsch 2008c).

Selection of tube length and diameter is an important factor in tube choice. The length of the tube should be taken from the level of the incisors/tip of beak to a distance safely past the larynx. In mammals, this is often reported to be just cranial to the thoracic inlet but 1/3 distance from the larynx is fine. In other species, knowledge of the tracheal anatomy is essential. In the case of penguins, the trachea bifurcates between 1 and 5 cm from the glottis depending on the species. Tracheal bifurcation is also seen in amphibians and chelonians. Often the bifurcation can be seen at intubation but radiography can be useful in assessing tube placement if unsure. Length is directly proportional to resistance and the shortest length of tracheal tube should be used; often this requires cutting down the tube. The tube should be cut off at the level of the incisors/beak tip to reduce apparatus dead space and resistance. Another challenge is seen in some avian species that have a dorsal oriented projection of the

ventral cricoid cartilage into the glottis called the crista ventralis (McLelland 1989); this reduces the diameter of the tube that can be safely placed (Fig. 3.5a,b). Diameter selection is often down to the individual's choice and the need of the procedure. It is recommended to use the widest diameter tube that will easily pass through the vocal cords or the cricoid ring (or equivalent structure). The tracheal tube offers the narrowest point in the anesthetic circuit and, apart from possible valves in a circle, offers the greatest resistance, and therefore work of breathing, on expiration for the patient (Mitchell & Patel 2007). Smaller diameter tubes are easier to insert, cause less laryngeal damage, and have a lower incidence of tracheal irritation. However, smaller diameters increase airway resistance, have excessive cuff volumes, are difficult to use suction with in the airway, and are difficult to use with fiberoptic endoscopy. Larger tube diameters conversely have a lower work of breathing in spontaneously breathing patients, and tracheal suction is easier. They are harder to insert, have greater potential for laryngeal trauma, infolding of the cuff may lead to leakage around the cuff, and risk of excessive insufflation volumes can result in greater tracheal damage. Resistance is inversely proportional to the radius to the power of four; in practical terms, this means doubling the tube radius decreases the resistance by a factor of 16 (Middleton et al. 2012). While doubling the radius seems excessive, this is equivalent to moving to a 5-mm from a 2.5-mm internal diameter tube, which this author has noted with students using a laryngoscope (clear visualization) or not for feline intubation (limited visualization), this also holds for many zoo and wildlife species. The

Figure 3.5. (a and b) The crista ventralis is a projection from the ventral aspect of the cricoid cartilage found in a variety of avian species (a). This reduces the size of tracheal tube that can be used. This is not a bifurcation as can be seen when the dorsal larynx is removed (b) (Eastern white pelican, *Pelecanus onocrotalus*).

Figure 3.6. Intravenous cannulae can be used as tracheal tubes in extremely small patients. To attach to the anesthetic circuit a cut down 2.5-mL syringe and a standard 7.5 15-mm connector can be used as an adapter (African spurred tortoise, *Geochelone sulcata*).

number on the outside of a tube determines the internal diameter. Depending on the brand or type of tube used, there can be considerable variation on the external diameter. It is essential that the type and brand of tube used is recorded on the anesthetic sheet, not just the size of tube.

In extremely small patients, intravenous cannulae can be utilized as tracheal tubes. Care must be taken in ensuring the material (rigid to prevent collapse) and the length is suitable. Cannulae will attach to the end of a cut down 2.5-mL syringe barrel with a 7.5-mm tracheal tube connector inserted in the syringe lumen (Fig. 3.6), allowing connection to an anesthetic circuit. It should be noted that with such small tracheal tubes,

when using pressure cycled ventilators, the resistance to ventilation is not simply overcome by increasing flow rate and airway pressure as most ventilators measure the pressure at the connector end of the tube and not the lung pressure. Clinicians are advised to calibrate flow and pressure settings to individual cannulae if using them in this way.

Subglottic Devices

Tracheostomy Tubes Tracheostomy tubes are rarely used in zoo and wildlife patients. They are indicated in cases where intubation with supraglottic devices or tracheal tubes is impossible or where longer term airway management is required. The techniques used are similar to that described in the domestic species and their use has been described in various wildlife species (Brainard et al. 2008).

Avian Air Sac Cannulae Due to the unique anatomical and physiological adaptations of the avian respiratory system, airsac cannulae can be employed for management of upper airway obstruction or longer term respiratory support (Hawkins & Pascoe 2007).

Intrapneumonic Cannulae These have been reported in reptiles for intrapneumonic therapy. If already surgically placed, then these have the potential to be used for respiratory support or even induction if required; however, the author is unaware of them being used in this fashion (Wilkinson 2004).

AIDS TO TRACHEAL INTUBATION

Tracheal intubation is the most challenging airway management technique, yet is one that is considered basic and part of daily routines. Some species are easy

and offer no challenge while others are extremely difficult due to anatomical features and lack of species-specific equipment. There are many tools and techniques available that can increase our success of a rapid, safe, and effective intubation.

Laryngoscope

The laryngoscope should be considered a basic part of the anesthetic equipment. A laryngoscope consists of a light source, a handle, and a blade. The blade is designed to sit in the vallecula, just rostral to the epiglottis. A slight tilt of the blade drops the epiglottis and depresses the tongue providing improved visualization of the glottis. There are two basic types of light source: a screw on bulb at the end of the blade or a fiberoptic blade. Blades come in a variety of shapes, lengths, and sizes. Choice is down to the individual; this author prefers the macintosh (curved) and miller (straight with a slight curve at the end) blades and a custom-built 35-cm long miller blade. Laryngoscopes are relatively cheap, improve visualization, and can also be used to improve oral and dental visualization during health checks (Cook 2012).

Optical laryngoscopes have become available in the last decade that have the added advantage of a video monitor built into the handle which is linked to the tip of the blade, allowing accurate tube placement. One such device uses a series of mirrors similar to a periscope to achieve a similar result without the need for video or fiberoptic technology (Cook 2012). Some brands come with a built-in guide for the tracheal tube. While potentially useful, they are limited due to their expense, size (designed for humans) and limited use in the field.

Optical Stylets

Optical stylets are rigid or malleable laparoscopes or dedicated laryngoscopes used as stylets with the tracheal tube placed over the scope. The scope is used to identify the glottis and direct the tube into the glottis or place the scope in the glottis and slide the tube down into the trachea. These are often used elsewhere in the clinic for laparoscopy and their use is limited to a veterinary clinic due to the need for power and their general bulk.

Flexible Endoscopes

Flexible endoscopes are commonplace in large veterinary clinics and can be used in a similar manner to optical stylets. Dedicated flexible fiberoptic endoscopes for intubation are commercially available, but are often designed for humans and as such do not have the length often required for some of the larger patients seen in zoo practices. Cystoscopes and bronchoscopes are useful and of suitable size for most patients. They offer unparalleled flexibility and the ability to be used for nasal or oral intubation; however, they are expen-

sive when compared with other techniques and are not often seen in zoo animal or wildlife practice nor can they be used in the field. They also allow the direct visualization of tracheal and lower airway structures, which can be useful in certain cases.

Bougies and Stylets

Bougies or stylets are malleable, plastic-coated stylets that are passed through a partially visible glottis and then the tracheal tube is passed over the top. These are especially useful with soft, flexible tubes. Light wands are available and are similar to stylets with a light on the end: this allows transillumination of the neck and assessment of the level of tube placement.

Gags and Ropes

The use of ropes or bandage allow controlled opening of the oral cavity to facilitate intubation without the operator's fingers being placed between the teeth, and being put at risk of being bitten, or obscuring the view for the anesthetist intubating.

Gags are available as either wooden or plastic devices that can be placed on one side of the dental arcade or across both, the latter often having a hole to allow the tracheal tube to be passed through into the glottis. In the megafauna, large wooden bite blocks have been used to obtain safe access for intubation (Steffey 2006).

METHODS OF TRACHEAL INTUBATION

Tracheal intubation is relatively straightforward in most of the patients encountered in zoo and wildlife anesthesia. The mnemonic PEACH is extremely useful: Position, Equipment, Attach oxygen and equipment, Checks on patient, and Help if required (Maran et al. 2008). Assuming equipment selection is appropriate for the species and that all standard safety checks have been completed, the main factor for successful intubation to occur is the positioning of the patient. There is considerable variation between the species, but general comments hold true for most patients (Hartsfield 2007):

- Check the mouth for food or foreign material and wash out if required
- Open the oral cavity as wide as possible to facilitate passage of the tracheal tube
- Ensure the oral and laryngeal axis are as close together as possible by extending the neck and pulling the head rostrally
- Ensure the larynx is in midline: this is usually the case in sternal or dorsal recumbency intubation but it can drop down if intubating in lateral recumbency and may need to be manipulated into place
- Pull the tongue forwards and laterally
- Use aids to visualize the larynx when appropriate (unless undertaking blind intubation)

- Use appropriate tube diameter for the patient: be prepared to step down or up depending on findings at visual inspection
- Use topical local anesthetic spray depending on the need: in some species, laryngospasm can hinder the passage of a tracheal tube, and if unsure, then often better to use than not. Wait 30 seconds for this to take effect.
- Pass the tube into the glottis and into the trachea, ensuring the larynx is passed but the tube remains cranial to the bifurcation
- Confirm tube placement
- Secure the tube in place
- Attach to the anesthetic circuit
- Inflate the cuff to 25–34 cm H₂O

Direct Visualization

This is the preferred method of intubation. In animals with large oral cavities, this is relatively straightforward, and a clear view of the larynx can often be achieved. Using laryngoscopes or other aids can facilitate intubation and allow the use of large diameter tubes.

Blind Intubation

This technique requires the anesthetist to guide the tube into the glottis without being able to visualize the glottis. Blind intubation is possible, and is commonly practiced in a large proportion of the patients seen, for example, lagomorphs, artiodactylids, and perissodactylids. This technique requires knowledge of the anatomical features of that patient. Depending on the animal, this is often performed in lateral recumbency for large animals or sternal for smaller animals. In larger animals, the tracheal tube is measured against the outside of the animal to estimate the length required to reach the larynx; the tracheal tube is passed through the oral cavity, and the respiratory sounds are listened to. Once the larynx is reached, the sounds change, the animal may swallow, and the tube is passed gently into the glottis, and secured in the usual fashion. In smaller animals, a similar technique is used, but the anesthetist can listen through the tube as it is inserted. A single person can do this in both cases.

Palpation Intubation

This technique is used in large mammals where the anesthetist passes their hand through the oral cavity, into the pharynx, and feels for the glottis, passing the tube alongside their arm. This is quick and effective and often used in artiodactylids; however, care must be taken as if prolonged it can lead to hypoxemia (Riebold et al. 1995; Steffy 2006).

Retrograde Intubation

This is a technique where a hypodermic needle is placed into the trachea at the level of the second and

third tracheal cartilages and a guide wire passed out through the larynx and oral cavity, a tube then being passed over the guide wire and into the trachea. This technique is frequently used in rodents and smaller animals but can be used where direct visualization or blind techniques have failed. The cuff should be placed caudal to the needle insertion site to prevent leakage of anesthetic gases into the surrounding tissues, which could lead to subcutaneous emphysema or even pneumothorax (Hartsfield 2007; Pearce 2007).

Confirmation of Tracheal Intubation

Misplacement of the tracheal tube is the most common complication of intubation, especially when using blind techniques. The tube may be placed in the esophagus or a bronchi and it is important that confirmation of correct placement is obtained immediately after intubation takes place. Oesophageal tube placement can lead to insufflation of the stomach, increased risk of regurgitation, hypoxia, and potentially death. Bronchial intubation can lead to hypoxemia, lung or lobar collapse, and increased risk of barotrauma to the intubated lung. Methods to assess correct placement include (Sanehi 2007):

- Visual confirmation that the tracheal tube has passed through the glottis and is in the trachea.
- Palpation of the trachea on intubation: the anesthetists can feel the tube pass over the tracheal rings; this is not felt if the tube is in the esophagus
- Confirmation of respiratory gases passing through the tracheal tube on expiration. A quick fur pluck can be useful: this is held at the end of the tracheal tube, and on expiration, they bend away from the tube; if nothing happens, then either the fur is too stiff or the tube is in the esophagus. Note the anesthetist should not press on the thorax to elicit expiration; this can lead to regurgitation. An alternative is to put a hand close to the end of the tube and feel for the gas passing through.
- Attach the tube to the circuit and monitor the reservoir bag movement on expiration and inspiration
- Gentle pressure on the reservoir bag should result in the thorax expanding. However, this can on occasion also appear to happen with insufflation of the stomach. It also allows assessment of whether the tracheal tube is in a bronchi: the compliance decreases and unequal insufflation of the thorax may occur.
- Capnography is extremely useful and a normal capnogram for six breaths suggests tracheal intubation. False negatives can occur with large gas leaks, cardiac arrest, and severe bronchospasm where no trace would appear on the capnogram
- Auscultation of both sides of the chest suggest tracheal placement and not bronchial
- Radiography: often the tracheal tube appears on any thoracic radiographs and can be assessed for posi-

tion. Due to the 2D nature of this technique, it cannot be used alone for assessment.

Extubation

Extubation should occur at the time that a patient has the ability to swallow and protect their airway. If extubation is too early, then there is risk of aspiration and loss of airway; if too late, then it can lead to irritation and potential laryngospasm and sympathetic stimulation. In some cases, suction of the oral cavity is essential to prevent any aspiration at extubation. There are no rules on the best time to extubate, and the timing has to be assessed depending on the species, the ease of removal, the risk to the animal and the clinician, the procedure, and the ease of maintaining the airway if reintubation is required (Dugdale 2010; Gray 2007; Hartsfield 2007). Extubation should include:

- Administer 100% oxygen or air depending on the species
- Assessment followed by suction of the oropharynx and oral cavity under direct vision if required
- Untie the tube
- Deflate the tracheal tube cuff
- Apply positive pressure to the reservoir bag, immediately followed by removal of the tube (expiration immediately follows clearing any supraglottic secretions)
- Confirm airway patency and position of animal
- Supplementary 100% oxygen or air depending on the species
- (Placement of a nasal tube if required).

The anesthetist must be prepared for postextubation obstruction: edema of the upper airway, laryngeal spasm, soft palate or tongue obstruction, and laryngeal paralysis have all been reported (Rex 1971; Taylor & Clarke 2008). The airway must be maintained during recovery in a similar fashion to that outlined at induction.

Airway Idiopathic Trauma

Intubation is not entirely benign. The incidence of intubation-related trauma leading to the need for clinical intervention is low though. If care and consideration is taken during intubation, combined with suitable use of airway devices, then airway trauma can be minimized. Anesthetic trauma includes (Calder 2007):

- Dental damage can occur with inappropriate use of laryngoscopes, gags or ropes at the time of intubation.
- Nasopharyngeal damage can occur during nasopharyngeal intubation; accurate placement and knowledge of species anatomy can avoid this relatively easily.

- Oesophageal perforation while uncommon has been reported.
- Pharyngeal edema or trauma with excessive force at the time of intubation has been reported.
- Glottic damage: animal coughing or dyspneic postrecovery. This can occur with tubes of too large diameter or rough intubations, often passing after 1–2 days. If it persists or is considered severe, then examination under anesthesia is indicated.
- Tracheal damage can be acute or chronic. Acute rupture or perforation has occurred with excessive cuff pressure or through intubation itself: subcutaneous air is often apparent. Granulation tissue and edema can form, especially in excessively long procedures or animals that maybe being ventilated for a long time, for example, barbiturate poisoning in large felids (Saulez et al. 2009).

Cleaning and Disinfection

Most airway devices are reusable or clinics reuse systems that are designed to be disposable. It is essential that airway devices are appropriately decontaminated, cleaned, and sterilized before they are reused to prevent cross infection. Heat sterilization is preferred, with cold chemical sterilization used for some of the non-autoclavable tubes. If prion disease is considered a risk, then the equipment should be disposed of following a procedure.

Thermoregulation

Jeff C. Ko and Rebecca A. Krimins

MONITORING BODY TEMPERATURE

Body temperature is controlled by the hypothalamus; therefore, it is important to measure core body temperature that is in close approximation to the hypothalamus. A temperature sensor placed on the tympanic membrane theoretically monitors the blood flow in the branches of the internal carotid artery. The internal carotid artery supplies the hypothalamus, and thus reflects core body temperature. A sensor placed in the lower one-third of the esophagus can measure the temperature of aortic blood. If the sensor is placed in the proximal or middle third of the esophagus, it can be influenced by cool anesthetic gases in the endotracheal tube and give a falsely lower reading. Rectal temperature readings measure local changes in temperature and may depend on regional blood flow and other factors. Rectal temperatures may be somewhat different from core body temperature, but are often a useful way of monitoring relative changes in body temperature.

It is important to monitor body temperature during the perioperative period. The authors recommend monitoring body temperature every 5 minutes. The frequency of monitoring may be reduced for animals that are stressed by manipulation.

HYPOTHERMIA

It is estimated that 60–80% of all postoperative patients experience hypothermia. Hypothermia occurs when heat loss is greater than heat production. Hypothermia can be classified into primary or secondary based on the cause of the hypothermia (Oncken et al. 2001). Primary hypothermia results from a patient's exposure to a cold environment. Secondary hypothermia may result from the effects of anesthetic drugs or from illness, which alters heat production and effects thermoregulation.

Based on a retrospective study using 55 dogs and 77 cats, hypothermia was defined as mild (98–99.9°F [36.7–37.7°C]), moderate (96–98°F [35.6–36.7°C]), severe (92–96°F [33.3–35.6°C]), or critical (less than 92°F [33.3°C]). Hypothermia correlates with clinical signs of mental dullness, decreased heart and respiratory rates, decreased mean arterial blood pressure, central nervous system depression, and increased mortality rates.

Many small animal patients suffer hypothermia during thoracic or abdominal surgical procedures. A study in rabbits revealed that external heating devices are necessary for maintenance of normal body temperature during general anesthesia (Sikoski et al. 2007). Heat loss can also be dramatic in large animals when no steps are taken to prevent or treat hypothermia (Tomasic 1999). Avian species are homeothermic, with normal temperatures ranging from 98.6 (37°C) to 107.6°F (42°C). Heat dissipation is accomplished through panting and gular fluttering. Heat loss in birds during anesthesia can be rapid and dramatic. Hypothermia in avian patients can lead to decreased heart rates and cardiac instability. Reptilian species are heterothermic and require external thermal support during anesthesia. Reptiles do not have the ability to regulate body temperature perianesthetically and require thermal support until they are fully recovered (Heard 2001). Reptiles should be maintained near their preferred optimum temperature range. Also, reptiles should be monitored closely postoperatively to prevent hyperthermia and/or burns. Thermal burns can occur more easily in reptiles that are dehydrated with poor peripheral perfusion (Heard 2001).

PERIOPERATIVE HEAT LOSS

Patient heat loss during the perioperative period can be classified into four types: evaporative, conductive,

convective, and radiant. Evaporative heat loss stems mainly from airway and respiration. Conductive heat loss is due to a direct transfer of body heat to a cold surface (i.e., surgery table or floor). Convective heat loss is due to direct transfer of heat to ambient air. Radiant heat loss is due to the animal's body temperature being warmer than the environment; consequently, the body heat of the animal radiates to the surrounding. This is especially true when the skin of the animal is not covered; the heat is radiated through the skin to the cold environment. Animals being prepped for surgical procedures have their hair clipped or feathers plucked. These patients are then scrubbed with disinfectants and alcohol, which further enhances evaporative heat losses. Animals with wet hair may then be exposed to metal or uninsulated surgery tables and further heat loss occurs through conduction on the cold surfaces. Intraoperatively, dry and cold inhalant anesthetic gases and oxygen in the patient's airway increase evaporative heat and moisture losses. Appropriate oxygen flow rates are an important consideration in order to prevent excessive cooling in the operating room. Inhalant anesthetics also lower the patient's threshold response to hypothermia. A study by Tan et al. demonstrated that large dogs undergo significant reduction in core body temperature especially during the first two hours of anesthesia and surgery (Tan et al. 2004). The same hypothermic responses are anticipated in wildlife species undergoing anesthesia and surgery. Abdominal surgery induces radiant, convective and evaporative heat losses. Intravenous fluids or lavaging fluids should be prewarmed before using them because cold fluids can further increase body heat loss.

Postoperatively, transportation of the patient from the operating room to the recovery area is an additional source of heat loss. Often, the warming devices used in the operating room are discontinued and the recovery area may not have warming equipment or may not have the equipment prewarmed for the patient. Wet hair or feathers can become an additional cause of heat loss in the recovery area. This is especially vital when recovering wildlife species in its environment during cold weather. Even large animals must have their body temperatures monitored and these patients should continue to receive thermal support during anesthesia and recovery (Tomasic 1999).

Horses and other large animal patients that are recovered on cool, dry surfaces without supplemental heating sources can lose body heat rapidly and may have prolonged anesthetic recoveries (Tomasic 1999). Anesthesia induces hypothermia by inhibiting the patient's ability to thermoregulate. This inhibition reduces metabolic heat production, and inhibits the patient's ability to shiver. Some anesthetics, such as acepromazine, propofol, and inhalant anesthetics, tend to induce peripheral vasodilation, which can worsen

radiant heat loss. Anesthesia and surgery represent a scenario that often encompasses a combination of heat loss and decreased heat production.

Consequences of Hypothermia

Hypothermia may affect the central nervous, cardiovascular, respiratory, gastrointestinal, and metabolic systems of the animal. Conscious or sedated animals vasoconstrict their peripheral vasculature, shiver, exhibit piloerection, or puff their feathers in the early stages of hypothermia during the perioperative period. Perioperative mortality and morbidity are increased when hypothermia occurs. When core body temperature falls below 94°F (34.4°C), the animal's ability to thermoregulate is diminished and the animal loses the ability to shiver. Prolonged recoveries are the most commonly seen central nervous system sign associated with perioperative hypothermia. Anesthetic drug metabolism and ensuing recoveries are significantly prolonged when the animal is hypothermic. Shivering often occurs in response to hypothermia as the animal attempts to thermoregulate its body temperature. Shivering is due to striated muscle contractions attempting to produce heat. Through shivering, the body can increase the rate of heat production by two to five times. In cases of extreme hypothermia, the shivering response is abolished. However, when exogenous heat sources are provided to rewarm hypothermic patients, shivering response may resume. Shivering may be one of the most severe consequences of hypothermia during rewarming processes. Shivering increases myocardial oxygen consumption and can lead to complete cardiac arrest. It has been shown that shivering increases myocardial oxygen consumption 400–500%. Hypoxemia is a common consequence of hypothermia induced shivering. Hypothermia also shifts the oxygen dissociation curve to the left and decreases the downloading of oxygen from hemoglobin to tissues. This may further prolong anesthetic recoveries and increase the chance for complications.

Hypothermia affects myocardial conduction and can cause myocardial irritability and arrhythmias. Hypothermia also decreases cardiac output and blood pressure. During hypothermia, bradycardia may develop and it may not respond to anticholinergics. This is because hypothermia reduces depolarization of cardiac pacemaker cells thus resulting in bradycardia (Polderman 2009). This hypothermia-induced bradycardia is not vagally mediated, therefore it is often refractory to atropine or glycopyrrolate treatment. Under general anesthesia, hypothermia-induced bradycardia, coupled with anesthetic-drug-induced vagally mediated bradycardia, can put the animal in severe danger. Clinically, when bradycardia is nonresponsive to an anticholinergic treatment, it is important to double check whether hypothermia plays a role; the treatment of the bradycardia should be directed toward

the underlying cause. Ventricular arrhythmias, including ventricular fibrillation, can also occur during severe hypothermia. Hypoventilation, respiratory acidosis, and apnea may be sequelae of hypothermia during and after anesthesia. Hypothermia can also lead to clotting abnormalities and thrombosis. Gastrointestinal ileus may occur as a result of hypothermia. Decreased immune function may occur after prolonged hypothermia (Oncken et al. 2001).

Perioperative Hypothermia: Prevention and Treatment

Frequently, rewarming of hypothermic patients becomes necessary if preventative measures fail to prevent hypothermia. It has been suggested that a hypothermic patient should be actively rewarmed until a rectal temperature of 98.5°F (36.9°C) is reached. Reptiles should be maintained near their preferred optimum temperature range during the perioperative period. During rewarming procedures, coagulation parameters, the cardiorespiratory system, electrolytes, acid-base status, and mental alertness should be monitored.

The use of heating devices or methods of providing heat can be classified as warming from body surface to the core (externally supplied) and from the core to the body surface (internally supplied). Circulating heated water blankets and forced hot air warmers are typical warming devices that heat patients externally. Recently, a new device using an electric heat current with a reusable resistive polymer blanket covered by a polypropylene sheet (Hot Dog®) has been developed for human and veterinary use. Potential advantages of the resistive heating unit over forced-air warming include easy cleaning with a thin reusable blanket and silent operation (Kimberger et al. 2008). Using warm intravenous fluids, warm saline lavages, or warm water enemas are methods of warming a patient internally. All these methods have been shown to successfully decrease heat loss.

In avian patients, radiant energy heat sources were found to be effective in preventing hypothermia in doves (Phalen et al. 1996). In a study with Amazon parrots, a forced air warmer was superior in maintaining body temperature when compared with infrared heater or circulating water blanket (Rembert et al. 2001). Heat loss still occurred in birds anesthetized for greater than 30 minutes, but temperatures were maintained in acceptable ranges (Rembert et al. 2001).

Commercially available fluid warmers can be used to warm fluids or blood immediately prior to infusion. This includes incubating fluids prior to intravenous use on a patient as well as using in-line fluid warmers placed close to the patient. Operating room temperature should be maintained at 71–73°F or slightly higher. Some devices take time to reach desired temperature (up to 30 minutes), therefore heating water circulating blankets and pumps should be turned on and their temperatures maintained at appropriate ranges (around

Figure 4.1. Even large animals can become hypothermic while under general anesthesia. A zebra is covered with a forced hot air warmer and a large blanket to prevent radiant heat loss. In addition, the zebra is placed on an insulated pad to prevent conductive heat loss through the concrete floor.

104°F [40°C]) prior to the patient being anesthetized. The patient should be kept covered with towels or forced hot air quilt blankets during the perioperative period (Figure 4.1). Results from a study in dogs showed that using heated water blankets around the feet and legs was the preferable method of preventing heat loss (Cabell et al. 1997). This was compared with a heating blanket applied on the trunk of the anesthetized dogs. Forced hot air warmers can be effectively used to provide heat before, during, and after surgery. Forced hot air is filtered and delivered to the patient's skin through a convective quilt. The quilts have several configurations to accommodate incision site exposure and various patient positioning. The quilts can be placed under or on top of the patient. Most of the quilts are durable and can withstand extensive use, although they are designed to be disposable.

Anesthesia and surgery predispose patients to hypothermia. Management of perioperative hypothermia includes properly monitoring the animal's body temperature, preventing heat loss, and providing heat supplementation. This reduces the morbidity and mortality of the patient during the perioperative period.

HYPERTHERMIA

Hyperthermia can also occur in anesthetized patients. Hyperthermia may occur with prolonged, stressful inductions during high ambient temperatures. This is a common occurrence during wildlife capture. Pursuit of an animal for capture may lead to excessive stress, exertion and trauma. These can all contribute to hyperthermia in immobilized wildlife. Also animals with thick hair coats are prone to being overheated with warming devices. Some mammals, including carnivores, lose heat

through panting. Although advantages of using rebreathing (circle) systems include retaining and reusing expired heat from the patients, these system can also result in inadvertent hyperthermia. In addition, during hyperthermia, there is increased production of carbon dioxide. Carbon dioxide will interact with soda lime and generate additional heat through a chemical reaction (Thurmon et al. 1996). Malignant hyperthermia is a disease that can occur in pigs, dogs, cats, and horses. Malignant hyperthermia is characterized by increased aerobic and anaerobic metabolism in patients. Patients produce abnormal amounts of heat, carbon dioxide, and lactate, resulting in severe acid-base abnormalities. Hypercapnia may be the first sign of impending malignant hyperthermia in susceptible species. Certain anesthetic agents, including inhalants, contribute to the development of malignant hyperthermia. Expired carbon dioxide concentration and body temperature must be closely monitored during anesthesia.

If capture-related hyperthermia occurs in an immobilized animal, then immediate supportive measures should be used to lower the body temperature. Treating hyperthermia includes moving the animal to a cooler location, the use of cold water or ice topically, and administering cool intravenous fluids or cold water enemas. Supportive measures may also include the treatment of shock and the administration of nonsteroidal anti-inflammatory agents. Animals should be cooled gradually down to 103°F (39.4°C), and then cooling measures should stop. If cooling occurs too rapidly, coagulation disturbances, such as disseminated intravascular coagulation, may occur.

Immobilizing animals on warm days should be avoided whenever possible. Minimizing pursuit and capture times helps decrease stress-associated hyperthermia. Ventilation should be monitored closely and supported in hyperthermic animals.

A serious sequela of hyperthermia and capture is exertional rhabdomyolysis or capture myopathy. The reader should refer to Chapter 10 for more specific information about this potential complication.

Oxygen Therapy

Åsa Fahlman

WHY O₂?

Oxygen is essential for life. Cellular function is dependent on adequate oxygenation and acid–base balance. Low levels of oxygen in the blood (hypoxemia) can lead to inadequate oxygen levels in the body (hypoxia). Brain cell death can occur within minutes and tissue necrosis can result in multi-organ failure. Even short periods of severe hypoxemia can result in irreversible damage. It is best to prevent it! In humans, hypoxemia can lead to cognitive impairment, such as learning and memory deficits. Although difficult to show in animals, it may also happen to them.

Hypoxemia frequently occurs in anesthetized wildlife with the drugs and doses used in the wild as well as in captivity (Read 2003). Hypoxemia during anesthesia can cause significant morbidity and mortality both during as well as after the anesthetic event. Although not always detected, hypoxemia can readily be prevented or treated with oxygen therapy. Since the consequences of hypoxemia may be difficult to measure, a negative impact on an organ system does not need to be proven before oxygen therapy can be initiated. Oxygen therapy is often life saving and there are simple, safe, effective, and inexpensive methods of oxygen administration that can easily be performed during field conditions.

Oxygen therapy increases safety during lung and heart disease, elevated body temperature (increased metabolism), and apnea. Since it is not possible to closely examine the physical status of free-ranging wildlife before capture, oxygen supplementation throughout anesthesia will improve safety for the animal in case of pneumonia or heart problems. Wild animals darted from helicopters commonly develop hyperthermia, which increases oxygen consumption

(Hurst et al. 1982). Intranasal oxygen supplementation will meet the increased oxygen requirements and protects the brain against hyperthermic damage (Einer-Jensen et al. 2002). In case of apnea or airway obstruction, supplemental oxygen is beneficial since it increases oxygen concentration in the functional residual capacity and will delay the onset of hypoxemia. Oxygen will provide additional working time to correct the problem (Becker & Casabianca 2009). During anesthesia, hypoxemia due to drug-induced respiratory depression (hypoventilation) and recumbency-induced ventilation–perfusion mismatch respond well to treatment with oxygen. Oxygen therapy should be provided to all anesthetized animals. The vast majority of physiological studies in anesthetized wildlife demonstrate the presence of hypoxemia. Hypoxemia should be anticipated and prevented.

HYPOXEMIA AND HYPOXIA

Hypoxemia is defined as an arterial oxygen tension (partial pressure of oxygen; PaO₂) in the blood below the expected normal level. Hypoxemia and hypoxia are not synonymous, and may or may not occur together. Hypoxia implies inadequate oxygen levels in the whole body, or a specific region (tissue hypoxia). Tissue hypoxia rapidly leads to cell damage in the most sensitive organs; the brain, heart, kidney and liver.

What Causes Hypoxemia?

Hypoxemia can develop due a low inspired oxygen concentration (high altitude, low barometric pressure), hypoventilation, or due to intrapulmonary causes, that is, ventilation–perfusion mismatch, shunt, or diffusion impairment.

What Causes Hypoxia?

The most common cause of hypoxia is hypoxemia, although it may not lead to hypoxia if oxygen delivery can be improved. This can be achieved by increasing cardiac output or decreasing tissue oxygen consumption. Hypoxia may also result from poor perfusion, low levels of hemoglobin, inability of hemoglobin to carry oxygen, or if tissues are unable to use oxygen effectively.

OXYGEN SOURCES

Oxygen can be stored and delivered as compressed gas or in cryogenic liquid form, or it can be produced on site by oxygen concentrators that extract nitrogen from the air.

High Pressure Oxygen Cylinders

The most common source of oxygen are cylinders with compressed gas under high pressure (~2000 psi; pound-force per square inch). Oxygen cylinders are constructed from steel or aluminum and should be equipped with a pressure regulator, a flow meter, and a manometer. Using oxygen from cylinders without a regulator is extremely dangerous. The pressure regulator is necessary to provide oxygen at a safe working pressure. The flow meter measures and indicates the flow rate of oxygen in L/min or mL/min. The amount of compressed oxygen in the cylinder can be measured by the manometer, since the pressure declines proportionately as the contents are used.

Medical oxygen has a higher purity than industrial oxygen, which can contain high levels of impurities. If industrial oxygen is being used for oxygen therapy, it should be checked for purity before use.

Small light-weight aluminum cylinders are easy to carry during fieldwork. Administration of the minimum effective flow rate is desirable to prolong the life of the oxygen cylinders. Refilling cylinders may entail complex logistics in remote areas.

Safety Gaseous oxygen is nonflammable but strongly supports combustion and may present a fire hazard. Materials that normally would not burn in air could ignite in oxygen-enriched atmospheres. Filled oxygen tanks (liquid or compressed gas) must not come in contact with grease, oil, or other combustible material. There are restrictions for transportation aboard aircraft, including helicopters.

Prevent oxygen cylinders from falling over by properly securing them at all times. If the cylinder or its valve is damaged, it can become a missile and shoot off at a high velocity. This can cause serious injury to animals, people, and equipment.

Portable Oxygen Concentrators

Portable battery-driven oxygen concentrators are an extra useful source of oxygen in the field when logistics

and flight restrictions may limit the use of oxygen cylinders. Their advantages include a small size, low weight, easy to operate, rechargeable batteries, and cost-effective oxygen therapy. Fire and explosion hazards are less than with other oxygen sources. Oxygen concentrators do not store oxygen, it is produced on site. Maintenance consists of regular cleaning of the air inlet filter.

Portable oxygen concentrators were initially developed for home treatment of people and for travel applications (Chatburn & Williams 2010). They are also being used in human hospitals and field situations in developing countries, where oxygen cylinders pose considerable logistics and financial problems (Dobson 2001; Shrestha et al. 2002).

Depending on the device an oxygen concentration up to 96% can be produced by concentrating the oxygen in the air and separating it from the nitrogen through a series of filters. The current portable concentrators can provide oxygen by continuous flow up to 3L/min, by pulse dose delivery, or both. With pulse dose technology, the negative pressure of the patient's inspiration triggers oxygen delivery. Thus, oxygen is provided only during the inspiratory phase, which is the crucial time for participation of gas exchange in the lungs. In comparison, oxygen delivered during exhalation is wasteful, as occurs during continuous flow of oxygen. It is important to note that the setting on an oxygen concentrator with pulse dose delivery is *not* equivalent to a continuous flow of oxygen. The pulse volume (in mL/breath) that corresponds to a setting and the maximum oxygen production per minute vary with different devices (Anonymous 2007; Bliss et al. 2004; Chatburn & Williams 2010). With a *fixed pulse volume*, the concentrator delivers a constant pulse volume of oxygen independent of respiratory rate. With *fixed oxygen minute volume*, a constant volume of oxygen is delivered per minute, so the pulse volume per breath decreases as respiratory rate increases. In addition, the variability in the patients' breathing pattern influences the fraction of inspired oxygen (FIO₂) delivered. The portable oxygen concentrators available on the market have all been produced for human use. Bench testing has only been performed at respiratory rates between 10 and 35 breaths/min. As a consequence, physiological differences between animals and humans may influence the efficacy when used in animals.

Stationary oxygen concentrators are being used in animal hospitals, but the use of portable concentrators has not yet been reported in domestic animals. The use of portable oxygen concentrators in wildlife is described later in this chapter.

Liquid Oxygen Containers

When oxygen is cooled below -119°C it becomes a liquid that can be stored under low pressure in insu-

Figure 5.1. Intranasal oxygen supplementation from a portable battery-driven oxygen concentrator to a bighorn sheep in Alberta, Canada.

lated containers. It converts to a breathable gas when warmed. Portable units for liquid oxygen can be filled up from a stationary source and must be kept upright at all times. Liquid oxygen can cause severe cold burn injuries, is not allowed on aircrafts, and is very costly (Fig. 5.1).

METHODS OF ADMINISTERING OXYGEN

Oxygen can be administered to anesthetized animals intranasally, via face mask, endotracheal tube, tracheal catheter, or with flow-by technique. In conscious animals, oxygen cages and Elizabethan collar canopies can also be used. Noninvasive oxygen therapy is simple, quick, safe, and requires minimal training.

Intranasal Oxygen

Intranasal oxygen supplementation (insufflation) is a practical, simple, and effective method for increasing arterial oxygenation. The FIO_2 will vary according to the oxygen flow rate, the minute ventilation, the breathing pattern, the size of the anatomic reservoir (i.e., the nasopharynx), and the depth of anesthesia (Loukopoulus & Reynolds 1996; Yam 1993). Variations within and between subjects should be considered.

Nasal insufflation with oxygen is a safe and simple method to protect the brain against hyperthermic damage (Einer-Jensen et al. 2002). In anesthetized pigs and rats, brain temperature decreases when the nasal cavities are flushed with oxygen. Intubated animals have no airflow through the nasal cavities, and if oxygen is provided via the endotracheal tube only, this cooling mechanism is bypassed.

Placement Intranasal oxygen supplementation can be administered by unilateral or bilateral placement of a

Figure 5.2. Oxygen supplementation administered to a bighorn sheep via two nasal lines secured with tape.

lubricated nasal line into the nasal cavity. The nasal line can be inserted a short bit into the nostril, or pre-measured and marked before advanced through the ventral meatus to the level of the medial canthus of the eye. If advanced further, oxygen will be delivered in the caudal nasopharynx, and may enter into the esophagus, which increases the risk of gastric distention. Insertion of a single nasal line ~2cm into the nasal cavity in brown bears effectively treats hypoxemia with low flow oxygen therapy (Fahlman et al. 2010). The nasal line should be secured as close to the nares as possible to prevent displacement. It can be secured by tape, sutures, or staples (Fig. 5.2).

Nasal Lines Nasal lines, also called cannulas or catheters, can be made up of various types of soft flexible plastic or rubber tubing, including feeding tubes and urinary catheters. Nasal cannulas with short prongs designed for people can be used in animals. The device consists of a plastic cannula, which can be put around the ears or neck, and single or double prongs, which are placed in the nostril(s). An inexpensive nasal line can be made from a fluid extension set, but the end must be smoothed to avoid damage of the nasal mucosa. Multiple fenestrations at the distal end reduce the risk of mucosal jet lesions.

Unilateral or Bilateral Nasal Oxygen Supplementation A unilateral catheter is as effective as bilateral catheters for oxygen supplementation of the same total

flow rate. When comparing a specific flow rate administered to dogs via one nasal catheter to that same flow rate divided between two catheters, there was no difference in PaO₂ and FIO₂ (Dunphy et al. 2002). High flow rates administered through a single nasal catheter may cause jet lesions in the nasal mucosa and discomfort in conscious patients. Bilateral catheters are useful if high flow rates are necessary, but can result in a FIO₂ that could produce oxygen toxicity if provided for a prolonged period.

Complications Oxygen may not be properly delivered if the nasal line becomes kinked, blocked with secretions, dislodged from the nostrils, or disconnected from the oxygen source. Complications reported with the use of intranasal catheters in dogs include nasal discharge, coughing, and mild epistaxis upon insertion due to inappropriate dorsal passage (Fitzpatrick & Crowe 1986; Loukopoulus & Reynolds 1996). Gastric distention may occur if incorrectly positioned in the nasopharynx or esophagus, or at high flow rates (5L/min to a 10 kg dog = 500 mL/kg/min) (Fitzpatrick & Crowe 1986).

Flow-by Oxygen

The flow-by technique includes holding an oxygen line as close as possible to the nose of the animal. Advantages include that it is very simple, well tolerated, and has no complications. A short distance between the end of the oxygen line and animal's nose is important to enable treatment of hypoxemia. In dogs, when the line was held 2 cm from the nose and a flow rate of 2L/min was used, the mean FIO₂ value increased to 37%, whereas from 4 cm, the technique was unreliable to use (Loukopoulus & Reynolds 1997). Disadvantages of the flow-by technique include that it requires constant supervision, it is wasteful of oxygen, and it is not as effective as other ways of oxygen administration.

Intra/Transtracheal Oxygen

Oxygen can be administered into the trachea through a nasal line inserted via the nasopharynx (nasotracheal insufflation), through an endotracheal tube, or through a transtracheal catheter. The anatomical dead space is bypassed when delivering oxygen directly into the trachea. A transtracheal catheter can be placed percutaneously into the cervical trachea after aseptically preparing the area. Tracheal gas samples can be collected from the catheter, or it can be connected to a gas analyzer for continuous measurement of the FIO₂ and end-tidal carbon dioxide (EtCO₂).

Humidification or Not?

The normal mechanism of the upper respiratory tract usually provide adequate humidification when oxygen is delivered intranasally, by face mask, or with flow-by technique at a low flow rate. Humidification may be

necessary to prevent mucosal drying when oxygen is delivered directly into the trachea, at high flow rates, or during prolonged supplementation.

DETECTION OF HYPOXEMIA AND MONITORING THE EFFECTS OF OXYGEN THERAPY

Oxygen is a drug. When oxygen is used, a dose should be prescribed and response to treatment should be monitored and therapy adjusted accordingly. The lowest possible oxygen flow needed to maintain normoxia should be used.

Monitoring is essential to detect physiological alterations and to evaluate the effect of therapy. In humans, continuous monitoring of oxygenation and ventilation during and after anesthesia is mandatory.

Clinical Signs of Hypoxemia and Efficacy of Oxygen Therapy

Hypoxemia, like hypercapnia and acidosis, is often clinically silent and not easily detectable without specific monitoring devices and measurement of arterial blood gases and pH. Clinical signs that can be suggestive of hypoxemia include dyspnea, cyanosis, tachypnea, tachycardia, elevated blood pressure, and restlessness. Severe hypoxemia is associated with bradycardia, arrhythmias, and impaired myocardial contractility. Cyanosis may not be visible if hypoxemia is associated with peripheral vasoconstriction or anemia. Clinical signs are nonspecific and not sensitive enough to ensure recognition of hypoxemia.

Patients that respond favorably to oxygen therapy may show improved mucus membrane color, decreased respiratory rate and effort, decreased heart rate, and reduced anxiety (Fitzpatrick & Crowe 1986). In immobilized North American elk (*Cervus elaphus*), the frequency of body and limb rigidity decreased in animals as PaO₂ increased during oxygen supplementation. The lowest frequency of muscle rigidity, head, neck, and limb movements were observed when PaO₂ was ≥ 70 mmHg (Paterson et al. 2009).

Pulse Oximetry

Pulse oximeters provide continuous noninvasive assessment of hemoglobin oxygen saturation in arterial blood (SpO₂). The SpO₂ values should be $>95\%$; lower values indicate hypoxemia. Pulse oximetry is a valuable tool for measurement of SpO₂, but it is important to be aware of the limitations with the technique. Pulse oximetry is less sensitive than arterial blood gas analysis (PaO₂) for detection of hypoxemia. The tendency for pulse oximetry to underestimate saturation at high oxygen tensions and to overestimate saturation at low oxygen tensions can lead to a significant risk of undiagnosed hypoxemia and makes it unsuitable as the sole monitor of oxygenation. In brown bears (*Ursus arctos*),

hypoxemia can be missed if arterial oxygenation is evaluated based on pulse oximetry only and not arterial blood gases (Fahlman et al. 2010).

During oxygen therapy, pulse oximetry may not accurately reflect the effect of treatment. In brown bears supplemented with intranasal oxygen, despite a $\text{PaO}_2 > 100 \text{ mmHg}$ and calculated hemoglobin oxygen saturation values (SaO_2) $\geq 96\%$, pulse oximetry-derived measurements of SpO_2 were $< 90\%$ (Fahlman et al. 2010). Similar inconsistent pulse oximetry values have been reported during oxygen therapy of white-tailed deer (*Odocoileus virginianus*) and bongo antelopes (*Tragelaphus eurycerus isaaci*) (Mich et al. 2008; Schumacher et al. 1997). In wolverines (*Gulo gulo*), the SpO_2 values measured prior to intranasal oxygen supplementation increased from 50–74% to 90–100% when oxygen was provided (Inman et al. 2009).

Arterial Blood Gas Analysis

Blood gas analysis is considered gold standard for measurement of arterial oxygenation. Arterial blood samples can be used to evaluate the adequacy of oxygenation (PaO_2 and SaO_2), ventilation (PaCO_2), acid–base status (pH and PaCO_2), and the oxygen-carrying capacity of blood (PaO_2 , HbO_2 , Hb total, and dyshemoglobins).

Collection of Arterial Blood Samples Arterial blood can be collected percutaneously from palpable arteries, such as the femoral, auricular, radial, or brachial artery, depending on species. Arterial blood should be confirmed by the use of self-filling syringes (arterial pressure should cause the blood to flow into the syringe), or by visualizing a pulsed flow from an open needle stick. Firm pressure should be applied postsampling at the puncture site for a minimum of 2 minutes to avoid development of a hematoma. For multiple samples, an arterial catheter can be placed.

Arterial samples should be collected anaerobically for analysis of blood gases (PaO_2 and PaCO_2), pH, and lactate. Any air bubbles should immediately be expelled and the syringe capped. Immediate analysis is necessary to minimize the risk of affected values. Syringe material, storage temperature, and time before analysis can significantly affect the blood gas and pH results, depending on species (Deane et al. 2004). Storage in plastic syringes in room temperature should be avoided, and even if stored in glass syringes in iced water, changes will occur with time.

Field Analysis Battery-driven portable clinical analyzers enable blood analysis in remote settings where this previously was not possible. Analysis can be challenging during field conditions since portable analyzers are made for indoor laboratory settings. The i-STAT[®]1 Portable Clinical Analyzer (Abbott Laboratories, Abbott Park, IL, USA) is sensitive to extreme ambient temperatures and high humidity. The analyzer operates only

Figure 5.3. The i-STAT[®]1 Portable Clinical Analyzer and cartridges used for field analysis.

within $+16$ to 30°C and does not allow testing outside this temperature range. In hot climate, it can be stored with ice packs in a polystyrene box in an insulated cooler bag. In cold climate, a hot water bottle placed in the box will prevent cooling of the analyzer. Thermoses with hot water can be brought to the field to refill the hot water bottle. The i-STAT[®] cartridges must be stored in a refrigerator. The cartridges may be stored at room temperature for 2 weeks or 2 months, depending on cartridge type, and they should not be returned to the refrigerator once they have been at room temperature. Do not allow cartridges to freeze (Fig. 5.3).

The i-STAT[®]1 analyzer has been validated with good accuracy and precision for humans, dogs, and horses (Sediame et al. 1999; Silverman & Birks 2002; Verwaerde et al. 2002). Although widely used in wild animals, validation remains to be performed for wildlife species. The oxygen dissociation curve and the p50 value varies between humans, domestic, and wildlife species (Clerbaux et al. 1993).

What Do Arterial Blood Gases Tell You?

Arterial blood gas analysis detects the presence and severity of hypoxemia and is the best way to evaluate the effect of oxygen therapy.

PaO_2 The arterial oxygen tension reflects the *oxygen uptake in the lungs*. The oxygen tension (partial pressure of arterial oxygen; PaO_2), is measured in mmHg or kPa

(1 mmHg = 0.133 kPa). The PaO₂ reflects only free oxygen molecules dissolved in plasma, and not those bound to hemoglobin. Low values indicate hypoxemia.

It is important to note that a normal PaO₂ does not equal adequate tissue oxygenation, which also depends on oxygen transport (hemoglobin concentration) and oxygen release (p50). The p50 value is the PaO₂ at which the hemoglobin is 50% saturated with oxygen and describes the position of the oxygen dissociation curve, which is essential for the oxygen release to the tissues. However, oxygen delivery can be compromised by poor circulation, which may be improved with administration of intravenous fluids.

P(A-a)O₂ Difference In order to evaluate adequacy of gas exchange within the lungs, the alveolar-arterial oxygen tension difference [P(A-a)O₂], also called the “A-a gradient”, can be determined. The alveolar oxygen tension (PAO₂) is calculated by using the alveolar gas equation:

$$PAO_2 = FIO_2 \times (P_B - P_{H_2O}) - (PACO_2 / RQ),$$

where FIO₂ is the fraction of inspired oxygen (0.21), P_B is the barometric pressure (760 mmHg at sea level), and P_{H₂O} is the saturated water vapor pressure at 37°C (47 mmHg), and RQ is the respiratory quotient. The RQ is determined by dividing CO₂ production in the body by its O₂ consumption, which varies with diet, health status, stress, and other factors. An RQ of 0.8 can be used for carnivores and omnivores (high protein or fat diet), and 1.0 can be used for herbivores (high carbohydrate diet). An elevated A-a gradient (>15 mmHg at FIO₂ 0.21) indicates an impaired oxygen exchange, that the lungs are not transferring oxygen properly from the atmosphere to the pulmonary circulation.

SaO₂/SpO₂ Arterial oxygen saturation is the percentage of oxygenated hemoglobin in relation to the amount of hemoglobin capable of carrying oxygen. Hemoglobin oxygen saturation determined by pulse oximetry is abbreviated SpO₂ to distinguish it from saturation determined by arterial blood sampling (SaO₂). Portable blood gas analyzers, such as the i-STAT®1, calculate SaO₂ from measured PaO₂, pH, and PaCO₂ on the basis of standard oxygen dissociation curves in humans. Co-oximeters measure SaO₂, which is gold standard for determination of oxygen saturation.

PaCO₂ The arterial carbon dioxide tension (partial pressure of arterial carbon dioxide (PaCO₂)) reflects alveolar ventilation. Elevated PaCO₂ values (hypercapnia) indicate hypoventilation. Mild to moderate hypercapnia may be beneficial because it stimulates the sympathetic nervous system and supports cardiovascular function by positive inotropic effects and vasoconstriction, and enhances the release of oxygen from hemoglobin into the tissues. Severe hypercapnia can result in hemodynamic instability, tachyar-

rhythmia, impaired myocardial contractility, narcosis, and coma (Johnson & Aufran de Morais 2006). Hypercapnia can be treated with tracheal intubation and mechanical ventilation. Oxygen therapy does not treat hypercapnia.

Temperature Corrected or Not? Body temperature has an important impact on measurements of blood gases (Bisson & Younker 2006). Blood gas analyzers measure the pH and blood gas partial pressures in blood at 37°C (uncorrected values). By entering body temperature, the analyzer will calculate temperature corrected values using certain algorithms. During hyperthermia, the uncorrected PaO₂ and PaCO₂ values will be lower and the pH will be higher than temperature corrected values would indicate. In case of hypothermia, an uncorrected PaO₂ may overlook a significant hypoxemia. When arterial blood gas values and pH are interpreted and reported, always report if the values are temperature corrected or not, and report body temperature.

Venous Blood Gases There is a large difference between arterial and venous oxygen values. Peripheral venous blood can never be used to assess oxygenation (lung function) or ventilation. Venous blood gases reflect the adequacy of tissue oxygenation and tissue carbon dioxide clearance.

Blood Gas Reference Values

In normally ventilating, conscious domestic mammals breathing air at sea level, the PaO₂ usually range between 80 and 100 mmHg and the PaCO₂ range between 35 and 45 mmHg. In awake animals at higher altitude, the PaO₂ will be lower due to a lower barometric pressure. The PaCO₂ can be lower as a result of altitude-associated compensatory hyperventilation.

Blood gas reference values for nonanesthetized wild-life are seldom available, but have been documented in some species. In unrestrained standing white rhinoceros, a mean ± SE (range) PaO₂ of 98 ± 1 (90–109) mmHg and a PaCO₂ of 49 ± 1 (44–54) mmHg were reported (Citino & Bush 2007). In unsedated standing and laterally recumbent African (*Loxodonta africana*) and Asian (*Elephas maximus*) elephants, blood gas values did not differ between the species. The mean ± SD PaO₂ values decreased from 96 ± 2 mmHg while standing to 84 ± 3 mmHg during lateral recumbency, whereas the PaCO₂ value stayed the same (44 ± 1 mmHg) (Honeyman et al. 1992). Remarkably low PaO₂ values of 56 ± 9 (52–60) mmHg were reported in unsedated Arabian oryx (*Oryx leucoryx*) restrained in a drop-floor crate, but the presented values were not temperature corrected and rectal temperature was not reported (Kilgallon et al. 2008). If the animals were hyperthermic, temperature corrected values would be higher than the presented uncorrected values. In unsedated North American elk habituated to chute restraint, a mean ± SD (range) PaO₂ of 100 ± 12 (87–

121) mmHg and a PaCO_2 of 39 ± 4 (33–42) mmHg were documented during intranasal administration of medical air (Paterson et al. 2009).

Target PaO_2

Arterial oxygenation during anesthesia should be maintained within normal physiological limits. The goal with oxygen therapy in hypoxemic animals is to improve the animal's arterial oxygenation to reach a minimum target PaO_2 that could be expected in a normal awake animal. Arterial oxygenation varies with altitude according to the alveolar gas equation. The target PaO_2 can be calculated using the local barometric pressure for the altitude where anesthesia takes place. For example, the PaO_2 expected for conscious bighorn sheep at an altitude of 1500 m above sea level is approximately 73 mmHg, calculated using the local P_B and assuming a PaCO_2 of 35 mmHg, $P_{\text{H}_2\text{O}}$ of 47 mmHg, an RQ of 1.0, and a $P(\text{A-a})\text{O}_2$ difference of 15 mmHg. In comparison, the expected PaO_2 at 2200 m above sea level would be 62 mmHg (Fahlman et al. 2012).

Discontinuing Oxygen Therapy

Oxygen should be supplemented continuously throughout anesthesia. If discontinued, the beneficial increases in arterial oxygenation associated with oxygen administration diminish rapidly (Dunphy et al. 2002; Fahlman et al. 2010). This has been shown in a wide variety of species, such as rhinoceros, brown bears, white-tailed deer, and bongo antelopes. Arterial oxygenation can fall to baseline values within 10 seconds if oxygen therapy is interrupted (Fitzpatrick & Crowe 1986). This indicates the necessity to provide oxygen throughout handling of anesthetized wildlife, also when moving the animals (Fig. 5.4). Intermittent oxygen therapy has been compared with bringing a drowning person to the surface—occasionally! (West 2003).

What If Oxygen Therapy Fails?

If hypoxemia persists despite oxygen therapy, physiological alterations should be considered and the oxygen delivery equipment should be inspected. Check the following:

- Does the animal have a patent airway? Is the animal apneic? Is intubation and manual ventilation needed?
- How is the animal's breathing pattern? Rapid shallow breathing increases dead space ventilation.
- Can the animal be repositioned from dorsal or lateral to sternal recumbency to reduce the degree of ventilation/perfusion mismatch? Is there a pneumothorax?
- Is there severe ruminal tympany? Is the nasal line kinked, blocked, or dislodged from the nostril? Is it incorrectly placed in the esophagus? Is the oxygen cylinder empty? Is the flow rate too low? Is the correct pulse dose setting chosen on the oxygen concentrator? Is the maximum oxygen production of the

Figure 5.4. Oxygen therapy provided when moving an immobilized desert bighorn sheep in Nevada.

device adequate for the size of the animal? Is the ambient temperature, relative humidity, and altitude within its operating conditions? Is shunting present? Severe hypoxemia that is unresponsive to oxygen supplementation may be due to high shunt fractions.

Common Misconceptions

Hypercapnia can be treated with oxygen.

Oxygen therapy does not treat hypercapnia. Carbon dioxide elimination depends on alveolar ventilation. Alveolar ventilation = respiratory rate \times (tidal volume—dead space).

An increase in respiratory rate improves ventilation.

Rapid shallow breathing mainly ventilates dead space. An increase in respiratory rate and/or tidal volume may improve ventilation.

Oxygen therapy causes respiratory depression (hypoventilation) by abolishing the hypoxic respiratory drive.

This is a theory that is still under debate and the mechanism for the elevated PaCO_2 is not fully understood. In human patients receiving oxygen therapy, some actually experienced an increase in ventilation, in some it was unchanged, and in some ventilation decreased (Schmidt & Hall 1989). Suggested reasons for elevations in PaCO_2 included the release of hypoxic vasoconstriction with an increase in alveolar dead space, changes

in ventilation–perfusion ratio relationships, and the Haldane effect, but without changes in respiratory drive (Benditt 2000). Withholding oxygen therapy in an attempt to maintain ventilatory drive may be harmful and is not advisable; treatment of hypercapnia consists of mechanical ventilation. During anesthesia of wildlife, hypercapnia is a common side effect, also when oxygen therapy is not provided. For example, a mild hypercapnia ($\text{PaCO}_2 < 55 \text{ mmHg}$) has been documented in brown bears during low oxygen flows (0.5–3 L/min), as well as in unsupplemented bears (Fahlman et al. 2010, 2011a). When similar flow rates were supplemented to white-tailed deer, a marked hypercapnia ($\text{PaCO}_2 > 60 \text{ mmHg}$) developed in some animals (Fahlman et al. 2011b). Elk anesthetized with xylazine-carfentanil developed severe hypercapnia ($\text{PaCO}_2 > 80 \text{ mmHg}$) during intranasal oxygen supplementation at 10 L/min (Paterson et al. 2009).

OXYGEN CYLINDER USE IN WILDLIFE

In the literature, specific oxygen flow rates are sometimes recommended for treatment of hypoxemia without experimental evidence that supports the statements. In the following section, the effect of oxygen therapy has been evaluated by blood gas analysis, unless stated otherwise. When interpreting data and publishing research results, it is imperative to not focus only on mean values since for the individual animal it may be critical to detect and correct hypoxemia.

Ungulates

Hypoxemia in white-tailed deer immobilized with butorphanol-azaperone-medetomidine (BAM) can be corrected with intranasal oxygen at a relatively low flow rate of 3 L/min (Mich et al. 2008). The efficacy of even lower flow rates have been evaluated in white-tailed deer anesthetized with medetomidine-ketamine (Fahlman et al. 2011b). A flow rate as low as 1 L/min (14–18 mL/kg/min) effectively treats hypoxemia in white-tailed deer. During field work, use of the minimum effective flow rate extends the life of the oxygen cylinder. A D-cylinder containing 425 L oxygen will last over 7 hours at a flow rate of 1 L/min, compared with only 2.4 hours if using a flow rate of 3 L/min.

Intranasal oxygen at 2.5 L/min effectively treats hypoxemia in adult rhebok (*Pelea capreolus*) immobilized with carfentanil-xylazine or etorphine-xylazine (Howard et al. 2004). In adult guanacos (*Lama guanicoe*), an intranasal flow rate of 4 L/min is sufficient for treatment of hypoxemia during anesthesia with medetomidine-ketamine-butorphanol (Georoff et al. 2010).

An intranasal flow rate of 5 L/min is sufficient for treatment of hypoxemia in immobilized bongo antelopes (Schumacher et al. 1997). Intranasal oxygen at

3–5 L/min has been evaluated in bongo and eland antelopes (*Tragelaphus oryx*) during three different circumstances: manual restraint in a drop floor chute, manual restraint following sedation, and chemical immobilization (Boyd et al. 2000). The mean PaO_2 values increased $> 100 \text{ mmHg}$ in all groups, although some chemically immobilized animals remained hypoxemic despite oxygen therapy.

In North American elk, an intranasal flow rate of 10 L/min treated hypoxemia during immobilization with xylazine-tiletamine-zolazepam (Read et al. 2001). In another study on elk, intranasal oxygen was administered at 10 L/min prior to induction and during immobilization with carfentanil-xylazine (Paterson et al. 2009). The arterial oxygenation improved, but individual animals remained hypoxemic despite oxygen therapy, and severe hypercapnia with PaCO_2 values up to 100 mmHg was reported.

In desert bighorn sheep immobilized with butorphanol-azaperone-medetomidine, hypoxemia has been treated successfully with intranasal oxygen at 6 L/min (Fahlman et al., unpubl. data). Preoxygen PaO_2 values of 45–54 mmHg increased to 144–210 mmHg during oxygen therapy.

In a crossover study in immobilized reindeer with hypoxemia, animals that received intranasal oxygen at 6 L/min had significantly higher PaO_2 values (range 95–313 mmHg) compared with unsupplemented animals (26–70 mmHg) (Risling et al. 2011).

Based on pulse oximetry, in immobilized takin (*Budocas taxicolor*) (body weight ~200 kg) receiving intranasal oxygen at 4–6 L/min, the mean SpO_2 value increased above 90% (Morris et al. 2000). Anesthetized Przewalski's horses (*Equus ferus przewalski*) were hypoxemic despite intranasal oxygen at 10 L/min, according to pulse oximetry and arterial blood gas analysis (Walzer et al. 2009) (Table 5.1).

Rhinoceros Immobilized rhinoceros commonly develop hypoxemia, which can be more severe during lateral than sternal recumbency (Fahlman et al. 2004; Morkel et al. 2010; Wenger et al. 2007). Intranasal oxygen at a flow rate of 5–10 L/min rapidly increases the PaO_2 to $> 150 \text{ mmHg}$ in black rhinoceros calves in sternal recumbency, and to $> 90 \text{ mmHg}$ in white rhinoceros calves, irrespective of their body position (Fahlman et al. 2004). In adult white rhinoceros with severe hypoxemia during lateral recumbency, an intranasal flow rate of 15 L/min increases the PaO_2 to a less critical level. Oxygen should routinely be supplemented throughout the immobilization period, since hypoxemia in rhinoceros quickly resumes if oxygen is discontinued (Fahlman et al. 2004).

Tracheal insufflation of oxygen has been evaluated for treatment of severe hypoxemia ($\text{PaO}_2 35 \pm 9 \text{ mmHg}$) in adult and subadult white rhinoceros in sternal

Figure 5.5. Arterial blood sampling from an auricular artery during intranasal oxygen therapy to a white rhinoceros in Kruger National Park, South Africa.

recumbency (Bush et al. 2004). After nasotracheal intubation, oxygen supplementation was provided at a flow rate of 15–30L/min, depending on the size of the animal. Although the mean PaO₂ increased (PaO₂ 96 ± 59mmHg), the high standard deviation shows that some rhinoceros remained severely hypoxemic.

With severe ventilation perfusion mismatch, poorly ventilated areas of the lung may become physiologic shunt. Oxygen therapy becomes less effective in the presence of intrapulmonary shunting, and insufficient at shunt fractions over 50%.

Hyperthermia is common when helicopter-darting free-ranging rhinoceros, and muscle tremors are frequently seen during opioid immobilization. Since hyperthermia and muscle tremors increase the oxygen consumption, these are additional reasons to provide oxygen therapy to immobilized rhinoceros (Fig. 5.5).

Elephants Both African and Asian elephants are prone to develop severe hypoxemia during immobilization. Oxygen insufflation at 15–20L/min in the trunk of an adult Asian elephant, or into endotracheal tubes in juvenile African elephants in lateral recumbency initially increased PaO₂ to >100mmHg (Fowler & Hart 1973; Heard et al. 1986). The PaO₂ decreased progressively during immobilization, and hypoxemia resumed in some animals. Oxygen was also supplemented to intubated African elephants at 15L/min via a Hudson demand valve attached to the end of the endotracheal tube. The PaO₂ increased up to 516mmHg, followed by

Table 5.2. Recommended flow rates of intranasal oxygen to anesthetized brown bears in relation to their body mass

Body Mass (kg)	Flow Rate (L/min)
10–25	0.5
25–100	1
100–200	2
200–250	3

a progressive decrease. A simple and effective portable ventilator have been developed to provide oxygen and intermittent positive pressure ventilation during immobilization of intubated elephants (Horne et al. 2001). When oxygen is delivered in synchrony with the elephants breathing pattern, PaO₂ values over 400mmHg has been recorded. Both oxygenation and ventilation can be readily controlled even under remote field conditions by the use of this device.

Carnivores

Bears Hypoxemia occurs during anesthesia of brown bears, black bears (*Ursus americanus*), and polar bears (Caulkett & Cattet 1997; Caulkett et al. 1999; Fahlman et al. 2011a). Low flow rates of intranasal oxygen is sufficient for treatment of hypoxemia in brown bears anesthetized with medetomidine-zolazepam-tiletamine, based on arterial blood gas studies (Fahlman et al. 2010). The minimum effective oxygen flow rates were determined to improve safety for the bears and to reduce the number of oxygen cylinders needed during remote field work. Flow rates from 0.5 to 3L/min markedly improve arterial oxygenation in brown bears weighing up to 250kg (Table 5.2). Oxygen should be provided throughout anesthesia since hypoxemia can occur at any time during anesthesia of bears and recur if oxygen supplementation is discontinued.

Brown bears anesthetized with carfentanil citrate given p.o. in honey were supplemented with intranasal oxygen at 6L/min. Relatively low values of partial pressure of oxygen of 64 ± 10 (51–86) mmHg might be explained by low body temperatures (34.0–36.7°C) or the possibility of mixed venous-arterial samples when sampling sublingual vessels (Mortenson & Bechert 1996).

Wolverines Free-ranging wolverines anesthetized with medetomidine-ketamine at 500–1300m above sea level in Sweden develop impaired arterial oxygenation, based on arterial blood gas analysis and pulse oximetry (Fahlman et al. 2008). Altitude was responsible for approximately 30% of the reduction in PaO₂, while ventilation–perfusion mismatch probably was the major cause. Intranasal oxygen supplementation at a flow rate of 0.5–1.5L/min improves oxygenation, as shown with pulse oximetry in wolverines anesthetized with the same drug combination in Montana at 2500m elevation. Oxygen therapy is considered essential for

safe handling of anesthetized wolverines (Inman et al. 2009).

Tigers Oxygen supplementation to Siberian tigers (*Panthera tigris altaica*) anesthetized with xylazine or medetomidine in combination with midazolam-ketamine has been described. Intranasal oxygen was administered at 6L/min if the SpO₂ was below 80%, based on pulse oximetry. Arterial blood gas analysis did not indicate hypoxemia, since all tigers had PaO₂ values ≥ 89 mmHg whether or not receiving oxygen (Curro et al. 2004).

Cheetah Adult cheetahs (*Acinonyx jubatus*) anesthetized with tiletamine-zolazepam-medetomidine in captivity were intubated and administered oxygen at 2L/min by the use of a semiclosed circle anesthetic machine. Although PaO₂ values were over 500 mmHg, their mucous membranes were pale to cyanotic, which probably was attributed to medetomidine-induced peripheral vasoconstriction (Deem et al. 1998).

PORTABLE OXYGEN CONCENTRATOR USE IN WILDLIFE

The efficacy of a portable oxygen concentrator with pulsed delivery has been evaluated for treatment of hypoxemia during anesthesia of selected wildlife species (Fahlman et al. 2011b, 2012). Arterial blood samples were collected before (pre-O₂), during, and after oxygen supplementation in brown bears, bighorn sheep (*Ovis canadensis*), reindeer (*Rangifer tarandus*), and white-tailed deer. The tested device weighed 4.5 kg and the rechargeable batteries could provide power for up to 8 hours (EverGo™ Portable Oxygen Concentrator, Respironics®). It delivered oxygen in a pulsed flow with pulse volumes from 12 to 70 mL, up to a maximum capacity of 1.05 L/min. Oxygen was delivered intranasally, and the pulse dose setting was adjusted according to the animal's respiratory rate.

In brown bears, the arterial oxygenation improved significantly from mean \pm SD (range) pre-O₂ PaO₂ values of 73 ± 11 (49–93) mmHg to 134 ± 29 (90–185) mmHg during supplementation (Fahlman et al. 2012). All bighorn sheep and reindeer were markedly hypoxemic with pre-O₂ PaO₂ values of 40 ± 9 (28–55) mmHg and 45 ± 13 (31–56) mmHg, respectively. Following successful oxygen delivery from the concentrator, arterial oxygenation improved in all reindeer and most bighorn sheep, although target PaO₂ was not reached in all animals. The limited response in bighorn sheep may have been due to tachypnea, high shunt fractions, as well as limited capacity of the evaluated device. At cold temperature and high altitude, a decreased oxygen concentration may be delivered.

In hypoxemic white-tailed deer, pulsed delivery of oxygen from the concentrator was equally effective to

a continuous flow of 1L/min from an oxygen cylinder. The FiO₂ was measured via a tracheal catheter. During supplementation from the concentrator, the PaO₂ was 115 ± 31 mmHg. With cylinder oxygen at 1L/min, the PaO₂ was 138 ± 21 mmHg (Fahlman et al. 2011b).

Oxygen therapy from portable oxygen concentrators have great potential for use in animals and during field anesthesia. The efficacy may be influenced by the animals' respiratory rate and the pulse dose setting on the concentrator, and species-related differences in physiology during anesthesia, such as the degree of intrapulmonary shunting. Further research is needed to evaluate available devices in various species and under different conditions.

POSTANESTHETIC EFFECTS OF HYPOXEMIA

There are few reports on the actual effects of hypoxemia during and after anesthesia in wildlife, but since the consequences of hypoxemia are difficult to measure, a negative impact does not have to be proven before oxygen therapy should be initiated.

Immobilization-Induced Hypoxemia and Recovery

Reindeer that were severely hypoxemic during immobilization took a longer time to recover to standing than animals supplemented with oxygen during immobilization (Risling et al. 2011). In North American elk, recovery time was significantly shorter in animals receiving nasal oxygen during immobilization than in animals receiving medical air (Paterson et al. 2009). In white-tailed deer that received oxygen during immobilization, there was a trend toward more rapid recovery than in unsupplemented hypoxemic deer (Mich et al. 2008).

Oxygen Therapy during Recovery

Although difficult to evaluate in wildlife, hypoxemia during the immediate postanesthetic recovery period is common in domestic animals such as dogs and horses (Jackson & Murison 2010; McMurphy & Cribb 1989). Oxygen supplementation is often provided to horses in the recovery room after anesthesia. Wild animals may also benefit from oxygen therapy during the recovery period. Routine oxygen supplementation throughout anesthesia and the recovery period has been recommended for hypoxemic white-tailed deer, since full reversal to standing required 5–20 minutes (Mich et al. 2008). Hypothermic animals will benefit from oxygen supplementation during recovery from anesthesia because shivering increases oxygen consumption.

OXYGEN TOXICITY

Prolonged exposure to high oxygen concentrations should be avoided since oxygen toxicity depends on

the duration of treatment and the concentration delivered (FIO₂). A general rule is to not administer an FIO₂ higher than 60% for more than 24 hours, and an FIO₂ of 100% for maximum 12 hours to prevent pulmonary changes associated with oxygen toxicity. Intubation is required to for administration of 100% oxygen (FIO₂ 1.0). The lowest FIO₂ possible should be used to achieve normoxemia and thus reduce the risk for oxygen toxicity. Wild animals are seldom anesthetized for prolonged periods, and with intranasal oxygen supplementation, the FIO₂ does not reach possible toxicity levels.

Oxygen toxicity should be prevented since there is no therapy for the toxic pulmonary changes. Cellular oxygen injury by toxic free radicals lead to cellular death. Accumulation of toxic oxygen metabolites acutely causes endothelial cell damage, resulting in alveolar edema, hemorrhage, and congestion. In the late stages of oxygen toxicity, fibrosis will develop (Mensack & Murtaugh 1999).

6 Analgesia

Douglas P. Whiteside

INTRODUCTION

Over the past decade, pain management has emerged as an important discipline in veterinary medicine, with significant growth of scientific knowledge in neuro-anatomy and neurophysiology across the vertebrate taxa. Pain is often now referred to as the fifth vital sign. Optimal management of pain, and the development of future analgesic strategies, requires a lucid understanding of the pathophysiology of pain across taxa, and of the basic pharmacology of the analgesic drugs used to treat it. While pain can be a protective mechanism against acute injury, it also can be a chronic, nonrelenting, and crippling sensory experience that leads to severe stress, with profound changes in normal behavior and in neuroendocrine, metabolic, and immune responses (Kehlet 1997; Kehlet & Wilmore 2002; Lemke & Creighton 2010).

Many myths have been associated with pain management in captive and free-ranging wildlife species, and this has led to poor analgesia use in the past. New understandings and techniques have allowed us to develop improved strategies for analgesia and to promote education in their use. Adequate pain relief is not only humane but improves recovery. Understanding that pain is a continuum across species allows for more effective treatment.

Zoo and wildlife clinicians face a number of unknown variables compared with their companion animal counterparts, due to the tremendous diversity of species they are presented with, marked differences in physiology across the vertebrate taxa, lack of diagnostic techniques and pain scoring systems to adequately evaluate pain, and the paucity of pharmacokinetic or clinical studies for free-ranging and captive wildlife species. However, the physiological, behavioral, and ethical consequences of inadequate pain

management behoove us as responsible clinicians to make every effort possible to prevent or control pain in the animals under our care (Hess 2010).

Numerous barriers exist to appropriately managing pain in wildlife species, these include: lack of familiarity with current therapeutic modalities and techniques, concerns regarding drug induced adverse effects or toxicity, inadequate species-specific pharmacokinetic and clinical efficacy data, economic considerations, poor assessment of pain, and personal views on pain perception. However, studies of behavior demonstrate that animals not only experience pain, but remember the experience and try to avoid it in the future. No longer should the question be asked “does the animal experience pain?”, but rather “what kind of pain can the animal experience?” Species variability in the expression in pain can occur due to a failure to recognize species-specific pain behaviors, difference in pain sensitivity, and the conscious response of a species. Pain does not always lend itself to objective measures, so the art of medicine should not be overlooked in favor of the science (Hawkins 2006; Nolen 2001; Paul-Murphy et al. 2004b).

This chapter is an overview of analgesia across vertebrates and invertebrates, and readers are encouraged to refer to other chapters for references on pharmacology and for more species-specific information.

PHYSIOLOGY OF PAIN

Pain is a complex sensation that requires integration of nociceptive and other sensory input at the cortical level, while nociception is the neural response to a noxious stimulus. The International Association for the Study of Pain defines pain as an unpleasant sensory and emotional experience associated with actual or

potential tissue damage. The inability to communicate pain, and the lack of understanding whether the vast captive and free-ranging species that are worked with actually experience the emotional experience of pain, does not negate the fact that all potential or actual tissue damages in animals should be considered painful. In addition, it must be recognized that neonates are capable of experiencing pain; in mammals, the pain pathways necessary for pain perception are well developed in late gestation, and in humans, the spinal cord sensory nerve cells are more excitable in infants with an amplified, prolonged response and larger receptive field to pain. As a result, painful experiences in early life may produce long-term alterations in sensory processing and pain sensitivity (Anand & Hickey 1987; Fitzgerald & McIntosh 1989; Walker 2008).

Our understanding of pain is based primarily on mammalian studies, although the recognition of pain and its treatment is receiving much more attention now in nonmammalian species. An understanding of the pathophysiology of pain is important to enable more effective management and target future research. Pain can be classified anatomically as somatic or visceral pain, or temporally as acute or chronic. While a significant amount of research has been carried out with acute pain, there is still a paucity of information regarding chronic pain. Pain also is commonly categorized as physiologic or clinical (inflammatory or neuropathic in origin). Physiologic pain is protective in nature, well localized, proportionate to the peripheral stimulus, and subsides once the inflammatory process resolves. Clinical pain occurs with significant tissue trauma and inflammation and is pathological or debilitating in nature. It is diffuse, disproportionate to the peripheral stimulus, and can continue beyond the resolution of the inflammatory process. Clinical pain can take on a disease character in pathological states, such as inflammation, neuropathy, cancer, viral infections, chemotherapy, and diabetes. This state is manifested as an increased sensitivity to painful stimuli (hyperalgesia) or withdrawal behavioral responses to innocuous stimuli (tactile allodynia). Furthermore, individuals with chronic pain often show maladaptive, disease-induced, therapy-resistant deviations from normal tactile sensation, such as paraesthesias and dysesthesias (Kuner 2010; Lemke & Creighton 2010; Truini & Cruccu 2006).

Ascending Nociceptive Pathways

Most tissues are rich in afferent nociceptors, the free nerve ending receptors that are responsible for the detection of thermal, mechanical, or chemical noxious stimuli. Most of these receptors are nonselective cation channels that are gated by temperature, chemical ligands, or mechanical shearing forces. Activation of these channels increases inward conduction of sodium and calcium ions, which ultimately depolarizes the

membrane and generates a burst of action potentials. Tissue trauma leads to the release of inflammatory mediators from damaged cells (H^+ , K^+ , and prostaglandins), plasma (bradykinin), platelets (serotonin), mast cells (histamine), and macrophages (cytokines). Some of these inflammatory mediators activate nociceptors directly (bradykinin), whereas others sensitize nociceptors (prostaglandins). Release of neuropeptides, such as substance P, leads to vasodilation and edema, resulting in further activation and sensitization of nociceptors. Ultimately, tissue trauma and inflammation produce a “sensitizing soup” of chemical mediators that convert high threshold nociceptors to low threshold nociceptors. This is known as peripheral sensitization (Lemke & Creighton 2010; Muir & Woolf 2001).

Somatic tissues have a higher density of nociceptive nerve fibers and smaller receptive fields, whereas visceral tissues have a lower density of nociceptive nerve fibers and larger receptive fields. These anatomical differences may account for some of the qualitative differences between somatic (discrete) and visceral (diffuse) pain. The stimuli are converted to an electrical signal (transduction), which is then transferred via myelinated $A\beta$ and $A\delta$ fibers (sharp pain, rapid transmission) or unmyelinated C fibers (dull burning pain, slow transmission) to the spinal cord dorsal horn cells (nerve conduction), where they synapse with second-order neurons. Visceral pain, in contrast to somatic pain, lacks the fast and slow components (Julius & Basbaum 2001; Woolf & Ma 2007; Yaksh 2009). Polymodal C fibers can adapt to a variety of physiologic changes with responses to hypoxia, hypercapnea, hyperthermia, hypothermia, hypoglycemia, hyperosmolarity, hypoosmolarity, and lactic acidosis (Craig 2003).

Second-order projection neurons in the spinal cord are responsible for transmission of signals (projection) to the thalamus, hypothalamus, medulla, pons, and midbrain. Spinal inhibitory and excitatory interneurons are responsible for gating and modulating nociceptive input from the periphery. The spinothalamic tract is the major ascending nociceptive pathway. Additionally, propriospinal neurons that project across several dermatomes are present in the dorsal horn and are responsible for segmental reflexes associated with nociception. Glutamate is the primary excitatory neurotransmitter in the dorsal horn of the spinal cord. Nociceptive as well as non-nociceptive fibers corelease glutamate and neuropeptides, such as substance P and neurokinin A. Activation of a specific type of glutamate receptor, the NMDA receptor, plays a key role in the development of central sensitization, known as “wind up” (Lemke & Creighton 2010; Muir & Woolf 2001; Woolf & Chong 1993).

Third-order supraspinal neurons integrate the input from spinal neurons, thalamus, hypothalamus, medulla, pons, and midbrain and project to the somato-

sensory and insular (interoceptive) cortex where the pain is perceived (perception), and there are linkages with the autonomic nervous system. Projection from neurons in the lateral thalamus to neurons in the insular and secondary somatosensory cortex appears to be responsible for the sensory-discriminative aspects of pain. Projection from neurons in the medial thalamus to neurons in the anterior cingulate cortex appears to be responsible for the motivational-affective (emotional) aspects of pain. Projection from neurons in the motor thalamus to neurons in the primary somatosensory cortex appears to be responsible for sensory and motor integration. Once received by the conscious brain, the brain interprets and gives cognition to nociceptive signals, giving rise to a state of pain-induced distress (Kuner 2010; Lemke & Creighton 2010).

Antinociceptive Descending Pathways

Modulation or inhibition of nociceptive input at the spinal and supraspinal levels is the basis for descending antinociceptive pathways. This modulation leads to hyposensibility or a lack of pain in spite of inputs coming in from the periphery. The antinociceptive pathways begin at the supraspinal level (thalamus, hypothalamus, midbrain, medulla, and pons) with indirect input from the insular cortex and the anterior cingulate cortex. Release of norepinephrine, endogenous opioids (endorphins, enkephalins, and dynorphins), and gamma-aminobutyric acid (GABA) inhibits synaptic transmission between primary afferent neurons and projection neurons by inhibiting neurotransmitter release and hyperpolarizing the postsynaptic membrane, which effectively shuts down the key synapse in the dorsal horn. This has evolutionary value because they can enable the organism to ignore pain in critical situations, such as flight or fight, and may contribute to analgesia produced by a variety of non-pharmacological pain control approaches, such as transcutaneous electrical nerve stimulation and acupuncture (Kuner 2010; Lemke & Creighton 2010; Muir & Woolf 2001).

PRINCIPLES OF PAIN MANAGEMENT

Effective analgesic therapy blunts the neuroendocrine response, reduces major complications, produces discernible changes in posture and behavior, and improves outcome (Carli & Schricker 2009; Mosley 2011; Wu & Liu 2009). The World Health Organization outlines a three-step analgesic ladder for the control of cancer pain in people, which has been well received and adapted by the veterinary community for managing pain. Nonopioids, generally nonsteroidal anti-inflammatory drugs (NSAIDs), are used for mild pain. If the pain persists, or is of moderate intensity, it is treated with the combination of a nonopioid and a “weak” opioid. More severe pain dictates that a “strong”

opioid replace the “weak” opioid, often at higher doses or titrated to the degree of pain. At any of these levels, adjunctive analgesia (e.g., local anesthetics, α -2 agonists, NMDA antagonists, tricyclic antidepressants, anticonvulsants, corticosteroids, and nutraceuticals), can be used to augment analgesia, taking into consideration the potential interactions and side effects.

Pain management should not just revolve around drugs, and whenever possible, a more holistic, multimodal approach should be taken. Environmental conditions should be optimized for the species. Weight loss and adjunctive therapies, such as chondroprotectants, physical therapy and rehabilitation, acupuncture, dietary manipulations, and even surgery, also play an important role in the multimodal approach to pain (Koski 2011; Rychel et al. 2011; Truini & Cruccu 2006; Whiteside et al. 2006). Atraumatic surgical technique is always the most effective method to prevent peripheral and central sensitization and the development of pain postoperatively (Lemke & Creighton 2010).

There are five major classes of analgesic drugs, and each class blocks or modulates nociceptive input at one or more sites of action (Fig. 6.1). Alpha-2 agonists and opioids alter the central perception of pain. Activation of supraspinal and spinal alpha-2 receptors and opioid receptors also inhibits synaptic transmission in the dorsal horn of the spinal cord. Peripheral and central neural blockade with local anesthetics inhibits the development of central sensitization, as does administration of dissociative anesthetics, such as ketamine, which block NMDA receptors on projection neurons. COX inhibitors such as NSAIDs reduce the synthesis of prostaglandins, which reduces inflammation and limits the development of both peripheral and central sensitization (Grimm & Lamont 2007; Lemke & Creighton 2010).

Trauma and inflammation sensitize the peripheral nervous system, and the subsequent barrage of nociceptive input produces sensitization of neurons in the dorsal horn of the spinal cord. Peripheral and central sensitization of nociceptive pathways plays a central role in the development of pathological pain (Woolf & Chong 1993). Blockade or attenuation of ascending nociceptive pathways or activation of descending antinociceptive pathways by different classes of analgesic drugs usually provides better analgesia with fewer side effects than unimodal therapy with a single class of analgesic drugs. Because peripheral and central neural blockade with local anesthetics are the only analgesic techniques that can produce complete blockade of peripheral nociceptive input, these techniques are the most effective way to attenuate sensitization of the central nervous system and the development of pathological pain (Carli & Schricker 2009; Lemke & Creighton 2010; Lemke & Dawson 2000).

Behavioral responses are one of the first observable signs that an animal is reacting to a stimulus. Whenever

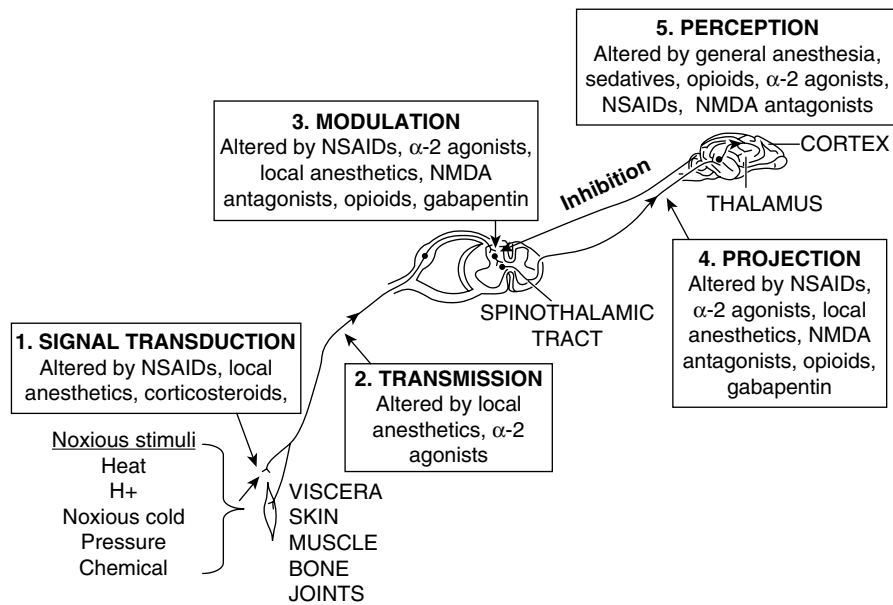

Figure 6.1. The pain pathway.

possible, species-specific pain scores should be developed that incorporates established normal behaviors and alterations associated with pain. However, using a consistent generic scale (e.g., 1–10 scale) can also be of great value to evaluate pain and response to therapy (Hawkins 2002; Paul-Murphy & Hawkins 2012; Sneddon 2009).

PAIN AND ITS MANAGEMENT IN VERTEBRATE SPECIES

Historically, it was a commonly held belief that mammals had a higher neurological capacity to experience pain compared with other nonmammalian species, and that this capacity was directly related to the phylogenetic hierarchy. However, biochemical, anatomical, and physiological studies convincingly show the transmission, mediation, and central processing and modulation of painful stimuli in the lower vertebrates is analogous to mammals (Chandaroo et al. 2004). Neuroanatomy is largely conserved among vertebrate animals within the peripheral nervous system and CNS (Brenner et al. 1994; Chandaroo et al. 2004). While mammals, birds, and reptiles, have more highly developed specialized sensory cortical regions of thickened gray matter covering the telencephalon known as the neopallium or neocortex, the relative lack of pallial development in amphibians and fish unfortunately has formed the basis for biases that the latter do not experience pain but rather only nociception (Striedter 1997). However, fundamental features that have been conserved throughout pallial evolution. The less evolved pallium still can execute similar physiological functions in fish and amphibians as higher vertebrates, as

the neural basis for consciousness involves widespread integration of differentiated neurons in the pallial and subpallial regions of the brain (Chandaroo et al. 2004; Davis & Kassel 1983; Echterler & Saidel 1981; Northcutt 1981; Saidel et al. 2001; Wullimann & Rink 2002). A summary of commonly used analgesics in nonmammalian vertebrates and in mammals is provided in Table 6.1 and Table 6.2, respectively.

Fish

Fish nociceptors are physiologically identical to higher vertebrates, responding to mechanical pressure, heat, and noxious chemical stimuli (Ashley et al. 2007; Sneddon 2004; Sneddon 2009). Of the three major classes of fish, Osteichthyes (bony fishes) have both types of polymodal fibers (A δ and C fibers), with A δ fibers being the predominant type (Ashley et al. 2007; Chandaroo et al. 2004; Sneddon et al. 2003b; Webber 2011). In Chondrichthyes (elasmobranchs), only A δ fibers have been identified (Chandaroo et al. 2004; Coggeshall et al. 1978) while the Agnatha (hagfishes and lamprey) primarily have C-type fibers (Matthews & Wickelgren 1978).

Fish also show similar organization of their major spinal pathways (spinothalamic tract and trigeminal tract) as to other tetrapods, and analogous biochemical mediation of nociception (Ronan & Northcutt 1990; Sneddon 2009; Webber 2011). In teleosts, several peptides may transmit and modulate nociceptive signals (e.g., substance P), and the behavioral and autonomic nervous system responses to noxious stimuli are specifically indicative of detection (Chandaroo et al. 2004; Ide & Hoffmann 2002; Ostlund & Von Euler 1956; Weld & Maler 1992). Electrical activity during noxious

Table 6.1. Commonly used analgesics in nonmammalian vertebrates

Analgesic	Avian	Reptiles	Amphibians	Fish
Opioids				
Buprenorphine	0.25–0.5 mg/kg IM (pigeons) (Gaggermeier et al. 2003) No evidence of analgesic efficacy in studied psittacines (Paul-Murphy et al. 2004a)	No evidence of analgesic efficacy	46–100 mg/kg SC, IC q 24 h (Koeller 2009; Stevens 2004)	No evidence of analgesic efficacy
Butorphanol	1.0–5.0 mg/kg IM q 3–24 h (Hawkins 2006; Hawkins & Paul-Murphy 2011; Klaphake et al. 2006; Paul-Murphy et al. 1999; Sanchez-Migallon Guzman et al. 2011a; Sladky et al. 2006)	1.5–8.0 mg/kg SC, IM UID-BID (Greenacre et al. 2008) Questionable efficacy in some studied species. Respiratory depression and profound sedation at > 10 mg/kg 2.5 mcg/h patch q 72 h (Gamble 2009)	25–33 mg/kg SC q 8–12 h (Stevens 2011) 0.5 mg/L continuous bath q 24 h (Koeller 2009)	0.25–0.5 mg/kg IM q 24 h (Davis et al. 2006; Harms et al. 2005) No efficacy in studied elasmobranch (dogfish) No data available
Fentanyl	0.02 mg/kg IV (raptors) (Pavez et al. 2011)	0.1–1.0 mg/kg SC, IM q 24 h (Mans et al. 2011)	0.8 mg/kg SC q 24 h (Stevens 2004, 2011) No data available	0.25–0.5 mg/kg IM
Hydromorphone	Not recommended	Watch for sedation and respiratory depression > 0.5 mg/kg		
Morphine	Not recommended	Saurians, Chelonians: 1–5 mg/kg SC, IM, IT q 24 h (Hawkins 2006; Mans et al. 2011; Mauk et al. 1981) Crocodilians: 0.3 mg/kg q 24 h (Kanui & Hole 1992)	114 mg/kg SC q 12 h (Stevens 2004, 2011)	5–40 mg/kg IM, IP q 24–48 h (Baker et al., 2010; Newby, Wilkie, and Stevens, 2009; Nordgreen et al., 2009) No data available No data available
Nalbuphine	12.5 mg/kg IM (Sanchez-Migallon Guzman et al. 2011b)	No data available	No data available	No data available
Remifentanyl	No data available	No data available	2.8 mg/kg SQ (Mohan & Stevens 2006)	No data available

stimulation has been recorded in the forebrain and midbrain of rainbow trout, goldfish, and Atlantic salmon (Dunlop & Laming 2005; Nordgreen et al. 2007), and this electrical activity differed according to stimulus type (e.g., simple touch vs. noxious, potentially painful stimuli). In addition, rainbow trout and carp exposed to noxious stimuli underwent global gene expression changes to their brains, particularly the forebrains, which mirrors the importance of the forebrain in mammalian pain processing (Reilly et al. 2008; Sneddon 2009).

Opioid receptors and endogenous substances (e.g., enkephalin-like) are present in the brain and spinal cord of studied fish species, and often demonstrated a similar distribution pattern to that of higher vertebrates (Alvarez et al. 2006; Buatti & Pasternak 1981; Li et al. 1996; Porteros et al. 1999; Rosenblum & Callard 1988; Sneddon 2009). Administration of morphine can blunt physiological and behavioral changes associated with noxious stimuli in fish species (Ehrensing et al. 1982; Nordgreen et al. 2009; Sneddon 2003b). COX enzymes also have been identified in a zebrafish (Grosser et al. 2002; Teraoka et al. 2009).

Recognition of Pain in Fish Current behavioral studies of pain in fish are restricted to a very small number of species (rainbow trout, common carp, and zebrafish) and two models of pain (subcutaneous injection of noxious substances such as acetic acid and bee venom, and thermonociception). As fish are one of the most diverse vertebrate groups, there is a definite need for future research to include a wider range of species, different pain measures, and different models of pain. However, these studies have provided further proof that fish have a capacity to detect, conceptualize, and subsequently respond to nociceptive stimuli. There is growing scientific evidence to support the case for fish perceiving and experiencing some of the negative affective aspects of pain. It is clear that a painful stimulus does result in adverse changes in behavior and physiology, which may impair the welfare and well-being of fish (Chandroo et al. 2004; Correia et al. 2011; Reilly et al. 2008; Roques et al. 2010; Sneddon 2003; Sneddon et al. 2003b; Sneddon 2011; Webber 2011).

The paucity of comprehensive clinical baseline data for the majority of fish species complicates the identification of pain and or distress in fish. Depending on the environment, it may be difficult to observe behavioral changes, especially with secretive species. Most behavioral changes in fish after noxious stimulation occur in the period immediately after the treatment for up to 6 hours, often peaking between 1 and 1.5 hours. Goldfish and trout demonstrate learned avoidance behavior after exposure to a noxious stimulus (Overmier & Hollis 1990; Ehrensing et al. 1982; Sneddon et al. 2003a). Clinical signs ascribed to pain in fish are anomalous behaviors, such as rubbing the affected

area, rocking from side to side with the pectoral fins, decreased activity or swimming behavior, increased gill ventilation (opercular) rates, decreased feeding behavior, color changes, changed postural positions in the water column, increased cortisol levels, and exocytosis of mucous from gill cells. In rainbow trout, the administration of morphine significantly reduced all of the behavioral and physiological changes described above, further demonstrating that they were specifically due to pain (Ashley et al. 2009; Chandroo et al. 2004; Reilly et al. 2008; Sneddon, 2011; Sneddon et al. 2003b; Webber 2011).

Analgesia in Fish Although empirical usage of analgesics in fish has become more widespread in a captive setting, its use in a field setting has been minimal where invasive surgeries such as implantation of intracoelomic electronic transmitters occurs (Harms & Lewbart 2011). The lack of approved analgesics for fish further complicates treatment. There have still been relatively few studies of analgesic use in fish, and varying results highlight the challenge of extrapolating findings between species.

Sladky et al. (2001) demonstrated that red pacu (*Piaractus brachypomus*) anesthetized with eugenol, the active ingredient in clove oil and an effective studied anesthetic in numerous fish species, did not blunt the responses to a noxious stimulus compared with tricaine methanesulfonate (MS-222), and no other published studies have demonstrated an analgesic effect of eugenol in fish. Alpha-2 agonists, such as medetomidine, induce sedation in studied fish but also have failed to demonstrate analgesic activity (Neiffer & Stamper 2009). Local anesthetics, such as lidocaine and benzocaine, have been used for immersion anesthesia, and have been used anecdotally for their local effects, but have not been well studied in a research setting. Mettam et al. (2011) demonstrated that local infiltration of lidocaine (6.25–16 mg/kg) was the most effective analgesic compared with buprenorphine and carprofen in trout being injected with noxious acetic acid.

The elimination half-life of morphine in studied fish species is several fold longer than in mammals, ranging from 12.5 to 37 hours (Nordgreen et al. 2009). Parenteral morphine has been demonstrated to be effective in ameliorating the adverse physiological or behavioral reactions to noxious stimuli in goldfish, winter flounder (*Pseudopleuronectes americanus*), and trout, and to pain from gonadectomy in koi (*Cyprinus carpio*) (Baker et al. 2010; Newby et al. 2007, 2009; Sneddon 2003). However, it also was associated with a marked bradycardia and reduction in cardiac output initially, followed by a significant increase in heart rate for 48 hours afterwards, in treated winter flounder compared with controls. Interestingly morphine was found to be ineffective at studied doses (40 and 50 mg/kg) in gold-

fish in thermonociception experiments (Nordgreen et al. 2009), indicating the type of noxious stimulus may be important in determining the efficacy of an analgesic in fish. Morphine administered via the water had extremely slow uptake and is not recommended (Newby et al. 2009).

In koi, butorphanol (0.4 mg/kg), but not ketoprofen (2 mg/kg), was effective in reducing postsurgical pain-related behavioral changes, such as decreased activity and feeding behavior (Harms et al. 2005). At higher doses, butorphanol (10 mg/kg) provided antinociceptive activity in koi undergoing gonadectomy, but was associated with respiratory depression and abnormal buoyancy (Baker et al. 2010). However, even at higher doses, neither drug was effective in an elasmobranch, the chain dogfish (*Scyliorhinus rotifer*), for reducing minimum anesthetic concentrations (Davis et al. 2006). Intramuscular buprenorphine (0.01–0.1 mg/kg) did not provide evidence of analgesia in rainbow trout, while the NSAID carprofen did have some analgesic properties at higher doses (2.5 and 5 mg/kg), but decreased activity was noted at the higher dosage (Mettam et al. 2011). Tramadol administered intramuscularly (0.26–2.6 mg/kg) in common carp induced a prolonged dose-dependent analgesic response to a noxious electrical while still maintaining normal swimming and behavior, with analgesic effects lasting greater than 2 hours (Chervova & Lapshin 2000). In the author's experience, meloxicam used empirically at dosages of 0.2–0.3 mg/kg has produced analgesia based on behavioral changes; this remains to be studied scientifically.

Amphibians

Amphibian nociceptive afferents are analogous to the primary afferents of other vertebrates, including mammals, with both lightly and heavily myelinated (A β and A δ , respectively) and unmyelinated (C) afferent fibers found in mixed fiber peripheral sensory nerves (Stevens 2004, 2011). The majority of all impulses induced by noxious stimuli, such as pinching, pinpricks, and heat are conducted by slowly conducting C fibers, while epidermal application of dilute acetic acid evoked A δ and C fibers to a relatively equal extent (Hamamoto & Simone 2003; Maruhashi et al. 1952). Sensory afferents terminate in the dorsal horn of the spinal cord, and similar to mammals, pain-signaling neurotransmitters, such as substance P, glutamate, and calcitonin, have been identified (Inagaki et al. 1981; Lorez et al. 1981). Amphibian studies have demonstrated responsiveness to α -2 agonists and to local anesthetics. In addition, met-enkephalin and four types of opioid receptors (μ , κ , δ , and ORL-1) are abundant in the amphibian spinal cord and brain but exhibit less selective binding compared with mammals (Bradford et al. 2005; Newman et al. 2002; Stevens 2004; Walthers et al. 2005). There have only been a few studies that evaluated opioid receptor density in

amphibians, with μ receptors being more abundant than κ receptors in leopard frogs (*Lithobates pipiens*), but the reverse found in marine toads (*Bufo marinus*) (Brooks et al. 1994; Newman et al. 2002). Further research is required to elucidate opioid receptor densities in other amphibian species.

Although the spinal ascending nociceptive pathways in amphibians are not clearly defined, a single study in frogs identified that electrical stimulation of the sciatic nerve traveled through the spinal ascending pathways and produced evoked potentials in the thalamus and primordial hippocampus (Munoz et al. 1997; Vesselkin et al. 1971). Thalamocortical projections in anurans are more diffuse and less organized than in mammals, but terminate in the nonolfactory telencephalon as with other vertebrates. Similar to fish, there is minimal cerebral or limbic cortical pallial development but it is likely that other neural pathways have developed for the perception of pain (Stevens 2004, 2011).

Recognition of Pain in Amphibians The acetic acid test has been used for decades to assess amphibian nociception, with application of varying diluted concentrations and monitoring for a wipe response by the hindlimb (Coble et al. 2011; Pezalla 1983; Stevens 2011). Based on this test, dermal exposure to other noxious stimuli is likely to elicit a similar response. More recently, the Hargreaves test has been validated to evaluate thermonociception where heat is applied to the inner thigh of the frog in a specialized apparatus, and the frog is monitored for withdrawal movement of the hindlimb (Coble et al. 2011).

In the author's experience, decreased activity and feeding behavior, color changes, increased reclusive behaviors, and postural changes are associated with pain in amphibians. Painful amphibians also may spend more time in atypical locations (Duncan 2012). Koeller (2009) demonstrated that Eastern red-spotted newts (*Notophthalmus viridescens*) that underwent bilateral forelimb amputation did not eat for 72 hours post surgery when no analgesia was used, while feeding resumed within 24 hours in animals treated with intracoelomic buprenorphine or with butorphanol in their water. In addition, the animals that received no analgesia did not move in response to tapping on the aquarium glass until 72 hours post surgery, while analgesed newts moved at the first post surgical test point at 24 hours. Finally, abnormal postures in nontreated newts were observed for 72 hours post surgery, while 8/10 newts treated with buprenorphine or butorphanol had resumed normal postures within 4 hours, and all by 24 hours, post surgery.

Analgesia in Amphibians Numerous analgesics have been studied in a research setting in amphibians for brief noxious stimuli, but very little data exists for analgesic

use in a clinical setting for pain. The most effective studied analgesics to date in amphibians are the opioids followed by the α_2 -agonists, particularly dexmedetomidine. Although the μ -agonist opioids demonstrate more effectiveness compared with κ -agonists, owing to the decreased selective binding of the opioid receptors, both appear suitable for use in amphibians. Amphibians require higher doses of opioids compared with mammals; however, the analgesic effect of the opioid also last longer (Benyhe et al. 1990; Koeller 2009; Stevens 2004, 2011). Tramadol use has not been reported in the literature; however, the author has used it orally in aged marine toads with arthropathies (25 mg/kg PO q 48 hours) with positive clinical results. Further evaluation of tramadol use in amphibians is needed.

Of the few studied NSAIDs in amphibians, flunixin meglumine (25 mg/kg s.c.) has been the most effective for decreasing responsiveness to cutaneous noxious stimulation (Coble et al. 2011; Terril-Robb et al. 1996). Minter et al. (2011) demonstrated that the systemic administration of meloxicam at a dosage of 0.1 mg/kg once daily decreases the circulating serum prostaglandin E2 levels in North American bullfrogs (*Rana catesbeiana*) measured 24 hours after the induction of the inflammatory cascade through surgical muscle biopsies. Meloxicam (0.2 mg/kg s.c.) in African clawed frogs (*Xenopus laevis*) demonstrated a very mild analgesic effect against cutaneous noxious stimuli (Coble et al. 2011). It is quite probable that for analgesic effects, the dose needs to be increased, especially when compared with the flunixin dosage, which is approximately 20- to 25-fold higher than in mammals. The author has seen anti-inflammatory effects of meloxicam when administered parenterally (0.2–0.3 mg/kg) in frogs with cutaneous ulcers. Further research is needed to assess the clinical efficacy and toxicity of NSAID use in amphibians.

Local anesthetics should be used judiciously in amphibians due to potential systemic toxicity associated with dermal absorption; however, they can be very effective when local analgesia is required (e.g., microchip implantation and distal digital amputation). Topical applications of lidocaine, benzocaine, or a prilocaine-lidocaine (EMLA®) have all been used anecdotally for their local effects (Fig. 6.2). However, in one study that evaluated benzocaine and prilocaine-lidocaine as potential topical agents to induce anesthesia in leopard frogs, the latter was associated with 41.7% mortality at a dosage greater than 5 mg/kg (Guenette & Lair 2006).

Reptiles

Similar to mammals and birds, reptiles possess the appropriate neuroanatomical components for nociception with well-developed antinociceptive mechanisms. A δ nociceptors have been isolated in the oral mucosa

Figure 6.2. Topical application of a local anesthetic cream (lidocaine/prilocaine) in a White's tree frog (*Litoria caerulea*) prior to microchipping.

and facial skin of snakes that are similar to those in primates, and the arrangement of the spinal cord in reptiles is similar to that in mammals. Spinal projections between the brainstem and the superficial layers of the dorsal horn have been identified in Tokay gecko lizards (*Gekko gecko*), and are analogous to those in mammals that promote spinal inhibition. In addition, neurotransmitters responsible for nociceptive modulation in other vertebrates have been identified in reptiles, and nociception can be modulated with analgesics used in other taxa. Opioid receptors are present throughout the central nervous system, although the efficacy of opioid agonists may vary between species. Cyclooxygenase enzymes can be inhibited by the use of nonsteroidal anti-inflammatories in reptiles (Kanui et al. 1990; Kanui & Hole 1992; Liang & Terashima 1993; Mosley 2011; Ng et al. 1986; Reiner 1987; ten Donkelaar & de Boer-van 1987; Schaeffer & Waters 1996; Seebacher & Franklin 2003; Sladky et al. 2007, 2008, 2009; Sladsky 2010).

Recognition of Pain in Reptiles Clinical experience and research demonstrate that reptiles display a number of behaviors that are consistent with pain in mammalian species, including decreased activity levels and appetite, immobility, guarding of painful limbs or regions, changes to ambulation patterns, exaggerated withdrawal, escape or avoidance responses, and attempts to bite. Other clinical signs that may be noted are vocalizations, behavioral changes, closed eyes, color changes, hunched appearance or not resting in a normal posture, excessive scratching, flicking, or biting at painful areas, elevated heart rates, and abnormal respirations (Duncan 2012; Eatwell 2010; Kanui & Hole 1992; Machin 2007; Mosely 2011; Stoskopf 1994). Tortoises can accurately locate a tactile stimulus applied to

the shell, and respond by rubbing at the stimulated area with a foot (Rosenberg 1986; Stein & Grossman 1980). However, it is important to realize that some reptiles may suppress some pain-related behaviors when an observer is present (Fleming & Robertson 2006). It is essential to learn the normal repertoire of species-specific behaviors in order to interpret abnormalities that may represent pain.

Analgesia in Reptiles In general, the opioids have been the most studied analgesic in reptile species; however, there are increasing studies with other analgesics being reported. In the anole lizard (*Anolis carolinensis*), intraperitoneally administered morphine at 5 mg/kg slowed the tail-flick response to a noxious stimulus (Mauk et al. 1981). Green iguanas (*Iguana iguana*) demonstrated significantly reduced tail movement after an electrical stimulation when intramuscular morphine (1 mg/kg) was administered (Hawkins 2006), while crocodiles developed significant latencies in response to painful stimuli with maximal effect at 0.3 mg/kg (Kanui & Hole 1992). Morphine also has demonstrated analgesic effects in red-eared sliders (*Trachemys scripta*) and bearded dragons (*Pogona vitticeps*); however, profound long-lasting respiratory depression was noted in the turtles at higher doses. When morphine was administered intrathecally (0.1–0.2 mg/kg) to red-eared slider turtles, it resulted in thermal antinociception of the hindlimbs for up to 48 hours (Mans et al. 2011). Morphine at studied doses was not found to be effective in corn snakes (*Elaphe guttata*). The duration of action may vary considerable between species, and the onset of action of morphine may be delayed for 2–8 hours after administration (Sladky et al. 2007, 2008). Hydromorphone has been used anecdotally by the author in lizards, snakes, and turtles with apparent clinical analgesic effects, although sedation and respiratory depression were noted at dosages higher than 0.5 mg/kg. Transdermal fentanyl patches (2.5 µg/h) applied to prehensile tailed skinks (*Corucia zebrata*) achieved serum concentrations that would equate to effective analgesic levels in human patients (Gamble 2009). Further research with hydromorphone and transdermal fentanyl is needed to evaluate their analgesic effects.

Although butorphanol has been used frequently as an analgesic with variable clinical results, few studies support its analgesic properties in reptiles. In red-eared slider turtles and bearded dragons, it did not yield significant antinociceptive effects (Sladky et al. 2007, 2008). However, in snakes at higher dosages (20 mg/kg), it did result in thermal antinociceptive effects (Sladky et al. 2008). Olesen et al. (2008) demonstrated that butorphanol did not have analgesic properties in ball pythons (*Python regius*). In green iguanas, butorphanol (1 mg/kg) did not have an isoflurane sparing effect on minimum alveolar concentrations (Mosley

et al. 2003); however, analgesia was noted at dosages between 1.5 and 8.0 mg/kg in electrostimulation experiments (Greenacre et al. 2006). Buprenorphine has not demonstrated analgesic activity in red-eared slider turtles or green iguanas, with profound respiratory depression noted in the former species (Greenacre et al. 2006; Sladsky 2010).

Studies with tramadol use in reptiles is limited; however, the drug appears to hold promise as an effective analgesic. In bearded dragons, a significant analgesic effect was noted in electrostimulation experiments at 11 mg/kg (Greenacre et al. 2008). Long-lasting analgesia (up to 96 hours) was noted with oral tramadol administration (10–25 mg/kg) in red-eared sliders; however, a significant decrease in ventilation rates were noted and at the highest dose sedation with flaccid neck and limbs was noted. Dosages of 5 mg/kg did not suppress ventilation and provided analgesia for at least 24 hours. (Baker et al. 2011). The author has noted apparent analgesic effects for 48–72 hours in several species of lizards and snakes with dosages between 10 and 25 mg/kg, with profound sedation and respiratory depression often noted at the higher doses for the first 24 hours.

NSAIDs are the most widely used analgesic in reptiles, with very few clinical studies to evaluate their pharmacokinetics or clinical efficacy (Greenacre et al. 2008; Mosley 2011; Olesen et al. 2008; Read 2004). As such, it is difficult to recommend effective and safe dosing intervals as plasma concentrations of NSAIDs do not always directly correspond with clinical efficacy (Mosley 2011). Meloxicam has been used most frequently by clinicians with no reports of toxicity in reptiles. Daily intramuscular administration of meloxicam (0.2 mg/kg) or carprofen (2 mg/kg) for 10 days in green iguanas did not yield any significant alterations to hematological or serum biochemical parameters (Trnková et al. 2007), and high daily oral doses of meloxicam (1 or 5 mg/kg) for 12 days did not induce any histological changes to renal, hepatic or gastric tissues (Divers et al. 2010). In green iguanas dosed orally or intravenously at 0.2 mg/kg, plasma concentrations associated with analgesia in other species were maintained for 24 hours (Divers et al. 2010). In red-eared sliders, intramuscular administration of meloxicam (0.5 mg/kg) provided for the most consistent clinical pharmacokinetic behavior with a terminal half-life of 7.57 hours, while oral bioavailability was only 37% (Rojo-Solís et al. 2009). Olesen et al. (2008) found no discernable effects on mitigating changes in physiological parameters in ball pythons undergoing surgery when comparing preoperative meloxicam (0.2 mg/kg i.m.) to saline. However meloxicam (0.4 mg/kg i.m.) was effective in significantly decreasing tail movement responses in bearded dragons to electrostimulation, as was carprofen (2 and 4 mg/kg i.m.) and ketoprofen (2 mg/kg i.m.), compared with saline (Greenacre et al.

2008). Ketoprofen bioavailability when administered intramuscularly in green iguanas was 78%, with a longer terminal half-life compared with dogs (Tuttle et al. 2006). The longer half-life of studied NSAIDs necessitates judicious use in compromised reptiles.

Local anesthetics are commonly used for surgical procedures in reptiles, and can be an effective local analgesic (Bennett 1998; Hawkins 2006). Care must be taken to avoid accidental overdose, especially in small patients. Dosages should not exceed 10 mg/kg for lidocaine, 5 mg/kg for bupivacaine, or 25 mg/kg for mepivacaine (Eatwell 2010; Mosley 2011; Wellehan et al. 2006). For smaller patients, less concentrated commercially available solutions (e.g., 1% lidocaine or 0.25% bupivacaine) should be used to minimize the decreased efficacy of local anesthetics when they are diluted (Kanai & Hoka 2006; Kanai et al. 2007). Some clinicians, including the author, prefer to combine these two local anesthetics in a 1:1 ratio to enhance effects and duration, and minimize the potential for toxicity (Eatwell 2010). Clinical evaluation of local anesthetic use in reptiles is rare in the veterinary literature. A technique for a mandibular nerve blockade using 2% mepivacaine was described in crocodylians (Wellehan et al. 2006), and more recently, intrathecal administration of lidocaine (4 mg/kg) or bupivacaine (1 mg/kg) in red-eared sliders resulted in motor block of the hindlimbs for approximately 1 and 2 hours, respectively (Mans et al. 2011). Further research into local anesthetic use in reptiles is needed.

Other drugs such as NMDA antagonists, α -2 agonists, or gabapentin have not been clinically evaluated for their analgesic properties in reptiles, although based on experience in other taxa they may be beneficial (Mosley 2011). Complementary therapies such as acupuncture (Fig. 6.3) and cold laser therapy appear to be

Figure 6.3. Electroacupuncture in a black throated monitor (*Varanus albigularis ionidesi*) for cranial cervical trauma that had resulted in tetraparesis. The monitor had not improved with pharmaceuticals and aqua therapy, but significant clinical improvement was noted within three acupuncture treatments.

valuable based on clinical impressions, and deserve further study as well (Koski 2011).

Birds

The neurological components to respond appropriately to painful stimuli in avian species are analogous to those in mammals, with well-developed antinociceptive mechanisms to diminish pain, and modulation of pain pathways and behavioral responses to painful stimuli with pharmacological agents (Gentle 1992; Hawkins 2006; Machin 2007; Machin & Livingston 2002). Three types of nociceptors have been identified in birds: thermal and mechanical nociceptors, and high threshold nociceptors that are polymodal in nature and respond to mechanical, thermal, and chemical stimulation (Gentle 1992; Gottschaldt et al. 1982; McKeegan 2004; Necker & Reiner 1980). Opioid receptors are detectable as early as 10 days in embryonic chicks (Hendrickson & Lin 1980), and the μ , δ , and κ opioid receptors in birds are similarly distributed in the fore-brain and midbrain as seen in mammals, with κ receptors predominating in the few studied species, but with variability existing, even between strains of the same species (Csillag et al. 1990; Mansour et al. 1988; Reiner et al. 1989). Cyclooxygenase enzymes (COX-1 and COX-2) are widely distributed in birds, and can be modulated with NSAIDs (Lu et al. 1995; Mathonnet et al. 2001).

Recognition of Pain in Bird Species In general, similar to many wild species, birds tend not to show overt signs of pain as obvious distress behaviors may attract unwanted attention; rather, they will demonstrate more subtle or cryptic behavioral signs of their discomfort. As there are no universal indicators of pain in birds, the assessment of pain must take into account the species-specific normal behavior and individual behavior, strain, gender, age, concurrent disease states, type of pain, and the environment. In addition, it is important that behavioral observations occur at appropriate times for each species, such as observing nocturnal species at night (Hawkins & Paul-Murphy 2011; Hughes 1990; Machin 2007; Sufka et al. 1992).

Birds that are acclimated to handling may mask physiological changes often associated with pain, such as elevations in body temperature, respiratory rate, or stress hormones. However, birds that are comfortable with their environment also may more readily demonstrate painful behaviors, such as limb guarding or squinting of the eyes (Hawkins 2006; Heatley et al. 2000). In chickens, elevations in blood pressure were consistently associated with painful procedures; however, the measurement of blood pressures is not always feasible (Gentle & Hunter 1991). Immobility is a shared finding across numerous avian species, and in social species, isolative behavior can often be noted (Gentle 1992; Gentle & Hill 1987; Graham 1998; Paul-Murphy & Hawkins 2012). Many bird species that are

being handled will respond to acute painful procedures with vocalizations, excessive movement, and escape reactions, but with progression of the painful stimulus will revert to immobility. Normally passive birds may act aggressively when in pain. With prolonged pain, decreased appetite and activity are often noted, especially behaviors such as preening or dust bathing, although in some individuals, particularly with psittacines and mynahs, overgrooming and feather destructive behavior may ensue (Gentle & Hunter 1991; Hawkins & Paul-Murphy 2011).

Analgesia in Birds Based on pharmacodynamic studies and clinical experience, butorphanol is the recommended opioid for use in avian species at a dosages of 1–5 mg/kg intramuscularly every 3–24 hours, as it has poor oral availability (Hawkins 2006; Hawkins & Paul-Murphy 2011; Klaphake et al. 2006; Paul-Murphy et al. 1999; Sanchez-Migallon Guzman et al. 2011; Sladky et al. 2006). In some species, particularly *Buteo sp.* raptors and corvids, it can be associated with profound sedation at the higher dosages. In pharmacokinetic studies, the half-life is only 1–2 hours, so frequent dosing may be necessary depending on clinical need (Paul-Murphy & Hawkins 2012; Riggs et al. 2008; Sanchez-Migallon et al. 2008; Sanchez-Migallon Guzman et al. 2011a). An experimental liposome encapsulated butorphanol holds promise for the future as it provides analgesic effects for 3–5 days after a single subcutaneous injection of 15 mg/kg (Paul-Murphy et al. 2009a; Sladky et al., 2006). Another κ -agonist and partial μ -antagonist that may of future clinical use is nalbuphine hydrochloride. In Hispaniolan Amazon parrots (*Amazona ventralis*), it increased pedal thermal withdrawal thresholds for up to 3 hours after single intramuscular administration of 12.5 mg/kg (Sanchez-Migallon Guzman et al. 2011b).

Other opioids, such as fentanyl and buprenorphine, have demonstrated mixed results in clinical studies. Fentanyl at 0.02 mg/kg intramuscularly in white cockatoos (*Cacatua alba*) was not effective; however, increasing it to 0.2 mg/kg yielded a positive analgesic response but was associated with undesirable hyperactivity (Hoppe et al. 2003). Under constant rate infusion studies in red-tailed hawks (*Buteo jamaicensis*), fentanyl significantly lowered the minimum anesthetic dose of isoflurane by 31–55%, so it may have greater clinical applications as an intraoperative analgesic (Pavez et al. 2011). Buprenorphine administered intra-articularly in domestic fowl, or intramuscularly at 0.1 mg/kg in African gray parrots, failed to demonstrate an analgesic effect (Gentle et al. 1999; Paul-Murphy et al. 1999, 2004a). However, at 0.25 and 0.5 mg/kg in pigeons, it was associated with a positive analgesic response for 2 and 5 hours, respectively, and deserves further study (Gaggermeier et al. 2003).

The pharmacokinetics of tramadol has been studied in bald eagles (*Haliaeetus leucocephalus*), red tailed hawks,

peafowl (*Pavo cristatus*), and Hispaniolan Amazon parrots with oral dosages between 5 and 11 mg/kg achieving serum levels equated with analgesia in humans (Black et al. 2010; Souza et al. 2009, 2010, 2011). Preliminary studies on its efficacy against noxious thermal stimuli in Hispaniolan Amazon parrots revealed that a dosage of 30 mg/kg provides analgesia for up to 6 hours, indicating that higher doses may be needed for clinical effect and that significant interspecific variability may exist (Souza et al. 2010).

The most frequently used NSAIDs in avian species are meloxicam, carprofen, and ketoprofen with selective use of celcoxib and piroxicam. Meloxicam is the most commonly used NSAID in zoological medicine, and has shown a wide margin of safety in a large and diverse number of species (Cuthbert et al. 2007; Hawkins & Paul-Murphy 2011; Naidoo & Swan 2008; Naidoo et al. 2008). Significant interspecific variation exists in birds, with elimination half-life in studied species ranging from as short as 30 minutes in ostrich (*Struthio camelus*), to over 3 hours in chickens, and 4 hours in ring-necked parakeets (*Psittacula krameri*) when administered intravenously (Baert & De Backer 2003; Wilson et al. 2005) and 16 hours after oral administration in ring-necked parakeets (Wilson et al. 2005). In Hispaniolan Amazon parrots, intramuscular dosages of 1 mg/kg every 12 hours were needed for effective analgesia for experimentally induced arthritis, but long-term studies have not been carried out to assess for adverse side effects (Cole et al. 2009). Based on the author's clinical experience, an initial dose of 0.2–0.5 mg/kg intramuscularly has proven efficacious in many species, and generally favorable clinical results noted with chronic oral usage at 0.2–0.3 mg/kg up to once daily with no complications. As with the other NSAIDs, further studies are needed to evaluate the pharmacokinetic and pharmacodynamic behavior of meloxicam in various avian taxa, as well as evaluation for adverse effects with chronic administration.

Carprofen has yielded variable results in studied species, with either a very high dose (30 mg/kg) needed to provide analgesia for experimentally induced arthritis in chickens (Hocking et al. 2005; McGeown et al. 1999), or a very short duration of action noted when a lower dose (3 mg/kg) was administered to Hispaniolan Amazon parrots (Paul-Murphy et al. 2009b). Ketoprofen administered orally or parenterally (2 mg/kg) to Japanese quail (*Coturnix japonica*) had a very short half-life of less than 35 minutes despite route of administration (Graham et al. 2005), while in mallard ducks (*Anas platyrhynchos*), an intramuscular dose of 5 mg/kg was associated with decreased levels of the inflammatory mediator thromboxane for up to 12 hours after administration (Machin et al. 2001), and provided analgesia against a noxious stimulus while under isoflurane anesthesia (Machin & Livingston 2002). However, in spectacled (*Somateria fischeri*) and king (*Somateria spectabilis*), eider ducks administration of ketoprofen at 2–5 mg/kg

IM was associated with severe renal tubular necrosis, visceral gout, acute rhabdomyolysis, and death in 40% and 83% of treated males, respectively, although gender-linked behaviors may have increased the susceptibility of these birds to side effects of ketoprofen (Mulcahy et al. 2003). In addition, ketoprofen has proven toxic to studied *Gyps* vulture species at dosages above 1.4 mg/kg (Naidoo et al. 2010).

Piroxicam has not been scientifically studied in avian species, but has been used successfully for the chronic treatment of arthritis in cranes (Paul-Murphy & Hawkins 2012). While other NSAIDs such as flunixin meglumine have been used historically, they have also been associated with a higher degree of undesirable side effects, such as renal toxicity and gastrointestinal ulceration (Pereira & Werther 2007). The most severe example of NSAID-induced renal toxicity is the diclofenac-linked severe decline of Asian *Gyps* vulture species (Green et al. 2004; Hussain et al. 2008; Meteyer et al. 2005; Naidoo & Swan 2008; Oaks et al. 2004).

Local anesthetics have been used successfully in a clinical setting, although there are very few scientific studies evaluating efficacy, and none that have evaluated time to effect, or duration of activity. Birds may be more sensitive to the effects of local anesthetics owing to more rapid absorption and delayed absorption compared with mammals, thus lower doses are often indicated to avoid signs of toxicity, such as drowsiness, recumbency, seizures, cardiovascular effects, and death (Hawkins & Paul-Murphy 2011; Hocking et al. 1997). Regional infiltration is generally effective for joints and soft tissue; however, brachial plexus blockade with high dose lidocaine with epinephrine and bupivacaine failed to prevent nerve transmission in chickens and mallard ducks (Brenner et al. 2010; Figueiredo et al. 2008).

Gabapentin has been used at a significantly higher dosage than mammals as an adjunctive treatment for suspected neuropathic pain in a few species, with abatement of self-mutilation (Doneley 2007; Shaver et al. 2009; Siperstein 2007), although based on the author's experience, its efficacy is highly variable, and further studies are indicated. Other drugs, such as NMDA antagonists, have not been evaluated, while complementary therapies, such as acupuncture, physiotherapy, and the use of nutraceuticals, have been anecdotally effective and are in need of further study (Crouch 2009; Koski 2011; Rychel et al. 2011).

Mammals

Despite advances in pain management, compared with the lower vertebrate species, there is still a paucity of scientific studies evaluating species-specific pain responses and analgesia in wild mammals.

Recognition of Pain in Mammals In general, many of the recognized clinical signs associated with pain in

domestic mammals may be seen in wild species, although they are often more subtly expressed, especially in prey species that may not display behavioral alterations to a painful event. Often, remote evaluation is needed to truly evaluate the degree of pain. It is important for clinicians to understand the normal behavior of species in order to evaluate for such changes in behavior that may be related to pain (Flecknell 2008; Hawkins 2002).

Objective assessment of pain can be done through evaluation of physiological and biochemical (e.g., alterations in corticosteroid levels) indices and behavior. The former indices are often difficult to assess in the conscious animal. Nonspecific clinical signs, such as tachypnea, trembling, bruxism, salivation, muscle spasms, sweating in species capable of doing so, and dilated pupils, can be associated with pain in mammals, while it is often difficult or impossible to evaluate for more specific changes such as tachycardia or pyrexia in the conscious animal. Changes in facial expressions, such as wrinkling the brow, frowning, or grimacing, are not usually recognized (Williams 2002). Other subjective measures should be evaluated, such as changes in demeanor; altered social interactions; variations in feeding or foraging patterns; changes in posture, mobility, or activity level; alterations of sleep-awake patterns; self-directed behaviors, such as looking, biting, kicking, chewing, or rubbing of painful areas; changes in vocalization; and altered response to touch (Bufalari et al. 2007; Machin 2007; Walker et al. 2010). Any of these measures may be altered with pharmacologic agents. In some social species, pain responses may elicit assistance or directed aggression from conspecifics within the social group (Sanford et al. 1996).

Analgesia in Mammals Much of the analgesic drug selection and doses used in mammals is extrapolated from domestic and laboratory species, although much-needed studies of analgesics in wildlife continue to expand.

Opioids are frequently used for analgesia in a zoological setting, but less frequently with free-ranging wildlife owing to the potential for sedation. Pharmacokinetic (PK) and pharmacodynamic (PD) studies are limited, but include PK of butorphanol in elephants (Tana et al. 2010), PK and PD of butorphanol in llamas (Carroll et al. 2001), PK and PD of morphine in llamas (Uhrig et al. 2007), and PK of fentanyl patches in llamas (Grubb et al. 2005). These studies highlight the need for species-specific studies, as extrapolation from taxonomically related species is not always appropriate.

Even though the duration of activity of butorphanol is relatively short compared with other opioids, it is still frequently used as an analgesic (maned wolf: McNulty et al. 2000; microchiropterans: Wellehan et al. 2001; African lions: Kolata 2002; Egyptian fruit bats: Lafortune et al. 2004; Asian elephants: Abou-Madi et al.

2004; white-tailed deer: MacLean et al. 2006; African hedgehog: Done et al. 2007; otariid seals: Haulena 2007; parma wallabies: Okeson et al. 2009; polar bears: Velguth et al. 2009; prehensile-tailed porcupine: Guthrie & deMaar 2011). Opioid formulations of longer durations such as buprenorphine (lions: Kolata 2002; polar bears: Velguth et al. 2009; hyena: Hahn et al. 2007; pinnipeds: Moore et al. 2010), hydromorphone (squirrel monkey: Wellehan et al. 2004; binturong: Spriggs et al. 2007), fentanyl patches (llama: Grubb et al. 2005; binturong: Spriggs et al. 2007), or epidural morphine are used frequently for analgesia by clinicians in a zoological setting, and are more commonly reported in the literature. Based on clinical experience, tramadol also is an effective analgesic in many species, and its use has been reported in large felids (McCain et al. 2008, 2009), Western lowland gorilla (Rush et al. 2010), binturong (Spriggs et al. 2007), pinnipeds (Moore et al. 2010), and Atlantic bottlenose dolphin (Schmitt & Sur 2012).

Meloxicam is the most widely administered NSAID in zoological species, with increasing applications in free-ranging wildlife. Its pharmacokinetics have been studied in nondomestic species, such as mini-pigs, baboons, and rodents (Busch et al. 1998), and rabbits (Carpenter et al. 2009). It has been used parenterally or orally in most mammalian families by the author with no observed or reported side effects. Based on the reported literature and the author's experience, oral dosages required for complexed stomached species are higher than those for simple monogastric species. (Chai et al. 2009; Dadone et al. 2011; Okeson et al. 2009; Pye et al. 2008, 2010; Twomey et al. 2010; Whiteside & Black 2004; Whiteside et al. 2006).

Carprofen and ketoprofen also are frequently used NSAIDs for captive and free-ranging mammals. In general, carprofen has been found to be efficacious (Dutton et al. 2002; Mylniczenko et al. 2005; Velguth et al. 2009). However, even in taxonomically similar species, there may be profound difference, as Walker et al. (2011) reported it was not effective in controlling postsurgical pain in Stellar sea lions when administered at dosages suggested by Dold et al. (2004) based on PK and PD studies in California sea lions. The pharmacokinetics of ketoprofen have been studied in elephants (Hunter et al. 2003) and its anecdotal use has been reported in a wide variety of species (golden lion tamarin: Bronson et al. 2005; exotic ruminants: Howard & Richardson 2005; sun bear: Mylniczenko et al. 2005; pinnipeds: Fauquier et al. 2008; Rush et al. 2012; Dennison et al. 2007; koalas: Pye et al. 2008; bongo: Gyimesi et al. 2008; Gyimesi et al. 2011; agoutis: Zimmerman et al. 2009).

NSAIDs, such as phenylbutazone and flunixin meglumine, are still utilized for analgesia, particularly with larger mammalian species (rhinoceros: Wack et al. 2010; Harrison et al. 2011; giraffe: James et al. 2000;

exotic ruminants: Howard & Richardson 2005; Gyimesi et al. 2011; deer: Mansfield et al. 2006; elk: Larsen et al. 2000; Stellar sea lions: Walker et al. 2009; bison: Minter et al. 2011). The PK of phenylbutazone have been carried out in Asian and African elephants (Bechert et al. 2008) and dromedary camel (Kadir et al. 1997), with the PK of flunixin also studied in dromedary camel (Oukessou 1994).

The PK of ibuprofen has been studied in Asian and African elephants (Bechert & Christensen 2007), and its use has been reported in primates (Bronson et al. 2005; Robbins et al. 2009; Wellehan et al. 2004), and Indian rhinoceros (Bertelsen et al. 2004). Its use in carnivore species is not recommended based on side effects noted in domestic canids and felids. Other sporadically used NSAIDs include deracoxib, firocoxib, tepoxalin, etodolac, tolfenamic acid, and naproxen, which are occasionally reported in the literature (Hohn et al. 2007; Stringer et al. 2012; Williams & Junge 2007). Care should be exercised if using these, as the PK or PD behavior, or the potential negative side effects, are not known.

Corticosteroids are infrequently used for pain management in exotic species owing to the potential negative side effects; however, the use of medium- to long-acting steroids, such as triamcinolone acetate and medroxyprogesterone acetate, have been used successfully for joint infusions in mammals with arthritis refractory to other therapies.

Local anesthetics are frequently used with zoological species, and their use continues to expand in a free range setting. They are effective when used topically, epidurally, intra-articularly, intrapleurally, or intra-abdominally, for specific nerve blocks (such as dental blocks for tooth extractions or endodontic procedures [Fig. 6.4 and Fig. 6.5], or regional nerve blocks), non-specific infiltration, such as ring blocks or line blocks,

Figure 6.4. Infraorbital nerve block with bupivacaine in a gray wolf (*Canis lupus*) prior to an endodontic procedure.

Figure 6.5. Mental nerve block with bupivacaine in an Amur tiger (*Panthera tigris altaica*) for an endodontic procedure. This dental block would be useful for premolar extraction for aging studies as well.

or for intravenous regional blocks (Beasley & Rhodes 2007; Borkowski et al. 2009; Clarke & DeVoe 2011; Dadone et al. 2011; Mansfield et al. 2006; Morges et al. 2009; Mylniczenko et al. 2005; Pye et al. 2010; Schroeder et al. 2010). Care must be taken particularly with smaller species, to avoid approaching toxic dosages (Gyimesi & Burns 2009; Heard 2007).

In a clinical setting, the use of alpha-2 agonists, such as medetomidine, or NMDA antagonists, such as ketamine or amantadine, for analgesia independent from anesthesia are rarely described in the literature for exotic species. Anecdotal evidence suggests that ketamine at 1/10th of the anesthetic dose for a species is efficacious for analgesia or as a constant rate infusion at 0.01–0.02 mg/kg/min, which limits its use in a field setting (Cracknell 2007). The addition of magnesium (Mg^{+2}) with ketamine enhances its analgesic effect (Liu et al. 2001).

Gabapentin use, particularly as part of multimodal therapy for chronic neuropathic pain or chronic disease states such as with osteoarthritis or cancer pain, is apparently effective and warrants further study (Adkesson 2006; Bronson et al. 2008; Vonsy et al. 2009). Other adjunctive therapies, such as oral glucosamine sulfate, chondroitin, omega-3 fatty acid supplementation, or injectable polysulfated glycoaminoglycans, are frequently utilized in a zoological setting for chronic arthritides and are anecdotally effective (Pye et al. 2008; Roush et al. 2010; Stringfield & Wynne 1999; Whiteside et al. 2006); however, there are no supporting scientific studies that clearly demonstrate a benefit

with oral products, and there are legitimate questions of oral bioavailability, especially in herbivores. Recent analyses of multiple studies in dogs and humans indicate there is conflicting evidence as to the benefit to glucosamine, chondroitin, green lipped mussels, or methylsulfonylmethane (MSM) supplementation (Aragon et al. 2007; Neil et al. 2005; Teets et al. 2010; Vandeweerd et al. 2012). Further research in their use in zoological species is indicated. Other modalities, such as acupuncture or cold laser therapy, also have produced favorable analgesic responses for osteoarthritis or neuropathic pain, and deserve further study (Cassu et al. 2008; Koski 2011; Maenaka et al. 2006; Rychel et al. 2011; Teets et al. 2010).

Pain in Invertebrates

There is growing scientific evidence that suggests that invertebrate species, especially the more advanced species found in the phyla Arthropoda and Mollusca, have the ability to experience pain, rather than just respond to nociceptive stimuli. This is based on the presence of suitable receptors and central nervous system, responsiveness to analgesics and anesthetics, physiological changes, avoidance learning, protective motor reactions, and cognitive abilities and sentience (Crook and Walters 2011; Barr et al. 2008; Elwood 2011). Many of the advanced invertebrate species have brains that relative to their body weight are larger than those in many vertebrates species, and have complex brain structures for sensory analysis, memory, learning, and decision making, which are analogous to the functions of the cerebral cortex in vertebrate species. (Elwood et al. 2009; Sandeman et al. 1992; Smith 1991).

Behavioral evidence for likely experience of pain has been demonstrated in several invertebrate species through avoidance learning research and protective motor reflexes. Etuarine crabs (*Chasmagnathus granulatus*) associated an electrical shock with a particular location for a minimum of 3 hours after the event, and even 24 hours later in multiple trials (Denti et al. 1988; Fernandez-Duque et al. 1992). Long-term behavioral changes were observed in hermit crabs (*Pagurus bernhardus*) in their shell that were shocked on the abdomen compared with crabs that were not shocked, which included sustained grooming of the abdominal shock location (Elwood 2011; Elwood and Appel 2009). Acetic acid or sodium hydroxide applied to the antenna or eye of glass prawns resulted in an immediate tail flick response followed by increased grooming or rubbing of the affected area. Topical application of the local anesthetic benzocaine markedly decreased these responses but did not interfere with swimming, indicating that analgesia and not anesthesia was achieved (Barr et al. 2008). Finally, some arthropods, such as spiders or crabs, will automatize limbs when injected with noxious substances known to be painful in vertebrates, such as the bee or wasp venom or acetic acid, or when exposed

to a hot plate or electric shock (Eisner & Camazine 1983; Elwood 2011; Fiorito 1986).

Further research is needed to fully characterize the pain experience and the pharmacokinetics and pharmacodynamics of analgesic drugs in invertebrate species. However, until such research is available, clinicians should consider the administration of analgesics to patients that are being subjected to a procedure that is deemed painful in vertebrates. This includes general anesthesia with a volatile anesthetic, such as isoflurane or sevoflurane, and administration of peri-procedural analgesics, such as local anesthetics (diluted lidocaine, bupivacaine, and benzocaine) (Cooper 2011; Gunkel & Lewbart 2007).

7 Physical Capture and Restraint

Todd Shury

INTRODUCTION

An important and often overlooked aspect of chemical immobilization of zoo and wild animals is proper physical restraint. How does one get close enough to be able to effectively and safely deliver the appropriate drug combination? Is it better to capture a group of animals or isolate individuals prior to immobilization? Would physical or chemical immobilization be more appropriate? The successful capture and restraint of wild species often requires a combination of physical and chemical restraint using a wide variety of capture and handling devices that are constantly evolving. As a result, there is no single ideal capture or restraint technique that can be successfully utilized for all occasions on a particular species because success depends on many biological, ecological and practical factors including topography, season, climate, age, condition, sex, costs, and logistics (Table 7.1 and Table 7.2).

Many techniques for the capture of free-ranging wildlife have been developed in the latter part of the twentieth century and have been extrapolated from zoos, wildlife parks, and the game ranching industry. This chapter will primarily focus on capture and restraint techniques for free-ranging North American mammalian species, with more limited coverage of reptile, amphibian, and avian species in other parts of the world and in captive situations. Properly applied physical restraint can be the most safe and efficient way to handle even large, dangerous animals if the people involved are knowledgeable about the likely behavior of the target animal(s) under stressful situations and are experienced with the technique being utilized.

Proper physical restraint of wild animals is as much an art as a science, and experience is a critical factor in reducing animal and human injury during physical

restraint. Even when people are familiar with the techniques being used, certain people often just have the “knack” for restraining animals without undue injury and suffering. Much has been written and discussed on the topic in the past 30 years, with many old techniques being refined and simplified and completely novel techniques being used for the first time as new technologies become available (Fowler 1995; Fowler & Miller 2003). Many of the physical restraint techniques discussed are applicable to both captive and free-ranging wildlife, while the capture techniques primarily apply to free-ranging situations only. This chapter simply outlines the basic techniques in physical restraint and capture. For a more complete description of species-specific techniques, readers should consult the chapters on specific taxa later in the textbook or consult online references that describe species-specific techniques in detail (refer to Webliography). Several sets of taxon-specific guidelines have also been developed by various societies to help researchers choose capture and restraint techniques that are appropriate for the species being restrained.

MAMMALS

Cervidae, Bovidae, and Antilocapridae (Artiodactylids)

Remote Capture Techniques Many indigenous cultures around the world originally developed physical capture techniques for efficiently harvesting large hoofstock, and some of these techniques have been modified for live capture for wildlife research and intensive game farming over the past 30 years. Some techniques have been developed for mass capture, while others such as helicopter net gunning are designed for individual

Table 7.1. Principles and considerations of humane physical restraint in zoo and wild animals

General Principles	Other Considerations
Must be safe for all people involved	Cost
Must minimize potential for injury and mortality of subject animals	Season
Should be easy to apply with minimal training and experience	Time of day
Should allow rapid return to normal physiological state	Age and sex of animals
Equipment should be quick to set up and take down (portability)	Number of personnel required
Easily implemented regardless of body size or gender of restrainer	Need for adjunct sedative drugs
Should minimize amount of time that animals are restrained	Presence of environmental hazards and predators
	Animal behavior when stressed
	Capture efficiency and selectivity (wild species)

Table 7.2. Comparison of physical capture techniques for free-ranging wildlife

Technique	Cost ^a	Capture Efficiency ^b	Portability ^c	Potential for Injury ^d	Selectivity ^e	Species
<i>Mass capture techniques</i>						
Corral (boma)	Low	High	Low to moderate	Variable	Non-selective	Ungulates, bovids, goats and sheep
Drive nets	Moderate to High	High	Low	Moderate	Non-selective	Ungulates, bovids, goats and sheep
Drop net	Low	Moderate	Moderate	Moderate	Moderately selective	Ungulates, goats and sheep, birds
Rocket net	Low	Moderate	Moderate	High	Moderately selective	Ungulates, birds
Pitfall /coverboard/ funnel traps	Low	Moderate	High	Low	Non-selective	Amphibians, reptiles, small mammals
<i>Individual capture techniques</i>						
Foot snare	Low	Low	High	Low	Moderately selective	Birds, canids, felids, ursids, mustelids
Box traps	Low	Low	Low	Low	Nonselective	Birds, most mammals
Cage traps	Low	Low	Low	Low	Nonselective	Birds, most mammals
Mist nets	Low	High	High	Low	Moderately selective	Birds, bats
Helicopter net gun	High	High	High	Moderate	Highly selective	Ungulates, bovids, goats and sheep, ursids, canids
Foot hold traps	Low	Low	High	Moderate	Moderately selective	Canids, felids, mustelids

^aCost per animal captured on a relative basis.

^bNumber of animals that can be quickly captured in a short period of time.

^cEase of changing to different capture locations in quickly and efficiently.

^dPotential for injury to the captured animal.

^eAbility to avoid capture of nontarget species or individuals.

capture (Table 7.2). Research on the comparative efficacy and level of morbidity and mortality associated with different capture techniques for wild artiodactylids have recently been published (Barrett et al. 1982; Boesch et al. 2011; Conner et al. 1987; DelGiudice et al. 2001; DeYoung 1988; Jacques et al. 2009; Kock et al. 1987a, 1987b; Scotton & Pletscher 1998; Webb et al.

2008). Proper technique selection followed by appropriate training is critical to success when physically restraining zoo and wild animals.

Wild artiodactylids are trapped primarily for research, translocation projects, and population monitoring. Many techniques for physical restraint of domestic, zoo and game farmed cervids and bovids

have been developed in North America recently (Fowler 1995; Fowler & Miller 2003; Franzmann 1998; Haigh & Hudson 1993), and boma or corral traps have been extensively used for game capture in Africa for decades (Ebedes et al. 1996; Openshaw 1993).

Box traps are one of the most widely used individual capture techniques, consisting of a wooden or metal structure that is designed to trap a single animal so that it can be physically or chemically restrained. Designs have been developed for the capture of North American ungulates, such as deer (*Odocoileus* spp.), elk (*Cervus elaphus*), moose (*Alces alces*), bighorn sheep (*Ovis canadensis*), and mountain goats (*Oreamnos americanus*) involving baiting animals into the trap followed by a mechanical or remotely operated device to close the trap. Animals are generally baited with hay, grain, fruit, or salt depending on local food preferences. Wooden box traps have been used for several decades in North America to trap white-tailed (*Odocoileus virginianus*) and mule deer (*Odocoileus hemionus*), bighorn sheep, and Rocky Mountain goats. These are essentially a plywood box with a top-hinged door or vertical guillotine slide that is tripped by either a floor plate or cross wire. These traps work best if there are few or no openings to allow light in, as darkness has a calming effect on trapped animals, causing them to struggle less. Once captured, either animals can be chased into a net placed over the opening to the trap and physically restrained, or larger animals can be injected via pole syringe or blow-pipe through a small opening. Care needs to be taken to ensure that box traps are placed in relatively flat areas so the trapped animal does not roll down a slope and in areas that are not exposed to the elements. Modifications that make these traps lighter and more portable have been published recently (Anderson & Nielsen 2002).

Clover traps work on the same principle as box traps but are constructed of mesh netting over a steel tubular frame rather than a structure with solid walls. They have been used to successfully capture many ungulates in North America and are considerably lighter and more portable than most box traps because they can be easily collapsed for transport. Animals can either be physically restrained by collapsing the trap or chemically immobilized depending on the extent of restraint required, although recent evidence suggests that chemical immobilization of cervids in Clover traps may be associated with higher morbidity and mortality rates compared with free-range darting (Boesch et al. 2011; Haulton et al. 2001). Disadvantages are that animals may be more exposed to adverse climatic conditions while trapped (e.g., snow, wind, and rain) and may become more stressed as a result of disturbance in urban areas (Anderson & Nielsen 2002). Injuries and mortality can be sustained through capture of more than one animal in a trap or by appendages or legs being caught in netting material that is inappropriately

sized. Clover traps are primarily used for capture of white-tailed deer and mule deer in North America using various baits such as hay, grain, or salt.

Helicopter net gunning was originally developed in New Zealand in the 1970s for capturing red deer (*Cervus elaphus*). It has become a favoured method of capture for North American ungulates over the past twenty years because it can be adapted to a wide variety of animals, allows for selection of different age and sex classes, and large numbers of animals can be handled and captured in a short period of time relative to chemical immobilization (Jacques et al. 2009; Jessup et al. 1988; Webb et al. 2008). It is useful for short, nonpainful procedures such as application of radiotelemetry collars and blood sampling without the need for chemical immobilization.

When painful procedures such as tooth removal or surgery are used with net-gunned animals, adjunct procedures, such as local analgesia, sedation or chemical immobilization must be used to provide adequate analgesia. Intranasal sedation with alpha-2 agonists has been used in elk (Cattet et al. 2004) and reversal can be accomplished with intranasally delivered reversal agents where appropriate (Shury et al. 2010).

Hobbles are generally applied to the ipsilateral front and hind limbs at the level of the metacarpophalangeal joints as a human safety measure following net gun capture. Blindfolds are strongly recommended to reduce stress and calm the animal while being handled. Chase and hazing times (slower, higher altitude flight to push animals out into open areas) need to be kept as short as possible to minimize risk of capture myopathy and hyperthermia. Hazing times are generally less than 10 minutes and chase times are generally less than 2–3 minutes. Temperatures in excess of 42.2°C are potentially life threatening for bighorn sheep (Jessup 1999). Peracute mortality from helicopter net gunning most commonly occurs as a result of cervical fractures and dislocations (Barrett et al. 1982), while subacute mortality also results from capture myopathy and/or hyperthermia (Barrett et al. 1982; Jacques et al. 2009; Kock et al. 1987a). This risk can be minimized by attempting to slow animals prior to net placement by turning them or waiting for deep snow conditions in northern areas and minimizing transport distances and chase times (Jacques et al. 2009).

Bovids and ungulates are generally only safely handled for short periods of 15 minutes or less in lateral recumbency with few complications. If longer periods of restraint are required, reversible sedation with an alpha-2 agonist delivered intranasally or intravenously should be considered as an adjunct procedure.

Net size should be appropriate for the species being captured, with most nets being in the range of 9–17.6 m². A lightweight extremely strong material is required for net construction and durability (Barrett et al. 1982). Appropriate mesh size is also important to

prevent the animal escaping prematurely and to allow quick entanglement.

Net guns can also be fired from the ground for capture of antelope and other species (Firchow et al. 1986; O'Gara & Yoakum 2004), but care must be taken to ensure that the weights do not hit the animal, causing severe injury. Helicopter net guns have been used to capture bighorn sheep, mountain goats, deer, elk, moose, bison, and antelope in North America. Advantages of net gun capture include selectivity, rapid immobilization so injuries can be avoided, and the ability to release animals quickly without drug residues. Disadvantages include lack of utility in heavily treed environments, and potential for high mortality and morbidity in some species (Barrett et al. 1982; Jacques et al. 2009).

Corral traps or bomas have been used extensively for the mass capture of most artiodactylid species in Europe, North America, and Africa. This is perhaps the oldest and most widely used capture technique for ungulate species for purposes of translocation, research, and testing (Ebedes et al. 2002). Individual animals can then be individually restrained or chemically immobilized once captured. Animals tend to remain quite calm while undisturbed within a boma and large numbers can be captured quickly and effectively in open terrain.

Drive nets are useful to capture ungulate and bovid species where other techniques are not practical, such as heavily treed or steep terrain or in urban environments (López-Olvera et al. 2009; Locke et al. 2004; Mentaberre et al. 2010). Nets are typically strung between poles or trees in an area where animals can be flushed into a narrow opening or other suitable area. It is critical that adequate numbers of people are available to physically restrain animals once they are entangled in the net. One or two people per animal are generally required depending on the size of animals captured. A variation of this technique is drop netting, which works fairly reliably for cervids species and may be useful in mountainous or steep terrain (Conner et al. 1987).

Animals can be driven into nets on foot, by horseback, or by vehicles (snowmobile or truck) or aircraft (helicopter or fixed wing). Care must be taken when using aircraft or vehicles that animals are not chased at excessive speeds or long periods of time as mortality from cervical and leg fractures, capture myopathy, and hyperthermia are often the result (O'Gara & Yoakum 2004). Some researchers have used dense vegetation and water in combination with physical restraint instead of nets for small deer species (Duarte 2008).

Handling and Safety Considerations Most bovids and ungulates that are 60–70 kg weight or less can be physically restrained by a single person of medium build. Larger animals require additional personnel or individuals of large stature for safe physical restraint.

Hobbles that are constructed of leather, canvas or synthetic materials are very useful for safely restraining hooves and legs. Blindfolds are a necessary tool for animals that are to be physically restrained because they reduce stress (Fowler 1995; Mitchell et al. 2003) and protect the eyes from damage. They can be made from a variety of materials but should be able to be removed quickly and should be comfortable for the animal.

Other safety items include foam and rubber balls or hose that can be placed on the sharp tips of horns to prevent injury to handlers for species such as mountain goat, bison (*Bison bison*), and musk oxen (*Ovibos moschatos*). Horns of young bovids and sheep are easily damaged during capture when nets are used due to slippage of horn sheaths that are loosely attached in younger animals. This can lead to moderate to severe blood loss, but long-term damage is usually not severe with the exception of disfigured horns for the remainder of the animal's life. Male cervids and caribou (*Rangifer tarandus*) and reindeer of both sexes should not be captured during the season of antler growth (May–July in northern hemisphere) if possible due to the high vascularity and potential for blood loss and associated pain when rapidly growing antler is damaged. Physical restraint and capture should be avoided on slippery surfaces such as ice and steep slopes due to the potential for injury.

In captive and semi-captive situations, artiodactylids can be easily and efficiently handled in specially designed handling facilities that include chutes, paddocks, and runs specifically designed for each species. The evolution of the game farming industry in North America has led to the development of sophisticated squeezes that utilize drop floors, padded sides, and hydraulics to minimize struggling and injury (Haigh 1999). Individual animal habituation is an important prerequisite, if at all possible for successful physical restraint in these systems regardless of species (Grandin 1993; Meyer et al. 2008). Crash gates are an important component of bison handling systems that allow animals to be more easily restrained in a mechanical or hydraulic neck squeeze (Haigh 1999). Holding pens and runs need to be designed with walls that are high enough to prevent escapes (10 ft or higher for sheep and goats) and designed to minimize injury to animals and humans during use. Points where animals are squeezed into narrow areas need particular attention to detail, and specific flight distances of each species needs to be considered during design.

Captive artiodactylids can be habituated to routine handling procedures, such as venipuncture, vaccination, and/or physical examination with minimal restraint in a chute or box stall depending on individual animal temperament (Citino 2003; Wirtu et al. 2005). The simplest systems use a circular or semi-circular tub with movable walls that squeeze the animal between them. It is important to have a large number

Figure 7.1. Wild elk restrained in a padded manual squeeze near Banff National Park, Canada.

of access panels to be able to gain access to all parts of the animal safely.

Well-designed box chutes have been successfully used for restraint of wild elk in Banff National Park for venipuncture, TB testing, and deworming, and for wild bison and elk in Elk Island National Park in Canada for several decades (Fig. 7.1).

Canidae/Felidae

Remote Capture Techniques Helicopter net gunning has proven to be a very successful method for capturing some large carnivores in North America, including grizzly bears (*Ursus arctos*), black bears (*Ursus americanus*), and wolves (*Canis lupus*). Wolves can be safely restrained after being netted using a forked stick or pole snare to control the muzzle and head of the netted animal. Hobbles are useful to restrain the legs, and nylon dog muzzles or duct tape can be used to restrain the mouth safely without chemical immobilization (Fig. 7.2). Bear species generally require chemical immobilization after netting to safely handle these animals, with the net providing a quick way of immobilizing the animal so it does not injure itself in terrain with natural hazards (water and steep slopes). A common complication of net gunning large carnivores is the ability of the animal to chew its way out of entanglement; therefore, animals need to be either darted or restrained very quickly (within 1 minute) after the net is fired. Medium-sized canids such as coyotes (*Canis latrans*) and wolves have also been captured very successfully with helicopter net gunning. Deep snow conditions are a definite advantage when attempting to capture canids using this method as they are highly maneuverable on bare ground. Snowmobiles and all-terrain vehicles have also been used for capture of coyotes by using a throw net in open, prairie envi-

Figure 7.2. Timber wolf physically restrained with hobbles and duct tape on the muzzle for application of a radio collar.

ronments (Gese & Andersen 1993; Moehrenschrager 2002). African wild dogs have been successfully captured using boma traps following herding by helicopter (English et al. 2008).

Various restraint traps designed to catch animals by a limb are used to capture wolves, coyotes, foxes, procyonids, and some mustelids. The most widely used method of capture utilizes a modified foothold trap designed to minimize injury in captured animals (Earle et al. 2003; Sahr & Knowlton 2000). These traps use padded jaws and laminated jaws to reduce potential for injury on the trapped limb (Kreeger 1999). Swivels and drags are typically used instead of staking traps so that the trap becomes entangled in vegetation reducing the rotational force on trapped limbs.

Other foothold traps such as leg snares are generally constructed of wire cable coated with protective coating and many are activated with a spring. Leg snares have been used for successfully capturing pumas (*Felis concolor*) (Logan & Sweanor 2001; Logan et al. 1999), lions (*Panthera leo*) (Frank et al. 2003) and Siberian tigers (*Panthera tigris altaica*) (Goodrich et al. 2001) and a modified snare within a oval shaped container called an EGG (EGG Trap Company, Springfield, SD) trap has been widely used for capturing raccoons (*Procyon lotor*) and possums (*Didelphis virginiana*) (Austin et al. 2004; Hubert et al. 1999) with minimal injury. Canada and the United States retain international agreements with the Russian Federation and the European Union to develop humane foothold traps for capture of furbearing animals in the fur trade that came into force in 2007 (refer to Webliography). These traps have been tested to ensure they cause minimal injury to trapped animals (Andelt et al. 1999). Frequent trap checking is critical (minimum every 24 hours) to prevent injury to trapped canids and felids.

When used in winter, limb ischemia, and frostbite can occur as circulation is impaired in the trapped limb, so these types of traps should be used with caution at temperatures below 0°C. Tranquilizer tabs impregnated with propiopromazine or diazepam are a useful adjunct and have been used successfully to tranquilize and reduce injury in trapped wolves (Sahr & Knowlton 2000) and coyotes captured in neck snares (Pruss et al. 2002). Most wild canids up to 60 kg in size can be safely restrained without chemical immobilization for short procedures, such as application of radio collars and venipuncture. Longer or more invasive procedures, such as tooth removal or implant surgery, require chemical immobilization.

Various commercially available and homemade cage or box traps constructed of wire and plastic mesh or completely enclosed wooden or metal boxes are used for capture of procyonids, small- and medium-sized canids, and most felid species (de Wet 1993; Grassman et al. 2004; Harrison et al. 2002; Mudappa & Chellam 2001; Wilson et al. 1996). Animals are baited into the trap which is triggered by a floor plate with a vertical guillotine or hinged door that closes when the animal is inside. Animals can then be hand injected or injected with a pole syringe if chemical immobilization is required. Physical restraint using a snare pole or gloves can be used on smaller species or for restraint of a limb or the muzzle. Extreme care must be exercised with the use of a snare pole when used over the thoracic area. Ensuring that a front limb is ensnared along with the neck or thorax for very short periods of restraint will help prevent asphyxia from thoracic compression. Box traps and cages provide the additional advantage of providing security and safety from predation or attack while the animal is trapped, unlike other restraint devices, such as foothold traps, with the disadvantage that they are not as portable.

Regardless of trap type being used, the frequency of trap checking needs to be 12 to 24 hours or less for most species. The potential for self-injury, hypothermia, hyperthermia, dehydration, frostbite, and other complications is much higher the longer the animal remains restrained or trapped (Cattet et al. 2003). More frequent trap checks are desirable, if possible, in terrain that is easily accessible. A variety of trap-monitoring devices, such as VHF trap transmitters, have been developed to increase the frequency of trap checking in more remote areas (Darrow & Shivik 2008).

Neck snares with stops have been successfully used for capture of coyotes in North America (Pruss et al. 2002), offering an alternative capture technique in areas where foothold traps or box traps are ineffective or prohibited. Tranquilizer tabs are a useful adjunct to help prevent injuries from struggling in a neck snare (Pruss et al. 2002). Circumference of the neck snare is of critical importance to prevent nontarget captures and to decrease the potential for injury and mortality.

Felid species that utilize trees for safety and cover such as puma, jaguar, panthers (*Felis* spp.), bobcat (*Lynx rufus*), and lynx (*Lynx canadensis*) can be captured with the use of trained tracking hounds (Apps 1996, 1999; Deem 2004; Taylor et al. 1998). Treed felids are generally chemically immobilized with a variety of remote drug delivery techniques including blowpipes, pole syringes, dart pistols, and rifles. Injuries occur when dogs attack immobilized animals and when immobilized animals fall from heights greater than 5 m. These are prevented by securely tying up dogs prior to darting and using nets, slings, or inflatable devices to cushion falls. Drug dosage can be a critical factor when chemically immobilizing large felids in trees and needs to be considered when choosing an appropriate drug combination (Beier et al. 2003).

Captive felids in zoo environments are generally captured or restrained with hoop nets, squeeze cages, or chemical immobilization depending on their size. Felid species <14 kg can be safely handled with a net and gloves (Fowler 1995), while larger felids require specialized squeeze crates or snare poles for safe handling. Previous habituation and acclimation to handling facilities is extremely helpful in handling large felids without chemical immobilization for venipuncture and vaccinations. Best practices and trap certification for both live capture and killing traps have been developed for most commercially important furbearer species in the United States and Canada (refer to Webliography).

Handling and Safety Considerations Heavy leather gloves are very useful when handling infant large felids or medium-sized felids as their teeth and claws can inflict serious damage to anyone holding them. Bacterial infections are common sequelae to felid and canid bite wounds, and all bite wounds should be considered contaminated and treated appropriately (Brook 2005). Restraint bags designed for domestic cat restraint are useful for restraint of small- and medium-sized cats for very short procedures, such as venipuncture, injection, or vaccination, while hobbles and blindfolds are often used for larger canids.

Firearm backup is recommended for the larger felids when immobilized in case of spontaneous arousal. Snare poles are useful to restrain the feet of large felids when immobilized as a backup restraint mechanism or strapping them to a table or other flat surface when anesthetized. Small- and medium-sized canids can be easily restrained by hand if the feet and muzzle are adequately restrained (Fig. 7.3).

Ursidae

Remote Capture Techniques Aldrich leg snares have been used as a primary means of capture for various ursid species around the world for both research and management purposes for decades. They have the advantage of being portable, highly efficient, and easy

Figure 7.3. Wild coyote physically restrained with hobbles and nylon muzzle after capture in modified foot hold trap.

to set in remote locations (Johnson & Pelton 1980). The basic design involves a braided steel cable that forms a loop and is activated by a spring steel throwing arm (Jonkel 1993) that captures the bear above the carpal joint. These devices are usually anchored to a large tree and set in a hollowed out area in the ground. Injuries are often sustained in leg snares from biting or chewing on digits, fractured limbs, muscle damage, capture myopathy, distal limb edema due to impaired circulation, and cuts and abrasions at the site of contact with the snare cable (Cattet et al. 2003, 2008). Although very uncommon, intraspecific predation has also occurred with the use of these devices for capture of grizzly bears in Canada (Gibeau & Stevens 2002).

Culvert traps are a variation of a box or cage trap on a larger scale and specifically designed for ursids. They were originally made from culverts used for road construction and are manufactured in a wide variety of designs. They have the advantage of protecting the trapped bear from the elements and predators. They have the disadvantage of being quite large and unwieldy and are generally only used in road-accessible areas, although some are designed specifically for use in remote areas and delivered by helicopter. They are used routinely for management of problem black and grizzly bears throughout North America (Jonkel 1993) and for research on Malayan Sun bears (Te Wong et al. 2004). They are also useful for recovering chemically immobilized bears and for transporting them once they are recovered (Caulkett & Cattet 2002). Injuries primarily occur in the oral cavity (lacerations and broken teeth) due to chewing on mesh or openings in

the trap designed for accessing the animal. Mortalities are very rare but can occur when multiple animals are trapped or animals sustain trauma due to falling guillotine doors.

In captive situations, bears are usually isolated individually in separate pens or enclosures prior to chemical immobilization. Sows with dependent cubs may or may not be separated prior to immobilization of the sow depending on the stress level of the individual. Most bears with the exception of cubs <25 kg need to be chemically immobilized to be handled safely. Cubs can be physically restrained or captured with nets or blankets. Climbing gear may be necessary to retrieve cubs of certain species, such as black bears, which routinely climb trees to escape.

Handling and Safety Considerations For safety considerations, it is good practice to have an armed guard equipped with a firearm when capturing and immobilizing adult bears. This is not to protect against the immobilized bear recovering spontaneously, but to protect the immobilization team from other bears that are often attracted to the site (Caulkett & Cattet 2002). Personnel need to be trained in firearm use and must be prepared to use lethal force if necessary.

Hobbles should be applied to the limbs of immobilized bears to restrict mobility if the animal should spontaneously arouse. Equipment and pharmaceuticals to deal with injuries sustained from capture (antibiotics, wound dressings, and antiseptic agents) should be carried in the field when capturing wild bears.

Mustelidae/Procyonidae/Viverridae

Remote Capture Techniques Small- and medium-sized mustelid species—fisher (*Martes pennanti*), marten (*Martes americana*), mink (*Mustela vison*), and weasels (*Mustela* spp.)—can be physically restrained for short procedures using a cone-shaped cotton or mesh bag, which can be used to restrain an animal for examination once it has been captured in a box trap or other device. A method for physical restraint of mink with gloves is described by Fowler (1995) which can be modified for fisher, marten, river otter (*Lontra canadensis*), and small raccoons. Squeeze cages are also useful for mustelids to provide a method of quick restraint for intramuscular injections, such as vaccination or injection of chemical immobilization drugs. Cage traps, box traps and padded foot hold traps are most commonly used for capture of wild mustelids and viverrids (Blundell et al. 1999; Hubert et al. 1996; Serfass et al. 1996). Hancock traps have also been widely used for capture of river otters, although they are not as portable as other trap types and tooth damage is frequent (Blundell et al. 1999). Hoop nets work very well for initial capture of captive mustelids and viverrids in zoos followed by physical restraint with gloves or chemical immobilization.

Homemade box traps made from locally available timber have been used for wolverine (*Gulo gulo*) capture in North America due to the large home ranges and remoteness of habitat (Copeland et al. 1995; Lofroth et al. 2008). Trapped animals are then chemically immobilized with pole syringes or dart pistols. A flashlight is required to visualize the animal as these traps are usually quite dark inside.

Skunks (*Mephitis* spp.) present a formidable challenge if physical restraint is used alone due to their defensive use of spraying musk from their anal sacs when threatened. For this reason, chemical immobilization is always preferred unless extraordinary precautions are taken to prevent contact with the musk (safety glasses and protective clothing).

Handling and Safety Considerations Heavy- or medium weight leather gloves are a necessity for handling most medium and large mustelids and viverrids due to their extremely sharp teeth and propensity for biting when threatened. Most species can be handled by grasping firmly around the base of the head with one hand and the tail with the other hand (Fowler 1995), but a sturdy grip is required due to their extreme flexibility and maneuverability.

Most mustelid species are very susceptible to stress especially when wild animals are held in captivity (Fernández-Morán et al. 2002; Hartup et al. 1999) for a period of time. Skunks, bats, foxes, and raccoons are considered natural reservoirs of rabies virus in North America, so care should be taken to ensure personnel working with these species are vaccinated and trained to avoid exposure. Parasitic zoonoses, such as *Bayliscaaris* spp., cause severe neurological disease in humans and are also very prevalent in wild mustelids (Kazacos & Boyce 1989) so care should be taken to avoid exposure to feces.

Rodents and Lagomorphs

Remote Capture Techniques Various cage and box traps are widely used for live capture of rodents and lagomorphs. Small wild rodents <1 kg such as mice, voles (Muridae) and ground squirrels (Sciuridae) are typically live trapped in either wire cage traps or metal box traps (Sherman™ or Longworth™ traps) as part of ecological research studies or for pest removal. Specialized protective gear is required for handling certain species of small mammals that carry zoonoses, such as hantavirus and tularemia (see Handling and Safety Considerations). Sherman and Longworth traps are small aluminum box traps that are widely used for capturing small wild rodent species. Insulated bedding in the form of cotton or polyester fiberfill and a food source is required for microtine rodents due to their propensity to develop hypothermia and hypoglycemia (Jones et al. 1996).

Wild lagomorphs are generally trapped in wire cage traps baited with food. Injuries to teeth result from chewing on wire, so wood or plastic boxes with solid sides have been used to prevent this (Sharp et al. 2007). Lagomorphs, especially snowshoe hare, are prone to hypoglycemia (trap sickness) if trapped in box or cage traps, therefore, a source of food should be provided or traps should be checked frequently (Feldhamer et al. 2003).

Aquatic rodents, such as beaver, muskrat, and nutria, can be captured in specialized hinged cage traps called Hancock or Bailey traps or wire cage traps set on land (Rosell & Kvinlaug 1998). Care must be taken to prevent traps from tumbling into water and drowning animals. These species can also be netted from boats or chased from lodges and houses (Rosell & Hovde 2001) into nets.

Pit traps are occasionally used in conjunction with drift fencing for small microtine rodent capture by burying a round metal or PVC container which is 20–40 cm in diameter in the ground 40–50 cm deep (Jones et al. 1996).

Handling and Safety Considerations Mice and rat-sized rodents can be handled with latex exam gloves by grasping the skin over the nape of the neck for short periods of restraint and non-invasive treatments. Larger rodents and lagomorphs require support if picked up or carried in this manner. Rats (*Rattus* spp.) and muskrats (*Ondatra zibethica*) are usually held by the tail with the feet allowed to grasp a surface such as a wire cage. Heavy leather gloves are required for larger species, such as muskrat, beaver, and nutria, to prevent injury to the handler from biting. Species with haired tails such as squirrels, marmots (*Marmota* spp.), and packrats (*Neotoma* spp.), should not be restrained by the tail only as the hair and skin can easily slip causing severe injury (Fowler 1995). Laboratory techniques that are well developed for mice, rats, guinea pigs, and hamsters often fail to restrain their wild counterparts unless personnel are very experienced in handling these species.

Medium-sized rodent, such as hyrax, agoutis, marmots, and woodchucks, can be netted and restrained manually for injections, quick examinations, venipuncture, and vaccinations. Specially designed squeeze cages that allow the animal to be forced against the side of wire cage or box are very useful for these rodent species.

Most lagomorphs can be manually restrained by grasping them around the base of the head with one hand and supporting the body and restraining the hind legs with the other hand. Severe spinal injuries can result if the hind legs of hares and rabbits are allowed to kick and flail while restrained. Gloves are important to prevent scratches and bites when handling larger hares and rabbits. Nets are useful for initially capturing lagomorphs in small enclosed spaces until they can be manually restrained. Specially

designed restraint cages are used for handling domestic lagomorphs in laboratories.

Larger rodent species such as capybara (*Hydrochoerus hydrochaeris*) beaver (*Castor canadensis*), and nutria can be netted and physically restrained for short periods for quick injections or vaccinations only (Fowler 1995). More invasive handling requires chemical immobilization. Beavers should not be hoisted by the tail alone, but can be restrained on the ground using the tail and a hand around the base of the head (Whitelow & Pengetley 1954).

Porcupines (*Erythron dorsatum*) are specialized rodents with various-sized quills that present a challenge for physical restraint. North American porcupines have barbed quills approximately 1–4 cm long while Old World porcupines such as crested porcupines (*Hystrix* spp.) have extremely long stout quills up to 45 cm long (Fowler 1995) that are capable of severe injury. North American porcupines use their tail as a quill delivery system and contrary to popular belief, are incapable of “shooting” their quills. Sturdy plastic garbage pails or tubs with bottoms cut out can be used to capture porcupines in small enclosures instead of nets where they can be chemically immobilized using a pole syringe or hand injection. Crested porcupines have particularly thin, fragile skin and are prone to injury and laceration from pole syringes (Fowler 1995). Brooms or small plywood boards are useful to safely move porcupines into enclosures or transport containers, although they often tend to go backwards with quills flared rather than forward like most mammals.

Plexiglass or clear plastic induction chambers are very useful for induction of gas anesthesia in rodent species that are not easily handled or prone to injury such as porcupine and voles.

Zoonoses are a major concern with many species of wild and domestic rodents and suitable precautions need to be taken when handling them. Hantaviruses are carried subclinically by several rodent species in North America including the white-footed deer mouse (*Peromyscus maniculatus*), cotton rat (*Sigmodon hispidus*), rice rat (*Oryzomys palustris*), and white-footed mouse (*Peromyscus leucopus*). Prevalence varies dramatically with geographical location and year and so the known carrier species should be considered infected at all times. Virus is shed primarily in saliva, urine and feces so exam gloves and HEPA filters should be worn to prevent transmission while handling. Plague (*Yersinia pestis*) is enzootic in prairie dogs in the American Midwest and great gerbils (Wimsatt & Biggins 2009) in central Asia and is carried by many other wild rodent species. Humans are generally infected through the bite of an infected flea from rodents or from domestic cats that have been exposed to infected rodents and their fleas. Lyme disease caused by the spirochete *Borrelia burgdorferii* is carried primarily by *Ixodes* spp. ticks

found on many rodent hosts, but particularly deer mice in eastern and Midwest United States.

Monotremes/Marsupials

Handling and Safety Considerations Medium-sized marsupials with tails such as kangaroos and wallabies can be safely restrained for short procedures by grasping the animal by the tail and grasping the head with the other free hand to control head movement. This is most easily accomplished against a wall or other solid vertical surface. Large male adult kangaroos can be difficult to restrain, and the hind feet are formidable weapons, so blankets or tarps can be used to initially tackle the animal and a minimum of two people are required. Koalas are captured by use of long snare poles or simply grabbed from branches of trees. Other marsupials can generally be restrained by hand and caught with nets.

Primates

Small- and medium-sized non-human primates (monkeys, vervets, and capuchins) are usually captured in box or cage traps or captured manually with long-handled nets (Rocha et al. 2007). Larger ape species, such as orangutan (*Pongo pygmaeus*) and gorillas (*Gorilla* spp.), require chemical immobilization using remote delivery techniques and are generally not physically restrained with the exception of neonates.

Handling and Safety Considerations Captive primates in the 3–12 kg range can be manually restrained by a person with heavy leather gloves by holding the front limbs and body in one hand and the hind limbs in the other hand. A face mask, shield, or safety glasses are also required for non-human primates due to the risk of zoonotic diseases (see later). Long-sleeved coveralls and leather gloves with sleeve extensions should also be considered to prevent bites and scratches. Most primates possess considerable strength and agility for their size, a fact often underestimated by inexperienced personnel.

Primates and great apes over 12 kg should be chemically immobilized unless extensive training and habituation to procedures has been previously completed. Many zoos and research centres train primates to present limbs through custom-designed restraint cages and boxes for venipuncture, TB testing, vaccinations, and other minor procedures. Great apes such as orangutans, gibbons, chimpanzees, and gorillas generally require chemical immobilization for safe restraint, unless extensive training has been completed. Commercial squeeze cages are available for most species that facilitate short procedures such as injections and visual exam of TB testing.

When any physical restraint of primate species is going to be necessary, appropriate safety measures should be in place to ensure protection from zoonoses. Herpes

B virus causes a fatal encephalitis in humans and is carried by macaque (*Macaca* spp.) species (Johnson-Delaney 2005). Primate keepers and any staff potentially coming in contact with fecal material or urine need to wear masks, eye protection, and latex gloves as a minimum to prevent exposure when handling animals and when cleaning enclosures. Other potential zoonoses include hepatitis, HIV, Ebola viruses, and many others (Krauss et al. 2003). The potential for reverse zoonoses should also be considered when handling primates, and measures to prevent sick humans from coming in contact with primates should also be considered. Bite wounds can also be quite severe, causing severe pyoderma and fasciitis.

Bats

Remote Capture Techniques Mist nets strung in various configurations, heights, and lengths are a versatile, portable and inexpensive way to capture most bat species. Their use is limited at roost sites where numerous bats could be potentially captured as bats need to be untangled from the net, allowing the capture of single bats usually. Mist nets can be constructed of monofilament nylon, braided nylon, or braided Dacron polyester (Kunz et al. 1996) and set up in numerous configurations wherever bats are found (Kunz et al. 2009). Care must be taken when extracting bats from mist nets, as their delicate wing bones and membranes are easily damaged. Wearing light leather gloves and allowing the bat to bite and hang on is often helpful to allow extraction (Kunz et al. 1996).

Harp traps and Tuttle traps consist of vertical wire strands attached to springs within a rectangular frame that has a cloth or burlap bag attached to the bottom to catch bats that fly into the wires. Larger versions of this trap have been successfully used to capture megachiropteran bat species as well (Tidemann & Loughland 1993). These traps are very useful for capturing bats at roost sites as well.

Handling and Safety Considerations Small bat species (<100g) can be held in the palm of the hand firmly but gently in a manner as described for passerine birds with the thumb and index finger restraining the head. Larger megachiropterans require two hands to restrain the wings and head effectively. Open weave cloth or mesh bags with drawstring tops are useful for temporary holding or transport of bats (Kunz et al. 2009). Physical restraint should be minimized in most bat species as hyperthermia results from excessive struggling and stress (Heard 1999). Light leather gloves, such as golf gloves, are used for handling microchiropteran species while heavier leather gloves should be used for large pteropid bats.

Injuries to bats can be sustained to patagia, wing bones, and leg bones from improper restraint and attempting to dislodge bats from wire and net surfaces

too forcefully (Heard 1999). Personnel working with bats must be vaccinated against rabies, as most species are potential carriers of rabies virus or other lyssaviruses (Heard 2003). Other viruses with zoonotic potential are also carried by bats including Hendra, Nipah, Menangle, and Tioman viruses which are carried by bats in South-east Asia and Australia (Krauss et al. 2003). An important fungal disease, *Histoplasma capsulatum* has been linked to aerosol inhalation of bat guano in roosting caves, so masks with HEPA filters are recommended when working in caves where bats roost (Huhn et al. 2005).

Suidae/Tapiridae/Tayassuidae

Remote Capture Techniques Tapirs (*Tapirus* spp.) in captive facilities are generally quite docile and many procedures can be accomplished with the animal standing or gently rubbed down and put in an almost hypnotic state. Foot trims, detailed exams, TB testing, radiographs, and venipuncture can often be performed if animals are trained and habituated to these procedures. Tapirs are generally either rubbed along the sides or back with a comb or a gloved hand which will cause them to lie down in ventral or lateral recumbency. If animals cannot be trained to this procedure, chemical immobilization is required. Tapirs can also be gently herded with brooms or boards into squeezes and crates for treatment or injection.

Wild and exotic suid species such as warthogs (*Phacochoerus* spp.), red river hogs, (*Potamochoerus porcus*), babirusa (*Babryrousa babyrussa*), and collared peccaries (*Tayassu tajacu*) can be physically restrained and captured using many of the same techniques used for domestic pigs, including snare poles and ropes, but they are much more difficult to restrain on a kg per kg basis. Most species have extremely sharp teeth and tusks and are capable of causing significant injury or death to people attempting to restrain them. Peccaries and small-sized pig species (<20 kg) can be caught with nets and restrained by stretching them out on a floor or mat by grasping the hind legs and head with gloved hands (Fowler 1995). Adult pigs, warthogs, and babirusa must be either chemically immobilized or run through chutes and trained through operant conditioning to accept procedures such as vaccination and treatment (Morris & Shima 2003).

Camelidae/Giraffidae

Members of this group of wildlife require special handling and restraint procedures, which are well described elsewhere (Bush 2003; Fowler 1995, 1998, 2003; Fowler & Cubas 2001). Typically, large chutes are used to physically restrain giraffes, and a long training and habituation period is generally required to facilitate many routine health procedures such as foot trimming, physical examination, and venipuncture in such facilities. Wild giraffes are often herded into boma corrals to

facilitate capture and restraint using vehicles and helicopters. Ropes are often used on chemically immobilized giraffes to enable heavily sedated animals to be properly positioned during the induction and recovery periods. Camelids can generally be restrained in similar fashion to equid species using halters, ropes and specially designed squeezes. Interested readers are referred to the species-specific chapter on camelids and giraffe species later in the textbook for further detail on physical restraint involving these species.

Elephants

Specialized facilities are required to house and allow proper physical restraint of elephants in captivity (refer to Webliography). Capture of adult wild elephants generally involves chemical immobilization using remote drug delivery techniques.

BIRDS

Ratites

Most large ratite species, such as adult ostrich (*Struthio camelus*), can be physically restrained safely and easily for many procedures using custom fitted hoods and appropriate handling facilities, which include triangular stocks, chutes, and boards to herd birds safely. Male ostrich are particularly aggressive during the breeding season and caution should be used when physically restraining an adult male ostrich. Ratites defend themselves with their powerful legs, which can strike out very quickly in a forward direction. Juvenile ratites can be easily restrained by grasping them from behind around the sternum and holding them with the legs dangling. The legs of juvenile ratites are prone to injury and should not be forced into position, but allowed to dangle freely. Once hooded, ostrich are easily restrained or walked short distances into a corner where venipuncture, physical exams, radiographs, ultrasound, and other husbandry procedures can be performed. The head of ostriches can be grasped and pulled toward to the ground to limit the risk of kicking out (Smith 2003). Smaller ratite species, such as emu (*Dromaius novaehollandiae*) and rhea (*Rhea americana*), can also be physically restrained by walking up to the bird and grabbing it from behind with both hands at the base of the wings and restraining the bird either standing or on the ground. Hoods are not applied to emus and rhea as they often become more agitated when hooded. Doing this in a darkened room with solid walls and soft flooring helps avoid injuries. Cassowaries (*Casuaris* spp.) are an exception and chemical immobilization is usually recommended for these birds due to their aggressive nature and ability to seriously injure and kill humans with their sharp and powerful claws. Juvenile cassowaries can be safely physically restrained as described for rheas and emus.

Waterfowl (Anatidae) and Wading Birds (Herons, Cranes, and Storks)

Remote Capture Techniques Remote capture of waterfowl is well described elsewhere (Bookhout 1994; Bub 1991) and consists of using rocket nets, hand nets, nets strung across waterways, and cage traps of various sorts. Capture of wild waterfowl species is often timed to coincide with molting as capture is made easier by the fact that birds cannot fly for a period of several weeks. Appropriate-sized nets can be used to capture birds in enclosures or aviaries where they can be physically restrained for most procedures. Bites can be inflicted on handlers from larger goose and swan species. Injuries to birds are often inflicted on carpi and feet from being crowded into areas with concrete or other hard surfaces, so rubber flooring or mats on walls are often used to decrease injuries in these areas.

Wading birds, such as cranes, storks, and herons, can inflict serious eye damage with their sharp, pointed beaks so safety glasses or face shields are definitely required. These birds are generally herded gently with brooms or boards into corners where they can be grasped by the head and body. The bird is generally held with one arm around the body to restrain the wings and support the body while the other hand restrains the head and neck. The legs are restrained proximal to the hocks only as fractures and capture myopathy result from struggling when attempts are made to restrain the legs more distally (Swenger & Carpenter 1996).

Galliforms (Pheasant, Grouse, and Partridge)

Pheasant, grouse, partridge, and ptarmigan (*Lagopus* spp.) species are fairly easily handled with light gloves to protect from spurs and bites in larger species. Hoop nets are widely used in zoos for capturing these species, which are usually found on the ground. Some male pheasants (*Phasianus* spp.) have sharp spurs that can inflict injury to handlers, and the males can be aggressive during the breeding season. These birds are restrained by holding the bird next to the body, thus restraining the wings between the arm and body, with the other hand restraining the legs. The head does not usually need to be restrained as these species rarely peck once restrained (Fowler 1995).

Wild galliforms are generally trapped in box traps baited with grain or other feedstuff or with mist nets or hoop nets (Mahan et al. 2002; Skinner et al. 1998). Cloth or mesh bags are very useful for holding individual birds for short periods of time or for transport. Birds will settle down considerably if kept in a dark area rather than in bright light. Cardboard boxes are also useful for transport of groups of birds. Capture myopathy and trauma are the main injuries sustained from trapping of wild galliforms (Hofle et al. 2004; Nicholson et al. 2000; Spraker et al. 1987).

Hawks, Owls, and Falcons

Most raptor species can be physically restrained if the talons and wings are restrained adequately to prevent injury to themselves and the handler. Their extremely sharp talons are the main defensive weapon to be avoided when physical restraint is required. Nets are useful to initially capture fully flighted birds in aviaries or pens in appropriately sized nets that will capture the bird without injury.

Hawk species are best restrained with leather gloves by grasping the talons quickly and deftly with one hand with the palm facing toward the chest of the bird. The bird can then be dangled upside down until the wings and head can be grasped. These birds are best held against the chest or side with the wings folded and head facing toward the back of the person holding. Stockinette or mesh bags are useful to restrain birds temporarily for weighing and venipuncture, banding, or radiographs without the need to be holding them. Care needs to be taken to ensure that chest excursions are not restricted when using any physical restraint technique with avian species. The beak also needs to be avoided as painful injuries can be sustained by large hawks, eagles, and owls (Fig. 7.4).

Wild hawks and owls are captured by a variety of methods, including box traps, nets, and leg snares (Bub 1991). Eagles are captured by chasing with vehicles (Ostrowski et al. 2001), on nests or with snares (Hol-lamby et al. 2004).

Passerines

Remote Capture Techniques Nylon mist nets are the primary method of capture used for free-ranging and captive passerines in large aviaries. Passerine species include the thrushes, sparrows, finches, and others. Many methods of setting these nets have been described depending on the target species and its preferred habitat (arboreal, ground, and wetland). Most species can be

Figure 7.4. Eurasian eagle owls being restrained for examination and weighing following initial capture with a net in a captive enclosure.

held using a banders hold in which the palm of the hand is used to gently cup the body to restrain the wings with the head being restrained between the index and middle fingers (Massey 1999). Many of these species need to be handled as little as possible as they are prone to exertional shock and hypoxia from being overrestrained and not allowing the sternum to lift to allow air exchange in the lungs. The other method of restraint is to hold them in one hand by grasping the legs gently proximal to the hock joints with the index finger between the legs and the thumb and ring finger on either side. This works well if the birds are not flapping and struggling to escape or there is a need to transfer the bird from one person to another. Passerine species should be transported in dark containers or boxes to reduce flapping and struggling and can be removed using a towel or net to initially capture and restrain the bird. Most passerine species have fragile leg bones and rapid metabolic rates, and so injury and mortalities often result from prolonged or rough handling.

Psittacines

Most psittacine species can be physically restrained for most basic procedures, including venipuncture, beak trims, nail trims and physical examinations. Large macaws and parrots often need to be anesthetized for a thorough and less stressful exam. Most captive psittacines can be captured from a perch using a net or towel depending on their level of tameness. Once captured, they are removed from the towel or net by grasping the head and mandible between the fingers of one hand and grasping the feet and wingtips in the other hand. Placing the bird in dorsal recumbency on a table or with a pad or towel underneath will facilitate restraint. Gloves may or may not be used for psittacine restraint based on the temperament and size of the bird being restrained. Care needs to be taken with larger species as they can inflict serious injuries with their powerful beaks. Detailed restraint and exam techniques for psittacines can be found in Romagnano (1999) and Abou-Madi (2001). Smaller species can be restrained as described for passerine birds. Those interested in wild psittacine capture are referred to Bub (1991).

REPTILES

Lizards, Skinks, and Geckos

Lizard species can be safely restrained if the head and tail are adequately restrained to prevent injury to the handler and the animal. Carnivorous lizards (e.g., monitors and tegus) can be particularly difficult to handle while young green iguanas (*Iguana iguana*) and geckos (*Gekkonidae*) are fairly docile to handle. Lizard species should not be restrained solely by the tail as many species can shed their tail (autotomy), so additional support and restraint must be used for the head and

Figure 7.5. Blue-tongued skink restrained in a towel.

body. Small lizard species can be restrained in one hand with the head between thumb and forefinger and the ring and little finger wrapped around the pelvis to restrain the body and tail (Divers 1999). If possible, medium-sized lizards should initially be grabbed over the dorsal pelvic area and pinned against a table or other flat surface and then grabbed behind the head while grabbing the forelegs, to where they can either be wrapped in a towel or held against the body (Fig. 7.5). Towels or hoods placed over the head will facilitate handling of larger lizards, providing a calming effect. Leather gloves are very useful for large iguanas and monitors to prevent bites and scratches. Special precautions need to be taken to avoid the bite of poisonous species such as the Gila monster (*Heloderma suspectum*) and Mexican beaded lizard (*Heloderma horridum*).

REPTILES

Turtles/Tortoises

Most small- and medium-sized chelonians can be grabbed by the shell and supported by the carapace with the other hand. Larger species (e.g., snapping turtle) require more dexterity and skill as well as protective equipment. A variety of aquatic traps have been used for freshwater turtle capture in the wild and detailed references should be consulted prior to wild capture (Dunham et al. 1988; Simmons 2002; Voigt 1980).

AMPHIBIANS

Amphibians can generally just be grabbed by hand and restrained by supporting the body on the opposite hand. Disposable exam gloves should be worn and changed between individual animals to prevent disease transfer and to prevent toxin absorption to restrainers from certain species (e.g., cane toads). Moistened towels or gauze sponges may be useful to gain traction on

slippery amphibian skin but care must be taken not to damage the integument while handling. Wild amphibians are generally captured using pitfall or funnel traps in conjunction with drift fencing or cover boards (Crosswhite et al. 1999; Mitchell et al. 1993).

Regardless of the species or animal being physically restrained, experience and specialized knowledge of anatomy and physiology are mandatory prerequisites to successfully handle most wild and zoo animals without undue distress and suffering. The following chapters outline detailed taxa specific methods for proper physical restraint of the most commonly handled zoo and wild animals. Specialized holding and restraint devices are absolutely necessary in some situations, while smaller or more docile species may only require personal protective equipment.

Zoo and Wildlife CPR

Søren Boysen

INTRODUCTION

Cardiopulmonary cerebral resuscitation (CPCR) consists of both basic and advanced life support, as well as postresuscitation care and management. Guidelines have been established in the human profession focusing on evidence-based medicine. Unfortunately, veterinary and wildlife literature is sparse, consisting of a few retrospective studies and no prospective or clinical trials to compare strategies. As such, most veterinary guidelines and recommendations are based on extrapolation from human medicine, experimental animal models, and expert opinion.

In the absence of specific evidence-based veterinary studies, many of the recent human consensus statement guidelines would seem reasonable to apply to veterinary and wildlife patients, at least until such veterinary and wildlife studies can be performed to support or refute these recommendations.

One of the main recurrent themes in recent consensus statements is the increased emphasis on providing minimally interrupted high-quality chest compressions throughout advanced life support interventions. Any interruption in chest compressions decreases survival (Deakin et al. 2010; Neumar et al. 2010). Therefore, chest compressions should only be paused long enough to enable specific interventions and should never exceed 5–10 seconds whenever possible, in order to help minimize no-flow times (Deakin et al. 2010; Neumar et al. 2010).

With the recognized grave prognosis associated with cardiopulmonary arrest (CPA), the other recurrent emphasis in human consensus statements focuses on a “track-and-trigger” system. This system is designed to improve monitoring and to detect the deteriorating patient, which will enable therapeutic interventions, and will hopefully prevent CPA.

Objectives of CPCR

- To apply the knowledge and skills necessary to provide basic and advanced life support in arrested patients
- To be able to systematically organize the personal and equipment necessary to perform basic and advanced life support based on pharmacologic and physiologic principles.

DEFINING BASIC AND ADVANCED LIFE SUPPORT

Basic life support (BLS) is derived from the human profession and generally refers to out-of-hospital emergency interventions that are implemented until more advanced procedures can be instituted in a hospital setting. Although classically associated with cardiopulmonary arrest, BLS is used in a number of life-threatening situations (choke, shock, drowning, etc.). It usually focuses on the ABC's (airway, breathing, and circulation) and does not tend to include invasive procedures or pharmacological therapies. In contrast, advanced life support (ALS), which still uses the techniques of BLS, is essentially the application of more advanced procedures designed to further support breathing and circulation. Advanced life support therefore is an extension of BLS. These more advanced procedures often include drugs and invasive procedures (i.e., venous access techniques, open-chest surgery, chest tubes, etc.), which tend to occur in hospital-like environments. Arrests or life-threatening conditions occurring in the field where limited equipment or supplies and fewer highly trained staff are available would be an example of BLS. Arrests occurring in the hospital setting where more advanced procedures can take place

with a greater number of trained staff available will most often include ALS technique.

CARDIOPULMONARY ARREST (CPA) AND CPR: STRATEGY

In the presence of CPA, it should not take more than 10 seconds to identify that a patient is in a state of arrest and for CPR measures to be initiated.

Confirm the Presence of an Arrest

Assess Respirations Loss of spontaneous breathing (regard and/or auscultate the thorax): if within 10 seconds there is doubt if the patient is breathing normally act as if it is not normal and intervene. Confusion may exist when animals are in CPA and agonal breaths are present. These agonal breaths must not be confused with respirations and CPA should proceed in their presence.

Assess Heart Beat and Pulses Loss of heart beat (auscultation) and absence of pulses (femoral artery palpation).

Assess Neurologic Responsiveness Loss of consciousness with fixed dilated (unresponsive) pupils.

Pulmonary Arrest without Cardiac Arrest

When respiratory arrest occurs without cardiac arrest (absence of respiratory effort with a palpable pulse) intubate and give 2–4 large breaths. Follow pulse and ECG to be sure the patient does not progress toward complete CPA. If the animal does not start to breathe spontaneously after several seconds, or the partial pressure of carbon dioxide remains greater than 55 mmHg, start positive pressure ventilation using normal resting respiratory rates for the species. If patient progresses to cardiac arrest, begin chest compressions immediately and consider decreasing the respiratory rate to 2/3 the normal resting respiratory rate (see below).

Note: The presence of an ECG waveform does not rule out cardiac arrest (see pulseless electrical activity). A palpable pulse or other means of ensuring spontaneous circulation (i.e., capnography) should be used to rule out cardiac arrest.

The Alphabet of an Arrest: A, B, C

After confirming the presence of CPA, the ABCs of CPR are the mainstay in applying CPR. There are six steps of CPR adapted from the human resuscitation council guidelines: A, B, C and D, E, F.

Airways Verify that the airways are open. Confirm that the respiratory tract is patent (not obstructed by masses or foreign bodies) and intubate the animal as quickly as possible while minimally interrupting chest com-

pressions (If possible, do not stop chest compressions for >5–10 seconds to intubate the patient).

If the animal is intubated at the time of arrest, make sure the tube is patent and in the right location (not esophageal), is not obstructed with mucous, and is not kinked. Also make sure the cuff is inflated in preparation for positive pressure ventilation. It is difficult to provide good lung expansion and tidal volumes when the endotracheal tube cuff is not inflated. High volume low pressure cuffs are preferred over low volume high pressure cuffs due to the risk of pressure necrosis of the tracheal mucosa (Plunkett & McMichael 2008). In cases where the upper airway is obstructed by something that is not easily removed/corrected (masses or laryngeal collapse for example), a tracheostomy tube may be required to secure the airway. Again, try to minimize the interruption in chest compressions to perform a tracheostomy.

Breathing (Ventilation) Patients that experience CPA should ideally be intubated and ventilated. The optimal tidal volume and respiratory rate (or even inspired oxygen content) to use during CPR to achieve adequate oxygenation and carbon dioxide removal is unknown, and may vary between individuals, breeds, and species.

Given that blood flow to the lungs is greatly reduced during CPR, ventilation to perfusion ratios (V/Q) are likely maintained with lower tidal volumes and respiratory rates than is normal for the patient (Neumar et al. 2010). Hyperventilation, which is very common when providing positive pressure ventilation during CPR, can be harmful because it increases intrathoracic pressures, therefore decreasing venous return to the heart and subsequently cardiac output and cerebral perfusion pressures (Aufderhiede & Lurie 2004; Aufderhiede et al. 2004). It is therefore necessary to try and find the balance between hypoventilation (too few breaths or incomplete expansion of the lungs with each breath) and hyperventilation (giving too many breaths at too high a pressure such that cardiac output is impaired). Although this has not been determined in most species, given tidal volume requirements and respiratory rates are generally lower during CPR than in healthy patients, 2/3 to the lower limit of the normal resting respiratory rate are typically chosen (Neumar et al. 2010; Plunkett & McMichael 2008).

When providing positive pressure ventilation for the CPR patient, avoid over inflation of the lungs (if a pressure gauge is available, do not exceed 20 cmH₂O pressure), yet make sure the chest rises with each breath delivered (Plunkett & McMichael 2008). Make sure the endotracheal tube cuff is inflated to ensure adequate tidal volume delivery to the lungs.

Positive pressure ventilation can be delivered by connecting the patient to an anesthetic machine and using the rebreathing bag to deliver a breath, ambu-

bag, or demand valve depending on the size of the animal and what is more readily available.

Most anesthetic machines contain pressure gauges, which allow pulmonary pressures to be followed during positive pressure ventilation. With anesthetic machines, the pop-off valve can be closed or partially closed during compression of the rebreathing bag to allow filling of the lungs; however, care should be taken not to exceed 20 cmH₂O of pressure during compression of the reservoir bag (Deakin et al. 2010; Neumar et al. 2010; Plunkett & McMicheal 2008).

An ambu bag is an inexpensive but very useful piece of equipment to have in the crash cart and can be used with room air until an oxygen source can be located and connected to the ambu bag. Although not common, pressure gauges can also be used with ambu bags. Ideally, the ambu bag should be connected to 100% oxygen using high flow rates. Use of a reservoir bag with the ambu bag (available on some ambu bags) will further increase the inspired oxygen content during positive pressure ventilation (the reservoir bag will fill with oxygen, which the ambu bag draws from during the delivery of a breath, decreasing the chance that the ambu bag will mix room air with the delivered oxygen flow). Avoid overinflating the lungs, but make sure the chest rises with each breath delivered.

Regardless of the positive pressure method used, inspired oxygen content should initially be set at 100% if it is available (Plunkett & McMicheal 2008). Following ROSC and return of spontaneous respirations, the inspired oxygen content should be titrated to a level that provides adequate partial pressure of arterial oxygen or hemoglobin saturation ($\text{PaO}_2 \geq 70 \text{ mmHg}$ and $\text{SaO}_2 \geq 93\%$) while minimizing the risks of oxygen toxicity.

Circulation In the absence of a palpable pulse or an auscultable heartbeat, and signs consistent with CPA (loss of consciousness and absence of respiratory effort), cardiac massage should be initiated to provide blood flow to the coronary circulation of the heart and cerebral circulation of the brain.

There are two forms of cardiac massage: external cardiac massage and internal cardiac massage.

External Cardiac Massage External cardiac massage (ECM) remains the most commonly used form of cardiac massage in cases of CPA. With a few rare exceptions (open-chest surgery, pleural space diseases, etc.—see later in the chapter), it is the initial starting point for all cases of CPR.

Although ECM will only generate a small amount of blood flow, if started early and performed properly, it can provide a critical amount of blood flow to the brain and myocardium, which may be sufficient to achieve return of spontaneous circulation (ROSC) or may provide the critical flow needed until more exten-

sive procedures can be instituted (i.e., open-chest cardiac massage).

If ECM is to be successful, given the small flow it can achieve, it is vital that it be performed correctly. In general, compressions should be started immediately upon identification of CPA and interruptions in chest compressions must be kept to an absolute minimum and only for essential interventions (i.e., endotracheal intubation, defibrillation, or catheter placement). When an essential intervention is deemed necessary, interruption in compressions should not exceed 5–10 seconds in duration (Deakin et al. 2010; Neumar et al. 2010).

Technique of External Cardiac Massage: General Upon suspicion of or after confirming an arrest, the identifying individual should start ECM while calling on others for assistance (this may involve an alarm system or air horn in larger hospitals where staff may be spread out). It is best to have a minimum of three people to perform CPR.

A well-equipped and frequently stocked crash cart (or mobile resuscitation kit for field work) should be readily available and rapidly accessible in areas where an arrest may occur (see appendix on how to stock a crash cart for various situations).

Place the animal in right lateral recumbency if possible (this may not be feasible in patients weighing more than 100 kg). The compressor can stand on the dorsal or ventral aspect of the patient, at the level of the chest, depending on preference (Plunkett & McMicheal 2008).

If at least two people are present, the goal should be to provide respirations as well as cardiac massage.

If only one person is present and the patient is not intubated, then external cardiac massage should be initiated, as the compression and relaxation of the chest during cardiac massage is usually sufficient to provide adequate movement of air within the respiratory system to allow gas exchange to occur (rationale for changing the mnemonic from ABC's of CPR with at least two individuals present to CAB's if only one person is present) (Deakin et al. 2010; Neumar et al. 2010). Intubate and start positive pressure ventilations as soon as help arrives.

If only one person is present and the patient is already intubated, give 30 chest compressions and two ventilations until help arrives (Deakin et al. 2010; Neumar et al. 2010).

Minimize interruptions and provide high-quality compressions. When interruptions are essential, try to avoid exceeding 5–10 seconds of interrupted compressions.

Providing good quality chest compressions (especially in larger patients) can be exhausting, and it is recommended that the person providing the chest compressions be changed every 2 minutes (Malzer

et al. 1996; Orliaguet et al. 1995). The interruption in compressions during the exchange should be minimal.

Maintain the airway, provide oxygen support as soon as possible, and ventilate the lungs with the most appropriate equipment immediately available (see breathing).

Ventilate the patient with PPV at a rate appropriate for the species. Avoid hyperventilating the patient (both rate, pressure, and tidal volume). Slow delivery of breaths, with an inspiratory time of 1 second and enough volume to produce a normal chest rise, should be used (Plunkett & McMicheal 2008).

The importance of uninterrupted chest compressions cannot be over emphasized. In human studies even short interruptions to chest compressions are disastrous for outcome and every effort must be made to ensure that continuous and effective chest compressions are maintained throughout the resuscitation attempt (Deakin et al. 2010; Neumar et al. 2010).

A CPR leader should monitor the quality of CPR and alternate CPR providers or technique if the quality of CPR is poor. Continuous ETCO₂, if available, can be used to indicate the quality of CPR: although an optimal target for ETCO₂ during CPR has not been determined, values less than 10 mmHg tend to be associated with failure to achieve ROSC and may indicate that the quality of chest compressions are inadequate.

Provide chest compressions at a rate appropriate for the species; see later.

Avian Patients Avian patients may be placed in dorsal recumbency, and external compressions are performed by compression of the sternum; the method and force applied will depend on the mass of the bird. With very small avian patients compressions can be performed with one or two fingers at a rapid rate (up to 200 minutes), in very large patients, such as ratites, compressions are performed as described later, for mammalian patients >10 kg.

Mammalian Patients ≤1 kg Very small mammalian patients can be placed in lateral recumbency on a solid surface in right lateral recumbency; the person performing CPR should place two fingers over the chest, immediately caudal to the forelimb. Compressions should be initiated at a rate of 150–200 compressions/minute. Small mammals can be difficult to intubate, if intubation is possible, intermittent positive pressure ventilation can be initiated at a rate of 20–30 breaths/minute. If intubation is not possible, mask ventilation may be attempted.

Mammalian Patients 1–10 kg For quadrupeds between 1 and 10 kg in weight, with the animal in right lateral recumbency, place the palm of the hand on the sternum with the fifth to sixth intercostal space between the

finger and thumb. This allows direct compression of the heart when the fingers and thumb are squeezed together. The fingers and thumb of the opposite hand can be placed over the first hand if more vigorous compressions are required.

Avoid using only the fingertips to compress the chest as this may result in poorer efficacy and decreased blood flow (Plunkett & McMicheal 2008).

Mammalian Patients 10–100 kg For patients between 10 kg and 100 kg in weight, with the animal in right lateral recumbency, the person performing chest compressions should keep his/her shoulders, elbows, and hands in a straight line so the weight of the upper body is transferred into the compressions via the arms, which will minimize effort and maximize the quality of compressions. With these patients, the widest point of the chest is chosen. For patients exceeding 70 kg, the approach described for patients greater than 250 kg may be more beneficial if the initial response does not appear to be working.

Mammalian Patients 100–250 kg There is no published literature on any technique to perform CPR in patients between 100 and 250 kg in body weight, and therefore recommendations at this time are based solely on the opinions and experiences of the author. The author tends to use a technique between the techniques described for patients between 10 and 100 kg, and those ≥250 kg. With the patient in right lateral recumbency, the CPR provider can use one foot placed over the widest part of the chest (with the knee and hip in a line over the foot) to perform compressions with the goal to compress the chest by approximately 30% in a 1:1 compression to relaxation rate. Alternatively, the CPR provider, starting in a crouched position, may use one knee to “fall” on the patient at the widest point of the chest just caudal to the left elbow. Again, the idea is to transfer enough force to compress the chest by 30% in a 1:1 compression to relaxation ratio. If this is not achievable, then a change to the technique for patients ≥250 kg should be considered.

Mammalian Patients ≥250 kg There is a paucity of information regarding external cardiac massage in large animal patients, one prospective study has been performed in horses, which demonstrated that the most effective technique of performing thoracic compression in adult horses was to place the animal in right lateral recumbency and induce compressions by having the person performing CPR fall from a standing or crouched position onto their knee, with the knee striking the chest immediately posterior to the left elbow. Compression rates of 40, 60, and 80 compressions/minute were compared. A compression rate of 80/minute resulted in the best improvement in cardiac output. The authors' comment that this technique is

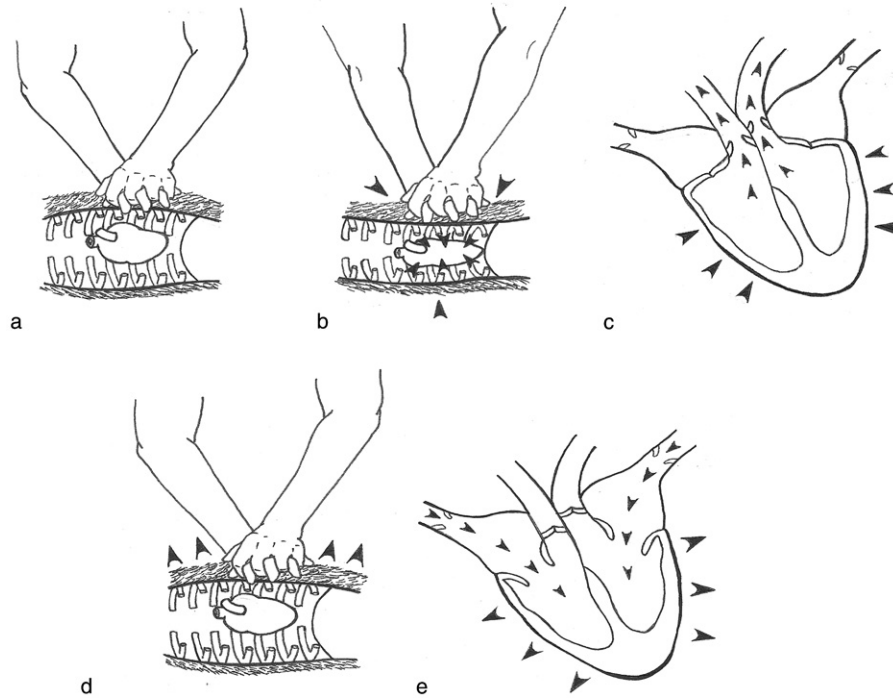

Figure 8.1. (a) The chest in a relaxed state with proper positioning of the hands over the heart. (b) Compression of the heart, between the right and left chest walls. (c) Blood is forced into the aorta and pulmonary artery as the mitral and tricuspid valves are active and act to prevent back flow of blood into the atria. (d) During relaxation and chest recoil, the heart reexpands. (e) The valves open and blood passively fills the heart.

physically demanding for the operator, and it may be best used intermittently, for short periods, in order to distribute cardiotoxic drugs (Hubbel et al. 1993).

Maximizing External Cardiac Massage Experimental studies show that the most effect ECM can provide at best 30–45% of normal cardiac output (Andreka & Fenneaux 2006; Plunkett & McMicheal 2008).

It is well established that the success of establishing coronary and cerebral blood flow during closed CPR is determined by the quality of the chest compressions. The chest should be compressed approximately 1/3 of the thoracic width at the widest point of the chest (Plunkett & McMicheal 2008).

In addition to the degree of compression, the frequency of compressions is also very important and should follow guidelines for the species and its weight.

Chest compression to chest relaxation time should be approximately 1:1, making sure full chest recoil is attained between each compression relaxation cycle (Plunkett & McMicheal 2008).

Providing compressions greater than recommended for the desired weight and species does not provide any additional advantages and can decrease filling time during the recoil of the relaxation phase. Compressions below the recommended range are associated with a poorer outcome.

In general, there are two theories that have been proposed to help explain the blood flow that is obtained during external cardiac massage: the cardiac pump theory and thoracic pump theory.

The Cardiac Pump Theory With the cardiac pump theory, direct compression of the heart between the two sides of the rib cage results in forward blood flow (Fig. 8.1). Blood flow results because the pressures created on the heart allow the valves (particularly the mitral valve) to function as they would normally (preventing back flow of blood when the heart is compressed, and opening when it is relaxed during decompression/recoil of the chest). This mechanism is probably the most prominent means of blood flow during CPR in animals less than 15 kg, or during internal cardiac massage (Plunkett & McMicheal 2008).

Blood flow is not influenced as much by the duration of compression as it is by the frequency of compressions.

Although it was initially believed that the cardiac pump theory was responsible for blood flow in animals of any size, subsequent studies in larger animals using ultrasound and angiography have demonstrated that cardiac valves are not functional during external chest compressions (the chest is too wide to compress the heart between the two sides of the chest), and another

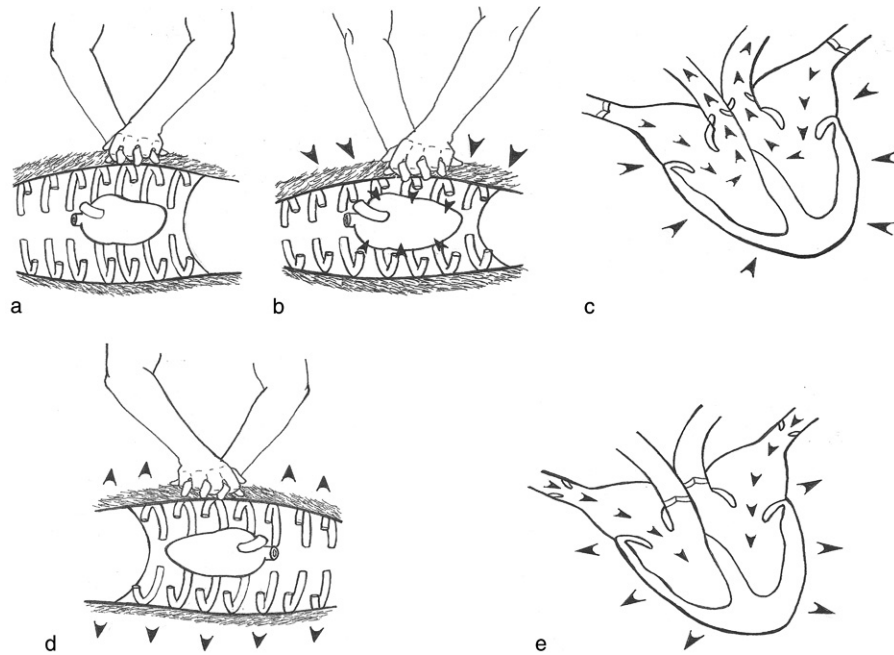

Figure 8.2. (a) The hands are placed over the widest part of the chest. (b) The chest size decreases, but the heart is not directly compressed between the two opposing rib cages. (c) Increases in intrathoracic pressures push blood out of the heart and thorax into the arteries. Note that the tricuspid and mitral valves are open and the heart is acting as a passive conduit. The venous valves play a role in preventing back flow of blood. (d) The chest expands during the relaxation phase. (e) Blood reenters the thoracic vessels and heart passively during the relaxation phase of external CPR. Note: The heart (and cardiac valves) is passive. There are antireflux valves at the thoracic inlet.

theory has been proposed for blood flow in larger animals (the thoracic pump theory).

The Thoracic Pump Theory With the thoracic pump theory, it is not direct compression of the heart that results in blood flow, but rather the changes in intrathoracic pressure during compressions and relaxation of the chest. With this theory, the heart is a passive conduit and acts similar to a large blood vessel. It is therefore the blood within the thoracic cavity (large vessels and heart) that acts as a blood reservoir. With compression of the chest, the pressures within the thoracic cavity increase, forcing blood to move out of the thorax (Fig. 8.2). Blood is forced cranially through the arterial system due to the presence of valves in the venous system and because the jugular veins are collapsed during the compressive phase of external cardiac massage. This mechanism likely accounts for the majority of blood flow in animals greater than 15 kg in body weight (Plunkett & McMicheal 2008).

Intermittent Abdominal Compression and Continual Abdominal Compression With this technique the abdomen is compressed during the relaxation phase of chest compressions in an effort to move more blood from the abdomen into the thorax. The technique is difficult (but not impossible) to coordinate at frequencies of 80 to 100 compressions per minute. It also

requires an additional person to apply the intermittent abdominal compressions. The risk of regurgitation of stomach contents (due to increased pressures created in the abdomen and sometimes directly on the stomach) is greater with this technique and patients should be intubated. Abdominal trauma with lacerations of the liver and spleen have been reported with these techniques (Plunkett & McMicheal 2008). An alternative to intermittent abdominal compression is continuous abdominal compression where the abdomen is wrapped or pressure is manually applied in a continuous fashion to the abdomen.

Impedance Threshold Device (ITD) The thoracic impedance threshold device is a unidirectional valve that is connected to the end of the endotracheal tube. The valve is sensitive to pressure and will not open until a certain pressure is achieved (it is a spring loaded valve that will typically open around 12 mmHg pressure).

In patients receiving closed chest CPR without the ITD in place, negative intrathoracic pressures that occur during relaxation help to draw blood back into the chest as air freely enters the mouth, trachea, and lungs. With the ITD in place, the negative pressure in the thoracic cavity during elastic recoil is increased (due to the fact the valve on the ITD remains closed until 12 mmHg pressure is reached), which allows more blood to enter the thorax during the relaxation phase

of chest compressions than would normally enter the thorax without the use of this device.

Studies in people have shown improved return of spontaneous circulation and short-term survival when the ITD is used.

Arrests during Anesthesia

If the animal is under anesthesia during the CPA, consider discontinuation of volatile anesthesia or administration of a specific antagonist; if it is safe to do so, this will depend on the species being worked on and the environment.

Confirm the proper connection and function of the anesthetic machine if time permits (tubing free of obstruction, oxygen on and flowing, proper connection to the endotracheal tube, etc.) and begin positive pressure ventilation by using the reservoir bag and pop-off valve. The pop-off valve can be closed or partially closed during compression of the reservoir bag to allow filling of the lungs; however, care should be taken not to exceed 20cmH₂O of pressure during compression of the reservoir bag. At the same time, the chest should visibly rise during delivery of breaths. Ventilate the animal with 100% oxygen if possible.

Frequency of positive pressure ventilations should be based on the lower resting respiratory rate of the species undergoing CPR (see above).

Begin external chest compressions in the absence of an auscultable heart beat or palpable pulse.

OPEN-CHEST OR INTERNAL CARDIAC MASSAGE

Depending on the situation, species, and quality of life of the patient, open-chest CPR may or may not be a viable option. Given the equipment needed to perform open-chest CPR, the personnel needed, and the intensive postoperative care, including chest tubes, it is generally not a viable option in wildlife under field conditions. However, provided there is a sufficient number of trained staff to perform open-chest CPR and the equipment and facilities necessary to perform the technique and manage the patient postoperatively, it may be possible in some settings.

In the absence of ROSC within 5 minutes of closed chest compressions, or in the face of pleural space disease, rib fractures, pericardial effusions, flail chest, diaphragmatic hernia, severely obese animals (provided the owners are well informed and consent to the procedure), or in cases where the thorax is already open (i.e., sternotomy), or even during open abdominal surgery (where the diaphragm can easily be accessed and incised to allow the hand to be passed into the thorax via the diaphragm to perform direct cardiac massage), open-chest CPR should be performed (Plunkett & McMichael 2008).

The advantages of open-chest CPR are significant: visualization of the heart (visible ventricular fibrillations) and tonicity of flaccidity of the heart, which helps determine venous return and cardiac filling; direct cardiac visualization and cardiac access for administration of CPR drugs; drainage of the pleural or pericardial spaces if diseased; and finally, manual occlusion of the caudal aorta to divert blood to vital organs and better perfusion of vital organs.

Multiple studies have demonstrated that open-chest CPR with direct cardiac compressions result in far greater blood flow than closed chest CPR. As such, through improved cerebral and cardiac flow, the chances of return of spontaneous circulation are much higher. However, if open-chest CPR is to be attempted it must be done early and should not be delayed until after 10–20 minutes of closed chest CPR has been attempted. If the chest is going to be opened to improve the chances of CPR, it must be done early (ideally within 5 minutes of the arrest if closed chest CPR is not successful in this 5 minute time frame). Always have the materials to perform open-chest CPR readily available.

Indications for Open-Chest CPR

- At least 3 people
- CPA during surgery: thoracic or abdominal (can access the chest via an incision through the diaphragm during open abdominal surgery)
- Inability to generate ROSC or good flow during closed chest CPR
- Intrathoracic disease: pleural or pericardial effusion, diaphragmatic hernia, pneumothorax, and flail chest
- External factors: marked obesity, severe subcutaneous emphysema
- Ineffective external CPR after 5 minutes (unable to generate good femoral pulses or adequate ETCO₂).

Technique for Internal Cardiac Massage

1. Place the animal in right lateral recumbency.
2. Rapidly shave and soak the area with alcohol over the left fifth intercostal space (it is better to be dirty and alive than sterile and dead). Shave a 2- to 3-in strip of fur from the sternum ventrally to spine dorsally (the width of the clipper blades in one pass).
3. Make an incision through the skin and subcutaneous tissues over the 5th intercostal space with a scalpel. Start dorsally and cut to the sternum ventrally.
4. With scissors, penetrate the thorax (traverse the muscles to enter the pleural space) at the level of the costochondral junction of the fifth intercostal space. Starting lower than the costochondral junction runs the risk of cutting the internal thoracic

Figure 8.3. Anatomic location of the internal thoracic artery (red) and vagal nerve (yellow) for canid and felid species, which should be avoided when opening the thorax and pericardium respectively.

artery, which runs ventral to the costochondral junction (Fig. 8.3).

5. Retract the ribs (finichetti rib spreaders or manually) to visualize the heart. One can cut or break the ribs to improve visualization and improve exposure if needed; however, do not interrupt compressions of the heart to do this (have an assistant do this).
6. Start cardiac compressions. Take the heart in the palm of the hand and massage from the base to the apex. Wait for the ventricles to refill before the next compression is delivered. If the ventricles do not fill quickly enough to allow 80–100 beats per minute to be delivered, consider increasing venous return by providing abdominal compressions, administering fluids or blood, or having an assistant occlude the caudal vena cava just caudal to the heart. Try to avoid using the fingertips to compress the heart, as this may result in less effective flow rates and increases the risk of traumatic cardiac rupture.
7. The pericardial sac can be opened to improve cardiac massage, to allow visualization of fine ventricular fibrillation, and to help get a feel for cardiac filling between compressions. It is easiest to hook the phrenicopericardiac ligament with the index finger (in a sweeping caudal to cranial direction) and incise the pericardium over the ligament as opposed to cutting the pericardial sac directly over the heart (which runs the risk of accidental laceration of the myocardium).
8. If there is return of spontaneous circulation, the thorax must be copiously lavaged, with warm sterile

saline before closing. A chest tube should be placed prior to chest closure. The chest should then be closed by passing large suture (0) or wire around adjacent ribs. The muscle layers, subcutaneous tissue, and skin are closed routinely.

THE ALPHABET OF AN ARREST: D, E, F

Drugs

Epinephrine Epinephrine remains the gold standard with external cardiac massage through its alpha sympathomimetic effects, particularly its arterial vasoconstrictive properties. (Deakin et al. 2010). Despite this, there is no placebo-controlled clinical study to demonstrate that the routine use of any vasopressor at any stage during cardiac arrest increases neurologically intact survival to hospital discharge. Animal models suggest a delay in the delivery of vasopressor drugs following the onset of cardiac arrest may be associated with a worse outcome (Wenzel et al. 1999).

Based on experimental animal models, it has been shown that blood flow during external cardiac massage can be slightly increased with the administration of epinephrine. Principally through its sympathomimetic effects, epinephrine improves the efficacy of ECM through an increase in transdiastolic pressure of the aorta. Note that it is the difference between the aortic pressure and the right atrial pressure during diastole that determines coronary circulation, a primary goal of ECM. Epinephrine may also improve cerebral perfusion through improved carotid flow as a result of redistribution of carotid flow from the external to the internal carotid arteries.

The dosage and frequency of epinephrine varies from 0.01 to 0.1 mg/kg of 1:1000 ratio repeated at 3–5 minute intervals (Neumar et al. 2010). These recommendations are based on “expert opinion” and the optimal dose is unknown. Higher doses have been associated with increased cardiac workload and myocardial injury, although they may be more efficacious in cases of pulseless electrical activity. There are also no data to support repeated doses of epinephrine. However, until further studies can be completed to support or refute epinephrine, or to prove another vasopressor is more efficacious, the standard of care is to administer epinephrine at 3–5 minute intervals during CPR at a dose of 0.01 mg/kg. Do not discontinue chest compressions to administer epinephrine or any other drug. If 0.01 mg/kg fails to provide ROSC after one to two boluses, a 0.1 mg/kg dose or use of vasopressin can be considered.

Vasopressin The only alternative that has shown promise when compared with epinephrine is vasopressin. Vasopressin is a vasoconstrictor and an antidiuretic. In CPR models in animals, vasopressin showed greater improvement in cardiac output than epinephrine.

Further studies are needed to confirm any true benefit in morbidity and mortality; however, its use is now accepted and the current recommendation is that an IV dose of vasopressin can be given in place of the first or second dose of epinephrine (Neumar et al. 2010).

Atropine Atropine is a parasympatholytic agent. It inhibits the effects of acetylcholine and increases heart rate. Its primary indication is in situations of increased vagal tone leading to arrest. Atropine is no longer recommended for routine use in the management of PEA/asystole in people (Neumar et al. 2010); however, given there is no evidence to suggest it has detrimental effects during bradycardic or asystolic cardiac arrest, it may still play a role in the veterinary profession for these conditions (see notes on PEA and asystole).

Bicarbonate In humans, the routine administration of sodium bicarbonate during cardiac arrest and CPR or after ROSC is not recommended. It may be beneficial in cases where the arrest was caused by hyperkalemia (i.e., urethral obstruction, uroabdomen, or Addisonian crisis resulting in cardiac arrest due to severe hyperkalemia) or preexisting metabolic acidosis was present. If given, blood gasses should be followed serially to determine response to therapy and the possible need for repeat doses. It is important that ventilation be maintained if bicarbonate is administered to prevent paradoxical CNS acidosis.

Lidocaine and Amiodarone There is no evidence that antiarrhythmics given during cardiac arrest increase survival to discharge. Their use may be considered in ventricular fibrillation or pulseless ventricular tachycardia when defibrillation is not available. Amiodarone is recommended over lidocaine in the human literature (Neumar et al. 2010).

Calcium Gluconate, and Glucose All have been used during CPR; however, they should only be given when indicated (i.e., preexisting conditions).

Routes of CPR Drug Administration

There are generally five routes of drug administration during CPR; via a central venous catheter (jugular vein), via a peripheral venous catheter (i.e., cephalic or saphenous), via an intraosseous catheter, via the trachea (through a small 5- to 8-g red rubber tube passed through an endotracheal tube), and intracardiac (only recommended if the chest is open during open-chest CPR). Do not discontinue cardiac massage during the administration of drugs via any route!

There are many choices to administer drugs during CPR. Central line administration is the most rapid and preferred route to administer drugs given the proximity of the catheter tip in relation to the heart (Emerman et al. 1998). However, it takes time to place

central lines, they are associated with more risk, and it requires greater skill to place a central line compared to a peripheral line. Unless a central line is already in place, it is recommended that a peripheral catheter be placed and used for CPR. If there is anticipated difficulty in placing a peripheral line, the newer IO catheters can be placed in under 10 seconds and show equal efficacy to peripheral lines (Neumar et al. 2010).

Drugs delivered via a peripheral venous catheter should be followed by a bolus of fluids (10–20 mL/kg) to push drugs administered peripherally from the venous access site toward the heart to allow drugs to reach the heart (Emerman et al. 1990).

Endotracheal administration is less frequently used in human CPR due to the unpredictable plasma concentrations achieved when drugs are delivered via this route (Neumar et al. 2010). However, it is still frequently used in the veterinary profession due to the difficulty of placing venous catheters and the cost and availability of alternative routes such as IO catheters. The optimal dose of drug to administer via the tracheal route, for most drugs, is also unknown. If using the endotracheal route the dosage should be two to three times the IV drug dosage. Evidence suggests the dose of epinephrine via the IT route may need to be 3–10 times the IV dose (Hornchen et al. 1987). With the exception of bicarbonate all drugs given IV can also be given via the endotracheal route. To ensure the drug reaches the small airways and does not remain in the endotracheal tube the author prefers to administer the drugs via a long 5- to 8-g red rubber feeding tube (the tube is passed through the endotracheal tube). A small bolus of 5 mL (the volume of the catheter used) of sterile water (provides more rapid absorption of the drug than 0.9% saline) is then flushed through the red rubber tube following the administration of the drug to ensure the drug does not remain in the catheter. Alternatively the drug can be directly diluted with 5–10 mL of sterile water and injected directly through the endotracheal tube. The patient should also be ventilated with two to three rapid breaths to help distribute the drug within the lungs.

In humans, rapid intraosseous catheters and IO drug administration has all but replaced endotracheal drug administration. All drugs that are administered IV can be given IO at the same dosage. IO drugs should be followed with a bolus of fluids similar to IV drugs in order to push them from the IO space into the circulation and towards the heart. Studies in people have demonstrated that IO injection of drugs achieves adequate plasma concentration in a time comparable to injection through a central venous catheter.

Intracardiac administration of drugs is no longer recommended due to the risk of lacerating coronary vessels, injury leading to arrhythmias and accidental intracardiac muscle injection. Given the evidence to support alternative routes its use should be reserved for

cases of open-chest CPR when the heart can be directly visualized. A drug dose chart is included in Table 8.1.

Electrocardiogram

There are 3 common fatal arrhythmias reported in association with CPA. One may proceed to another.

Ventricular Asystole Ventricular asystole is characterized by an absence of all electrical ventricular activity: The ECG tracing is a flat line (see Fig. 8.4a).

Atropine is no longer recommended for asystole in the human profession given the lack of any demonstrable benefit with its administration. However, in people, most cardiac arrests (including asystole) are

Table 8.1. Cardiopulmonary cerebral resuscitation drug doses

Drug	Dose	2,5kg	5kg	10kg	15kg	20kg	25kg	30kg	40kg	50kg
Epinephrine, 1:1000, 1 mg/mL	0.1 mg/kg (0.01 mg/kg)	0.25	0.5	1	1.5	2	2.5	3	4	5
Atropine, 0.5 mg/mL	0.05 mg/kg	0.25	0.5	1	1.5	2	2.5	3	4	5
Lidocaine, 20 mg/mL	2 mg/kg	0.25	0.5	1	1.5	2	2.5	3	4	5
Bicarbonate, 1 mEq/mL	1 mEq/kg	2.5	5	10	15	20	25	30	40	50
External defibrillation	2–5J/kg	5–12,5	10–25	20–50	30–75	40–100	50–125	60–150	80–200	100–250
Internal defibrillation	0.2–0.5J/kg	0.5–1.25	1–2.5	2–5	3–7.5	4–10	5–12.5	6–15	8–20	10–25
Vasopressin, 20 u/mL	0.2–0.8 u/kg	0.07	0.13	0.25	0.38	0.5	0.63	0.65	1.0	1.25

Notes: Drugs are in mL per kg, administration IV, double or triple the dose if given endotracheally.

Figure 8.4. (a) ECG tracing of ventricular asystole. Note the absence of any electrical activity (b). An example of pulseless electrical activity (PEA). Note that the ECG tracing can vary from near normal to vary bizarre depending on the electrical activity present. The key to note is that there is synchronous electrical activity from the heart in the absence of a detectable pulse. (c–e) ECG tracing of coarse ventricular fibrillation progressing to fine ventricular fibrillation.

caused by primary myocardial pathology, which is in contrast to many of veterinary patients who experience asystole as a result of increased vagal tone and not primary myocardial pathology. Therefore, given many veterinary patients may arrest without the rhythm being observed, it is still reasonable to administer atropine in conjunction with epinephrine until studies prove otherwise. This is especially true if the arrest may have been the result of increased vagal tone.

Pulseless Electrical Activity This is the most common arrhythmia reported as a cause of arrest in veterinary patients. Electrical mechanical dissociation is characterized by a visible ECG tracing (electrical activity present in cardiac muscle cells), in the absence of myocardial contractility (Fig. 8.4b). There is current passing through the conducting system of the heart resulting in a detectable ECG rhythm, but the muscles fail to contract or fail to contract with sufficient force to generate enough cardiac output to move blood through the vascular system or produce a palpable pulse. Treatment of this arrhythmia is difficult and often unsuccessful.

Epinephrine is recommended in cases of pulseless electrical activity at a dose of 0.01 to 0.1 mg/kg. When PEA is identified ECM should be started immediately while IV access is secured and epinephrine can be administered. Epinephrine can be continued every 3–5 minutes. Similar to other arrhythmias, ECM should be continued for at least 2 minutes before rapidly checking the rhythm, and interruption in chest compressions should be minimized (less than 5 seconds) while the pulse and rhythm are evaluated. If a pulse is detected, post cardiac care is initiated. If the rhythm does not produce a palpable pulse or asystole is noted, then chest compressions and CPR should be restarted immediately and continued for 2 minutes before another rhythm check is repeated.

Atropine is no longer recommended for PEA in the human profession given the lack of any demonstrable benefit with its administration. However, as previously discussed asystole, cardiac arrests in veterinary patients often result from increased vagal tone, not myocardial pathology as in humans. Therefore, given many veterinary patients may arrest without the rhythm being observed, it may still be reasonable to administer atropine in conjunction with epinephrine, especially if the arrest may have been the result of increased vagal tone.

Ventricular Fibrillation This is the most common arrhythmia that occurs in people, often as a result of myocardial infarctions. It is characterized by a completely disorganized and anarchic rhythm, which results in complete absence of coordinated or effective ventricular contractions. It may be coarse or fine (Fig. 8.4c–e). By far the best therapy for this arrhythmia is electrical defibrillation, which transiently depolarizes all cardiac cells simultaneously (complete cardiac stand-

still), with the hope they will restart in a synchronized pattern (Deakin et al. 2010; Neumar et al. 2010).

If a defibrillator is available it is still important to emphasize minimizing the duration of the preshock and post-shock pauses and the continuation of compressions during charging of the defibrillator is recommended. It must also be emphasized that compressions should be started immediately following defibrillation and the total time to perform defibrillation should not interrupt chest compressions for more than 5–10 seconds. Deliver a single shock dose and immediately resume chest compressions. Do not interrupt chest compressions to allow rhythm analysis. Instead, continue chest compressions for two minutes, while monitoring response to ECM before checking the rhythm analysis or deciding if a second shock should be delivered.

The earlier defibrillation is delivered following identifications of ventricular fibrillation the greater the chance of success. If an initial single charge fails to convert VF, then three-stacked shocks may be considered. A single shock dose of 2–5 J/kg (preferably biphasic, although monophasic is acceptable) is recommended as a starting current.

Although biphasic defibrillators are phasing out monophasic defibrillators and monophasic defibrillators are no longer being produced, they are likely to play a role in the veterinary profession for many years to come. If given a choice a biphasic defibrillator should be used as they have been shown to be more effective at terminating ventricular arrhythmias at lower energy levels, have demonstrated greater first shock efficacy and have greater first shock efficacy for long duration VF compared to monophasic defibrillators. Wearing rubber gloves has been shown to decrease the risk of an accidental shock being delivered to CPR givers.

Defibrillation may be transthoracic (external) or transcardiac (internal). If a defibrillator is not available a precordial thump (strong quick thump on the chest wall over the heart, or a direct “flick” of the heart itself if the chest is open) can be attempted. The idea is to traumatically depolarize the heart or stun it. Given the widespread availability of electrical defibrillators in the human profession the precordial thump is no longer recommended; however, in the veterinary profession, where defibrillators or even amiodarone and lidocaine may not be as readily available, the precordial thump may still have some benefit.

Fluids

Resuscitation with fluids is only recommended in cases of confirmed hypovolemia and reflex administration of fluid boluses to arrested patients should be avoided as they can lead to volume overload and pulmonary edema (Deakin et al. 2010). Intravenous fluids are the preferred route of administration. However, in the absence of an intravenous catheter, intraosseous administration is also equally effective. If medications are given

during CPR, a 10-mL/kg fluid bolus should be given through the same catheter as the drug to help ensure it reaches the heart.

MONITORING EFFICACY OF CPR

Palpation of the femoral pulse is one of the easiest techniques to monitor the efficacy of CPR without the need for specialized equipment. If CPR efforts do not produce a palpable femoral pulse then a change in external massage technique or changing to open-chest CPR should be considered. It should be noted, however, that palpation of a femoral pulse may indicate venous rather than arterial flow (there are no valves in the inferior vena cava), and does not always correlate to effective CPR. Palpation of a pulse when chest compressions are stopped is a fairly reliable indicator of ROSC (Neumar et al. 2010). Do not discontinue chest compression for more than 10 seconds to assess if a pulse is present or not.

Other methods of assessing efficacy of CPR include placement of a well-lubricated doppler flow probe on the eye, evaluation of the ECG waveform and measurement of end tidal carbon dioxide.

Measurement of end tidal CO₂ remains one of the most consistent and reliable measures of CPR and for the detection of ROSC. Unlike ECG analysis, it also does not require an interruption in chest compressions to monitor (Neumar et al. 2010). Although specific parameters have not been established, an end tidal CO₂ of at least 10 mmHg is likely to represent efficacious CPR (Grmec & Klemen 2001; Kolar et al. 2008; Pokorna et al. 2009). With the return of spontaneous circulation, the end tidal CO₂ will rapidly rise and should reach close to 30 mmHg (Fig. 8.5) (Ahrens et al. 2001; Sehra et al. 2003).

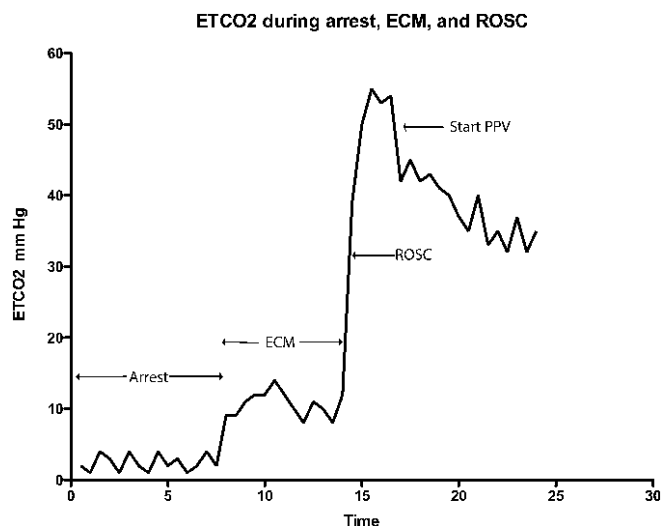

Figure 8.5. End tidal carbon dioxide measurement and its association with cardiac arrest, effective external cardiac massage (ECM), return of spontaneous circulation (ROSC) and initiation of positive pressure ventilation (PPV).

In humans, end tidal CO₂ is also used to confirm endotracheal tube placement, which may also be applicable in some animal species, particularly those that are difficult to intubate.

DISCONTINUING CPR

The risk of permanent severe neurologic injury is significant after 15–20 minutes of CPR without ROSC. It is therefore reasonable to discontinue CPR efforts after 20 minutes if ROSC is not reestablished (Plunkett & McMichael 2008). This time frame may vary depending on the underlying cause, conditions under which CPR is performed, and ultimately the quality of life of the patient.

PROGNOSIS AND RETURN OF SPONTANEOUS CIRCULATION?

The success of CPR is dependent on many factors, including the underlying cause, the training of personnel, species, duration of the arrest, and the equipment available. In general, the prognosis is poor with very few patients recovering with normal neurologic function (however, this does vary depending on the underlying cause). The majority of veterinary literature relating to prognosis following CPA is derived from small animals, which demonstrates that 30% of patients will have ROSC, 5–10% will be discharged from the hospital, and 1% will have a return to normal function. Discharge from respiratory arrest alone varies from 25–60% of small animal patients. The chance of re-arrest following return of spontaneous circulation is 35–70% in small animal veterinary patients.

CPA caused by anesthesia, drug overdose, increased vagal tone, or electrolyte imbalances tend to have a better prognosis than patients with serious underlying critical illnesses, such as sepsis, SIRS, or neoplasia. Early intervention is also an important factor influencing prognosis, and patients with significant underlying illness (pulmonary or cardiovascular instability, arrhythmias, marked hypothermia, anesthesia) should be monitored closely to help identify patients at increased risk and allow earlier intervention. In addition, well-trained staff (frequent practice of CPR) with a properly equipped facilities (crash cart (Table 8.2), oxygen, suction, etc.) will further increase the chances of success. Finally, the prognosis also tends to vary with the species affected, with small animal veterinary patients having a better prognosis compared with large animal patients (Fig. 8.6).

There is a very high chance of a second arrest in patients that are successfully resuscitated and have achieved ROSC. Close intensive monitoring is needed, and most patients require vasopressors. Mechanical ventilation may also be necessary for a period of time following ROSC to decrease the chance of a second arrest.

Table 8.2. Sample crash cart setup

Drugs	IV fluids and equipment
Epinephrine 1:1000	Lactated Ringer's
Atropine 1/120 grain	0.9% Saline
Lidocaine 2%	Hypertonic saline 7.5%
Sodium bicarbonate 8.4%	Hetastarch 6%
Dextrose 50%	Rapid infuser
Calcium gluconate 10%	IV catheters, tape, gauze, wrap
Dobutamine	IV sets (pediatric and adult)
Dopamine	IV extension tubing
Dexamethasone SP	Blood filters (dog and cat)
Soludelta cortef	Bone marrow needles
Naloxone	EZIO or other automated IO device
Flumazinil	
Respiratory	Needles
Endotracheal tubes	Syringes
Laryngoscope	Scalpel blade
Stylets	Mayo scissors
Suction apparatus	Sponge forceps
Yankauer suction tip	Hemostats
Thoracocentesis set (60-cc syringe, three-way IV access stopcock, extension tubing)	
Ambu bag	Red rubber tubes (5F and 8F)
Thoracic impedance device	
Chest tubes kits	Defibrillator/EKG monitor
Tracheostomy tube kits	Doppler monitor/sphygmomanometer/cuffs
Pulse oximeter	Hematocrit tubes, glucometer, lactate meter, azosticks
	Serum, EDTA, heparin, and citrate tubes

9 Field Emergencies and Complications

Jon M. Arnemo, Alina L. Evans, Åsa Fahlman, and Nigel Caulkett

INTRODUCTION

Chemical immobilization of wild animals is a form of veterinary anesthesia conducted under difficult circumstances. The risk of severe side effects, injuries, and death can never be completely eliminated. In addition, all immobilizing drugs are toxic and some are potentially lethal to humans (Haymerle et al. 2010; Kreeger & Arnemo 2012); see Chapter 13 on human safety.

Chemical immobilization of free-ranging wildlife should only be considered when necessary for research or management goals. Captures should be carried out by a team of professionals with proper training, experience, and expertise in wildlife capture, veterinary anesthesia, animal handling, and human and animal first aid and CPR techniques.

All captures must be properly planned, and species-specific capture protocols should be developed. Doses required for immobilization of free-ranging animals are generally higher than those required in captive individuals (Kreeger & Arnemo 2012). In general, overdosing is probably safer than underdosing because extended induction times may cause increased stress and risk of complications.

Chemical immobilization of free-ranging wildlife is a challenging procedure. It is generally not possible to access the patient for a preoperative physical examination or laboratory work. Even if anesthetic risk could be determined, there are generally only a few effective protocols available for each species. Induction of anesthesia in wildlife can be extremely stressful and can result in stress related injuries. Free-ranging wildlife are subject to the elements and are often at risk for hypothermia or hyperthermia. Field personnel may be required to work on species for which there is very little background information. Extrapolation between similar

species may be required, but can result in unexpected complications. Human and animal safety must also be considered.

Wildlife anesthesia should be a cooperative effort between biologists and veterinarians. A team approach is invaluable and draws on the strengths of the different specialties. It is essential to include experienced personnel on the capture team and to consult with experienced wildlife managers, biologists, and veterinarians to determine anticipated complications, animal behavior when stressed, and the current approaches to dealing with the target species.

PRECAPTURE CONSIDERATIONS

Planning

Before any wildlife capture procedure, an appropriate plan of action must be devised. The species should be researched to determine the most effective and current technique for capture. Communication, evacuation, and first aid protocols for capture personnel must also be established. Field equipment must be carefully selected.

If potentially dangerous animals are targeted, an appropriate firearms backup should be in place. Personnel should be trained in human first aid, firearms safety, and, when applicable, helicopter safety, wilderness survival skills, rock climbing, and avalanche rescue.

Generally the target animal will need to be approached to within 10–40 meters for accurate drug delivery. Animals may be stalked, approached in a vehicle or helicopter or trapped or snared prior to approach. Trapping has the advantage of limiting movement during the capture event, but it can be more stressful than helicopter capture (Cattet et al. 2003b).

Situation

Capture sites should be preplanned and chosen based on their suitability, for example, to avoid roads, communities, and natural hazards, such as rough terrain or open water. The capture should be planned at an appropriate time of the year, for example, ungulates may be captured in winter to decrease the risk of hyperthermia and to allow for tracking in snow or visualization of animals in a deciduous forest. If specific animals are not targeted, the capture team can choose an animal located in a relatively safe capture environment. Current literature and experts in the field should be consulted prior to the capture to ensure the most suitable technique is used. It may be possible to close areas where wildlife are captured to the public.

It is becoming increasingly necessary to immobilize wildlife in urban environments that contain many hazards. In an urban environment, particular attention must be made to traffic. It is often advisable to enlist the help of law enforcement officers for crowd and traffic control. In these situations, attempts at capture usually continue until the animal is under control or euthanized, increasing the risk of injury and adverse effects (e.g., myopathy and hyperthermia). Often, the personnel involved in these captures are wildlife managers, such as wardens or conservation officers. Therefore, it is important to use drug combinations with a rapid onset and a high margin of safety.

Terrain

The ideal capture site should allow good visualization of the animal during the induction period. Particular attention should be paid to open bodies of water, as some species may enter the water after dart placement and be at risk of drowning. Mountainous terrain has obvious risks associated with it. Capture personnel with climbing experience are valuable when working in mountains or canyons. Forest is also hazardous as animals may be difficult to track beneath the canopy. Dogs trained in tracking wildlife species are useful if a darted animal is lost out of sight. Telemetry darts may also be useful in these situations. Some species, such as black bears and mountain lions, may climb trees to escape capture. Equipment should be available to cushion their fall or to facilitate removing the animal from the tree (Fig. 9.1).

Weather

Weather conditions often dictate if wildlife capture is possible. Helicopter work is not possible in high winds or foggy conditions. In remote locations, sudden changes in the weather may be a hazard to personnel. It is important to keep track of current and changing conditions during wildlife capture.

Snow and rain can lead to hypothermia, particularly if wind is also present to enhance convective heat loss. Small mammals are most susceptible to hypothermia.

Figure 9.1. Preparation of a cushioned landing area for a bear cub, prior to immobilization in a tree.

Figure 9.2. Cooling a hyperthermic lynx in a pond.

However, hyperthermia is generally a more serious concern as several of the drug regimens used for wildlife capture impede thermoregulation and lead to hyperthermia (Cattet et al. 2003a; Klein & Klide 1989). Hyperthermia is a serious complication that can be difficult to treat in field situations. When possible, captures in the summer should be planned for the cooler hours of the day. Animals can also become hyperthermic in cold temperatures if they experience physical exertion during the induction period. Also, even in hot tropical climates, small animals can develop hypothermia during anesthesia. Provision should be made to prevent heat loss and to actively cool animals if needed (Fig. 9.2).

Target Species

Prior to embarking on a capture session, it is important to become as familiar as possible with the target species, including a search of current literature and consultation with experts for that species. Nontarget animals may include animals of the right species, but the wrong sex or age class. If traps are used, nontarget species may be caught. Researchers need to anticipate which nontarget species may be trapped, determine if nontarget animals must be anesthetized (e.g., if they are too aggressive to release directly or if they should be marked for other research groups), and be familiar with the best current techniques for anesthesia of these species. Wildlife managers need to be familiar with techniques for all the species they may encounter in the course of their work.

Emergency Equipment

Space limitations dictate what type of equipment can be carried in a field situation. However, capture should not take place unless all necessary equipment can be brought to the animal. A portable oxygen source should be part of the standard field equipment (Fig. 9.3).

Hypoxemia is a common complication of wildlife anesthesia (Caulkett & Arnemo 2007; Read 2003). Oxygen therapy is fundamental for prevention and treatment of hypoxemia during anesthesia. Lightweight aluminum cylinders, combined with a sturdy regulator, are handy for field use. Portable battery-powered oxygen concentrators are also useful, especially in remote locations where logistics with oxygen cylinders can be difficult (Fahlman et al. 2012). Oxygen therapy is further described in Chapter 5.

Equipment for airway support, including appropriately sized endotracheal tubes and a bag valve mask (resuscitator) to enable mechanical ventilation should be included in an emergency kit. As ruminants are

Figure 9.3. Use of a portable oxygen concentrator to provide supplemental inspired oxygen to a brown bear cub.

predisposed to rumenal tympany during anesthesia, it is wise to carry a rumen tube to facilitate decompression of the rumen. A small surgical kit should also be carried to treat lacerations and other injuries (see checklist in Kreeger & Arnemo 2012). Equipment should be carefully chosen to withstand use in a field situation and to be as lightweight and compact as possible.

Immobilizing Drugs

Drug needs must be anticipated; it is wise to budget for at least 50% more drug than is actually needed for the target animals. This will help offset any wasted drug from lost darts or poor dart placement. Resuscitation equipment must be available for use in the target animals. A basic emergency kit containing epinephrine, atropine, local anesthetics, and reversal agents should always be carried. A checklist of emergency drugs can be found in Kreeger and Arnemo (2012).

Capture Techniques

Physical capture, such as net gunning, rocket nets, drive nets, traps, and snares, can induce greater stress than chemical immobilization (Boesch et al. 2011; Cattet et al. 2003b), with higher rates of trauma and mortality (Arnemo et al. 2006; DelGiudice et al. 2001, 2005; Jacques et al. 2009; Webb et al. 2008). Also, injury and even death of humans are not uncommon during physical capture of wildlife (Jessup et al. 1988; López-Olvera et al. 2009). Jessup et al. (1988) reported that over a 12-year period, in New Zealand, there were 127 helicopter crashes and 25 human fatalities during net gun capture of red deer.

Physical restraint should be of short duration, and administration of sedatives or anesthetics are recommended to prevent or reduce distress (Arnemo et al. 2005; Cattet et al. 2004; Mentaberre et al. 2010). In free-ranging wolverines captured with a snare pole, followed by drug injection by hand, the muscular activity related to struggling resulted in similar lactate levels as in wolverines captured by darting from a helicopter (Fahlman et al. 2008). In most cases, chemical immobilization is probably less stressful for a wild animal than handling with physical restraint alone. Contrary to widespread belief, chemical immobilization from a helicopter is perhaps the least stressful capture method for a wide range of mammalian species. In most circumstances, the animal can be rapidly approached, darted, found, handled, and treated, minimizing stress and the risks of capture.

Helicopter Safety

Helicopters can be hazardous, and appropriate training and protective equipment, such as helmets, will help to minimize the risk of injury. Particular attention must be paid to the height of the rotor when entering and exiting the helicopter, especially when landing in

Figure 9.4. Even with lightweight, low velocity darts, impact can cause trauma. This photo shows dart impact trauma in a lynx.

uneven terrain or on hillsides. A harness that allows only enough room for the darter to attain the proper position is essential. Detailed reviews of helicopter safety are found in Nielsen (1999), Kock and Burroughs (2012) and Chapter 13.

ANIMAL SAFETY CONSIDERATIONS FOR REMOTE DRUG DELIVERY EQUIPMENT

Remote drug delivery systems have the potential to produce serious injury and death, if used inappropriately. The major sources of injury arise from dart impact trauma, high velocity injection of dart contents, and inaccurate dart placement. Dart impact trauma (Fig. 9.4) results from dispersion of energy on dart impact. Impact energy is represented by the following equation: $KE = 1/2M \times V^2$ where M = mass of the dart and V = velocity (Kreeger & Arnemo 2012). High velocity is the major factor resulting in trauma. To minimize trauma, use the lowest velocity that will result in an accurate trajectory at a given distance. Practice with a darting system at a variety of distances is vital to minimize velocity. The other major factor is the mass of the dart. Darts with a lower mass will have less impact energy. This should be a consideration in choice of a darting system, particularly in smaller animals that are more prone to trauma. Inaccurate dart placement can result in injury, most frequently if darts penetrate the abdomen, thorax (Fig. 9.5), or vital structures of the neck. The major factors that can lead to inaccurate dart placement are a lack of practice with the darting system, attempting dart placement over an excessive range, and inherent inaccuracy of the darting system. The final source of injury is related to high velocity injection of dart contents. Systems that expel drug via an explosive charge can produce severe tissue disruption

Figure 9.5. Poor dart placement results in a high risk of complications and injury, including pneumothorax.

and trauma (Cattet et al. 2006). These systems should only be used on large, well-muscled animals. Volume of injection should be minimized to decrease the degree of tissue trauma. When possible, darts that deliver their contents via compressed air should be used to minimize trauma. The choice of system depends on the range required, the drug volume used and thus the size of the dart, and individual characteristics of the target animal. A more complete review can be found in Bush (1992), Isaza (2007), Kreeger and Arnemo (2012) and Chapter 11.

COMPLICATIONS

Stress

Fear, chasing, physical restraint, and/or chemical immobilization of wild animals will elicit an acute stress response that may compromise the physiologic homeostasis of an animal and cause distress. The capture event, as well as the immobilizing drugs, influence the physiology and homeostasis of the animal. Muscular activity associated with chasing, excitement and resistance to handling results in lactic acid build-up and an increased body temperature. Increasing lactic acid levels lead to reduced blood pH and subsequent acidosis. Immobilizing drugs interfere with normal respiratory function and thermoregulation, and can lead to respiratory depression, acidosis, hypoxemia and hyperthermia. Blood levels of oxygen and carbon dioxide are closely related to, and affected by, acid-base balance and electrolyte concentrations. Minute changes in body temperature, respiratory patterns, and metabolic demands can alter this balance, resulting in neurological or myocardial dysfunction, multi-organ failure, capture myopathy, or acute mortality (Williams & Thorne 1996). See Chapter 12.

The time of intensive helicopter pursuit and the time of physical restraint should be minimized to decrease the risk of stress-related problems, including capture myopathy, hyperthermia, and trauma. The level of exertion the animal develops can be more important than the duration and distance of helicopter pursuit. In one report, ungulates that were chased rapidly over short distances develop a more severe acidemia compared with if they are run longer distances at slower speed (Harthoorn & van der Walt 1974). The extent of physical exertion may also be influenced by the conditions, including incline, altitude, snow depth, and ambient temperature.

In cases of acute distress, immediate reversal of immobilization and release of the animal should be considered unless effective treatment can be initiated. Emergency drugs including epinephrine, atropine, doxapram, local anesthetics, and reversal agents should always be carried. Fluids for i.v. treatment of shock or hypo- or hyperthermia should be available.

For translocations, administration of short- or long-acting tranquilizers is indicated to prevent distress (Ebedes 1993; Read et al. 2000; Read & McCorkell 2002). Fear is a potent stressor and following capture, a blindfold and earplugs should be used to decrease visual and auditory stimulation.

Induction

Dart placement is the most important determinant of induction time with quickest absorption occurring after injection in large muscle masses, such as the neck, shoulder, or hindquarters. Other factors that may influence induction time include the dose received, the animal's physical condition, age and sex, and its sensitivity to the immobilizing drugs. Animals that are excited or stressed can have induction times that are considerably longer than calm animals. As soon as the dart is placed, the time should be recorded and the animal must be carefully observed to ensure that it is not lost or injured during the induction period.

If a helicopter is used in pursuit, it must retreat so that the animal can be observed with less stress for the animal. The helicopter may need to steer an animal away from potential hazards, such as cliffs or open water.

Initial Assessment

Initial approach to an immobilized animal is a dangerous time. The animal should be observed from a safe distance to determine that there is no purposeful movement. When α_2 -adrenergic agonist-based protocols are used, for example, medetomidine-ketamine and xylazine-tiletamine-zolazepam, there should be no movement of the head or limbs prior to approach. If tiletamine-zolazepam alone or opioids are used, there may be some involuntary movement in adequately immobilized animals. The position of the animal

Figure 9.6. Using a pole to check that the bear is safely anesthetized before approaching.

should be observed from a distance to ensure that the position of the head and neck all ensure a patent airway. Respiratory movements can also be observed from a distance. Once it has been determined that the animal is safe to approach, the animal should be cautiously approached accompanied by a firearm backup if necessary. It is important to leave safe exits for the capture team and the animal. Auditory stimulation, such as clapping or shouting, should be employed as the animal is approached to gauge the animal's response. If there is no response to auditory stimulation, the response to tactile stimulation should be gauged. It is advisable to use a stick or pole to extend reach when stimulating the animal (Fig. 9.6). When it is safe, the palpebral reflex can be checked. A set of vital signs, including rectal temperature, respiratory rate, and heart rate, should be obtained. The eyes should be lubricated with an isotonic ophthalmic solution or gel, and a blindfold should be placed to decrease visual stimulation and to protect the cornea from dust and sunlight. Earplugs are useful to minimize auditory stimuli. At this point, hobbles may be considered to limit movement in the event of a sudden recovery.

Anesthetic Depth and Arousal

Depth of anesthesia should be closely monitored throughout the procedure. Factors that increase the risk of sudden arousal include loud noises (especially distress vocalization of young), movement of the animal or changes in the body position, or painful stimuli. Techniques for monitoring depth of anesthesia depend on the anesthetic agent. Tiletamine-zolazepam usually produces reliable anesthesia with predictable signs of recovery. As anesthesia lightens, spontaneous blinking will occur, with carnivores often developing chewing and paw movements. They will start to lift their head and may attempt to raise themselves with their forelimbs. Animals showing signs of recovery, including

spontaneous blinking, generally require a “top-up” unless they can be left to recover. The choice of drug depends on the length of the remaining procedures and depth of anesthesia needed. Tiletamine-zolazepam, ketamine, or medetomidine can be used, although top-up doses of tiletamine-zolazepam can significantly prolong recovery, and should only be used if >30 minutes of additional down time is required. Ketamine or medetomidine are drugs of choice if 5–20 minutes of additional time is needed. Top-up drugs can be given intramuscularly or intravenously, with intravenous drugs acting faster with shorter duration than intramuscular drugs.

Respiratory Depression and Hypoxemia

Hypoxemia is a common complication during wildlife anesthesia. Reasons for hypoxemia and respiratory depression, as well as treatment, are discussed in detail in Chapter 5.

Hyperthermia

Rectal temperature should be monitored throughout anesthesia. Most species are prone to hyperthermia. Causative factors include high ambient temperatures, excessive muscular exertion from prolonged pursuit, and interference with normal thermoregulatory mechanisms by anesthetic drugs. Symptoms include rapid, shallow breathing, panting, and weak, rapid, or irregular heart rate, and ultimately, convulsions and death. A rectal temperature of 40°C or 2–3°C greater than normal is cause for concern. Rectal temperatures in excess of 41°C are an emergency and should be treated aggressively. Treatment in the field can include moving the animal into shade, spraying with cold water, cooling in a lake or stream, fanning, packing ice or snow in the inguinal and axillary regions, cool intravenous fluids, and cold water enemas. It is difficult to actively cool large animals, and antagonism of anesthetic agents to allow the animal's normal thermoregulatory mechanisms to recover should be considered. Hyperthermia greatly increases metabolic oxygen demand, and in the face of hypoxemia, is a particularly serious complication. Hyperthermic animals should receive supplemental oxygen.

Intravenous administration of cool fluids can help to decrease body temperature even at low volumes (5–10 mL/kg, repeated if necessary). Hyperthermia may be prevented by avoiding immobilization or capture on very warm days or limiting activities to the coolest part of the day. Avoid prolonged intensive pursuit, keep stress to a minimum, and use the least stressful methods for physical restraint. Protect the animal from direct exposure to the sun.

Hypothermia

Hypothermia is a concern when animals are immobilized during low ambient temperatures, and in young

animals, animals with small body masses, and animals in poor body condition. Although body temperature is species specific, hypothermia in most mammals is characterized by a decrease in body temperature to below 35°C. If unchecked, it may result in prolonged recovery, acidosis, and arrhythmias. Causative factors of hypothermia include low ambient temperature, evaporative cooling from windchill, wetness, or precipitation and drugs that impair thermoregulation. Supportive procedures should begin when a declining trend in body temperature is noted and include an immediate attempt to increase body temperature by drying wet animals, covering the animal and providing external heat sources such as hot water bottles. Hypothermia may be prevented by avoiding immobilization or capture on very cold days. Protect the immobilized animal from low ambient temperatures and exposure to wind and precipitation. Keep it warm and dry by covering with blankets or a sleeping bag. Minimize conductive heat loss by maintaining the animal insulated from direct ground contact.

Vomiting and Regurgitation

Vomiting and regurgitation are emergencies in an immobilized animal. If inhalation of stomach contents occurs, aspiration pneumonia can result, requiring prolonged intensive care that usually is not possible for wild animals. In some species, vomiting is a common side effect of opioids and alpha-2 antagonists (Kreeger & Arnemo 2012). Animals should be positioned so that the nose is sloping downwards from the back of the head to decrease the risk of inhaling regurgitated materials. If vomiting occurs in smaller moveable animals, the animal should be placed in sternal recumbency with the head pointed downwards. A long-acting broad-spectrum antibiotic should be considered for animals showing signs of aspiration, such as witnessed aspiration events, rumen contents on the nose, or harsh lung sounds.

Bloat

Bloat during wildlife capture is usually caused by lateral recumbency or by rumenal atony following administration of alpha₂-adrenergic agonists. Ruminants should be positioned in sternal recumbency to reduce the risk of rumenal tympany. Tympany results from the inability to relieve gases from the rumen or stomach through eructation. Supportive treatment consists of placing the immobilized animal in sternal recumbency with the neck extended and the head forward, permitting saliva to drain. Move the animal from side to side over the brisket and elevate the front quarters of smaller animals. If positioning does not relieve the bloat, insert a lubricated and properly sized tube via the esophagus into the rumen to relieve pressure. Generally, in animals immobilized with alpha₂-adrenergic agonists, bloat will resolve following the administration of an alpha-2

antagonist. In the face of severe bloat, procedures should be completed, and the immobilization should be reversed. The last resort is trocharization of the rumen using a large bore (12.5 g or 2.5 mm), long (2.4–3.1" or 60–80mm) needle.

Trauma

During the process of immobilization and capture, physical injuries, such as contusions, lacerations, abrasions, punctures, and fractures, may be inflicted on the animal accidentally or as a result of mishandling. Minor lacerations may be flushed, cleaned, and protected with an insect repellent. An appropriate long-acting antibiotic may be given to help prevent infection. Closure may be considered for large lacerations; they should be flushed copiously, cleaned, and debrided. These lacerations are often contaminated, and if they are closed, appropriate drainage must be considered in the closure. Fractures and other serious conditions are difficult to treat effectively and will often require that the animal be euthanized for humane reasons.

Physical trauma may be prevented by taking notice of any hazard in the environment that may cause injury to the animal during capture and by careful handling. If traps, snares, nets, or other forms of manual capture or restraint are used, they should be appropriate for the species, and set by well-trained individuals.

Pneumothorax

An uncommon cause of hypoxemia includes pneumothorax. Dart penetration of the thoracic cavity can result in pneumothorax. It may be possible to treat pneumothorax with thoracocentesis. Equipment should be carried to perform thoracocentesis in the field. See Sigrist (2008) for instructions on thoracocentesis.

Myopathy

Most free-ranging, wild animals exert themselves only infrequently to escape danger. They are not conditioned for running hard over long distances. Chasing wild animals by helicopter or motor vehicle for capture causes a tremendous amount of stress, resulting in intensive muscular activity. The effects of sympathetic exhaustion from sustained stress, combined with intense muscular exertion, are causative factors of various life-threatening syndromes, known as *exertional myopathy* (Paterson 2007; Spraker 1993; Williams & Thorne 1996); see Chapter 15.

Exertional myopathy is difficult to treat and prevention is of utmost importance. Capture myopathy may be prevented by reducing capture stress, fear, and exertion (by limiting chasing time), minimizing visual and auditory stimulation, handling, and restraint of the captured animal and by providing a stress-free recovery environment. More details and treatment options are presented in Chapter 12.

Recovery

Considerations for recovery will vary depending on the choice of drug and the situation. In most situations, reversible drugs are desirable. If reversible drugs are not used, the animal should be observed until it is able to ambulate, to protect itself from other animals, and to avoid environmental hazards. Prior to reversal, equipment should be removed from the capture site. The animal should be placed in a suitable position and the airway should be clear. Typically, one person should remain with the animal to administer the reversal drug and thereafter retreat to a safe distance to observe the animal's recovery. Antagonists should be administered IM unless there is an immediate need for rapid recovery.

Environmental factors during recovery are critical and expected recovery times must be considered. Before reversal agents are given, animals should be placed away from hazards, such as cliffs or open water. They should also be placed out of the wind and sun. In species that move a lot during recovery, such as wolves immobilized with tiletamine-zolazepam, capture personnel should remain at the site to steer the animal away from hazards.

Mortalities

Typically, the highest mortality rates are seen in the early stages of a project; before capture methods are refined, drug doses are adjusted and the immobilization team has gained adequate experience and training. Moreover, an increased risk of mortality may also be seen when captures are carried out for specific purposes, such as health evaluation of animals under environmental or pathogenic stress. Mortalities caused by capture and anesthesia of free-ranging mammals can be grouped into three categories: (1) direct effects of the immobilizing drug, for example, respiratory depression, shock, hyperthermia, and asphyxia due to tympany or vomiting. (2) Indirect effects, for example, drowning during induction or recovery, pneumothorax due to misplacement of darts, and trauma from dart impact. Such mortalities might be a direct consequence of the drug used, for example, etorphine often induces hyperthermia, and this may cause the animal to actively seek water for cooling, with drowning as a possible sequela. (3) Secondary effects caused by the capture process, for example, trauma from traps, long-term effects from chasing or stress (exertional myopathy), separation of dam-offspring, and various problems with radiocollars or implantable transmitters. The secondary effects, however, have nothing to do with the anesthetic risk *per se* and should be treated as a separate entity.

A mortality rate greater than 2% during chemical immobilization is unacceptable for any mammalian species and requires that the anesthetic protocol be reevaluated (Arnemo et al. 2006). By using immobilizing

drugs and doses with proven safety, proper remote drug delivery systems, and established capture methods and techniques, a skilled and experienced capture team will minimize the risk of anesthetic mortality.

In the event of mortalities, the situation should be evaluated to assess the cause of the mortality and future preventative measures. A necropsy should be performed either on-site, or the animal should be sent to a diagnostic laboratory. The necropsy can be helpful for determining if the animal was abnormal or if a healthy animal died under anesthesia.

Euthanasia

Equipment or drugs for humane euthanasia should always be carried during animal captures. The method of euthanasia depends on the situation and species. In many countries, the veterinarian is legally responsible for the death of animals, including endangered species, that eat a euthanized carcass. If firearms or bolt guns are used (recommended if the meat will be salvaged), personnel must be trained in the use of the firearms and the appropriate bullet/bolt placement.

CONCLUSION

A thorough understanding of the inherent risks associated with animal capture is indispensable for prevention of capture-related injuries. Careful planning, close monitoring, and early intervention are essential for preventing morbidity and mortality.

10 Euthanasia

Murray Woodbury

INTRODUCTION

Euthanasia is the act of humanely causing the death of an animal. To be considered euthanasia rather than just the termination of a life, the act must minimize any pain, distress, or anxiety experienced by the animal prior to its death. An ideal euthanasia technique would induce a very rapid loss of consciousness in the animal followed by cardiac and respiratory arrest and the loss of brain function (American Veterinary Medical Association [AVMA] 2013). The method would also be reliable, irreversible, and relatively safe for the operator. This ideal method, and indeed many of the recommended techniques for domestic and laboratory animals, are usually not possible in the zoo or under field conditions where many of the factors involved with euthanasia are not well controlled. Under these circumstances, the taking of an animal's life is more often humane killing rather than euthanasia. In zoos and wildlife environments, consideration for factors such as degree of control over the animal, operator and public safety, species peculiarities, and carcass disposal may result in some unavoidable pain and anxiety associated with a rapid and efficient death.

Wildlife and zoo veterinarians and any other person involved with animal research or management are ultimately responsible for the animals under their influence and should be prepared for the possibility of euthanasia in irreversibly diseased or injured animals. They should be familiar with the available techniques for the species and obtain and prepare the required materials and equipment in advance so that correct euthanasia is possible if necessary. Persons actually performing euthanasia should have the appropriate training and experience to ensure that pain and distress are minimized during the procedure.

CONSIDERATIONS FOR WILDLIFE AND ZOO SPECIES

The primary consideration should be providing a quick and painless death whenever possible. In wildlife and zoo situations where the animal is not well confined or restrained, this sometimes means the use of an appropriate caliber firearm to inflict a fatal wound. In free-ranging animals, a fatal headshot may be difficult to accomplish and accidental injury to the animal or an unintended target may be the result. A shot to the heart and lungs is more easily achieved and requires less skill from the operator. Death in this case is not as rapid but it is much more certain under free-ranging conditions (Canadian Council on Animal Care [CCAC] 2003). In other situations, whenever possible the chosen method or combination of methods should involve the use of a chemical or physical technique that first depresses the central nervous system to ensure immediate insensitivity to pain and relief from distress, fear, and apprehension, followed by the irreversible arrest of the animal's respiratory and cardiac function and subsequent brain death.

The practical problems associated with disposal of one large or several individual euthanized animals and the environmental risks posed to animal scavengers or humans in contact with a carcass euthanized with toxic chemicals must also be considered. Incineration, burial, or adulteration of the carcass with quick lime are acceptable but not always possible especially with megavertebrates or marine mammals. A chemical-free euthanasia protocol should be used where carcass disposal is not practical or possible.

Consideration should be given to the collection of postmortem samples for diagnostic or research purposes. Where animals are sacrificed for scientific study or disease surveillance the method of euthanasia should

not destroy the tissues or organs of interest. For instance, a gunshot to the brain is not appropriate where animals are to be tested for rabies or other central nervous system diseases.

Methods

The choice of a suitable method of euthanasia depends on the species, size, weight, and behavioral characteristics of the animal. The type of restraint possible, the facilities and equipment available, the number and skill of assisting personnel, and the risks involved should be considered. Economics and the number of animals to euthanatize can also affect the decision.

Literature specific to the species of interest should be consulted when planning euthanasia or activities that could result in euthanasia. Detailed recommendations for euthanasia can be found in the 2013 Guidelines on Euthanasia (formerly the Report of the AVMA Panel on Euthanasia) (AVMA 2013) and the Guidelines on Euthanasia of Nondomestic Animals (American Association of Zoo Veterinarians [AAZV] 2006). Much of the information in this chapter is derived from these sources.

Depending on the chosen method of euthanasia, death results from hypoxia, central nervous system depression, physical damage to the brain, or a combination of these mechanisms. The means of inducing these changes can be chemical, physical, or electrical (Table 10.1). Current guidelines on euthanasia (AVMA 2013) classify methods as acceptable, conditionally acceptable, or generally unacceptable. Conditionally accepted methods are those that may be acceptable for emergen-

cies, or unplanned euthanasia, where rapid killing rather than true euthanasia is achieved. Some unacceptable methods may become acceptable when used in euthanasia protocols where deep anesthesia is provided prior to using the method. Such combined methods are called two-stage protocols, and are especially important when animals cannot be adequately restrained to receive primary methods, such as intravenous euthanasia drugs or a precisely applied physical means of euthanasia. The first stage generally renders the animal unconscious so that it can be approached or humanely restrained for a lethal secondary procedure.

The use of immobilizing drugs followed by a chemical or physical method of euthanasia should be considered to gain control over the movements of free-ranging animals or when close restraint is either too stressful or impossible to achieve in a zoo setting. Immobilizing doses of sedative drugs, usually delivered by a dart gun or blow pipe, can be used to induce a rapid loss of consciousness, permitting the operator direct contact with the animal to subsequently administer suitable chemical or physical euthanasia. An important historical exception to this sequence is when succinylcholine is used as the immobilant drug (Schwartz et al. 1997). Succinylcholine rapidly induces paralysis but offers no analgesia or relief from distress or anxiety and its use as a primary method for euthanasia is not acceptable. In the past, it has been used in free-ranging wildlife because of its rapid onset and the relatively low risk posed from drug residues in the euthanatized animal (AVMA 2013). However, it is imperative to reach the paralyzed animal

Method	Primary Method for These Species	Secondary Method for These Species	Comments
Inhalant agents			
Volatile anesthetic agents		Amphibians, reptiles, small and medium mammals, hoofstock	Requires a follow up method to ensure death. Not generally suitable in the field or for species that breath hold or having low respiratory rates.
Carbon dioxide		Amphibians, reptiles, small and medium mammals, hoofstock	Concentration of CO ₂ must be >40% of inspired air. Can be used to render food animals unconscious but not generally recommended for euthanasia.
Carbon monoxide		Reptiles, small and medium mammals, hoofstock	Concentrations >10% in air are explosive. Odorless gas is toxic to humans and generally not used for safety reasons.
Nitrogen, argon		Small and medium mammals	Generally safe for operator. Motor activity continues until death which can be disturbing to viewers.
Chemical agents			
Barbiturates	All species		Ideal for most species but in amphibians and reptiles a secondary physical method is recommended. Creates carcass disposal problems from secondary toxicity. A controlled drug needing accounting.
T-61	All species		Mixture of three drugs. Must be used IV. Not a smooth as barbiturates. Not available in all countries.
Tricaine methanesulfonate (MS-222), Benzocaine HCl	Fish, amphibians		Leave animal in water bath for >10 minutes after resp. ceases. Requires buffering and disposal. Follow-up method needed to ensure death.

Table 10.1. (Continued)

Method	Primary Method for These Species	Secondary Method for These Species	Comments
Potassium chloride		Amphibians, small and medium mammals, hoofstock, and megavertebrates	Give by IV or intracardiac injection. Use only on anesthetized animals.
Neuromuscular blockers (succinylcholine, gallamine)		Reptiles, medium mammals, hoofstock, and megavertebrates	Unsuitable method for primary euthanasia but in limited circumstances might be useful for initial immobilization if followed rapidly by acceptable method.
Formalin, alcohols		Amphibians, small reptiles	Prior anesthesia needed. Very small animals only.
Physical methods			
Gunshot to the head or cervical neck	Unrestrained medium sized mammals, hoofstock, and megavertebrates	Large reptiles, small and medium mammals	Appropriate for free ranging animals in secluded areas or as secondary method. Requires operator training and skill. Safety concerns for unintended targets.
Stunning (concussion or electric)		Amphibians, reptiles, small mammals	Generally used in emergency situations when no other means available. Should be followed by a secondary method, for example, exsanguination.
Penetrating captive bolt to the head	Restrained hoofstock	Hoofstock	Adequate restraint or anesthesia needed prior to use. Operator training, skill, and specialized equipment needed.
Cervical dislocation		Small mammals	Small animals only (<200 g). Prior anesthesia recommended
Pithing		Amphibians, reptiles	Prior anesthesia needed. Generally used as a secondary method.
Decapitation		Amphibians, reptiles, small mammals	Prior anesthesia needed. Generally used as a secondary method.
Thoracic compression		Amphibians, reptiles	Not suitable for animals with a diaphragm
Exsanguination		Amphibians, reptiles, small and medium mammals, and megavertebrates	Not a primary method of euthanasia. Useful as a secondary method or confirmation of death.
Hypothermia/rapid freezing		Amphibians, small reptiles, small mammals	Prior anesthesia needed.
Kill traps		Small and medium mammals	Not acceptable in most applications
Maceration	Chicks, very young poultry		Requires special equipment. Birds must be delivered to the macerator without causing injury or distress
Explosives		Megavertebrates	Generally not recommended except when no other means available.

as quickly as possible to render it unconscious and insensitive using a secondary method such as a gunshot or penetrating captive bolt to the head. In the case of free-ranging animals, such rapid acquisition of the target animal is usually not possible, and a lethal gunshot should be used as the primary method. In zoo situations, alternate drugs for rendering animals insensible are available, making succinylcholine an obsolete and unacceptable drug for use in euthanasia protocols.

Assessing Death

Verification of death is important for ethical and safety reasons. Animals that recover from attempts at euthanasia can harm nearby personnel through violent physical struggle or defensive acts. Assessing whether death has occurred is especially important when

euthanatizing potentially dangerous animals and animals that can withstand long periods of anoxia. It is essential that personnel involved with euthanasia be trained to confirm death in the species of concern.

Signs of death include absence of breathing movements, absence of a pulse or a heart beat, discolored mucous membranes with no capillary refill, dilated and fixed pupils, and loss of the corneal reflex. Since none of these signs is universally consistent across species, a physical method of euthanasia such as decapitation or exsanguination should be used as a final step if there is any doubt that death has occurred.

Specific Recommendations

Birds The method most often recommended for birds is the parenteral administration of sodium pentobarbital,

preferably intravenously. Exposure to carbon dioxide gas is conditionally acceptable and, which can be used for euthanasia of large numbers of birds. It is also the only chemical method useful for birds intended as food. An overdose of inhalant anesthetics, such as halothane, isoflurane, and sevoflurane, is also conditionally acceptable but should be followed by a method that precludes recovery. Cervical dislocation, stunning, decapitation, or methods causing destruction of the brain, such as gunshot to the head or penetrating captive bolt, are all conditionally acceptable. Methods that are generally unacceptable for birds include potassium chloride injection, thoracic compression, exsanguination, and induction of hypothermia or rapid freezing in liquid nitrogen or dry ice. Where eggs with less than 50% of incubation time are involved, addling (shaking), puncture, freezing, or coating the shell with oil are suitable means.

Amphibians and Reptiles Euthanasia of amphibians is facilitated by their ability to absorb anesthetic drugs through their skin, making immersion in solutions of tricaine methanesulfonate (MS-222) or benzocaine HCl the recommended primary method in these species. Secondary methods such as decapitation, cervical dislocation, or exsanguination should always follow. Electrical or concussive means of stunning followed by decapitation can be conditionally acceptable in circumstances where other methods are not available. Methods that are unacceptable as the sole means of euthanasia include injection of potassium chloride, pithing, exsanguination, and induction of hypothermia or rapid freezing by immersion in liquid nitrogen or dry ice.

Parenteral injection of sodium pentobarbital is recommended as a stand-alone method for both amphibians and reptile species. Conditional chemical methods include inhalation of carbon dioxide gas or fluoridated gas anesthetics, such as halothane. Other conditional means are concussive stunning, decapitation followed by pithing, cervical dislocation, and for species such as crocodilians, captive bolt penetration of the brain. Immersion of smaller reptile species in formalin, formaldehyde, or ethanol is not acceptable without prior deep anesthesia. Potassium chloride injection, carbon monoxide asphyxia, and the use of neuromuscular blockers, such as succinylcholine or gallamine, without prior general anesthesia is unacceptable. Pithing, exsanguination, hypothermia from ice packing and rapid freezing with liquid nitrogen or dry ice are unacceptable except where they are used in a two-stage protocol.

Small- and Medium-Sized Mammals The method most often recommended is sodium pentobarbital injection, preferably intravenously, but also via intracardiac and intraperitoneal routes under some circumstances. Inhalation anesthetics, such as halothane, isoflurane, and sevoflurane, as well as carbon dioxide gas, are condi-

tionally acceptable in small mammals provided another method, usually physical, is used to ensure the termination of life. Physical methods, such as cervical dislocation or decapitation in smaller species, and gunshot or penetrating captive bolt to the head, can be used in medium-sized mammals that are under general anesthesia at the time. Thoracic compression is not suitable in mammals because of the presence of a diaphragm, nor is the induction of hypothermia by refrigerator, refrigerated water, or ice. Rapid freezing with liquid nitrogen is only appropriate for very small mammals already under general anesthesia or newborns and fetuses less than 4g. Administration of gaseous carbon dioxide, carbon monoxide, argon, or nitrogen is generally unacceptable unless preceded by general anesthesia. Neuromuscular blockade by drugs, such as succinylcholine, is not appropriate as a sole method of euthanasia, but can be used in some circumstances as chemical restraint in a two-stage procedure when followed rapidly by a suitable means of humane killing so that asphyxia and distress are minimized.

Hoofstock In addition to the generally recommended sodium pentobarbital injection, which can be expensive in large animals, administration of a penetrating captive bolt to the brain followed by exsanguination is a recommended method for euthanasia of hoofstock. However, both methods require adequate restraint and close contact with the animal to be effective. Remote delivery of drugs inducing general anesthesia followed by performance of the earlier methods on an immobilized animal is often best. Succinylcholine has been used in some circumstances as a chemical restraint drug in two-stage procedures followed by rapid killing so that asphyxia and animal distress are minimized. However, succinylcholine is not appropriate as a routine immobilizing agent or the sole method of euthanasia. This drug does not render animals unconscious or provide any physical or emotional pain relief. Its use without adjunct drugs or procedures is inhumane and therefore unacceptable (AVMA 2013).

Conditionally acceptable methods applied to hoofstock theoretically include lethal administration of gas anesthetic agents, such as halothane or isoflurane and gunshot to the head or cervical spine region. The latter method, although useful in situations where hands-on methods are not possible, requires operator skill and experience and a suitable firearm and ammunition. Administration of carbon monoxide gas, intravascular or intracardiac potassium chloride solution, or exsanguination are not acceptable without prior general anesthesia.

Megavertebrates and Marine Animals Injection of sodium pentobarbital, although also ideal in these species, requires adequate restraint and large, costly volumes of drug. Prior administration of general

anesthesia-inducing drugs such as potent narcotics can facilitate euthanasia with barbiturate. Penetrating captive bolt guns are generally ineffective in such large animals. Gunshot to the head or cervical region of large terrestrial species like elephants and rhinoceros can be appropriate as the sole means of humane killing in some emergency situations and at some locations, but is much less effective with large species such as whales. Explosives have been used to euthanatize beached whales but this method is generally not recommended because of the high level of expertise required and the inherent danger to personnel. Exsanguination is usually acceptable only when used secondary to a procedure that first renders the animal insensible.

SUMMARY

The best method of euthanasia for most captive and free ranging wildlife involves the use of two-stage protocols where the animal is first rendered insensible and then its life is terminated by some efficient and irrevers-

ible means. In those situations, where immediacy and urgency dictate that a more direct method be employed, especially for medium to large species, the use of a firearm is often the quickest and most practical way to humanely end an animal's life under the prevailing circumstances.

Remote Drug Delivery

Ramiro Isaza

INTRODUCTION

Practitioners of zoological medicine need to effectively and safely administer anesthetic drugs to nondomestic species. Prior to the development of effective anesthetics and remote delivery systems, veterinary procedures on nondomestic species were either impossible to accomplish or associated with unacceptably high mortality rates. This chapter examines the methods of anesthetic drug delivery with an emphasis on the commercial equipment available to the practitioner in North America.

DIRECT DELIVERY FOR COOPERATIVE ANIMALS

Training for Direct Drug Administration

The technique a clinician selects to administer anesthetic drugs to an animal depends largely on whether or not the animal is cooperative during the preinduction period. Often, the clinician assumes that most nondomestic species are either uncooperative or too dangerous to use traditional routes of drug administration. However, many nondomestic species can be behaviorally restrained following proper training and will often allow the veterinarian to perform a routine physical exam or administer medications on a regular basis. Animals trained for voluntary behavioral restraint are usually well socialized and taught to accept human manipulation. Intramuscular and even intravenous injections can be administered in the same manner as one would treat a domestic animal. For example, a chimpanzee can be trained to place its arm through the cage bars to receive intramuscular injections rather than be subjected to a darting. The more extreme examples are well-trained elephants or whales that permit direct manipulation despite their overwhelming size.

In other nondomestic species, various combinations of mechanical restraints and behavioral training are viable options (see Chapter 8). With proper techniques and safety precautions, manual restraint of smaller nondomestic species for direct-drug administration is often possible. Various mechanical restraint devices, such as horse stanchions or cattle chutes, typically associated with domestic hoofstock, can be adapted for the treatment of nondomestic species (Haigh 1999). An example includes teaching a giraffe or rhinoceros to walk through and stand in a chute for daily physical exams and routine treatments (Fig. 11.1). Once restrained, the animals can be induced with injectable agents or inhalant anesthetics.

In order for any of these methods of direct drug administration to succeed, prior training of the nondomestic animal is critical. Attempting to restrain an animal in an unfamiliar environment for direct drug administration is often unsuccessful, stressful, and dangerous for both the animal and the staff. Consultation with professional trainers and a clearly defined set of target behaviors needed for drug administration is the first step in the process. The trainer's relationship and trust with the animal should not be underestimated. Often an animal will refuse medication offered by a stranger yet will subsequently accept the same medication if presented by the trainer. Effective training prior to the anesthetic procedure can reduce the stress associated with anesthesia and increases the likelihood of compliance.

When feasible, behavioral training and restraint are usually less stressful to the animal, but the veterinarian must be aware of the limitations of this situation. Quiet, well-trained animals may become dangerous if placed in unfamiliar environments such as hospitals, or if given unexpected painful stimulations such as

Figure 11.1. Mechanical restraint of a giraffe using a chute.

injections. For example, having the anesthetic procedures begin in the animal's regular enclosure with its usual handler will often facilitate induction.

Manual Drug Delivery Routes for Cooperative Animals

Oral The use of oral anesthetics is occasionally useful in zoological medicine. Some induction agents can be simply sprayed into the oral cavity or placed inside a food item that is then offered to the animal. Oral administration of various anesthetics has been accomplished using pineapple juice, maple syrup, peanut butter, marshmallows, and honey (Thurmon et al. 1996). Oral carfentanil was administered to chimpanzees, tapirs, and bears trans-mucosally by mixing the injectable formulation of the drug into food (Kearns et al. 2000; Mortenson & Bechert 2001; Pollock & Ramsay 2003). The transmucosal formulation of fentanyl was evaluated for use as part of a preanesthetic protocol in great apes (Hunter et al. 2004). Wild animals can be baited with medicated food that is placed in traps or spread out on the ground. One example is the use of oral alpha-chloralose to capture birds (Hayes et al. 2003; Loibl et al. 1988). In situations where animals aggressively open their mouths when provoked, injectable anesthetics can be sprayed into the mouth or the nose for mucosal absorption (Grove & Ramsay 2000). In practice, all of these methods of oral administration are difficult to apply consistently as they require some measure of voluntary cooperation. Also, because the drug needs to be absorbed through the oral or nasal

mucosa, it must remain in contact with the mucosa and not swallowed. Generally, the inductions are prolonged and often unpredictable, but may occasionally work as pre-induction sedation.

Hand-Held Injection Hand injection is the most direct method of administering induction agents to an animal. It usually requires either exceptionally cooperative behavior or restraint for proper placement. For an effective intramuscular injection, even a restrained animal must be approached quietly and given the injection quickly.

The process of administering a hand injection generally involves the following steps:

1. A plastic disposable syringe with Leur-lock hub is selected to avoid needle detachment.
2. A large-gauge needle is selected to prevent breaking the needle during injection and allow fast deposition of the drug.
3. Double check that the needle is firmly attached to the syringe hub.
4. The syringe is loaded with an appropriate dose of the drug.
5. The filled syringe is then grasped between the index and the middle finger with the thumb over the plunger.
6. The injection site is selected.
7. A proper injection technique requires a quick flick of the wrist so that the plunger is pressed as the needle begins to penetrate the skin.

Slower placement of the drug, with aspiration prior to injection, will rarely succeed in unrestrained nondomestic species. The hand injection method of drug administration is considered dangerous for the person injecting the anesthetic. Trauma from bite wounds, kicks, and crushing injuries are common. Of equal concern is the possibility for self-injection subsequent to the animal's sudden movements or exposure to aerosol sprays from a broken syringe. Hand administration of potent narcotics such as carfentanil is therefore not recommended.

Pole Syringes A Pole syringe is essentially a hand injection with the added safety of a long pole. They were primarily developed for use in chute, cage, or trap-restrained animals. This allows the operator to avoid some of the potential trauma associated with direct hand injections. This added safety is, however, at the expense of control of the injection process. Poorly restrained animals invariably react to the needle by moving away or attacking prior to full injection. Similar to the hand injection, the technique requires a quick delivery through a large-gauge needle (14–18g). The needle is inserted in a large muscle, and then the pole is held in position until the drug is deposited.

Three types of pole syringes are available. The manual pressure pole syringe is a typical syringe body with an extended plunger to provide extra length. Once inserted, the plunger is pushed against the resistance of the animal's body. In the second type, the extension pole is attached to the body of the syringe with a second internal extension of the syringe plunger that is manually depressed to deposit the drug. The final type has a mechanism that has a spring or pressurized gas loaded plunger that is triggered when the needle presses on the skin. Although considered safer than hand injection, animals may still react to the needle and cause injury by moving or misdirecting the pole syringe.

REMOTE DELIVERY SYSTEMS FOR UNCOOPERATIVE ANIMALS

Unfortunately, in zoological medicine, many anesthetic procedures are performed on uncooperative animals for a variety of reasons. Animals that are not acclimated to human contact generally become agitated and aggressive when approached. This occurs in free-living species or in many captive animals, where routine direct human contact is discouraged. Some species, such as large carnivores or hoofstock, pose significant inherent risks to the veterinarians and keepers that preclude the possibility of using behavioral or physical restraint. Even in cooperative or human-habituated animals, trained behavior can significantly change due to illness or pain so that the training no longer helps facilitate direct anesthetic drug delivery methods (Fig. 11.2).

When injectable anesthetic agents are used in unrestrained nondomestic species, a remote delivery system consisting of a dart and projector is often the most practical option. Darts can be projected via a blowpipe, compressed air projector, or gunpowder cartridge rifle that will be discussed later (Bush 1992). All darts have

Figure 11.2. Use of a blowpipe for short range injection of a white rhinoceros that would react if hand injected.

four basic components: a drug storage compartment, a method of injecting the drug, a needle to penetrate the skin, and a stabilizer for accurate flight. The commercially available darts differ in their methods of drug expulsion, materials used in their construction, drug payload volumes, and dart attachments, such as the needle or tail. For this chapter, the method of drug delivery will be used to distinguish the darting systems.

Several homemade dart and projector systems have been described in previous literature (Barnard & Dobbs 1980; Haigh & Hopf 1976; Lochmiller & Grant 1983; Warren et al. 1979). This description and discussion of equipment will be limited to those drug delivery systems that are commercially available. The choice of delivery system is subject to the clinician's preferences, needs, or experience, but most commercial systems can be very effective when used by experienced operators. The similarity between available equipment systems allows some interchange of components that can be configured to meet the clinician's specific preferences. However, this interchangeability can also make using these products confusing when mixed together, and may lead to dart failure caused by subtle differences in the darting systems. Generally, it is recommended that one system be purchased, as the manufacturers have developed product lines that are effective and reliable when used as designed.

Historical Development of Remote Delivery Systems

The remote delivery of drugs was first used by indigenous hunters with poison tipped projectiles (Bush 1992; Nielsen 1999). Plant extracts containing curare were used by pre-Columbian South American Indians to produce effective neuromuscular blockage and muscle paralysis in animals. When these poison tipped darts are projected with long blowpipes they could be delivered by experienced hunters with extraordinary precision and with lethal effect. As the purpose of these hunters was to kill, the precision dosage delivery and margin of safety were not important considerations.

Until the second half of the twentieth century, zoological collections relied on manual restraint as the primary means of administering veterinary care. These restraints were dangerous for both the humans and the animals, often resulting in stress, injury, and occasional animal mortalities. In the mid-1950s a remote delivery device was described in the literature (Hall et al. 1953). It consisted of a metal drill bit with a gallamine and glucose paste packed into the grooves. The bit was attached to a dart and delivered with a Crossman air gun. Once the animal was paralyzed and the procedure completed, the gallamine was reversed. Although effective, the paste was absorbed slowly, and therefore, a flying syringe was developed to deliver liquid injections (Crockford et al. 1958). This aluminum dart used an acid base reaction to inject the drug. After extensive

modifications and improvements to this dart, it became the prototype for many of the modern darts in use today (Bush 1992). Around the same time, Colin Murdoch, a veterinarian and inventor from New Zealand, also developed a series of darts and projectors that became Paxarms. Subsequently, plastic two-chambered gas darts were introduced to zoological

medicine and developed into several commercial darting systems (Bush 1992). For further details, several authors have reviewed the development of darting equipment over the past 40 years (Bush 1992; Fowler 1995; Fritsch 1982; Harthoorn 1976; Nielsen 1999). A listing of currently available darts and delivery systems can be found in Table 11.1.

Table 11.1. Description of currently available darts by manufacturer

Manufacturer and Dart Description	Dart Type	Payload Volume (mL)	Dart Diameter (mm)	Needle Sizes (mm)	Tailpieces	Recommended Projector
Dan-Inject blow dart syringe	2 chamber	1.5, 3	11.8	1.1 × 25 or 1.2 × 38	Orange cloth	12-mm Dan-Inject 1.23 or 1.8-m (2-piece) blowpipe
Telinject blow dart syringe	2 chamber	1, 2	9.5	0.9 × 25 to 1.2 × 38 (3 gauges and 4 lengths)	Yellow cloth	10-mm Telinject 1 or 2-m blowpipe
Telinject blow dart syringe	2 chamber	1, 2, 3	10.8	0.9 × 25 to 1.2 × 38 (3 gauges and 4 lengths)	Orange cloth	11-mm Telinject 1 or 2-m blowpipe
Telinject blow dart syringe	2 chamber	5	14.0	0.9 × 25 to 1.2 × 38 (3 gauges and 4 lengths)	Red with yellow cloth or plastic tailpiece	14.5 Telinject 2.2-m high performance blowpipe
Dist-Inject mini-ject "softy" blow dart syringe	2 chamber	3.8	10.8	1.1 × 25 or 1.2 × 35	Red cloth	11-mm mini-ject 0.9-m blowpipe
Maxi-Ject veterinary syringe dart	2 chamber	1, 2	9.7	1.9 × 25 or 1.2 × 38	Yellow cloth	10mm maxi-ject 2 piece 1-m blowpipe
Maxi-Ject veterinary syringe dart	2 chamber	3	10.7	1.9 × 25 or 1.2 × 38	Red cloth	11-mm maxi-ject 2 piece 1-m blowpipe
Maxi-Ject veterinary syringe dart	2 chamber	5	13.7	1.2 × 38	Red with yellow cloth	14mm maxi-ject 2-piece 1-m blowpipe
TeleDart veterinary syringe dart	2 chamber	1, 2, 3	10.7	0.9 × 25 to 1.2 × 38 (3 gauges and 4 lengths)	Pink Cloth with yellow base	11-mm B11 or B16 blowpipe
Telinject "Vario" molded plastic syringe	2 chamber	1, 3	10.8	1.5 × 20 to 2.0 × 60 (2 gauges and 8 lengths)	Red cloth	11-mm Telinject Vario pistol or rifles
Telinject "Vario" molded plastic syringe	2 chamber	5, 10, 15, 20	12.2	1.5 × 20 to 2.0 × 60 (2 gauges and 8 lengths)	Red with yellow cloth	13-mm Telinject Vario pistol or rifles
Dan-Inject "S" series molded plastic syringe	2 chamber	1.5, 3	10.7	1.5 × 20 or 2.0 × 100	Red cloth	11-mm Dan-Inject model PI pistol or JM/IM injection rifles
Dan-Inject "S" series molded plastic syringe	2 chamber	5, 10	12	1.5 × 20 or 2.0 × 100	Red with white cloth	13-mm Dan-Inject model PI pistol or JM/IM injection rifles
Dist-Inject "mini-ject 2000" molded plastic syringe	2 chamber	3, 5	10.8	1.1 × 25 or 1.2 × 35	Red cloth	11-mm model 45 delta pneumatic 0.35-m blowpipes, or model 70 rifle with 11 barrel insert
Dist-Inject "mini-ject easy" molded plastic syringe	2 chamber	3, 5	10.8	1.1 × 25 or 1.2 × 35	Orange and yellow fins	11-mm model 45 delta pneumatic 0.35-m blowpipes

Manufacturer and Dart Description	Dart Type	Payload Volume (mL)	Dart Diameter (mm)	Needle Sizes (mm)	Tailpieces	Recommended Projector
TeleDart "TD" veterinary syringe dart	2 chamber	1, 2, 3, 5	10.8	1.5 × 20 to 2.0 × 60 (2 gauges and 8 lengths)	Pink with yellow cloth with red base	11-mm model RD206 TeleDart injection pistol or model RD706 TeleDart injection gun
Palmer Cap-Chur aluminum "Air inject" syringe	2 chamber	1, 2, 3, 4, 5	12.5	2.5 × 19 to 2.5 × 38 (11 lengths) (side port with nose plug)	Tetra plastic tail	12.7 Palmer Cap-Chur short, mid, and long range CO ₂ projectors
Dist-Inject "mini-ject unic" molded plastic syringe	Chemical	3, 5	10.8	1.1 × 25 or 1.2 × 35	Red cloth	11-mm barrel insert in model 70 or 50 rifles
Pneu-Dart "P" aluminum dart	Explosive	0.5, 1	12.5	2.0 × 6 to 2.0 × 50 (7 lengths)	Yellow plastic	12.7-mm Blo-Jector blowpipe
Pneu-Dart "P" aluminum dart	Explosive	0.5, 1, 1.5, 2, 3, 4, 5, 6, 7, 8, 10	12.5	2.0 × 6 to 2.0 × 50 (7 lengths)	Yellow plastic	12.7-mm Oplus-XT gauged CO ₂ /pistol, or model 178B air rifle
Pneu-Dart "C" aluminum l dart	Explosive	0.5, 1, 1.5, 2, 3, 4, 5, 6, 7, 8, 10	12.7	2.0 × 6 to 2.0 × 50 (7 lengths)	Orange plastic	12.7-mm model 193, 194, 196 and 2000 Pneu-Dart cartridge fired rifles
Palmer Cap-Chur aluminum dart	Explosive	0.5, 1, 2, 3, 4, 5, 7, 10, 15, 20	12.6	2.5 × 13 to 2.5 × 76 (11 lengths)	Yarn or plastic "Tetra"	12.7-mm #1300 mid-range pistol, #1200 long-range CO ₂ rifle

Dart Types

Two-Chambered Compressed (Pressurized) Gas Darts These darts are lightweight, two-chambered, and usually made of plastic or occasionally aluminum. The dart body is divided into dual chambers by a movable, rubber syringe plunger in the center (Fig. 11.3).

The anterior drug chamber is bounded by the central plunger and by a syringe hub that accepts a needle at the front of the dart. The posterior gas chamber is bordered anteriorly by the central plunger and a second, smaller movable rubber plunger in the back of the dart. The posterior plunger acts as a one-way valve that allows gas to be inserted through the posterior hub, but then occludes the posterior hub to prevent gas escape. The caudal part of the dart body has a syringe hub that accepts a tailpiece. The dart needles are hollow with a sharp, sealed tip. Several millimeters from the tip, the needles have an opening cut into the side for the medication to come through. A small silicone sleeve is then placed to cover this opening. The needle with the silicone sleeve in place is attached to the anterior hub of the dart (Fig. 11.4).

These darts are charged by placing the drug into the anterior chamber and compressed gas into the back chamber. The pressurized gas may be air introduced manually with an adapter attached to a syringe or butane liquid placed into the posterior chamber of the dart (Fig. 11.5).

Figure 11.3. Photograph and illustration of a two-chambered compressed gas dart. (a) Posterior plunger that is a one way valve allowing compressed gas to be introduced, but preventing escape. (b) Movable central syringe plunger that divides the two-chambers of the dart. (c) Side-ported needle with a silicone sleeve occluding the port.

Figure 11.4. Photograph of two side ported needles. (a) This needle has the side port exposed. (b) A similar needle with a silicone sleeve occluding the port.

Figure 11.5. Photograph of a two-chambered compressed gas dart being filled. (a) Posterior chamber of the dart. (b) Posterior plunger that is a one way valve allowing compressed gas to be introduced, but preventing escape. (c) Coupler that is needed to allow air to pass from the syringe to the dart. (d) Standard syringe used to force air into the dart.

Leakage of fluid is prevented by the silicone sleeve occluding the needle vent. As the needle enters the skin, the sleeve remains on the skin surface exposing the needle vent. The pressurized gas then pushes the central plunger forward and forces the drug out of the anterior chamber and through the needle. If the darts and needles are cleaned and maintained between usages, they are reusable. The plastic darts can be gas sterilized and the needles can be autoclaved or gas sterilized.

Because this dart type is relatively lightweight with a slow deposition of drug over several seconds, the injection is relatively nontraumatic to the animal. The dart's sharp needles make them ideal for penetration of most skin types. With proper selection of needle lengths and dart sizes, these darts can be used safely on a large variety of species. They are generally used for short ranges and preferably during good weather conditions, as their trajectories are easily affected by wind gusts. The primary disadvantages are that they can be destroyed by hitting unintended solid objects and their complexity makes them prone to dart failures.

Loading a two-chambered plastic dart involves the following steps:

1. An appropriate sized sterilized dart is removed from the package.

2. The dart is inspected for cracks and abnormal shape.
3. The dart is then tested by placing air pressure in both compartments to make sure that the plungers move correctly and that the dart does not leak. A metal connector is needed to couple regular 6 or 12cc syringes to the hub of the dart and inject air into the posterior chamber.
4. Next, an appropriate-sized, sterile needle is selected. It must be inspected for patency and for the presence of a sharp tip, free of burrs or bends from previous impacts.
5. The needle is then lubricated with sterile ointment and a silicone sleeve is placed over the needle tip and slid down over the needle vent. The sleeve is moved up and down the needle several times to be sure it moves easily before it is placed over the vent opening in the needle.
6. The needle is placed onto a syringe and air is forced into the needle to confirm that the sleeve has occluded the needle vent.
7. The dart is loaded by first displacing the posterior plunger (one-way valve) with a venting pin to make sure the posterior chamber is not pressurized.
8. The central plunger is then positioned to provide the correct volume for the drug in the anterior chamber.
9. The needle of a second syringe containing the drug is inserted through the anterior hub and the anterior chamber is then filled with the drug.
10. The needle with the preplaced silicone sleeve is attached to the dart. This attachment must be secure, with the needle firmly seated on the anterior dart hub.
11. A transparent safety cover is placed over the end of the needle.
12. The dart is held in a vertical position with the needle pointing upwards.
13. The dart is charged with either air or butane placed into the posterior chamber. The air or gas is forced in through the posterior hub, around the one-way valve, and into the posterior chamber of the dart. When properly charged, the rubber plunger at the back of the dart will be firmly pressed against the caudal portion of the posterior chamber.
14. Select the proper tailpiece for the dart. Inspect the tailpiece to ensure that it is clean, dry, and symmetrical.
15. The tailpiece is firmly attached to the posterior hub of the dart making the dart ready for use.

Blow Darts Several types of two-chambered darts use pressurized gas to push the drug into the animal (Fig. 11.6).

The first is the blow dart that is constructed of very lightweight clear medical-grade plastic, similar to the

Figure 11.6. Photograph showing the difference between two types of two-chambered compressed gas darts. (a) Blow dart. (b) Molded nylon dart.

Figure 11.7. Photograph of two needle types used in two types of two-chambered compressed gas darts. (a) A hypodermic needle that has the sharp tip occluded with solder used in blow darts. (b) A thicker, blunter, machined needle used in molded nylon darts.

material used in disposable plastic syringes. The blow dart body usually has a leur-lock syringe tip hub on the anterior drug compartment. The needle of the blow dart is sharp, constructed from a modified hypodermic needle that has a tip that is soldered closed and an opening cut into the side (Fig. 11.7).

Because of the blow dart's lightweight and sharper needles, they are meant to be projected by blowpipes. They are most accurate when used indoors. Blow darts should never be used in CO₂ or gunpowder cartridge propelled projectors as their light construction causes erratic flight at high velocities and they often shatter on impact.

Molded Nylon, Two-Chambered Plastic Darts These darts are heavier than blow darts and constructed of opaque synthetic polyamide polymer plastic (molded nylon). The construction of the dart body is more robust and often reinforced. The anterior hub has a thick collar to better seat the needle and provide additional strength to the needle attachment. These needles are machined from a thicker metal that resists bending or breaking better than the modified hypodermic blow dart needles.

These heavier darts are designed for use in CO₂ or compressed air powered projectors. They have improved

Figure 11.8. Photograph and illustration of a gunpowder explosive-powered dart. (a) Yarn tailpiece that is threaded into the back of the dart body. (b) Movable central syringe plunger, which contains the explosive charge. (c) Forward-ported needle with a wire barb is threaded into the front of the dart body.

ballistic properties that allow them to fly true at higher velocities. They are also made to withstand greater impact forces. This gives these darts a much greater range and ability to be used outdoors in moderately windy conditions. The blunter needles have no difficulty penetrating most animal skin when powered by these projectors; however, they are ineffective when projected with a blowpipe. When used correctly and at appropriate distances, these darts are safe and cause only minor trauma (Cattet et al. 2006). A variety of needle sizes are available. They can be fitted with barbs to decrease bouncing out of the animal. Impact absorbers can also be placed at the base of the needles to prevent them from penetrating beyond the intended depth and decreasing dart trauma (Wiesner 1998). The potential problems associated with these darts are that they can cause significant trauma when used with gas powered projectors at inappropriate close ranges. Clinical experience has demonstrated that these darts can be imbedded into the soft tissues of animals and can even cause long bone fractures.

Gunpowder Explosive Darts Explosive powered darts use a black gunpowder explosive cap to generate the force needed to discharge the drug. A movable plastic plunger is placed into the center of the dart body to separate the drug from the explosive cap and trigger mechanism (Fig. 11.8).

The anterior chamber holds the drug. The posterior chamber holds a metal explosive unit that contains an explosive cap, a weighted firing pin and a spring that keeps the firing pin away from the cap (Fig. 11.9).

The explosive unit is set behind the caudal aspect of the central plunger, and the back of the dart is sealed with a tailpiece. The needles are hollow, forward, or side ported, and do not need to be capped. The needles come in a large variety of lengths and are usually barbed.

These darts are loaded by placing the drug through the needle lumen and into the anterior chamber. When the dart hits the skin of the animal, the needle

Figure 11.9. Illustration of the tail section and trigger mechanism of a Pneu-Dart gunpowder explosive-powered dart. (a) Movable weight. (b) Spring that holds the weight back. (c) Explosive cap.

penetrates and the body of the dart is stopped by the skin surface. The forward momentum of the dart is carried to the metal firing capsule where the small spring is overpowered and the firing pin impacts the cap resulting in an explosion. The resulting expanding gas within the posterior chamber rapidly forces the plunger cranially and the drug out of the needle. The injection occurs within approximately 0.001 seconds and can cause considerable tissue trauma (Cattet et al. 2006; Kreeger 2002). Additionally, the explosive rate of the injection causes a rocket effect that propels the dart out of the animal. For the explosive unit to work, the dart must strike the animal with enough force at a perpendicular angle to the target site to trigger an explosion. This necessary force can result in significant dart trauma in small or delicate species.

Modular Gunpowder Explosive-Powered Darts The Palmer Cap-Chur dart kit comes disassembled in components so the operator can assemble the dart configuration that is needed. The body is an aluminum 12.6 mm (.50 caliber) tube with internally threaded ends. The aluminum syringe barrel comes in various lengths that can hold 0.5–20 mL of drug. The Palmer Cap-Chur charges come in three different power strengths that are selected for the appropriate dart volume; yellow for 0.5–3 mL, orange for 4–10 mL, and red for 15–20 mL. Improper selection of the charge strength can lead to dart failure. The metal explosive charge fits with its closed, rounded, cranial end into a pocket in the caudal aspect of the central plunger (Fig. 11.10).

The explosive unit must be oriented correctly with the open end facing caudally for the dart to discharge. The back of the dart is sealed with a tailpiece that screws into the internally threaded dart body. The needle is threaded into the anterior end of the dart. The needles are hollow, forward ported, and do not need to be capped. The needles come in a large variety of lengths and with several barb styles (Fig. 11.11).

Figure 11.10. Photograph demonstrating the steps in assembling the tail section and trigger mechanism of a Palmer Cap-Chur gunpowder explosive-powered dart. (a) The charge has been placed into the caudal pocket of the central plunger. The needle is pressing the weight and spring to demonstrate the proper orientation of the explosive charge. (b) The plunger and explosive charge have been inserted into the posterior part of the dart body. (c) The yarn tailpiece has been threaded into place.

Figure 11.11. Photograph of three needle types used in gunpowder explosive-powered darts. (a) Pneu-Dart needle with a green gel cone collar barb. (b) Palmer Cap-Chur needle with small metal collar. (c) Palmer Cap-Chur needle with wire barb.

This system is one of the oldest commercially available darts and has had many years of proven reliability. The variability in needle length and payload volume (tube size) makes this the most versatile darting system. From one kit, darts can be configured with short needles for carnivores or very large needles and barrels used for elephants and rhinoceroses. The dart components, except the explosive units, are reusable if cleaned and maintained properly. Keeping the dart components

sterile is challenging, but using unsterilized equipment may lead to dart induced infections (Bush & Gray 1972). The biggest weakness of the system is that the heavy darts and the explosive discharge of drug lead to tissue damage.

Loading a Palmer Cap-Chur dart involves the following steps:

1. The appropriate-sized sterilized dart components are removed from their packages.
2. The dart parts are inspected for cracks and abnormal shape. The needle, body, and tail are preliminarily assembled to ensure proper threading, and then passed through the syringe barrel of the projector to ensure that the dart passes freely.
3. A sterile, central, rubber plunger is selected and then lubricated. It is placed inside the body of the dart, and the plunger is moved back and forth within the length of the dart body to ensure that it moves easily.
4. The plunger is positioned in the caudal part of the dart body.
5. An appropriate strength metal explosive unit is fitted into the pocket in the caudal aspect of the rubber plunger. It is crucial to make sure that the explosive unit is oriented correctly, with the movable plate exposed caudally.
6. A tailpiece is selected and threaded into the caudal part of the dart body.
7. An appropriate sized needle with an acceptable barb style is selected. It must be inspected for patency and to make sure that it does not have a burr at the tip or is bent from a previous impact.
8. The needle is then threaded onto the cranial part of the dart body.
9. The dart is loaded by passing the needle of a syringe containing the drug through the dart needle lumen and depositing the drug into the anterior chamber of the dart. The syringe needle should be longer than the dart needle and the drug introduced slowly to avoid drug back flow from the dart needle.
10. Sterile water is used to completely fill the remaining volume in the anterior chamber of the dart.

Prefabricated Gunpowder Explosive-Powered Darts Prefabricated versions of the gunpowder explosive-powered darts, such as Pneu-Darts, are commercially available. The explosive system is similar, except that the explosive mechanism is preplaced in the dart by the manufacturers. The dart is made of a combination of aluminum or polycarbonate plastic body, a hollow needle, and a plastic tailpiece. The dart is purchased as a complete unit and cannot be taken apart. The function and limitations are similar to the modular systems.

The simplicity of the prepurchased dart makes this an appealing product. The operator selects the dart

volume, needle length, and barb configuration that will be needed for the anesthetic event. Most needles come with a green gelatin collar or barb to prevent the darts from being ejected from the skin when the dart discharges. Loading the dart is a simple matter of placing the drug through the dart needle and into the anterior chamber.

Pneu-Darts come in two types: the first is the "P" dart line, with a yellow tail, that is designed for blowpipes or CO₂ powered projectors. The other dart line is the "C" dart, with orange tailpieces, that are designed for the 22 blank-powered cartridge projectors. The major differences are the diameter of the tailpieces are larger in the "C" dart to help engage the rifled barrel, and the tensile strength of the spring in the explosive unit is weaker in the "P" dart. The Pneu-Dart line has several available configurations that include clear polycarbonate plastic bodies, tri-ported needles, and modified tailpieces to fit other brands of 13-mm projectors.

Loading a Pneu-Dart or similar dart involves the following steps:

1. Select a dart with the appropriate payload size and needle length from the package. Pneu-Dart markets a wide variety of dart sizes and needle combinations that must be preordered prior to the procedure.
2. Note the tailpiece color and package label to make sure that the dart type selected matches the intended projector. A yellow tailpiece indicates the "P" dart line designed for blowpipes or CO₂-powered projectors. An orange tailpiece indicates the "C" dart line designed for the 22 blank-powered cartridge projectors.
3. The dart is inspected for cracks and other manufacturing abnormalities. Make sure that the needle is patent and that the retaining device is correctly installed on the needle.
4. Inspect the dart for dirt or moisture damage that may have compromised sterility or function of the dart during storage and transport.
5. The dart is loaded by passing the needle of a syringe containing the drug through the dart needle lumen and depositing the drug into the anterior chamber of the dart. The syringe needle should be longer than the dart needle, and the drug introduced slowly to avoid drug back flow from the dart needle.
6. Sterile water is used to completely fill the remaining volume in the anterior chamber of the dart.

Miscellaneous Dart Types

Aluminum Two-Chambered Compressed Gas Dart Palmer Cap-Chur produces a two-chambered compressed gas dart that uses a threaded aluminum tube, but the standard explosive charge is replaced with a one-way valve system in the posterior chamber. This dart also has a closed needle with a side port vent and occluding

Figure 11.12. Illustration of a chemical reaction-powered dart. (a) Represents the loaded dart prior to impact. The chemical reagents are kept separated by a weight occluding the chemical chambers. (b) Represents the dart after impacting the target and during discharge of the drug. The weight was dislodged and the chemicals have mixed and produced a gas that pushes the central plunger forward.

sleeve over the needle. The function and loading of this dart is similar to the two-chambered gas darts.

Chemical-Powered Darts Chemical darts use an effervescent acid/base reaction to produce gas and thus inject the anesthetic (Fig. 11.12).

The design has a two-chamber configuration with the chemicals placed in the posterior chamber. Prior to discharge the chemicals are kept apart. Upon impact, a variety of mechanisms have been devised to allow the chemicals to mix and produce gas (Bush 1992). No chemical darts are commercially available in the United States, but they are used and available in Africa and Europe (Nielsen 1999). Because the drug compartment is not under pressure, open-ended needles can be used. The advantage is that the darts are easy to load and reliable in most field situations. The injection speed is slower than compressed gas or explosive charged darts, but this slow discharge is usually acceptable. The slow discharge is beneficial in that it causes minimal injection trauma and limited blow back from the dart.

Spring Powered Darts Spring-powered darts are not currently commercially available in the United States. The design is similar to the two-chambered dart, except the posterior chamber is replaced with a spring to provide the injection force. The spring is attached anteriorly to the central plunger and posteriorly to the back of the dart body. Trigger mechanisms usually involve silicone-capped needles that function similarly to the two-chambered darts. The dart body can be constructed of plastic or metal depending on the projector that will be used. The major problem with these darts is that the process of loading the dart is difficult and dangerous due to inadvertent spraying of the drug during the loading process.

Solid Drug Darts Solid drug projectiles can potentially be used to deliver anesthetics or sedatives. The principle of these solid bullets is similar to the original galamine paste projectiles described from the 1950s.

Several attempts have been made to develop a solid, lightweight, absorbable bullet (Bush 1992). The current versions are made of various materials, such as hydroxypropylcellulose, that dissolve and absorb into the muscle of the animal (Jessup 1993; van de Wijdeven 2002). An example is the BallistiVet system, which was developed for vaccination of domestic livestock, but can be applied to both captive and wild nondomestic species. As in the original descriptions of solid drug injection systems, the limitations of payload size and slow absorption are persistent obstacles in their use for primary induction of anesthesia.

Remote Delivery Projectors

Compressed Gas Projectors

Blowpipes Blowpipes consist of a long lightweight tube with a mouthpiece on one end. A blow dart is placed in the end of the pipe and compressed gas is provided by the operator blowing with a quick, strong breath through the tube. The longer the pipe, the greater the accuracy of the dart. Commercial blowpipes are available from several manufacturers in various pipe lengths, diameters, and shapes of mouthpieces. Selection is based on personal preferences for the mouthpiece and the diameter of the dart type selected.

Usage of a blowpipe requires practice. The pipe is held horizontally and grasped in the hand opposite to the dominant eye. To use a blowpipe correctly, look at the tip of the pipe and aim it at the target. Inhale deeply and then rapidly exhale in a manner that approximates a combination of coughing and spitting through the pipe. Because of the slow dart velocity, the dart will tend to fly in an exaggerated downward arc instead of a straight line. Effective blowpipe range is about 0.5–10 m.

Blowpipes are by far the most versatile, inexpensive, silent, lightweight projectors available. For short ranges, an experienced darter can have exceptional accuracy. The light darts combined with the slow velocity of the dart produce minimal impact and tissue trauma. The operator can adjust the dart speed instantly and therefore deliver the dart as gently as needed. Because darts may occasionally leak and the mouth must be placed on the mouthpiece, it is not recommended to project darts with dangerous drugs such as concentrated narcotics using a blowpipe.

Gauged Blowgun Projectors A modification to the blowpipe is the addition of an external source of compressed gas to eliminate the need for the operator to exhale through the pipe (Fig. 11.13).

These are designed to shoot the heavier machined two-chambered plastic dart or the type "P" Pneu-Darts. The basic components needed are a source of compressed gas, control of the gas pressure with a combination of a pressure gauge and valve system, and a trigger mechanism. These systems can be powered either by

Figure 11.13. Photograph of two Dan-Inject blowgun type projectors. (a) A model CO₂ PI pistol with an 11-mm barrel. The pistol is powered with a compressed CO₂ cartridge. (b) A JM Special rifle with 11-mm barrel. It is also powered by a compressed CO₂ cartridge.

air via a foot pump or by compressed carbon dioxide from a pressurized cylinder. Pressure gauges and release valves allow the pressures to be increased or decreased as needed during darting. A detachable, long barrel is then mounted on either a pistol handle or a rifle stock. The projectors can be equipped with a telescopic sight. Often, these projectors have barrels that can be interchanged to accommodate both 11- and 13-mm darts. The pistol is used for short range or indoors where space is limited. The rifles have more accuracy and are used outdoors. Careful selection of the dart type is important, as lightweight plastic blow darts will not fly correctly in these CO₂ powered projectors.

These systems are quiet, reasonably accurate, and a simple means of darting exotics for distances up to 5–30m. Many veterinarians in zoological collections use this system exclusively.

Air and CO₂ Rifles and Pistols The next group of compressed gas projectors are the pistols and rifles with a barrel permanently mounted onto a triggered compressed gas power source (Fig. 11.14).

The compressed gas power source can be provided by CO₂ cylinders or an attached air pump similar to a pellet gun. These projectors generally lack accurate pressure gauges and valve systems with the ability to change the gas pressure. Instead, they often have two or three preset steps for selecting power levels. They are usually designed for 12.5-mm (.50 caliber) metal darts such as Palmer Cap-Chur and type “P” Pneu-Darts. Due to their short barrels, the pistols are notoriously inac-

Figure 11.14. Photographs of three compressed gas-powered 12.7mm (.50 caliber) projectors. (a) Palmer Cap-Chur Model #1300 mid range pistol powered with 2 compressed CO₂ cartridges. (b) Pneu-Dart Model 178B air pump rifle. (c) Palmer Cap-Chur Model #1200 long-range rifle powered with two compressed CO₂ cartridges.

Figure 11.15. Photographs of two cartridge powered 12.7mm (.50 caliber) projectors. These guns are very powerful and used only outdoors for long range targets. (a) Palmer Cap-Chur Model #1000 extra long-range rifle. (b) Pneu-Dart Model 196 rifle.

curate at long range. In contrast, the rifles can be very accurate at moderate distances. Both systems, when used at short range, can cause significant trauma due to the lack of accurate pressure control.

Gunpowder Cartridge-Powered Rifles These rifles have permanently mounted barrels on a rifle stock. They are powered by .22 caliber blanks that come in several charge strengths with different amounts of gunpowder. In the Palmer Cap-Chur system, brown is the weakest cartridge, followed by green, yellow, and red (Fig. 11.15).

Although they lack pressure gauges, they often have methods of selecting power levels. These rifles are too powerful for short range or indoor use. In contrast to other darting systems, they have the longest effective range and can be used in windy conditions. They have 12.7 mm (.50 caliber) bore and are designed for 12.5-mm metal darts, such as Palmer Cap-Chur or type “C” Pneu-Darts.

Miscellaneous Projector Types

Crossbows and Bows Commercially available darts can be mounted on arrow shafts and delivered with crossbow and conventional bows. In Africa, several Ju/'Hoan bushmen were given arrows with Pneu-Darts attached at the tips. Using these arrows and their archery hunting techniques, they were successfully able to immobilize free-ranging lions and leopards (Stander et al. 1996). Archery based projectors are accurate, but if not controlled, the velocity of the heavy arrows will cause trauma to the animals.

Injection Collars Remote injection collars can be placed on an animal prior to release and used to inject the animal at a later time (Jessup 1993). Commercially available products have been used in white-tailed deer and wolves. The injection is triggered by remote control. Combined with telemetry and a safety collar release if the batteries are low, this can potentially be a valuable tool for wildlife. Application of these collars in zoological collections has been limited, but may be practical in situations that require multiple immobilizations in animals that are difficult to dart.

Darting Accessories

Many manufacturers provide practice darts and targets for their equipment. Usage of these darts is cheaper than using operational darts, and they are consistently weighted to help improve accuracy. Through practice, the operator develops proficiency with the equipment and reliable accuracy. During this practice, it is important to develop an understanding of the proper impact velocity that is needed to prevent excessive trauma.

Laser range finders and binoculars are useful in outdoor darting procedures. Calibrating the projector for selected distances is the best method of consistently producing accurate and atraumatic shots. Once the calibration is completed during practice sessions, using the range finder significantly improves range estimates and allows the operator to make confident and accurate projector settings. The binoculars are useful for selecting the target and then confirming that the dart has hit the animal.

Cleaning and Reusing Darts

Many of the remote drug delivery systems, such as pole syringes, two-chambered compressed gas darts, and the modular gunpowder explosive powered darts, are designed to be reusable. However, for proper function, these darts must be cleaned, maintained, and stored correctly. Specific procedures and maintenance recommendations should be obtained from the dart manufacturer and the preferences of the individual practitioner.

General dart cleaning and storage procedures:

1. Every effort should be made to locate and retrieve the dart after the procedure.
2. The retrieved dart should be placed into a labeled and secure container during transport prior to dismantling and cleaning.
3. Using gloves and proper eye protection, the dart should be inspected for residual drug or unreleased internal pressure.
4. While submerged under water, the dart is carefully disassembled. The water provides protection from drug aerosolization and also dilutes any residual drug from the dart. Alternatively, flowing tap water or disassembly in a safety cabinet can be used for this step.
5. After disassembly, each component of the dart is individually cleaned with warm soapy water and then inspected. The dart bodies are inspected for bending or cracks. Needles are inspected for patency, bending, or damaged retention barbs. Needle tips are inspected for sharpness and tip burs. Damaged parts should be discarded or repaired.
6. The dart parts should then be soaked in a disinfectant solution, carefully rinsed, and individually dried.
7. The dart components should be lubricated according to manufacturer's recommendations.
8. The darts components are then sorted and packaged in sealable containers or surgical instrument wrappers.
9. Finally, the dart components should be sterilized according to manufacturer's recommendations.

Drug delivery Problems

Dart Failure Although darts and their projectors have become indispensable tools in zoological medicine, dart failures are common. The most important factor causing a dart to miss the target is operator error from inexperience with the darting system. Each darting system has individual characteristics that must be learned by the operator. Accuracy and consistency are only developed with persistent practice.

Unfortunately, all darting systems are prone to high failure rates, and even when the darts hit their intended target, many fail to discharge. As the complexity of the darts increase, this becomes the most important factor leading to dart failure. Careful preparation and testing of the darts is an essential step prior to each darting. The various darting systems each have their critical or failure prone components that must be carefully checked by the operator. Maintaining the equipment in portable organized kits helps ensure that the proper components are available and facilitates the darting procedures (Fig. 11.16).

Examples of common problems are explosive charges that fail to fire, blocked dart needles, and central plungers that stick. Ambient temperatures can affect dart function and the performance of compressed gas darts. In very cold temperatures, darts may fracture on impact, drugs can freeze or become thick, and compressed gas exerts less pressure, causing incomplete discharges.

Figure 11.16. Photograph of a darting kit with essential components separated into compartments. Note that a radio is included to provide emergency communications.

Drug Failure The selection of anesthetic drugs is beyond the scope of this chapter, but can definitely cause immobilization failures. Improper deposition of the darted drugs can also produce unexpected results. Darts that deposit drugs into vascular structures or medullary cavities of bones can have rapid onset similar to intravenous administration. Conversely, deposition into skin, subcutaneous space, tendons, or other poorly vascularized tissues can have slow absorption. Some clinicians recommend the usage of hyaluronidase to improve absorption of drugs injected with darts (Kock 1992).

Drug interactions when mixed into a syringe must be considered, but have been poorly studied. Environmental conditions, such as freezing or heating, may also alter drug potency. Long-term storage of drugs in preloaded darts is questionable, as the drugs potency and purity may change with time (Kreeger et al. 2002).

Aerodynamics of Darts Darts have poor ballistic properties when compared with bullets or arrows. With variable shapes and shifting liquids, they are often very erratic in flight. As an example, bent darts or needles damaged by previous impacts can radically alter the flight trajectory. Aside from the shape, the velocity of the dart as it exits the projector is an important variable in prediction of the dart's trajectory. Fast muzzle velocities produce flat flight trajectories similar to a bullet. Although accurate, these faster velocities are associated with severe impact trauma and dart malfunctions. Further, all darts, even when properly loaded and balanced, will destabilize at very high velocities. This forces all darting systems to use relatively slow muzzle velocities. At these slower velocities, the darts tend to form a downward arced trajectory that is increased as the darting distance increases. This arc must be anticipated, and an experienced darter will compensate appropriately.

Figure 11.17. Photograph of three types of dart tails. (a) Four fin tail from a Dist-Inject mini-ject easy dart. (b) Cloth tail from a Dan-Inject molded S series dart. (c) Plastic tail from a Pneu-Dart C dart.

Figure 11.18. Photograph through the barrel of a rifle barrel showing the spiral rifling needed to cause a dart to spin on its horizontal axis during flight.

The tailpiece is designed to provide the dart with aerodynamic stability (Fig. 11.17).

Available tails range from finned tails similar to archery arrows, which are considered the best, to cloth tail stabilizers that can cause problems if they are asymmetrical. Rifling of the projector barrel is a method of increasing flight stability by forcing the projectile to spin on its horizontal axis (Fig. 11.18).

Unfortunately, few darts are capable of engaging the rifled barrel surface and therefore do not spin in flight. Additionally, some dart tails, such as cloth and finned configurations, actually resist the horizontal spin that the rifled barrel is intended to provide.

In addition to the aerodynamic considerations of unobstructed flight, environmental conditions associated with outdoor darting can have significant effects on dart trajectories. Objects such as plants may deflect the dart. Winds and wind gusts can cause darts to fly in unexpected directions. Helicopter down drafts can also affect darts. Due to their light weight, plastic darts are particularly prone to this problem.

Animal Injury Severe tissue injury, including hemorrhage, necrosis, and bone fractures, can occur whenever darts are used. Any projectile with a needle can cause injury when it hits an animal in an unexpected location. Sudden movements from the targeted animal can lead to inadvertent injury to either the target or other animals in the group. Examples of dart injuries to the eye, thorax, abdomen, and testicles are common. It is ultimately the operator's responsibility to only take shots that are likely to hit the expected target.

The site selection for darting is important. In most animals, the muscles of the upper hind legs are the safest selection. Occasionally, the base of the neck or the triceps can be targeted. When selecting the site, the animal must have sufficient muscle mass to allow for injection of the drug and safe impact of the dart. Most darting systems have a variety of needle selections that must be chosen to limit tissue trauma while effectively providing penetration and injection of the drug into the muscle. Needle length is selected on the thickness of the animal's skin and the expected depth of the muscle mass. Inappropriately long needles have the potential to fracture bones on impact. Thickness of the needle is dependent on the potential for the needle to break on impact, and broken dart needles retained in muscle tissue have been reported (Cohn 1998).

Darts primarily cause trauma on impacting the animal in direct relationship to the kinetic energy of the dart (Karlsson & Stahling 2000; Kreeger 2002). This energy can be estimated by knowing the mass and speed of the dart at impact in the following relationship: $KE = 1/2 (\text{Mass}) \cdot (\text{Velocity})^2$. It is important to note that the velocity is squared and therefore has the greatest influence on the injuries caused on impact. Thus, heavy darts are not always more harmful for the animal (Kreeger 2002). All darts require enough kinetic energy for the needle to enter the skin and trigger discharge, but excessive amounts are associated with trauma and dart failure. In extreme situations, the whole dart can be imbedded into the muscle or fracture a bone.

Darts can also injure tissues by forceful injection of drug (Cattet et al. 2006). This is particularly true of large-bore, open-ended needles that are discharged with explosive force. Evidence of tissue injury and necrosis has been documented with these types of darts (Cattet et al. 2006; Wiesner 1998).

Needle trauma caused by movement of the needle after discharge can be significant. Often, the first reac-

tion of a darted animal is to jump, run, or remove the dart. Barbs and collars on many dart needles are designed to keep the darts in the animals, but if they are retained for long periods or forcefully removed, they can lead to injury.

Infection of the dart site is generally rare, but can cause serious complications to routine darting procedures. The needle of the dart enters unprepared and often grossly contaminated skin. Some darts have been shown to directly introduce hair and other foreign material deep into the dart injection sites (Cattet et al. 2006). Unsterile darts and contaminated drugs can further inoculate the injection site. Once bacteria are introduced into the dart wound, they grow well in the traumatized tissues associated with the dart site. This combination of trauma, large needles, and unprepared injection site can produce significant and deep wounds that are likely to develop into clinical infections. Inspection of the dart site and local wound care during the anesthetic procedure is always recommended. Many practitioners also recommend the use of prophylactic antibiotics; however, the effectiveness of a single antibiotic injection is questionable and has not been prospectively evaluated. To minimize dart site infection, most darting systems can be sterilized prior to use and aseptic techniques can be used during the dart preparation (Bush & Gray 1972).

Human Safety Concerns during Darting Procedures

Dart projectors should be considered firearms and treated with the same precautions and basic gun safety to prevent accidental discharges. As in animals, the ballistic properties of all darts are able to inflict serious injuries to people. Darts are subject to radical changes in trajectory when they are deflected by wind, obstacles, and bouncing off animals. It is therefore imperative that the operator considers the position of all the personnel around, and particularly behind, the target before the trigger is pulled.

All the dart systems described earlier are designed to automatically discharge drugs, making them even more dangerous when they hit a human. In rare occasions, darts may expel the drug prior to full needle penetration or after bouncing out of the skin. In these cases, the drug can be aerosolized or sprayed onto the surface of the animal and can be a source of drug exposure. Emergency plans to deal with accidental drug exposure need to be in place prior to the immobilization procedures. It is important to have effective emergency communication equipment, such as a cellular telephone or two-way radios.

The most important safety considerations are proper planning and familiarization with the drug delivery method selected. Having each procedure well planned is essential so that everyone is cognizant of their roles and safety considerations. Prior practice and familiar-

ization with the equipment make the operator more confident and effective in delivery of the anesthetics. Ultimately, the responsibility for the safety of an anesthetic delivery is on the anesthetists and the operator of the equipment.

CONCLUSIONS

The methods of drug delivery to nondomestic species are essential to the practice of zoo animal and wildlife anesthesia. However, these methods are often complicated and must be learned and practiced before application. Each remote delivery system has both advantages and significant limitations. Practitioners interested in obtaining equipment should familiarize themselves with all the available systems. Commercial websites often provide detailed information and information on specific product lines. Classes and conference lectures can provide valuable comparative information and often provide the opportunity to use several products. Additional information is also available in other publications that describe the usage of this equipment for specific applications (Kock & Burroughs 2012; Kreeger et al. 2002).

12 Capture Myopathy

Jessica Paterson

INTRODUCTION

Capture myopathy (CM) is a noninfectious, metabolic disease of wild and domestic animals that can lead to significant morbidity and mortality. The condition is most commonly associated with pursuit, capture, restraint, and transportation of animals. CM may also manifest secondary to other diseases, or as a result of natural hazards encountered in the environment. It is characterized by metabolic acidosis, muscle necrosis, and myoglobinuria. Clinical signs include muscle stiffness, severe muscle pain, ataxia, paresis, torticollis, prostration, and paralysis. Animals typically become obtunded, anorexic, and unresponsive. Death can occur from within minutes or hours of capture to days or weeks after the inciting event.

CM has been described in a remarkably wide range of vertebrate species, primarily within the mammalian and avian taxa. A very similar condition has been reported in poikilotherms, including fish (Holloway & Smith 1982) (Hassanein 2010) and amphibians (Williams & Thorne 1996). A syndrome resembling CM has also been documented in lobsters (Ridgway et al. 2007). The disease has never been described in reptiles.

CM shares many similarities with the myodegenerative disorders of domestic cattle, sheep, horses, and swine, as well as exertional rhabdomyolysis (ER) in humans. The factors that contribute to the onset of CM can be highly unpredictable, and the manifestations of the disease often vary between species and individuals. Treatment generally has a low success rate, although recoveries have been recently documented and will be discussed later in the chapter. There continues to be a much greater emphasis on prevention in the literature.

HISTORY

CM has been termed muscular dystrophy, white muscle disease, overstraining disease, capture disease, cramp, leg paralysis, spastic paresis, stress myopathy, transport myopathy, incipient myopathy, degenerative polymyopathy, muscle necrosis, and idiopathic muscle necrosis throughout the literature. The condition is now most commonly referred to as CM, exertional myopathy, or exertional rhabdomyolysis. One of the earliest reports of lesions consistent with CM was reported in a white-tailed deer (*Odocoileus virginianus*) in 1955 (Hadlow 1955). The first description of the pathology of CM was in a Hunter's hartebeest (*Damaliscus hunteri*) (Jarrett et al. 1964). Throughout the late 1960s and early 1970s, CM was described in many free-ranging African ungulates (Basson et al. 1971; Harthoorn & Van Der Walt 1974; Hofmeyr et al. 1973; Mugeru & Wandera 1967). CM in other African mammalian species, including baboons (McConnell et al. 1974) and flamingoes (Young 1967), were also documented during the same time period.

The first documentation of CM in North America was most likely in mountain goats (*Oreamnos americanus*) in British Columbia (Hebert & Cowan 1971). The condition in these mountain goats was described as white muscle disease, but the findings more accurately fit CM. CM was reported throughout the late 1970s in several species of North American ungulates including white-tailed deer (Wobeser et al. 1976), elk (Lewis et al. 1977), moose (Haigh et al. 1977), pronghorn (Chalmers & Barrett 1977), and bighorn sheep (Demartini & Davies 1977).

THE HUMAN COMPARATIVE

CM is very similar to exertional rhabdomyolysis syndrome described in people (Warren et al. 2002). There

are hundreds of causes of rhabdomyolysis identified in people that are classified as either being acquired or inherited (Warren et al. 2002). Exertional rhabdomyolysis is one of eight forms of human-acquired rhabdomyolysis (Warren et al. 2002) and has traditionally been associated with military training (Smith 1968) and exhaustive endurance sports (Lin et al. 2006). Current research has recognized new exercise-related hyperthermic syndromes such as “white-collar rhabdomyolysis” (Knochel 1990) and raver’s hematuria (Sultana & Byrne 1996). Rhabdomyolysis has also been associated with people sustaining a TASER® shock, although the incidence rate is low and the evidence is controversial (Sanford et al. 2011).

Rhabdomyolysis is one of the leading causes of acute renal failure (ARF) in human patients (Vanholder et al. 2000). Progression of rhabdomyolysis to myoglobinuria and ARF was first described in humans during the London Blitz (Bywaters & Beall 1941). Civilians suffering from crush injuries died from ARF within 8 days of hospital presentation despite treatable, localized limb injury (Bywaters & Beall 1941).

ETIOLOGY

Exertional rhabdomyolysis, or CM, in animals is distinguishable from other types of rhabdomyolysis by its pathophysiology, as it affects both skeletal and cardiac muscles in response to extreme stress and muscular exertion (Williams & Thorne 1996). It is a complex and multifactorial disease. Spraker (1993) theorized that CM is an inherent mechanism that facilitates a symbiotic relationship between predator and prey. The prey animal experiences a relatively quick and painless death after capture by its predator, thus allowing the predator to conserve energy.

Other authors argue that CM develops in wild animals after an unnatural degree of stress and physical exertion (such as experienced during hunting or live capture) for which they are maladapted (Bateson & Bradshaw 1997; Harthoorn 1980). These authors believe CM is an iatrogenic disease and does not develop under the conditions of stress and predation naturally encountered in the wild. Chalmers and Barrett (1982) suggested that the stresses of fear and anxiety are the triggering mechanisms for CM that may be modified by genetic or acquired predispositions to the disease. These factors in turn may be exacerbated by iatrogenically induced circumstances, such as overexertion, disturbance, excessive handling, transportation, and shock (Chalmers & Barrett 1982).

PREDISPOSING FACTORS

There are many predisposing or contributing factors for CM. These factors can be placed into seven categories and remembered with the mnemonic SECONDS (Table 12.1).

Table 12.1. Predisposing or contributing factors for capture myopathy

S	Species
E	Environment
C	Capture related
O	Other diseases
N	Nutrition
D	Drugs
S	Signalment

Species

Prey species are considered the most susceptible to CM in the mammalian taxa, particularly ungulates. Highly susceptible African species include zebra, giraffe, nyala, tsessebe, duiker, roan antelope, red hartebeest, eland, springbok, kudu, giraffe, and female impala (Ebedes et al. 2002). North American species with apparent increased susceptibility to CM include white-tailed deer (Beringer et al. 1996) and pronghorn (Chalmers & Barrett 1977). Fallow and hog deer in Australia appear to be more excitable, and thus more susceptible to CM, compared with species such as rusa and samba deer (Presidente 1978).

The long-legged wading birds are particularly predisposed to CM within the avian taxa. The combination of struggle during capture and restraint in bags or cages where the birds cannot stand increases their susceptibility to CM (Green 2003).

Reports of CM in carnivores are rare but the disease can occur under certain conditions. A grizzly bear succumbed to CM approximately 10 days after capture by a leghold snare (Cattet et al. 2008). A retrospective analysis reported serum biochemistry results consistent with CM in 6% of grizzly bears (7/119) and 18% of black bears (29/165) trapped with leghold snares (Cattet et al. 2008). Captive-raised and free-ranging red foxes caught in foothold traps developed exertional rhabdomyolysis (Kreeger et al. 1990). A captive mountain lion was successfully treated after being diagnosed with myopathy due to secondary thiafentanil intoxication (Wolfe & Miller 2005).

Environment

Environmental factors that can increase the incidence of CM include extremes in ambient temperature, rain, and high humidity. The need for animals to negotiate steep terrain, difficult footing, or water hazards can also hasten the onset of CM.

Capture Related

Capture-related factors that contribute to CM comprise the largest category. Capture techniques that involve high chase speeds, prolonged exertion without rest, excessive handling, prolonged restraint, restraint that promotes struggling from unnatural positioning, crating, transport, subjection to fear stimuli over periods of

time, and renewed stresses, such as repeated moving and transport predispose animals to CM. Injuries induced by capture techniques, or by other animals, can also increase the incidence of CM. Eccentric exercises (when muscles are lengthening while trying to contract) have been positively correlated with a higher incidence of ER in humans (Lin et al. 2006).

Other Diseases

Underlying diseases and infections can make an animal more susceptible to CM. Severe worm and tick infections cause anemia and weaken the animal. Heartworm infection may compromise cardiopulmonary circulation. Animals that have utilized water sources that have a high salt content may have preexisting renal damage (Ebedes et al. 2002).

Nutrition

Nutrition is one area commonly overlooked as a contributing factor to CM. Animals with a preexisting vitamin E or selenium deficiency may be predisposed to developing CM (Hebert & Cowan 1971). Individuals on a high nutritional plane and carrying excess body fat, such as premigratory birds, may also be at higher risk. Providing food, water, and nutritional supplements to captured animals, particularly during prolonged transport or upon reaching the new destination, may reduce the incidence of CM (Ebedes et al. 2002).

Drugs

Rhabdomyolysis is a frequent complication of illicit drug consumption in humans and a frequent finding in drug-related deaths (Welte et al. 2004). It is estimated that toxins and drugs play a role in up to 80% of adult human cases of rhabdomyolysis (Gabow et al. 1982). Opiates are one of the most frequently implicated in primary drug-induced rhabdomyolysis (Warren et al. 2002). Controversial human literature suggests that abuse of mu opioids may lead to rhabdomyolysis through a directly myotoxic effect (Warren et al. 2002).

Potent mu opioids, such as fentanyl, etorphine, carfentanil, and thiafentanil, are often used in combination with alpha-2 agonists, butyrophenones, benzodiazepines, and cyclohexamines for wildlife capture. Wildlife species immobilized with opioid-based combinations frequently demonstrate side effects, such as excitement (Haigh 1990), spontaneous movement (Haigh 1990; Paterson et al. 2009), muscle rigidity (Haigh 1990; Paterson et al. 2009), hypoventilation, catecholamine release (Schumacher et al. 1997), and hyperthermia (Jessup 1984). These effects, combined with hypoxemia and elevated fluid loss, may significantly increase the risk of CM. It is important to recognize that nonopioid drug combinations can also cause similar side effects and predispose anesthetized animals to CM (Caulkett et al. 2000).

Signalment

In addition to species susceptibility described previously, the age and sex of an animal may also contribute to CM susceptibility. Extremely old and extremely young animals may be the most susceptible to CM in certain circumstances (Ebedes et al. 2002). Postrelease mortality was higher in yearling pronghorn compared with adults captured by helicopter-released net guns (Jacques et al. 2009). Human literature suggests males have a higher risk of developing severe ER (Lin et al. 2006). Some authors theorize that estrogens have a protective effect therefore reducing the risk for women (Lin et al. 2006). Male red knots were more likely to develop CM compared to females after cannon-net capture and banding (Rogers et al. 2004). Heavily pregnant African ungulates are considered more susceptible to CM than nonpregnant females (Ebedes et al. 2002).

Recent retrospective studies in bears and roe deer have shown differences in postcapture behavior between males and females of different ages (Morellet et al. 2009) and reproductive status (Cattet et al. 2008; Morellet et al. 2009). These variations in response to the capture process may indicate which individuals are more susceptible to morbidity and mortality from CM.

PATHOPHYSIOLOGY

Spraker (1993) described the pathogenesis of CM as involving three primary components: perception of fear, sympathetic nervous and adrenal systems, and muscular activity. The normal physiology related to these components has been described in detail by Spraker (1993). The pathophysiology of CM has also been extensively reviewed by Chalmers (1982), Spraker (1993), and Williams and Thorne (1996), and therefore is not discussed in detail in this chapter. Briefly, CM results from altered blood flow to the tissues and exhaustion of normal aerobic energy, particularly in skeletal muscle. Exhaustion of ATP in muscle cells leads to decreased delivery of oxygen and nutrients, increased production of lactic acid, and inadequate removal of cellular waste products (Spraker 1993). Damaged muscle cells undergo necrosis to a varying degree. Myoglobin released from these cells cause tubular necrosis in the kidneys and acute renal failure (Vanholder et al. 2000). Similar necrosis of cardiac tissue can occur as well (Williams & Thorne 1996).

CLINICAL AND PATHOLOGICAL SYNDROMES

Rhabdomyolysis literally means “dissolution of striped (skeletal) muscle” (Warren et al. 2002). Exertion-induced rhabdomyolysis leads to the breakdown of skeletal muscle fibers with leakage of intracellular contents, including creatinine kinase (CK) and myoglobin into the blood. Current diagnosis of rhabdomyolysis in humans requires the presence of tetraparesis, CK elevation more

than 10 times the upper reference limit, myoglobinuria, hyperkalemia, and coagulopathy (Melli et al. 2005). A CK concentration greater than 10,000 U/L in horses is indicative of myopathy (reference range 60–330 U/L) (Volfinger et al. 1994). Significant muscle injury in captured grizzly and black bears was diagnosed at CK levels greater than 387 U/L (reference range 0–387 U/L) and 421 U/L (reference range 0–421 U/L), respectively (Cattet et al. 2008; Teare 2002).

Despite the common mechanism of muscle breakdown, CM can manifest differently and have varying sequelae depending on the species, the individual, and the circumstances. One classification system defined four temporal syndromes of CM: hyperacute, acute, subacute, and chronic (Harthoorn 1973). Spraker (1993) also described four primary CM syndromes: capture shock, ataxic myoglobinuric, ruptured muscle and delayed peracute. The latter classification scheme will be discussed in detail in this chapter. When classifying specific clinical signs and gross and histologic findings into different syndromes of CM, it is important to recognize that the pathogenesis of CM is a continuum; some animals may show clinical signs and pathology that overlap one or more syndromes.

Capture Shock Syndrome

Acute death syndrome can occur during immobilization or within a short time after capture. Death usually occurs within 1–6 hours postcapture. Clinical signs include depression, hyperpnea/tachypnea, tachycardia, elevated body temperature, weak thready pulses, and death. Serum biochemical findings include elevations in serum aspartate aminotransferase (AST), creatinine phosphokinase (CK), and lactate dehydrogenase (LDH) enzymes. The most common postmortem lesions include severe small intestinal and hepatic congestion along with pulmonary congestion and edema. Frank blood and blood-tinged contents may be found within the lumen of the small intestine.

Histologic findings may include small areas of necrosis in skeletal muscle, brain, liver, heart, adrenal glands, lymph nodes, spleen, pancreas, and renal tubules. These lesions are most pronounced if the animal was hyperthermic. Small thrombi may occasionally be found in the capillaries in various organs (Spraker 1993).

Ataxic Myoglobinuric Syndrome

Literature suggests that this is the most commonly observed among the four syndromes. It may become evident several hours to several days postcapture. Clinical signs may include mild to severe ataxia, torticollis, and myoglobinuria. Serum enzymes (AST, CK, and LDH) and blood urea nitrogen (BUN) levels are elevated. Animals demonstrating mild signs are the most likely to survive. Animals with moderate to severe symptoms have a higher mortality.

Gross lesions can be seen in the kidneys and skeletal muscle. The kidneys are swollen and dark. The urinary

bladder is empty or contains a small amount of brownish urine (Fig. 12.1).

The cervical and lumbar muscles, as well as the flexor and extensor muscles of the limbs (appendicular skeleton) contain multifocal, pale, soft, dry areas, accentuated by small white foci in a linear pattern. The lesions are bilateral but not symmetrical. They are subtle in animals that die within 1–2 days after capture, but they are more pronounced in chronic cases. Animals with prolonged survival may have small ruptures within the necrotic muscles. Well-demarcated, gross changes to the hindlimb musculature of a nilgai and a Grant's zebra can be seen in Figure 12.2 and Figure 12.3, respectively.

Figure 12.1. Incised urinary bladder of the same white-tailed deer as pictured in Figure 12.4 demonstrating marked myoglobinuria (photo courtesy of Dr. Douglas Whiteside).

Figure 12.2. Hindlimb adductor muscle of a nilgai diagnosed with capture myopathy after escaping from a zoo exhibit. The animal survived for 1 week postescape. Note the sharp demarcation between normal muscle on the left-hand side and the affected adductor muscle on the far right that has a pale, dry appearance (photo courtesy of Dr. Scott Citino).

Figure 12.3. Gluteal musculature of a Grant's zebra diagnosed with capture myopathy. The affected muscle is on the far right. It is pale in color, appears to have a dry surface and it is isolated from normal muscle by a septum of deep fascia (photo courtesy of Dr. Scott Citino).

Histologic lesions are primarily localized to the renal cortex and skeletal muscle. Renal lesions are characterized by dilatation of tubules, moderate to severe tubular necrosis, and protein (myoglobin) casts. Muscular lesions are characterized by acute rhabdomyolysis. Myocytes are markedly swollen, with loss of striations and fragmentation and cleavage of myofibrils. Sarcolemmal nuclei are pyknotic in multiple areas. Sarcolemmal proliferation usually begins within 3 days of capture (Spraker 1993).

Ruptured Muscle Syndrome

Clinical signs of this syndrome do not usually manifest until 24–48 hours postcapture and animals initially appear normal. Physical exam findings include a marked drop in the hindquarters and hyperreflexion of the hock due to unilateral or bilateral rupture of the gastrocnemius muscle. Extreme elevations in AST, CK, and LDH are present. Blood urea nitrogen may be within normal limits or slightly elevated. Although most animals with ruptured muscle syndrome die within a few days, some may survive for several weeks.

Gross examination reveals massive subcutaneous hemorrhage of the rear limbs (as seen in Fig. 12.4), and multifocal small to large, pale, soft lesions in the forelimb, hindlimb, diaphragm, cervical, and lumbar muscles. Muscular lesions are similar to those described for the ataxic myoglobinuric syndrome but they are more severe and widespread. Lesions are bilateral but not symmetrical. Multiple, small to large ruptures may be found in necrotic muscle bodies. The gastrocnemius, subscapularis, middle and deep gluteal, semitendinosus, and semimembranosus muscles are often ruptured.

Figure 12.4. Left hindlimb of a captive white-tailed deer diagnosed with capture myopathy and exhibiting ruptured muscle syndrome. The left lateral musculature is exposed with the tarsus on the left. Note the marked subcutaneous hemorrhage surrounding the hindlimb muscles proximal to the tarsus (photo courtesy of Dr. Douglas Whiteside).

Histologic lesions are primarily located within the skeletal muscles and they are characterized by severe, diffuse necrosis. More extensive sarcolemmal proliferation, fibrosis, and muscular regeneration are evident in ruptured muscle syndrome compared to the ataxic myoglobinuric syndrome (Spraker 1993).

Delayed Peracute Syndrome

This syndrome is rare but can be seen in animals that have been in captivity for at least 24 hours. The animals appear normal if they are left undisturbed. When disturbed, captured, or acutely stressed, they will try to escape or run but stop abruptly and stand or lie still for a few moments. During this period, their eyes begin to dilate and death ensues within several minutes. These animals die in ventricular fibrillation and have elevated AST, CK, and LDH. There are usually no lesions, or a few small pale foci within the skeletal muscle at necropsy. When present, histologic lesions are characterized by mild to moderate rhabdomyolysis throughout the skeletal muscle, especially in the hindlimbs (Spraker 1993).

A syndrome called delayed acute CM was identified in three roe deer (Montané et al. 2002). These deer died 48 hours, 72 hours, and 8 days post-capture while being housed in a large enclosure. The authors reported no clinical signs of CM in the deer after capture or while housed in the enclosure until an unobserved, human-initiated pursuit took place. The animals most likely died 14, 41, and 21 hours, respectively, after the disturbance. Although the etiology is similar to delayed peracute syndrome, confirming a common pathogenesis based on available evidence is not possible.

DIFFERENTIAL DIAGNOSES

Differential diagnoses for CM in wildlife may include white-muscle disease, plant toxicities such as *Cassia occidentalis*, *Cassia obtusifolia*, and *Karwinskia humboldtiana* (Chalmers & Barrett 1982), malignant hyperthermia, early tetanus, hypocalcemia, and myositis. This is not an exhaustive list. Conclusive diagnosis of CM depends on history, clinical signs, clinical pathology, and gross and microscopic pathology (Chalmers & Barrett 1982).

TREATMENT

Treatment of CM generally has a low success rate, although animals have been rehabilitated with intensive efforts (Businga et al. 2007; Clark & Clark 2002; Rogers et al. 2004; Smith et al. 2005; Wolfe & Miller 2005). Costs and logistics associated with treating wild animals, particularly in field situations, pose significant challenges. Potential treatment options are discussed below.

Analgesia

Animals suffering from CM can experience severe muscle pain. Analgesia should be considered from an ethical and prognostic point of view. The distress and anxiety resulting from pain will make this disease more difficult to treat. Analgesics used will vary depending on the affected species. Judicious use of nonsteroidal anti-inflammatories is an option provided there is no concurrent steroid administration or indication of renal dysfunction. Opioid administration with or without a sedative should also be considered. Corticosteroids may alleviate pain and help preserve lysosomal membrane and capillary integrity (Muir et al. 2000b).

Dantrolene

Dantrolene sodium is a lipid soluble hydantoin analog used to treat and prevent malignant hyperthermia in humans and exertional rhabdomyolysis in horses (McKenzie et al. 2004). Dantrolene suppresses the release of calcium from the sarcoplasmic reticulum (Krause et al. 2004). Side effects associated with dantrolene include neurologic deficits, muscular weakness, and hepatotoxicity (McKenzie et al. 2004). Dantrolene was used in the successful treatment of severe rhabdomyolysis in a dog (Wells et al. 2009). There are no reports of dantrolene administration for the treatment of CM in wildlife or zoo animals. The drug would be impractical for field use due to its light sensitivity, insolubility, and expense (McKenzie et al. 2004).

Muscle Relaxants

Benzodiazepines, including diazepam, midazolam, and zolazepam, are centrally acting muscle relaxants that reduce muscle spasms and spasticity (Muir et al. 2000a).

Benzodiazepines are also anticonvulsants and may aid in calming obtunded and/or debilitated animals (Muir et al. 2000a; Wolfe & Miller 2005). Methocarbamol is another centrally acting muscle relaxant that has been used to successfully treat CM in a rhea (Smith et al. 2005). Limited pharmacokinetic data is available for this medication in veterinary species.

Dietary Supplements

Vitamin E and selenium are biological antioxidants administered as a prophylaxis or treatment for CM (Abbott et al. 2005; Businga et al. 2007). The efficacy of these supplements is contentious. Abbott et al. (2005) suggested increased survival rates in northern bobwhites injected with vitamin E and selenium after capture and relocation, although the study lacked adequate sample size. Rio Grande wild turkeys showed no improvement in survival when individuals were treated with vitamin E and selenium during trapping and relocation (Schutz 2009). Successful treatment of CM in birds has been achieved with (Businga et al. 2007) and without (Rogers et al. 2004; Smith et al. 2005) vitamin E and selenium supplementation.

Parentrovite was a balanced formulation of B vitamins with vitamin C in parenteral form. The drug was withdrawn from the human market in 1989. Parentrovite was administered to tsessebe to treat locomotory and capture stress but no conclusions could be made as to its effectiveness (Harthoorn & Harthoorn 1976). Reported use of multivitamin formulations for the treatment of CM could not be found in any recent literature.

Coenzyme Q₁₀ and L-carnitine were administered to a dog with rhabdomyolysis with the intention of supporting oxidative metabolism (Wells et al. 2009). These two nutrients are critical cofactors in cellular reactions required for energy production (Freeman & Rush 2005). Coenzyme Q₁₀ is also an antioxidant (Freeman & Rush 2005).

Hyperbaric Oxygen

Hyperbaric oxygen has been used as an adjunctive therapy in humans for severe rhabdomyolysis and acute renal failure (Abdullah et al. 2006). Hyperbaric oxygen (HBO₂) induces high oxygen partial pressure in all tissues, inhibits toxin formation, and promotes wound healing (Abdullah et al. 2006). The popularity of this therapy in veterinary medicine is increasing and may become more accessible in the future, particularly for highly valued captive animals.

Sodium Bicarbonate

Sodium bicarbonate is used to treat acidemia and alkalize the urine. Approximately 4 mEq/kg of sodium bicarbonate administered intravenously was successful in resolving metabolic acidosis and reducing mortality in captured zebra (Harthoorn & Young 1974). Alkaline-

izing the urine can reduce the risk of tubular obstruction by myoglobin casts; however, myoglobin is also intrinsically nephrotoxic (Lane & Phillips 2003). Blood gas analysis should ideally be used to titrate sodium bicarbonate therapy. Excessive administration may produce metabolic alkalosis or paradoxical cerebrospinal fluid acidosis (Muir et al. 2000b). The practicality of using this therapy in the field is limited.

Fluid Therapy

Intravascular volume expansion with balanced electrolyte solutions is effective in treating metabolic acidosis, hyperkalemia, dehydration, and myoglobinuria. Intravenous fluid therapy may also help to offset hypotension that occurs in some cases of CM. Parenteral fluid therapy was part of the successful management protocol for greater sandhill cranes (Businga et al. 2007), a rhea (Smith et al. 2005), and a mountain lion (Wolfe & Miller 2005).

Nutritional Support

Animals suffering from CM will usually not meet their nutritional requirements voluntarily. Decreased body condition, nutritional deficiencies, and weight loss may significantly impact prognosis. Nutritional supplementation was a vital component in the successful treatment of avians, including Australian shorebirds (Rogers et al. 2004), greater sandhill cranes (Businga et al. 2007), and a rhea (Smith et al. 2005).

Physical Therapy

Authors reporting successful treatment of CM in avians have stressed the importance of physical therapy for restoring muscle coordination, strength, and function (Businga et al. 2007; Rogers et al. 2004; Smith et al. 2005). Recumbent or severely debilitated birds have been supported in slings and gradually reintroduced to weight-bearing exercise (Rogers et al. 2004; Smith et al. 2005). Wading birds may recover from early symptoms of CM if their legs are bathed in water (Clark & Clark 2002). Physical therapy is relatively easy to perform on a small bird (or sedated ratite in the case of the rhea). Providing effective muscle support and exercise in other species may be challenging especially as it can take days to weeks for muscle function to return.

PREVENTION

Possible modes of preventing CM will depend largely on the species being captured, the goal of capture, the resources available, and the environment in which the capture is taking place. Operators must recognize environmental limitations, such as extremes in temperature or terrain. Handling should be minimal and performed by experienced personnel. Transportation must be as brief as possible and appropriate for the species and individual. Wild animals will also adapt better to

capture and confinement with prior training and desensitization.

Drugs chosen for immobilization should be tailored for rapid induction, rapid recovery, efficient delivery, and physiologic stability. Duration of anesthesia should be as short as possible and oxygen supplementation is generally recommended. Administration of tranquilizers, such as acepromazine (López-Olvera et al. 2007; Montané et al. 2007), azaperone (Mentaberre et al. 2010), haloperidol (Mentaberre et al. 2010), or long-acting alpha-2 agonists, such as zuclopenthixol acetate (Read et al. 2000), can aid in reducing stress during handling, transport, and confinement.

Researchers are continuously refining capture techniques and identifying methods of trapping that are more or less likely to cause CM. Culvert trapping and aerial darting resulted in less morbidity and mortality in black bears and grizzly bears compared with leghold snares (Cattet et al. 2008). Dugongs were more efficiently and safely caught manually at the surface of the water versus hoop-netting (Lanyon et al. 2006). Radio-controlled up-net enclosures were found superior to other traps for capturing chamois and may prove successful for a variety of ungulate species (Dematteis et al. 2010). Similar netting innovations have also been described for birds (Bush 2008). Jacques et al. (2009) found the probability of capture-related, postrelease mortality in pronghorn decreased by 58% when transport distance was reduced from 14.5 to 0 km (initial mortality was 25/281 or 8.9%). Similarly, capture-related, postrelease mortality decreased by 69% in pronghorn and white-tailed deer (initial mortality: 3/208 or 1.4%) when helicopter pursuit time decreased from 9 minutes to less than 1 minute (Jacques et al. 2009).

A recent retrospective analysis suggested a capture-related mortality rate of greater than 2% be considered unacceptable in any large mammalian species (Arnemo et al. 2006). The following study provides a case-specific, yet universally applicable example of how CM can be minimized (Harthoorn 1980). From 1973 to 1978, the mortality rate in captured and relocated animals in Transval provincial reserves in South Africa dropped from 15% to 1.1% (Harthoorn 1980). The high mortality rate was attributed to net capture with prolonged restraint, the capture of individuals rather than family groups, individual crating and transport, prolonged holding in slatted pens, further handling and transport after a rest period, and a sudden change in food. Survival rates were improved by reducing chase speeds, allowing periodic rests during drives over long distances, an almost a total absence of handling, capturing family or herd groups, transporting to the destination immediately after capture with no holding or quarantine, using plastic sheeting or Hessian funnels and corrals, reducing fear and stress by eliminating shouting and other noise, and ensuring minimal contact between the animals and the capture personnel.

CONCLUSIONS

CM remains a frustrating and poorly understood condition despite being frequently reported in veterinary literature. Its unpredictable and multifactorial nature poses a distinct challenge to those who study the disease. Developing a consistently effective treatment for CM will require a better understanding of how to stop the physiologic cascade once it has been triggered. The key to preventing CM lies in understanding the behavior and physiology of individual species. Wildlife capture must be carried out sparingly and with great planning and precision. Ultimately, the welfare of the animal must always be the first priority.

13 Human Safety during Wildlife Capture

Nigel Caulkett and Todd Shury

INTRODUCTION

Capture and anesthesia of zoo and wild animals is inherently dangerous for the people who carry it out. These risks can be elevated in free-ranging situations where the capture team may be subject to environmental threats. Prior to any capture, procedure steps must be taken to recognize potential risks to personal safety, and every attempt should be made to reduce the risk of injury. In the event of injury, there must be a well-thought-out treatment and evacuation plan to deal any and all situations.

This chapter will discuss some of the major risks to human safety that may be encountered during the capture and handling of wildlife. It will discuss methods to reduce risk, and finally it will discuss how to prepare for and deal with emergency situations.

RISKS TO HUMAN SAFETY DURING WILDLIFE CAPTURE AND HANDLING

Hazard Assessment

It is important to perform a hazard assessment of any novel job site prior to commencing work. The hazard assessment should identify any potential hazards and identify what steps can be taken to reduce the risks from these potential hazards. Ideally, a written document should be created that outlines these steps. Everyone on the capture team should be made aware of the risks and any precautionary measures that will be taken. Once personnel have been briefed of the risks and mitigation strategies, they should sign off that they have been briefed.

Environmental Risks

Before working in any environment it is important to be aware of potential hazards. Weather conditions can

pose a risk, particularly in areas where personnel may be exposed to extremes of temperature. In some environments, the weather may change very quickly; heavy fog or snow can disable helicopter flight and leave a crew stranded. Personnel should be well prepared for the weather conditions and terrain that may be encountered in their environment. In areas that have rapidly changing weather conditions, clothing should be carried to protect from adverse weather conditions. Work on animals in mountainous terrain requires a knowledge of mountaineering and the use of ropes and harnesses in potentially dangerous locations (Fig. 13.1).

Adequate water supplies are vital in any environmental condition. In remote areas, personnel should be prepared to spend the night outdoors if it is not possible to return to base. Altitude can be a problem if personnel are not properly acclimated. Personnel should be aware of potentially dangerous mammals, reptiles, or insects in a given environment. Communication is vital in emergency situations and a reliable method of communication should be established. In areas where cellular phones do not function, VHF radios may be an option. Satellite telephones function in most parts of the world.

Disease risks should be evaluated for a given environment, and steps should be taken to prevent exposure to infectious disease. Public health professionals should be consulted to determine disease threats and vaccine requirements or malaria prophylaxis in a given region. In some environments, the political situation can be hazardous. Capture personnel should be aware of human-related risk factors in a given environment.

Equipment Related Risks

Remote Delivery Equipment

Dart rifles and pistols have the potential to induce severe trauma if they are used inappropriately (Bush 1992; Cattet et al. 2006). They should be treated with

Figure 13.1. The use of ropes to approach a bighorn sheep on a cliff edge.

the same respect as firearms. Personnel using dart rifles and pistols should have appropriate firearms training and practice firearms safety rules.

Dart loading is a potentially hazardous procedure. The risk of drug exposure is increased during dart loading and during charging of darts that utilize compressed gas for their discharge. Darts should never be loaded alone, and should always be loaded on a steady surface, that is, never in a moving vehicle. There should be sufficient water available to dilute spills, and protective clothing (i.e., safety glasses, gloves, and coveralls) should be worn to prevent exposure to drugs. Darts should always be covered, to contain leaks, when they are charged. Loaded darts should always be stored in a sealed, impenetrable, leak proof container. An alternative solution is to load and pressurize darts inside a sealed container that can contain leaks or spills. The original concept, developed by Dr. Jerry Haigh, has been further refined and advocated to prevent exposure to hazardous drugs (K. Amos, personal communication). An example of a “splash box” can be found in Figure 13.2.

Firearms and Pepper Spray

A firearm backup is essential when working with potentially dangerous animals. Everyone working around firearms should receive firearms safety training, and only very experienced personnel should be in charge of providing the firearm backup.

It is important to choose a firearm that has sufficient impact energy to rapidly incapacitate the target species.

In some situations, animals other than the immobilized animal may be the major threat. In these situations, it is advisable to assign a dedicated person to the task of guarding the capture crew. Bear deterrent spray has proven to be an effective deterrent to bear

Figure 13.2. Loading a dart in a “splash box” (image courtesy of Dr. Keith Amass).

Figure 13.3. Bear deterrent spray.

attacks and should be considered as a nonlethal option of repelling wildlife attacks. It has been well studied as an alternative to firearms during bear attacks. A study of 72 adverse bear encounters in Alaska, between 1985 and 2006, revealed that pepper spray stopped undesirable behavior in 92% of brown bear incidents, 90% of black bear incidents, and 100% of polar bear incidents. When pepper spray was used, 98% of individuals deploying the spray were uninjured, and when injuries did occur, they were minor (Smith et al. 2008). This is very convincing evidence of the utility of pepper spray, given the nonlethal nature of this deterrent, it should be considered as a first line of defense. It is important to note that 14% of individuals using the spray experienced effects of the spray themselves (Smith et al. 2008), and that as this study documents use in bears, this may not be applicable to other wildlife species (Fig. 13.3).

Compressed Gas

Care must always be taken when transporting or delivering oxygen. Aluminum D or E cylinders can be easily transported in the field. It is important to secure the tanks as impact damage to the neck of the cylinder can result in a rapid escape of gas and create a missile. Oxygen should never be used around open flames or grease. People using compressed gasses should have appropriate safety training. In situations where it is undesirable to transport compressed gas, portable oxygen concentrators are proving to be a useful alternative to compressed gas cylinders.

Traps and Snares

Traps, snares, and nets are frequently used to facilitate physical capture. Net guns have the potential to induce severe injury if the victim is struck by a weight. Net guns are frequently used from a helicopter. Nets have the potential to induce a crash if they are deployed into the main or tail rotor.

Leg hold traps and snare springs can produce significant bruising or crush injuries. Culvert traps that have heavy guillotine-type doors can induce significant injury.

Helicopters

Wildlife capture work often involves low level highly technical flying. Capture may occur at altitude and sometimes in inclement weather. Helicopter crashes have been a significant cause of injury and death during wildlife capture work (Jessup et al. 1988). A highly skilled, experienced pilot and a well maintained aircraft is vital in these situations. It is also very important to make safe decisions about the weather conditions before embarking on a capture expedition.

Personnel working around helicopters should receive safety training. Helmets and fireproof clothing may decrease the risk of mortality during a helicopter crash.

Animal-Related Risks

Trauma

Animal-induced trauma is very frequent in personnel working with zoo and wild animals. In 1998, a special report in the *Journal of Zoo and Wildlife Medicine* reported a 61.5% incidence of major animal-related injuries in zoo veterinarians (Hill et al. 1998). The most frequently reported injuries were animal bites and kicks. Scratches, crush injuries, and horn wounds were also reported. This report recommended the use of long-sleeved shirts, lab coats, leather gloves, and face shields to protect from injury (Hill et al. 1998). A report on large carnivore attacks on people details some of the risk factors involved and number of attacks by species. This study discusses attacks in general, not attacks in zoo or wildlife capture situations (Löe & Röskaft 2004)

Zoonotic Infections

Zoonotic infections are relatively common in zoo and wildlife workers (Adejinmi & Ayinmode 2008; Stetter et al. 1995). These infections range from simple irritations to life threatening conditions. The study quoted a 30.2% incidence of zoonotic disease in zoo veterinarians. The most common infection was ringworm (reported by 28 veterinarians), followed by psittacosis (24 veterinarians) (Hill et al. 1998). Allergies are also a fairly common occupational hazard among zoo workers (Herzinger et al. 2005; Krakowiak et al. 2002). Simian retroviruses and herpesviruses can present a risk to animal workers and nonhuman primates in primate colonies; an excellent review of these risks and steps to decrease the risk of exposure is available (Weston Murphy et al., 2006).

Careful handling, protective clothing, and up-to-date vaccination status are important to prevent the transmission of zoonotic disease.

Drug-Related Risks

Anesthetic Gasses

Anesthetic gasses are commonly utilized by zoo veterinarians. Ninety-one percent of zoo veterinarians have reported using inhalant anesthetics and 10.9% reported an adverse exposure (Hill et al. 1998). The most commonly reported effects with halothane and isoflurane were headaches, dizziness, sleepiness, and light headedness (Hill et al. 1998). Nitrous oxide exposure was associated with dizziness and sleepiness. Chronic occupational exposure to nitrous oxide has been associated with decreased fertility and increased rate of abortion in dental assistants (Rowland et al. 1992).

Occupational exposure to all gas anesthetics should be minimized. The best method to minimize exposure is the use of an active scavenging system. In addition to active scavenging, delivery equipment should be well maintained to minimize leaks. It is further recommended that anesthetic gas exposure should be periodically monitored by an industrial hygienist (Hill et al. 1998).

Drugs Used for Remote Delivery

Drugs designed for remote delivery are often very potent. While this allows for the delivery of small volumes, it also increases the risk of intoxication from exposure to the drug. Capture drugs must always be handled with respect, and the level of vigilance must always be high. It is a good practice to always wear disposable gloves when drugs are handled. A face shield is also recommended when working with potent narcotics or concentrated medetomidine. Coveralls can be quickly removed if a drug is spilled on them. If a human antagonist is available, it should be drawn up and ready to administer. One should never work alone, and everyone on the capture team should be trained in first aid and CPR. It is important to maintain an increased

level of vigilance during the handling of drug vials, the loading and unloading of darts, and during pressurization of darts that utilize compressed air or butane for injection.

Potent Narcotics

Potent narcotics are commonly used for the capture and handling of ungulates. They are a group of drugs that demand respect and care in handling. The three drugs in common usage are etorphine, carfentanil, and thiafentanil. Carfentanil has been quoted to be 10,000 times as potent as morphine (Van Bever et al. 1976). Thiafentanil has been quoted to be 6000 times the potency of morphine (Stanley et al. 1988). Not only are these drugs potent, but they are also formulated in a relatively concentrated solution to increase their utility for remote delivery. Carfentanil is commercially available as a 3mg/mL solution. Thiafentanil is typically used as a 10mg/mL solution. These factors, taken together, will increase the risk of a significant human intoxication with exposure to a very small volume of drug.

There are several reports of human intoxication in the literature. Most of these reports detail human intoxication with etorphine (Anonymous 1976; Sheridan 1981; Summerhays 1976). One human fatality was reported from accidental injection of etorphine (Anonymous 1976). There is very little information concerning human intoxication from carfentanil or thiafentanil (Haymerle et al. 2010). It is likely that minor intoxications are not reported due to embarrassment (Haigh 1989).

The ultra potent narcotics have a high therapeutic index in comparison with older drugs, such as morphine (Wax et al. 2003). The therapeutic index of carfentanil in rats is 10,600 (Van Bever et al. 1976). It has been argued that the high therapeutic index may confer a higher level of safety in the event of human exposure. In October 2002, the Russian military used an "incapacitating gas" to end a hostage crisis at the Moscow Dubrovka Theater. The gas was most likely a mixture of carfentanil and halothane (Wax et al. 2003). Unfortunately, 127 of the 800 hostages died and 650 of the survivors required hospitalization. Given the high therapeutic index, this number of deaths was not anticipated by Russian officials (Wax et al. 2003). Obviously, it was not appropriate to directly extrapolate animal data to human beings (Wax et al. 2003). This incident stresses the need for a high level of vigilance when these agents are used.

A study published in 2010 (Haymerle et al. 2010) surveyed European zoo and wildlife practitioners and reviewed the literature regarding exposure to drugs used in wildlife capture and anesthesia. In 18 cases of exposure, the vast majority of individuals did not suffer severe symptoms; 2 of 18 individuals required administration of a narcotic antagonist. This study stressed the importance of proper personal protective gear and

the availability of a pharmacological antagonist (Haymerle et al. 2010)

Given the potential risks of these agents and their widespread use, it is surprising that there are very few published reports of accidental human intoxication. It is possible that this is the result of education and safe practice by zoo and wildlife veterinarians. A survey found that 65.1% of zoo veterinarians reported using ultrapotent narcotics and immobilizing agents (Hill et al. 1998). Of those who used these drugs, 86.7% had a written emergency protocol, 92.3% wore gloves, and 76.2% wore eye protection (Hill et al. 1998). This good standard of practice probably limits the incidence of adverse drug exposure in zoo veterinarians.

Prevention of exposure to potent narcotics is the best way to avoid intoxication. Protective clothing, gloves, and an eye shield should always be worn when these drugs are handled. Full face protection can be advantageous to prevent oral, ocular, or nasal exposure.

Symptoms of narcotic overdose in humans include nausea, dizziness, respiratory depression, and miosis. This can progress to coma and cardiovascular collapse with severe intoxication (Haigh & Haigh 1980). Rapid administration of a specific narcotic antagonist is vital in the face of severe intoxication. Naloxone has been advocated for this purpose, but it must be administered at a high dose, and due to its short half-life, repeated dosing will probably be required. A dose of 0.53–2mg/kg of naloxone may be required to antagonize the effects of carfentanil in humans (Petrini et al. 1993). This may require up to 14 10mL vials of 1mg/mL naloxone (Petrini et al. 1993). In emergent situations, it would be ideal to administer naloxone via intravenous administration; this may be difficult due to lack of training in human IV access, or due to the challenges of functioning well in an emergent situation. Intranasal administration of naloxone has proven to be a viable alternative to intravenous administration in a prehospital setting (Barton et al. 2005). This may well be a good option to treat intoxication with potent narcotics in field situations. Naltrexone is commonly used to antagonize potent opioids in wildlife (Allen 1989). It has the advantage of a long half-life, which reduces the risk of renarcotization following antagonism of carfentanil (Allen 1989). Naltrexone is available as a 50mg tablet for human use. It is advocated for the treatment of narcotic addiction and alcoholism. An oral formulation is less useful than an injectable form in emergent situations, particularly when intoxication may include nausea, vomiting, or coma. The oral formulation of naltrexone could prove useful after initial antagonism with naloxone, particularly in remote locations where medical help is difficult to access.

Intoxication from a large dose of an opioid can occur very rapidly. Personnel should always work in teams and everyone should be trained in first aid with a current CPR certificate. The major threat to life from

opioid overdose is from respiratory depression. A means of assisting respiration, such as rescue breathing with a pocket mask or ambu bag can provide the respiratory support that is required until the intoxication is treated. If oxygen is available it should also be utilized during rescue breathing.

Alpha-2 Agonists

There are several published reports that detail human deaths or intoxication from xylazine (Capraro et al. 2001; Carruthers et al. 1979; Fyffe 1994). In most of these reports, xylazine was self-administered, either in a suicide attempt or for recreational use. Intoxication is commonly characterized by bradycardia, hypotension, and respiratory depression. Treatment of xylazine intoxication is typically supportive care and the use of assisted, or controlled ventilation (Capraro et al. 2001; Carruthers et al. 1979; Fyffe 1994). Alpha-2 antagonists, such as yohimbine and tolazoline, are not typically used to treat xylazine intoxication in humans.

The use of xylazine has been widespread in veterinary medicine. It has proved to be an extremely useful drug for wildlife capture and handling. In recent years, there has been a drive to develop alpha-2 agonists with increased potency and specificity for the alpha-2 receptor. Medetomidine has proven to be a very effective drug for wildlife capture and handling. It can be formulated in a concentrated solution of 10–40 mg/kg. This concentration, combined with its high potency, makes medetomidine very attractive for wildlife handling. This same factor will increase the risk of human intoxication with a very small volume exposure. Dexmedetomidine is the pharmacologically active *d*-isomer of medetomidine. Dexmedetomidine is marketed in the United States as Precedex® (Hospira Inc., Lake Forest IL). Precedex is typically administered as an IV loading dose of 1 µg/kg, followed by an infusion of 0.2–0.7 µg/kg/h. Side effects at this dose include transient hypertension (during the loading dose), bradyarrhythmias, and hypotension. This dose is used to induce sedation and facilitate ventilation of ICU patients. An IV dose of 75 µg (total) induced significant bradycardia and an 18% reduction in blood pressure (compared with baseline) in human volunteers (Kallio et al. 1989). This dose would be equivalent to approximately 150 µg of medetomidine. If medetomidine is formulated to a concentration of 10 mg/mL, this dose will be contained in 0.015 mL of solution. A dose of 120 µg of medetomidine has been reported to induce sleep in 50% of human males (Scheinin et al. 1998). This dose is equivalent to 0.003 mL of 40 mg/mL medetomidine (Haymerle et al. 2010). It is obvious from these examples that the formulation of medetomidine routinely used in wildlife anesthesia is extremely potent and deserves the same degree of respect that is given to potent opioids.

Treatment of exposure to a toxic dose of an alpha-2 agonist will be supportive, as no alpha-2 antagonist is

currently approved for human use. In a field situation, the victim may benefit from administration of supplemental inspired oxygen and ventilatory support as needed. Airway protection will also be important if the victim becomes comatose. Heart rate and blood pressure should be monitored. Rapid evacuation to a medical facility is vital for the victim to receive appropriate treatment for hypotension and respiratory depression.

Phencyclidine Derivatives

There are two phencyclidine derivatives that are commonly used for wildlife anesthesia. Ketamine is typically used in combination with an alpha-2 agonist or a benzodiazepine tranquilizer. Telazol® and Zoletil® are 1:1 combinations of tiletamine, an arylcyclohexamine structurally related to phencyclidine and zolazepam, a benzodiazepine tranquilizer. There are case reports that detail human fatalities with self-administration of Telazol (Chung et al. 2000; Cording et al. 1999). These drugs are typically used to produce a state of dissociative anesthesia. One of the major side effects of ketamine is bizarre hallucinations; this has limited its utility in human anesthesia. Ketamine is a common drug of abuse. Its effects appear rapidly and include visual hallucinations and a dream-like state (Gahlinger 2004). Undesired side effects include confusion, delirium, tachycardia, palpitations, hypertension, and respiratory depression (Gahlinger 2004). A severe intoxication will result in loss of consciousness and the accompanying risks of respiratory depression or airway loss.

Ketamine is often snorted, with a typical abuse dose of 20 mg into each nostril (Stodder Cuddy 2004). It can be seen from the earlier discussion that a relatively low dose exposure of ketamine or tiletamine could produce intoxication. A low dose intoxication, which resulted in confusion or disorientation, could prove hazardous in a wildlife capture environment. In the event of a low dose intoxication, the victim should be removed from the capture team, reassured, closely monitored, and evacuated to a medical facility for observation. In the event of a high dose intoxication, the unconscious victim should receive supplemental oxygen, airway support, and rescue breathing if required. The victim should be rapidly evacuated to a medical facility for treatment.

EMERGENCY PREPAREDNESS

Every effort should be made to identify the risks associated with a planned capture procedure. It is always best to take steps to minimize the risk of human or animal injury. A preimmobilization plan will identify risks and allow the capture team to anticipate complications and take steps to mitigate risk. Unfortunately, risk reduction is not always 100% successful; therefore, it is vital

to develop an emergency response protocol that can be initiated if an accident occurs.

Preimmobilization Plan

A preimmobilization plan should identify potential risks associated with a capture event or research project. Many of these risks are outlined earlier. All members of the capture team should be briefed on these risks prior to the capture. The plan should outline everyone's role on the capture team. A team leader is typically identified. The plan should ensure that everyone on the capture team is appropriately trained in wildlife handling techniques. Anyone working directly with the animal should receive appropriate training in chemical immobilization. Ideally, everyone on the team should receive training in first aid and hold a current CPR certificate. If this is not possible, at least two team members should have this training. Personnel should be trained in the proper use of darting equipment. Helicopter safety and firearms training may be indicated. Additional training may be required. This may include training in communications, survival, or terrain-specific training, such as cold water survival or avalanche rescue. Field equipment should be checked prior to a capture event. First aid kits and human antidotes should be carried, and team members must know how to access and use them. Appropriate clothing should be carried for the terrain and weather conditions.

A system of communications should be established between capture team members and with any personnel that will be required for evacuation or medical treatment of an accident victim. An emergency response plan will need to be developed. This plan must clearly outline the steps that will be taken in the event of an emergency. The plan should be well thought out and flexible enough to deal with any foreseeable emergency.

Emergency Response Protocol

An emergency response protocol should be developed prior to commencing work on a project and should be in place at any facility where there is a significant risk to human safety from wildlife or zoo animal capture and handling. These protocols are often quite specific for a facility or location, and will need to be revised if wildlife capture is initiated in a new location. Good examples of a specific emergency response protocols can be found in the following references (Petrini et al. 1993; Tolo & Keyler 1998). The emergency response protocol should be developed in consultation with physicians who may be required to treat the victim and with emergency medical services (EMS) personnel who may be required to treat and transport the victim. The main components to the protocol are consultation with medical professionals, communication, treatment, and evacuation.

Consultation with Medical Professionals

In any true emergency, time to treatment is probably the most important factor that will determine outcome. Emergency room physicians may not be familiar with drugs that are commonly used for wildlife capture. Development of an emergency response protocol should include a visit to the hospital that a victim will be evacuated to in the event of an emergency. Drug package inserts and information regarding the capture drugs should be given to the medical staff that may be required to treat the victim. The effects of most of these drugs can be extrapolated from similar drugs used in human medicine. The visit should also include a means to set up a communication link, from the field, to assist with initial stabilization of the victim. In some locations, the victim may require evacuation by the capture crew. It is preferable to have the victim evacuated by EMS whenever it is available. The development of the emergency response protocol should include a visit to the ambulance service that would transport the victim. Ideally, a paramedic should be dispatched to stabilize the victim. Stabilization in the field may include venous access and possibly intubation and ventilation, this treatment can be lifesaving. Again, the effects of the drugs and antagonists should be discussed.

Communication

A reliable method of communication should be established with EMS and with the hospital. This may be as simple as a cellular telephone. In remote locations, VHF radios may be used, either directly to EMS or via a dispatcher. Satellite telephones are very useful for this purpose as they can be used from very remote locations. A communications link is vital in an emergency situation.

Treatment and Evacuation

In the event of an emergency, timely treatment in the field will have a major influence on outcome. In remote locations, where access to EMS is difficult, capture team members should receive advanced first aid training. A first aid kit must be carried with appropriate equipment to treat a major traumatic incident. The accident victim should never be left alone, and help should be summoned as soon as possible. In the event of a drug intoxication, the key to a successful outcome will be the rapid administration of antagonists and supportive care. The unconscious victim should receive airway support and oxygenation. Rescue breathing can be lifesaving in the face of respiratory arrest. Rescue breathing can be learned through a CPR course. Ideally, advanced training should be taken to become certified in the use of pocket masks, oral airways, oxygen therapy, and ambu bags. This will facilitate ventilation with a high inspired concentration of oxygen.

An evacuation plan must be developed for every situation. Ideally, EMS should be used for the evacua-

tion. Paramedics and EMT's are experts in this field and can ensure that the victim is cared for appropriately during transport. In remote locations, the capture team may need to evacuate the victim. The evacuation should be to the closest location for ambulance access, or directly to the hospital. If helicopters are used, it will be important to determine the best location for landing if there is not an established landing pad. The victim must never be left alone and should always be closely attended by someone who is trained in advanced first aid.

Capture and handling of wild animals is not without risk. It is vital to carefully plan for emergencies, as time spent planning and preparing for an emergency will generally dictate the outcome.

Invertebrates

Cornelia I. Mosley and Gregory A. Lewbart

INTRODUCTION

What sort of topic is invertebrate anesthesia and analgesia? A better first question might be “what exactly are invertebrates?” The invertebrates are a collection of animals, comprising more than 95% of the earth’s species, unified by the lack of a vertebral column. Barnes and Ruppert (1994) stated invertebrates are a group of unrelated taxa that share no universal “positive” traits.

Depending on the text or specialist(s), there are currently over 30 recognized phyla of invertebrates (not including the protozoans). Many of these phyla be considered “obscure,” but for no better reason than they may contain few species, microscopic representatives, or have no *obvious* economic value. In reality, each phylum and its members are important to the diversity and survival of the planet, even if the group is only studied by a small number of scientists. Unfortunately, relatively little is known about the veterinary, and more specifically, anesthesia/analgesia aspects, of many of these taxa. Writing a comprehensive book chapter for all invertebrate phyla would be an inefficient task. Consequently, we have elected to include, at least in this chapter, the most economically important and “visible” metazoan taxonomic groups.

The science of taxonomy is a dynamic and at times controversial branch of biology. We have elected to use the taxonomic terminology currently described in Ruppert et al. (2004), with the knowledge that some invertebrate zoologists may utilize a slightly different nomenclature for some groups.

Invertebrate anesthesia is still in its infancy and little research has been done to improve the understanding of the various anesthetic agents in this group of animals (Table 14.1). The goal of this chapter is to provide an overview of anesthetic concerns and tech-

niques in more commonly anesthetized invertebrates. It should be emphasized that more research is necessary to better understand and improve anesthesia in the different, and frequently unrelated, invertebrate species.

TAXONOMIC GROUPS

Mollusks

Anatomy, Physiology, and Natural History The mollusks are a diverse and large group of animals that occupy terrestrial, freshwater, and marine environments. There are probably about 100,000 described extant species in this huge phylum. Some are extremely important to the environment because of their ability to filter water and consume debris and detritus. Economically, they are one of the most important taxa on earth, and provide billions of dollars annually as a source of food, animals for pets, display, and research, and as jewelry, artwork, and the lucrative shell-collecting hobby.

Details of molluscan natural history, anatomy, and physiology can be found in a number of references, including Ruppert et al. (2004); Lewbart (2012), and any general invertebrate zoology text. Malacology is the term used to describe the study of mollusks.

Despite their wide variety of function and form, nearly all mollusks have the following traits in common at some point in their life history: a muscular foot for locomotion, gills for respiration, a calcareous shell for protection and a mantle to secrete it, ciliated planktonic larvae for dispersal, and a chitinous radula for feeding.

We have elected to divide up the mollusks into three separate groups. It should be noted that only the most economically important classes are discussed, as these are the groups that have received some attention with

Table 14.1. Immobilization and anesthetic drugs used in invertebrates

Invertebrate	Anesthetic Agent	Dosage	Induction Time	Recovery	Comments	Source
Gastropods Snails	Ethanol (5%)					Flores et al. (1983)
	Ethanol (21.9%) + menthol (0.042%)				10% Listerine solution	Woodall et al. (2003)
Great pond snail	Sodium pentobarbital	0.4 mg/mL H ₂ O	8 hours		Low mortality rate	Martins-Sousa et al. (2001)
	Isoflurane	MAC: 1.09%	<10 minutes	<10 minutes	Induction excitement	Girdlestone et al. (1989)
Sea snails	1-Phenoxy-2-propanol	8–16 mmol/L	1.5 hours		Stir solution well to avoid tissue damage	Wyeth et al. (2009)
	Magnesium sulfate or Mg Cl ₂	Intracoelomic	2–5 minutes		Good muscle relaxation	Clark et al. (1996)
Abalone	2-Phenoxyethanol	0.5–3 mL/L	1–3 minutes	5–20 minutes		White et al. (1996)
	Benzocaine	100 mg/L	13–28 minutes			Edwards et al. (2000)
Cephalopods Cuttlefish	Magnesium sulfate	4–22 g/100 mL water	5–8 minutes	3–35 minutes	Larger size = higher dosage	White et al. (1996)
	Sodium pentobarbital	1 mL/L	15 minutes	<80 minutes	Decrease in HR	Aquilina and Roberts (2000)
Octopus	Ethanol	15–30 mL/L	1 minutes	20 minutes	Size dependent induction/recovery timing	Sharma et al. (2003)
	Mg Cl ₂	>10–15 mL/L	6–12 minutes	2.5 minutes	Transient excitement	Harms et al. (2006)
Octopus	Ethanol	6.8 g/L	4 minutes	2.5 minutes	Excitement, not effective in cold water species	Gore et al. (2005)
	Mg Cl ₂ (7.5%)/H ₂ O	20 mL/L (2%)	1.5–13 minutes	1–10 minutes	Smooth induction and recovery	Andrews and Tansey (1981)
		50/50				Messenger et al. (1985); Culloty and Mulcahy (1992)

Bivalves									
Oysters	Propylene phenoxetol (1% solution) Mg Cl ₂ (3.5%)	1–3 mL/L	6–15 minutes	<30 minutes	Dosage is species dependent	Norton et al. (1996); Mills et al. (1997)			
Scallops	Mg Cl ₂ Chloral hydrate	30–50 g/L 4 g/L	1–2 hours 2–6 minutes 10–25 minutes	90 minutes 10 minutes 20–30 minutes	Variable effects, long induction and recovery, species + temperature dependent, see text for details Drug of choice Variable effects, temperature dependent	Norton et al. (1996); Mills et al. (1997), Culloty et al. (1992); and others Heasman et al. (1995) Heasman et al. (1995)			
Arachnida	Isoflurane/ sevoflurane	3–5%/4–6%	5–15 minutes	3–20 minutes	Induction chamber system	Pizzi (2012); Melidone and Mayer (2005); Cooper (2001)			
Spiders and scorpions	Lidocaine Ketamine	0.4–1 mg/g IM 40–90 µg/g IM	1.5 minutes 1 minutes	5–30 minutes 1–2 hours, Dose dependent.	Variable response	Brown et al. (1996) Brown et al. (1996)			
Crustaceans

regards to anesthesia and analgesia. Classes not covered include the Aplousobranchia, Monoplousobranchia, Polyplousobranchia (chitons), and Scaphopoda (tusk or tooth shells).

Gastropods

Anatomy, Physiology, and Natural History The gastropods are a large, important, and easily recognized group that includes the abalone, snails, nudibranchs, and sea hares, among others. Most are aquatic and have a well-developed head with eyes and other sensory organs, an external shell, muscular foot, and gills within a chamber for respiration. There are many exceptions, however, and one need only examine a common garden slug (no shell or gills and terrestrial) to appreciate the exceptions and diversity within the taxon.

Physical Restraint Gastropods are generally slow-moving and easy to restrain manually or with a protective container. While most gastropods are harmless to humans, members of the tropical genus *Conus* can inflict serious injury or even death with small toxic "harpoons," which are modified teeth from the radula.

Anesthetic Agents Used and Techniques Garden and pond snails can be anesthetized with menthol or 5% ethanol (Flores et al. 1983) or inhalant agents such as isoflurane (Girdlestone et al. 1989). A commercial 10% Listerine® solution (ethanol 21.9%, menthol 0.042%) in normal *Lymnaea* saline is commonly used to anesthetize pond snails (*Lymnaea*) in research settings (Woodall et al. 2003). Sodium pentobarbital at 0.4 mg/mL in water has been reported in freshwater snails (*Biomphalaria*) with a very slow onset (8 hours), but good effects and a low mortality rate (Martins-Sousa et al. 2001).

The drug of choice in queen conch (*Strombus gigas*) is magnesium chloride (30 g/L) (Acosta-Salmon & Davis 2007). Other agents (2-phenoxyethanol, menthol, benzocaine, and MS-222) failed to produce muscle relaxation.

Anesthesia via isoflurane for terrestrial snails requires an anesthetic chamber with the ability for fresh gas inflow and waste gas scavenging (Girdlestone et al. 1989). The minimum anesthetic concentration (MAC) of isoflurane in the pond snail is reported as 1.09 (Girdlestone et al. 1989). Induction is fast (<10 minutes), but an excitatory period is common. One disadvantage of using inhalant anesthesia is the need to take the animal out of the chamber for the procedure, which results in fluctuation of anesthetic depth and increased pollution. Furthermore, the depth of anesthesia may not be adequate for surgical procedures.

An anesthesia level reached in snails is defined when body and tentacle withdrawal response to gentle stimulation is absent. Tentacle withdrawal reflex remaining under inhalant anesthesia may suggest an insufficient depth for surgery (Girdlestone et al. 1989).

Ketamine and propofol do not induce anesthesia and might even show an excitatory, not a depressant, effect (Woodall & McCrohan 2000). Ketamine in combination with xylazine may have toxic effects (Martins-Sousa et al. 2001).

Some nudibranchs (marine gastropods), such as the opalescent sea slug (*Hermisidella crassicornis*) and *Tritonia diomedea*, have been successfully anesthetized with 1-phenoxy-2-propanol (PP) via bath application (Wyeth et al. 2009). An initial concentration of 8 mmol/L in appropriate water volume is recommended and can be increased to 16 mmol/L. Induction time can be 1.5 hours to achieve adequate muscle relaxing effects. It is important to stir the solution thoroughly to avoid tissue damage from undissolved PP (Wyeth et al. 2009).

Bigger sea snails, such as the California sea hare (*Aplysia californica*), can be anesthetized with intracoelomic administration of magnesium sulfate or magnesium chloride (Clark et al. 1996). Induction is fast (2–5 minutes) and smooth, leading to good muscle relaxation. Halothane and MS-222 seem to be ineffective (administered as immersion or intracoelomic) in this species (Clark et al. 1996).

Abalone Abalones (*Haliotis* sp.) are commercially farmed and frequently require physical examination and sizing, pearl seeding, and removal from holding tanks for maintenance and harvesting (White et al. 1996). Removal of abalones from the substratum is often only possible with mechanical assistance due to their ability to tightly adhering to the substratum. This forced removal may result in injury with slow recovery or even death. Therefore, a muscle relaxing or anesthetic agent may be necessary to avoid stress and mechanical injuries related to dislodging. Protocols used in abalones for removal include ethanol (3%), 2-phenoxyethanol (1–2 mL/L), benzocaine (100 mg/L), magnesium sulfate (2–24 g/100 mL), and sodium pentobarbital (1 mL/L) (Aquilina & Roberts 2000; Edwards et al. 2000; Sharma et al. 2003). Magnesium sulfate is administered in water (4–22 g/100 mL), with dose ranges depending on size of the abalone (higher doses for larger animals) (White et al. 1996). Induction time is fast (5–8 minutes) and recovery is uneventful (3–35 minutes, depending on dose and anesthesia time). Phenoxyethanol is administered at 0.05–0.3 mL/100 mL and also shows a fast induction period (1–3 minutes) and a recovery time of 5–20 minutes (White et al. 1996). Nembutal (sodium pentobarbital, 1 mL/L = 60 mg/L) produces good muscle relaxation with an induction time of 15 minutes and complete recovery (Aquilina & Roberts 2000; Sharma et al. 2003). In Sharma's study, induction time was size dependent, with larger animals needing longer time for complete relaxation (78 minutes) than smaller animals (34 minutes) (Sharma et al., 2003). A 50% decrease in heart

rate occurred during anesthesia and further decline continued when anesthesia was prolonged. Recovery was completed in all abalones by 80 minutes (Sharma et al. 2003). The water should be held at a temperature between 16 and 23°C for reliable effects (Aquilina & Roberts 2000; Sharma et al. 2003).

Clove oil (0.5–1.5 mL/L) and propylene phenoxtyol (2.5 mL/L) are not recommended since both agents can cause unacceptable high mortalities (Aquilina & Roberts 2000; Edwards et al. 2000). Tricaine methanesulfonate (MS-222) at 1 g/L and benzocaine (0.1 g/L) are ineffective as muscle relaxants in these abalone species (Aquilina & Roberts 2000). During induction, both MS-222 and propylene phenoxtyol cause major excitation, resulting in copious mucus production and loss of pigment (Aquilina & Roberts 2000).

Recovery from any anesthetic includes thorough washing of the abalone and exposure to fresh flowing seawater at their optimal temperature (18°C) until muscle strength returns.

Cephalopods

Anatomy, Physiology, and Natural History This group of predatory and specialized mollusks includes such familiar forms as the squids, cuttlefish, octopuses, and the chambered nautilus. Most of these animals are pelagic and have the ability for fast locomotion. They have closed circulatory systems, high metabolic rates, and advanced nervous systems that include excellent vision and tactile senses. Most have an internal skeleton (shell), with the exceptions being the octopuses (no shell) and the nautilus (external shell). Other interesting features of most members include the ability to “ink” when disturbed or threatened, suction-cup discs on the arms, and internal fertilization. All of the approximately 700 extant species are marine.

Physical Restraint Generally, these animals are difficult to handle, other than for a quick move or relocation, without sedation. Buckets, plastic nets, or other objects may be used to capture or restrain cephalopods.

Anesthetic Agents Used and Techniques Cephalopods should ideally be anesthetized in their own seawater to maintain the mineral balance. The two most commonly used anesthetic agents in these marine invertebrate species are magnesium chloride ($MgCl_2$) and ethanol.

Cuttlefish (*Sepia officinalis*) have been successfully anesthetized with 1.5–3% ethanol (15–30 mL/L) diluted in seawater (Harms et al. 2006). Inductions are rapid (1 minute), especially at higher doses, and dilution to a lower concentration (10–15 mL/L) to decrease the risk of overdosing should be considered. During inductions with lower concentrations of ethanol, occasional transient excitement has been noticed (Harms et al. 2006). If the procedure cannot be performed in the water,

Figure 14.1. A recirculating anesthesia system containing dilute ethanol with an anesthetized cuttlefish (*Sepia officinalis*). Note that two irrigating tubes are being used, one for each set of gills (photo courtesy of J. Bolyann).

anesthesia is maintained with a recirculating anesthesia system (Lewbart & Harms 1999) (Fig. 14.1). The anesthetic concentration of the water is adjusted over time to the depth of anesthesia desired.

If magnesium chloride ($MgCl_2$) is used as an anesthetic agent in cuttlefish, a 7.5% $MgCl_2$ stock solution can be prepared with distilled water (Gore et al. 2005; Scimeca & Forsythe 1999). This stock solution is mixed with a known amount of seawater to prepare an anesthetic concentration suitable for induction. A final concentration of 6.8 g/L (100 mL of the stock solution mixed with 1 L of seawater) has been reported to have an induction time of 6–12 minutes without side effects (Gore et al. 2005). Due to the size of the cuttlefish, a total water volume of 6–8 L is commonly needed. Induction is usually smooth and without a period of excitation. Decreasing the concentration via dilution may be necessary over time to adjust the depth of anesthesia.

Octopuses (*Octopus vulgaris*) are anesthetized in a similar manner. Two commonly employed anesthetic agents are ethanol and $MgCl_2$. Ethanol (2% v/v in seawater) can produce excitement during the short induction time (increased respiratory rate, attempts to climb out of the solution and ink ejection) (Andrews & Tansey 1981). Induction time has been reported to be 4 minutes and time to full recovery as 2.5 minutes (Andrews & Tansey 1981). Ethanol (2%) does not seem to be effective in coldwater species (below 15°C) (I.G. Gleadall, pers. comm., 2006).

Long-term anesthesia (5 hours) in longfin squids (*Doryteuthis pealii*) with magnesium chloride (0.15 mol $MgCl_2$ seawater solution) has been successfully achieved (Mooney et al. 2010). The animals were placed into the $MgCl_2$ solution until relaxed and nonresponsive with decreasing respiratory rate, then recovered in a $MgCl_2$ free tank and reimmersed when lightened. Increasing

Figure 14.2. Spiny lobster (*Panularis* spp.) anesthesia: This adult spiny lobster has been anesthetized with a eugenol immersion, followed by eugenol gill perfusion, for some diagnostic procedures (photo courtesy of M. Mehalick).

duration of anesthesia was noted with subsequent immersions (20–111 minutes) (Mooney et al. 2010).

Overall, $MgCl_2$ is the preferred anesthetic agent in cephalopods. It is used by preparing an isotonic solution of 7.5% $MgCl_2 \cdot 6H_2O$ (in distilled water) mixed with an equal volume of seawater (Messenger et al. 1985; Scimeca & Forsythe 1999). Induction time lies between 1.5 and 13 minutes with a short period of hyperventilation, then a gradual increase in arm flaccidity and righting reflexes; it is considered to be very smooth (Culloty & Mulcahy 1992; Messenger et al. 1985). Respiration will decrease and even cease if the anesthetic concentration is not decreased. The gills should be intermittently or constantly perfused with anesthetic seawater (Fig. 14.2). Time of recovery from $MgCl_2$ is fairly quick (1–10 minutes), but dependent on length and type of procedure (up to 20–60 minutes after prolonged procedures).

There is a controversy whether $MgCl_2$ produces adequate sedation and analgesia by blocking nerve transmission and neurotransmitter release, or acts only as a neuromuscular blocking agent (Clark et al. 1996). Differences in vertebrate versus invertebrate anatomy/physiology, as well as routes of administration seem to play a role in the effects, but the issue remains unresolved (Clark et al. 1996). An analgesic should be added to the protocol for any painful procedure to assure adequate patient care.

The use of urethane has been reported (Andrews & Tansey 1981; Gleadall 1991; Messenger et al. 1985) and was routinely used in the 1970s and 1980s, but despite good anesthetic effects, the traumatic effects on the animals were severe (excitement during the induction phase). Chloroform, chloral hydrate, gallamine, and CO_2 are unsuitable anesthetic agents in cephalopods as they can cause high mortality (Garcia-Franco 1992; Gleadall 1991; Mooney et al. 2010).

It should be emphasized that hypothermia, despite its popularity in the literature, is not an adequate anesthetic and should not be used in this group of animals due to its lack of analgesic and muscle relaxing properties. Mortalities and distress have been reported (Bower et al. 1999; Mooney et al. 2010). The underestimation of cardiovascular and respiratory system compromise during hypothermia, as well as in the phase of warming, may be one of the leading causes.

For recovery, the cephalopod is placed into a container with anesthesia-free seawater. Ideally, the water in this container is circulated and aerated. If spontaneous respiration is not present, gentle and slow mantle massage can be used until normal respiration is restored. The tentacles remain extended and flaccid in the first phase of the recovery and will retract in response to light pinching with progressive awakening (Harms et al. 2006).

Resuscitation of cephalopods includes squeezing and relaxation of the whole mantle/body for water circulation over the gills and hemolymph through the body (Harms et al. 2006). Anesthesia-free water should be directed over the gills for a washout effect.

Cephalopods are commonly monitored by visualization of their respiratory rate and pattern. Normal awake values for *O. vulgaris* in a weight range from 100 to 800 g are 26–30 breath/min (Andrews & Tansey 1981). The cardiovascular system is assessed by placing a Doppler probe on the dorsal area (above the aorta) or behind the gills (above either branchial heart) to monitor heart rate and blood flow. A pulse oximeter will likely give false readings due to the presence of hemocyanin instead of hemoglobin, but may be used for heart rate. In transparent species (especially with $MgCl_2$), the pallial organs can be observed. Depth of anesthesia is difficult to assess in cephalopods. One guideline is that the level of anesthesia seems adequate when no response to tactile and surgical stimuli is present (withdrawal of appendices or movement, contraction of the skin around the eye in response to pressure on the eyeball, withdrawal of the animal in response to a pinch of the skin over the eye [Andrews & Tansey 1981]). Further indicators of anesthetic depth are the flaccidity of the arms, loss of normal posture, and inability to regain normal posture after disturbance (Andrews & Tansey 1981). Respiration usually remains spontaneous and varies in depth and rate with the level of anesthesia (Mooney et al. 2010); a depression or cessation is a sign of critical deep levels of anesthesia.

Bivalves

Anatomy, Physiology, and Natural History This large and economically important group of highly evolved mollusks includes the clams, mussels, oysters, and scallops. They lack a well-developed head, are generally nonvisual (the scallops are an exception), feed by filtration utilizing the gills for food transport, and utilize a mus-

cular and sometimes large foot for locomotion. All of the approximately 8000 described extant species are aquatic, and nearly 80% of these are marine.

Physical Restraint Most bivalves are easy to handle and restrain safely. Nearly all will tightly close their calcareous valves when handled or disturbed and may require sedation or physical manipulation (prying) to open the valves, which are held fast by strong adductor muscles.

Anesthetic Agents Used and Techniques

Oysters Oysters are commonly anesthetized for pearl harvesting and seeding. There are four major pearl oyster species used in the cultured pearl industry (Mamangkey et al. 2009). Unfortunately every oyster species seems to be responding differently to the various anesthetic agents (Mamangkey et al. 2009).

Propylene phenoxetol can be used as a 1% solution to anesthetize oysters (*Pinctada albino*, *Pinctada margaritifera*, and *Pinctada maxima* and *Pteria penguin*) in a dose range from 1 to 3 mL/L. Higher doses induce a rapid and relative deep level of anesthesia (Mills et al. 1997) and may need decreasing throughout the procedure to decrease recovery time (Norton et al. 1996). Generally, concentrations are dependent on species and study design, and recommendations vary: 1–2 mL/L are safe and effective for most oyster species (Mills et al. 1997; Norton et al. 1996), but Mamangkey et al. (2009) recommend 2.5 mL/L for *P. maxima*, Kishore (2011) suggests 3.0 mL/L for *P. penguin*, and O'Connor and Lawler (2002) recommend 2.2 mL/L for *Pinctada imbricate* and *P. albina*.

The oyster should be placed hinge down in the solution, leaning against the walls of the aerated container to facilitate monitoring. Induction time is reported to be between 6 and 15 minutes. Adequate anesthesia is reached when the oyster gapes wide enough to part the gill curtain inside the shell and shows no responsiveness to handling (Mills et al. 1997) or contraction of the tissue to a stimulus (Norton et al. 1996). A decrease in stress from handling before placing oysters into the anesthesia container will improve the anesthetic effects and opening. Recovery time with propylene phenoxetol is short (10–30 minutes), although it depends on length of procedure, concentration of anesthetic, and temperature (Kishore 2011; Norton et al. 1996). Recovery tanks should be aerated.

The muscle contractility in invertebrates is dependent on the interaction between Ca^{2+} and Mg^{2+} . Magnesium chloride works via the Mg^{2+} effect of inhibiting the facilitating effect of Ca^{2+} at the synaptic transmission (Altura et al. 1987; Namba et al. 1995), and it is suspected that it works mainly as a muscle relaxant rather than an anesthetic.

Magnesium chloride has variable effects on oysters. Some studies describe little effect in pearl oysters

(*P. maxima*) (Mills et al. 1997; Norton et al. 1996), mainly due to long induction times (1–2 hours). Culloty and Mulcahy (1992) reported good anesthetic effects in flat oysters (*Ostrea edulis*), but also long induction and recovery times (90 minutes) at 3.5%. Suquet et al. (2009, 2010) found flat oysters (*O. edulis*) and Pacific oysters (*Crassostrea giga*) can be successfully anesthetized for gonad sampling by maintaining them for 2–3 hours in a 50 g/L MgCl_2 bath at 19°C (1/3 seawater; 2/3 freshwater). A study in Sydney rock oysters (*Saccostrea glomerata*) found MgCl_2 to be the only effective agent as a muscle relaxant at a concentration of 50 g/L with an onset time of 30 minutes to 6 hours (Butt et al. 2008). The effect of MgCl_2 seems dependent on species, concentration, duration, and water temperature with significant variable times to effect (Namba et al. 1995; Suquet et al. 2009, 2010).

Tricaine methanesulfonate and chloral hydrate are not effective in oysters (slow induction and recovery) and are associated with complications (death; some of it may be related to the low pH of unbuffered MS-222) (Norton et al. 1996).

Eugenol often produces a high mortality in oysters (Mamangkey et al. 2009; Suquet et al. 2009). Benzocaine also has a high mortality in a dose-dependent manner in the Pacific oyster (Suquet et al. 2009), but worked well in *P. maxima*, *Pinctada fucata*, *P. margaritifera*, and *P. penguin* at 1200 mg/L with a fast induction time of about 10–16 minutes (Acosta-Salmon et al. 2005; Kishore 2011; Mamangkey et al. 2009). Cases of body and/or mantle collapse have been reported with the use of benzocaine (Acosta-Salmon et al. 2005; Kishore 2011). Another disadvantage of using benzocaine is its inability to dissolve in seawater, which leads to an extensive preparation process (Acosta-Salmon et al. 2005; Kishore 2011; Mamangkey et al. 2009).

A drug that dissolves well and provides effective anesthesia with short induction time (13 minutes) and over 95% survival rate in *P. maxima* is 2-phenoxyethanol (3 mL/L) and can be recommended for this oyster species (Mamangkey et al. 2009).

Scallops Anesthesia in scallops may be required, but mainly for muscle relaxation. In general, the depth of anesthesia/relaxation is adequate when handling and stimulating of the mantle tissue fails to stimulate shell closure. Recovery is often defined as the regained ability for shell closure in response to handling (Heasman et al. 1995).

Magnesium chloride is the drug of choice in scallops due to its rapid and consistent induction and recovery. The agent is predissolved in seawater and then added to the aerated induction container to reach a concentration of 30–50 g/L. Induction times at these concentrations are quick and in the range of 2–6 minutes. Recovery time in scallops anesthetized with MgCl_2 seems to be consistently short (10 minutes) regardless

of concentration used or temperature (Heasman et al. 1995).

Chloral hydrate has variable effects in scallops, with significant changes in induction and recovery at different concentrations and temperatures (Heasman et al. 1995). A concentration of 4g/L produces anesthesia in about 10–25 minutes, if temperature is held at 24°C. Lower temperatures will significantly slow the induction period. Higher concentrations will shorten the induction time, but can result in high mortality. Recovery time at 4g/L is between 20 and 30 minutes, but varies widely depending on temperature (and concentration). Aerated seawater recovery tanks and continuously flushing with seawater will facilitate recovery.

Other drugs have been examined for scallop anesthesia with little success. MS-222 causes hyperactivity and hyperextension, benzocaine causes an initial hyperactivity, metomidate results in shell closure, ethanol does not seem to have any effect, and magnesium sulfate leads to high mortality (Heasman et al. 1995).

Giant Clams Giant clams (*Tridacna* sp.) have been anesthetized with propylene phenoxetol (Mills et al. 1997).

Arachnida

Introduction The arachnids are a large class of approximately 70,000 described species of terrestrial carnivorous chelicerates (Ruppert et al. 2004). All Chelicerata, a group that also includes the horseshoe crabs, scorpions, and sea spiders (Pycnogonida), belong to the phylum Arthropoda. Spiders, mites, and ticks make up the bulk of the arachnid species. Less conspicuous arachnids include the whip spiders, microwhip spiders, harvestmen, pseudoscorpions, tick spiders, and sun spiders. Tarantulas (Mygalomorphae) represent an important group of commonly kept arachnids that frequently require medical care.

Spiders (Araneae)

Anatomy, Physiology, and Natural History The spiders comprise one of the largest orders in the class Arachnida (which belongs in the subphylum Chelicerata). There are approximately 40,000 described species of spiders (Araneae) belonging to 3000 genera, with thousands more species as yet undescribed (Ruppert et al. 2004).

Spiders range in size from a body of less than a millimeter to over 9cm for large tropical tarantulas (Ruppert et al. 2004). The basic spider body plan includes two large segments, the cephalothorax and the abdomen, connected to each other by the pedicel. All spiders have four pairs of walking legs, paired chelicerae, and paired pedipalps. The fangs are located at the tip of the chelicerae and are used to immobilize prey, frequently by injecting venom. The male pedipalps are usually modified to aid in sperm delivery. The

spinneret is located at the distal end of the abdomen and is used to spin silk, an ability that virtually all spiders possess and use for a variety of functions.

Spiders are carnivorous and perform most of their digestion outside of the gastrointestinal (GI) tract (food is digested in a cavity adjacent to the mouth and the liquefied food is then ingested). The GI tract is divided into the foregut (mouth, pharynx, and esophagus), midgut (many branching cecae), and a short hindgut (Ruppert et al. 2004).

Spiders breathe through book lungs, trachea, or both. Tarantulas have two pairs of book lungs that are found on the ventral aspect of the abdomen. Most spiders have just one pair of abdominal book lungs and a pair of tracheae. Other combinations and modifications on these two plans are found within the order (Ruppert et al. 2004).

Spiders possess an open circulatory system with the hemolymph functioning in oxygen transport, immune defense, waste removal, and limb mobility through hydrostatic pressure. The heart is large and located in the dorsal abdominal segment. Most spiders excrete uric acid as well as adenine and guanine as their nitrogenous waste products. Malpighian tubules absorb these compounds from the hemolymph and direct them into the cloacal chamber, where they are excreted with the feces (Ruppert et al. 2004).

Spiders have two main nerve centers located in the cephalothorax: the subesophageal and supraesophageal ganglia. Spiders sense their environment in a number of ways, including vision, tactile reception, chemoreception, and vibration detection. These are accomplished with four pairs of eyes, tactile hairs, chemosensory hairs, and slit sense organs, respectively (Ruppert et al. 2004).

Sexes are separate in spiders and fertilization is generally internal. Female spiders produce egg sacs that may contain thousands of young, and there are varying degrees of parental care among spiders. While most spiders probably do not live longer than 2 years, some female tarantulas may live for several decades (Pizzi 2012).

Physical Restraint Physical restraint is commonly used to handle and transport spiders (Fig. 14.3). However, some tarantula species are capable of shedding urticating hairs, which can be quite irritating, especially to individuals allergic to these structures. Other drawbacks to manual restraint are injury to the animal and potential envenomation of the handler. It is advisable to wear latex gloves when handling spiders and to be cautious of dropping the spider or having it leap or fall to the ground.

Anesthetic Agents Used and Techniques Spiders are most commonly and successfully anesthetized with inhalant anesthetic agents. Many agents (halothane, isoflurane,

Figure 14.3. (a) Wearing latex gloves, or other protective measures, should be taken when handling many invertebrates, like this rose hair tarantula (*Grammostola rosea*). (b) Sensible physical capture and restraint are used to obtain a weight from this rose hair tarantula (photos courtesy of M. Mehalick).

sevoflurane, and desflurane) have been used, although halothane will not be available in the near future in North America. Of the potent inhalant anesthetics, halothane is least desirable for invertebrate anesthesia, because of the high likelihood of potential toxicity for personnel during gas delivery.

Several different induction chambers have been described (Cooper 2001; Melidone & Mayer 2005; Pizzi 2012) and used successfully for delivering inhalant anesthesia to spiders. These chambers are either commercially available induction chambers (invertebrate-specific or regular small mammal induction chambers) with appropriate fresh gas inflow and scavenging outflow, or simple self-made clear plastic containers (Fig. 14.4). Plastic containers without the use of an inflow and outflow system may be used by placing a cotton wool swab soaked with a small amount of inhalant agent into the box. The spider itself should be

Figure 14.4. Inhalant anesthetic chamber for terrestrial invertebrates. Pictured here is an anesthetized rose hair tarantula (5% isoflurane) (photo courtesy of M. Mehalick).

placed in a separate smaller container with small pores. The smaller container holding the spider is placed into the larger box, allowing the inhalant to diffuse into the box with the spider while ensuring that the spider cannot come into direct contact with the inhalant-soaked cotton swab. This method is not ideal because of the higher exposure risk to the personnel of the anesthetic agent, less control of the amount of anesthetic given to the spider, and higher risk of overdose. An induction chamber using anesthetic gas given via a precision vaporizer is much preferred. The advantages of the chamber technique are convenience of use, low cost, and safety to the patient associated with the set up. The disadvantage associated with this type of system is that the animal can only be temporarily sedated or anesthetized. For any physical examination or surgery, the animal is removed from the chamber, which limits the time for any procedure before the animal recovers. This may require repeated inductions, but also increases the exposure of the clinician and staff to the anesthetic gases. A surgery chamber has been developed (Melidone & Mayer 2005) that allows the clinician to perform the surgery or other manipulations on the animal without taking the animal out of the chamber.

Another interesting technique is to induce the spider in an anesthetic chamber and then place its abdomen (with the associated book lungs/tracheae) into a smaller chamber “sealed” with a latex glove (Fig. 14.5). This technique appears to have some merit when a procedure must be performed on the cephalothorax or limbs (Dombrowski 2006).

The most commonly used anesthetic agents for spiders are isoflurane and sevoflurane (Cooper 2001; Melidone & Mayer 2005; Pizzi 2012). The animal is placed into the chamber and the chamber is filled with

Figure 14.5. Since the spider's respiratory intake is located in the abdominal segment it appears that at least some species can be maintained on inhalant anesthesia, as shown here, while the limbs and cranial body parts are examined or manipulated. This is a rose hair tarantula (*Grammostola rosea*) (photo courtesy of M. Mehalick).

the anesthetic gas (about 3–5% for isoflurane; 4–6% for sevoflurane). To increase the filling time in larger chambers, the oxygen flow rate is high at the beginning (1–3 L/min), but can be decreased to a minimum if there are no major leaks in the system (300–1000 mL/min). Oxygen flow lower than 200 mL/min decreases the accuracy of the vaporizer and may decrease the amount of anesthetic agent in the chamber due to the uptake of the animal; the amount of CO₂ in the chamber may also be increased using low fresh gas flows. An appropriate scavenging system is necessary to decrease pollution and exposure of the staff to anesthetic gases. With increasing depth of anesthesia, the vaporizer can be adjusted (decreased over time). The MAC of the different anesthetic agents in spiders has not been determined.

Other agents, such as carbon dioxide (CO₂) and nitrogen (N₂), as well as hypothermia, have been used to immobilize spiders (Madsen & Vollrath 2000; Pizzi 2012). No reports about the amount of nitrogen used or the quality of nitrogen anesthesia could be found. Carbon dioxide is administered as a gas in a chamber, often producing 98% saturation. Dilution with air or oxygen is hard to achieve, resulting in an increased risk for mortalities (Pizzi 2012). Hypothermia is not an anesthetic and does not provide analgesia; hypothermia itself is considered to be painful, and should therefore not be used as an anesthetic.

Observing the spider for righting reflexes and leg movements assists monitoring depth of anesthesia. During induction it may take 10–15 minutes with several attempts of the spider to move and reposition

itself, until full immobilization has occurred. During the procedure leg movements in response to stimuli is an obvious sign of insufficient depth of anesthesia. An increase in heart rate and respiratory rate may be seen, but is often unrecognized. A deep level of anesthesia is more difficult to evaluate, and slow respiratory rate and low heart rates are often the only way to assess a patient for an excessive depth of anesthesia. An analgesic administered for painful stimulations may make it easier for the clinician to maintain a consistent level of anesthesia.

Respiratory rate is observed at the cranial lateral side of the animal. The heart rate can often only be monitored in larger spiders. The heart lies under the dorsal surface of the body. With a Doppler (pinpoint-crystal head) placed over the heart area a rate can be obtained. Normal heart rates are considered to be 30–70 beats per minute in large spiders and up to 200 beats per min in smaller species.

After turning off the inhalant and maintaining the animal on fresh oxygen flow or room air, the recovery from anesthesia is gradual and can take between 3 and 20 minutes, depending on the ambient room temperature and the depth of anesthesia during the procedure. Slow leg movements and righting attempts occur and increase over time. When fully awake, the animal should be returned to its enclosure and maintained at its preferred ambient temperature. Feeding after anesthesia should be withheld for 48 hours (Pizzi 2012).

Scorpions

Anatomy, Physiology, and Natural History There are about 1200 species of scorpions. Most are nocturnal and found in warm climates, such as the tropics and subtropics (Ruppert et al. 2004). They belong to the order Scorpiones and share many traits with their arachnid cousins, the spiders.

The basic anatomical plan consists of a cephalothorax, segmented abdomen, and telson, sometimes referred to as the sting (Ruppert et al. 2004). Although scorpions are infamous for their stinger and venom, a scorpion envenomation is rarely fatal to humans and normally induces only pain and discomfort. Scorpions can range in size from less than 10 mm to just over 20 cm.

Scorpions differ from spiders and most other arachnids in that they have a well-developed ventral nerve cord and exhibit viviparity with extended maternal care of the young in most species (Ruppert et al. 2004). For a more detailed account of scorpion anatomy, physiology, and natural history, please refer to Frye (2012) or Ruppert et al. (2004).

Physical Restraint Direct handling should be kept to a minimum for both the safety of the handler and the animal. Clear plastic containers, and in some cases, utensils, such as long forceps, can be employed for

moving an animal from one place to another (Frye 2012).

Anesthetic Agents Used and Techniques Scorpions are anesthetized similarly to spiders (see earlier section). An induction chamber using anesthetic gas in oxygen given via a precision vaporizer is preferred. Isoflurane or sevoflurane can be used.

Crustaceans

Anatomy, Physiology, and Natural History The crustaceans are a large and diverse group of arthropods that are all aquatic at some stage of their life history. Some authors consider this group, with over 40,000 described species, a subphylum of the phylum Mandibulata (Ruppert et al. 2004). Other workers still consider it a class of mandibulate arthropods that have two pairs of antennae, biramous appendages, compound eyes, segmented excretory organs, a well-developed protective carapace, and an aquatic nauplius larva (Noga et al. 2012). The majority of the most conspicuous and economically important crustaceans belong to the order Decapoda, which includes the crabs, crawfish, hermit crabs, lobsters, and shrimp.

Physical Restraint Some species can be manually restrained with gloved hands, or in some cases, with the help of utensils such as nets or tongs (Fig. 14.6). Since some crustaceans, such as lobsters and large crabs, can cause serious injury to handlers, care should be taken when manipulating or restraining these animals.

Anesthetic Agents Used and Techniques Crustaceans can be anesthetized with various agents. Depending on the animal's size and procedure, MS-222, isobutyl alcohol, eugenol, and intramuscular or intravenous

Figure 14.6. This blue crab (*Callinectes sapidus*) is being manually restrained while hemolymph is collected (photo courtesy of M. Mehalick).

injections of various anesthetics have been reported (Brown et al. 1996; Coyle et al. 2005; Ferraro & Presacco 1996; Gardner 1997; Oswald 1977; Quesada et al. 2011). Tricaine methanesulphonate is generally accepted as a noneffective agent to produce anesthesia in decapods (Gardner 1997; Oswald 1977) and only very high doses show some effect (>1 g/L) with very slow induction time (Brown et al. 1996; Gardner 1997).

Lidocaine (0.4–1 mg/g) can be injected intramuscularly into the tail and lasts for about 5–30 minutes in crayfish, depending on the dose administered, with an average induction time of 1.5 minutes (Brown et al. 1996). Lidocaine (70 mg/kg) administered intravenously to the blue crab (*Callinectes sapidus*) resulted in a light anesthesia with short induction time (12.5 seconds) and short duration of two to three minutes (Quesada et al. 2011).

Ketamine has been used in crawfish (40–90 mcg/g), (Brown et al. 1996), in Australian giant crabs (*Pseudocarcinus gigas*) (0.025–0.1 mg/kg IV) (Gardner 1997), and in blue crabs (20 mg/kg, IV) (Quesada et al. 2011) with variable response. Ketamine given intramuscularly to crawfish will provide consistent anesthesia (induction time: 1 minutes) for over 10 minutes (40 mcg/g) to almost 2 hours (>90 mcg/g) without excitatory side effects during induction or recovery (Brown et al. 1996). When ketamine alone was given to the giant crab intravascularly, a short period of excitement occurred, but induction time was fast (15–45 seconds) (Gardner 1997). Duration of anesthesia was dose dependent and lasted between 8 and 40 minutes. The blue crab showed reliable and deep anesthesia with ketamine administered IV for a short period of time (5 minutes) after a fast induction within a minute (Quesada et al. 2011). When ketamine (20 mg/kg) is administered with xylazine (20 mg/kg), greater depth with good muscle relaxation can be achieved (Quesada et al. 2011).

Tiletamine-zolazepam at 30 mg/kg IV also provides a smooth and relaxed anesthesia (induction time 37.5 seconds, duration 5 minutes) (Quesada et al. 2011).

Xylazine has shown good anesthetic effects in adult giant crabs, when used at doses between 16 and 22 mg/kg IV (Gardner 1997) or in common shore crabs at 70 mg/kg IV (Oswald 1977). Induction seems to be smooth and fairly fast (3–5 minutes), and immobilization lasts 25–45 minutes (depending on the dose administered). Side effects, such as bradycardia, extrasystoles, and dysrhythmias, have been reported with high doses (70 mg/kg) (Oswald 1977). Xylazine alone (20 mg/kg, IV) administered to the blue crab only resulted in light anesthesia of short duration (Quesada et al. 2011).

An intravascular injection can be performed in adult giant and blue crabs through the arthropodial membrane, either midline between the cephalothorax and first abdominal segment, or dorsally at a 45° angle

between carapace and the coxa of the swimming period (Gardner 1997; Oswald 1977; Quesada et al. 2011) using a small needle (25 or 27 gauge). The needle is gradually advanced until hemolymph is obtained and the drug is then administered (Quesada et al. 2011).

Intracardiac administration of drugs such as ketamine has been reported in the blue crab, but resulted in high mortality rate (Quesada et al. 2011) and therefore should be reserved for euthanasia. Intracardiac injections are performed by advancing a 25-gauge needle through the midline of the arthroal membrane of the hinge of the carapace by aiming the needle toward the cervical groove, in which the pericardial sinus is situated (Quesada et al. 2011).

Etomidate (16 mg/kg) has been used in the blue crab, but showed no anesthetic effects (Quesada et al. 2011). Propofol seems to be contraindicated in the blue crab as it only produces light anesthesia with severe distress at 20 mg/kg IV. Distress was expressed by twitching, tremors, and limb autotomy (Quesada et al. 2011). Similarly, pentobarbital (60 mg/kg IV) resulted in unreliable anesthesia with violent dysphoria (Quesada et al. 2011).

Procaine (25 mg/kg IV) has also been used in crabs and provides good anesthesia with a very short induction time (20–30 seconds). This included a 10-second long excitatory phenomena that lead to tonic contraction before paralysis. Duration was very long (2–3 hours) with slow recoveries (Oswald 1977) and may be reserved for long-term experimental anesthesia.

For smaller crabs, in which an IV or IM injection is impractical, clove oil can be used as a bath treatment and has shown a 16-minute onset of anesthesia at a dose of >0.125 mL/L and a long recovery phase (2.5 hours). Once the animal is anesthetized, a reduction of concentration is necessary, because clove oil at 0.125 mL/L over a longer period of time is also used for euthanasia (Gardner 1997).

In shrimp, clove oil (eugenol) has become increasingly popular to anesthetize or sedate shrimp to reduce stress during transport. Benefits of eugenol are the apparent safety for shrimp and the lack of withdrawal time for consumption in some countries (Akbari et al. 2010; Coyle et al. 2005; Parodi et al. 2012). Some studies have looked at the effect of eugenol in different type of shrimp species. The Indian shrimp (*Fenneropenaeus indicus*) has been successfully sedated with eugenol (1.3–3.7 mg/L) (Akbari et al. 2010). Eugenol and AQUI-S™ (active ingredient is isoeugenol) have also been used to sedate and anesthetize freshwater prawn *Fenneropenaeus indicus* (Coyle et al. 2005). The effect on induction and recovery time is dose dependent (100–300 mg/L) with a higher safety margin for eugenol over AQUI-S (Coyle et al. 2005). The optimal dose of eugenol in white shrimp was 175 µL/L, producing rapid induction and recovery (Parodi et al. 2012). The essential oils *Lippia alba* (1000 µL/L) and *Aloysia triphylla*

(300 µL/L) also produce sedation and anesthesia in white shrimp (Parodi et al. 2012).

Tricaine methanesulphonate and 2-phenoxyethanol were found to be ineffective to sedate freshwater prawns (Coyle et al. 2005).

Eugenol is also commonly used for sedation and immobilization in lobsters to facilitate handling and diagnostic procedures. When eugenol is added to the water at 75–100 ppm, the American lobster (*Homarus americanus*) becomes reliably immobilized within 10 minutes (Waterstrat & Pinkham 2005). After transferring the animal to an aerated flow-through aquarium, recovery was achieved in 8 minutes (Waterstrat & Pinkham 2005).

Lobsters (*Homarus americanus*) can be euthanized with injectable potassium chloride (KCl) causing cardiac arrest (Battison et al. 2000). A 330-mg/mL solution of KCl is prepared and 1 g/kg is injected into the hemolymph sinus containing the ventral nerve cord (Battison et al. 2000). This sinus can be accessed by a 20-gauge needle placed at the base of the second pereopod (walking leg). The leg can be rotated internally and extended caudally. The needle is advanced until hemolymph is reached and the KCl solution is injected (Battison et al. 2000). Following a 15-second period of rigid extension of the claws and legs, cardiac arrest will be achieved in 1–2 minutes and can be confirmed by a Doppler (Battison et al. 2000).

Monitoring Crustaceans Crustacean heart rates can be assessed by applying ECG pads with ample gel on the shell above the heart. Alternatively a Doppler probe placed on the carapace over the heart can be used (Noga et al. 2012; Quesada et al. 2011). The normal heart rate for lobsters is between 5 and 20 beats per minute with a circadian influence (higher at night) (Aguzzi et al. 2004) and 30–70 beats per minute for the shore crab (Styrishave et al. 2003), depending on pH and temperature. Battison et al. (2000) reported heart rates of 19–60 with a mean around 40, depending on temperature. The blue crab showed a heart rate around 180 beats per minute under water, but when taken out of water, precipitously dropped to a few beats/min (Quesada et al. 2011).

Depth is evaluated in crustaceans by the relaxation of the body and the ability to withdraw extremities and very slow withdrawal of their antennae (Gardner 1997). A deep anesthesia is considered when complete limb immobility is achieved and abdominal flap and chelae are relaxed. A loss of righting response and loss of defense behavior marks induction, and its return will characterize recovery (Gardner 1997; Quesada et al. 2011).

Insects

Anatomy, Physiology, and Natural History The insects are an incredibly diverse and numerous group that some taxonomist term the Hexapoda. With nearly a

million described species, they are the true taxonomic champion of sheer species numbers and diversity. Most species are terrestrial, some are aquatic, and the only habitat they have not exploited is the ocean (some are found in the intertidal zone). Insects are arthropods with three major body segments (head, thorax, and abdomen) and three pairs of legs. Most have keen eyesight, well-developed mouthparts, sensory antennae, and wings. They have an open circulatory system that contains hemolymph and gases are exchanged through spiracles that open into a system of tracheae. Most species lay eggs following internal fertilization.

Physical Restraint In most cases, insects can be handled and restrained manually without risk to the animal or handler. In some cases, gloves are recommended as a protective measure and various utensils can be employed to immobilize or restrain insects. Much depends on the size and species of insect being worked with (Fig. 14.7).

Anesthetic Agents Used and Techniques Carbon dioxide (CO₂) gas remains popular for immobilization of insects in entomological research, although multiple side effects, including convulsion and excitation at induction, are well recognized and mortality is high (Champion de Crespigny & Wedell 2008; Nicolas & Sillans 1989; Valles & Koehler 1994). Its use remains controversial, and a more progressive approach would be the use of a volatile anesthetic agent, such as isoflurane or sevoflurane. This requires a chamber apparatus to allow for appropriate delivery and scavenging of the inhalant agent (Walcourt & Ide 1998).

The use of ether (diethyl ether) is limited due to its high flammability, but ethyl acetate has been used in

Figure 14.7. Hemolymph collection from a Madagascar hissing cockroach (*Gromphadorhina portentosa*): This mature male hissing cockroach has been sedated with inhalant isoflurane for hemolymph collection.

the green lacewing (*Chrysoperla rufilabris*) (Loru et al. 2010). A few drops of ethyl acetate are placed on a cotton ball in an induction chamber, and the insect is observed until movement ceases, at which point the treatment is removed (Loru et al. 2010). Ethyl acetate seems to have a small margin of safety and therefore overdosing and mortality are a concern.

Echinoderms

Anatomy, Physiology, and Natural History The echinoderms are a diverse phylum of about 6000 extant marine species in six classes that all share, at least at some point in their life history, pentamerous radial symmetry. Familiar members of this phylum include the sea lilies, feather stars, sea stars, brittle stars, sea urchins, sea biscuits, sand dollars, and sea cucumbers. Echinoderms have a water vascular system that is used for feeding, locomotion, and transport of coelomocytes used in the immune response. Nearly all species have a skeleton composed of calcareous ossicles, and in some cases, these ossicles are fused to form an external structure called the test (e.g., sea urchins). The nervous system is composed of a nerve ring with associated radial nerves (there are no ganglia). Fertilization is external, and most species have planktonic larval forms.

Physical Restraint Many species can be readily handled safely and effectively without anesthesia or sedation. Most tend to be slow moving and quite hardy (one exception being the brittle stars). Certain species of sea urchins can inflict a painful “sting” with movable, sharp spines. Nets, tongs, and gloves can aid in the safe handling of many species.

Anesthetic Agents Used and Techniques Echinoderms can be anesthetized/immobilized with MgCl₂, MS-222 or menthol (Harms 2012). Ideally, the sea star (starfish) is anesthetized in its own seawater (i.e., the water they are adapted to in their aquarium), to keep temperature and water content (including pH and salinity) consistent. To a known amount of that water, an MgCl₂ solution (7.5–8% in tap or seawater) is administered. A 1:1 mixture has been reported (McCurley & Kier 1995), and may be necessary for induction, but adjustments over time during maintenance of anesthesia may have to be made (gradually administer more seawater). Tricaine methanesulphonate can be used in a concentrated form (1–10 g/L in seawater) (Hendler et al. 1995; O’Neill 1994). Other reported anesthetic agents are menthol (2.5–5% in sterile seawater) (Costello & Henley 1971) and propylene phenoxetol (2 mL/L in seawater) (Hendler et al. 1995; Van den Spiegel & Jangoux 1987).

Recommendations for anesthetizing adult sea urchins (*Paracentrotus lividus*) are made by Arafa et al. (2007). A range of MgCl₂ can be used (5–20 mmol/L), but least mortality rate for longer anesthesia times (transports etc.) is achieved with 5 mmol/L. Sea urchins

are not good at regulating changes in osmotic and ionic levels, therefore, it is important that the magnesium concentration has the same tonicity as the animal/seawater (Arafa et al. 2007; Namba et al. 1995). Magnesium chloride at 5 mmol/L has similar osmotic pressure, which makes it the ideal concentration for anesthetizing adult sea urchins for longer periods of time (Arafa et al. 2007). Juvenile green sea urchins (*Strongylocentrotus droebachiensis*) can be paralyzed for detachment with potassium chloride (KCl) (0.25–5%) (Hagen 2003). Duration of paralysis is dose dependent (10 minutes for 0.25%, 24 hours at 5%). No mortality was seen under 5%, but will increase to 100% at a 10% concentration of KCl (Hagen 2003). Magnesium chloride at 10% will also reach a state of paralysis and detachment, lower doses being ineffective. 2-phenoxyethanol is effective at 3%, but the narrow safety margin (lethal dose is 4%) makes it a less recommended anesthetic agent for juvenile green sea urchins (Hagen 2003).

PAIN MANAGEMENT

Whether invertebrates feel pain is still an unanswered topic of debate. The crux of the argument may lie in the differentiation between nociception and pain per se. Nociception describes the neurophysiologic components leading to the sensation of pain, but excludes the central perception of nociceptive input that ultimately leads to the sensation of pain. In other words, nociception is an involuntary rapid reflex response and lacks the negative emotional response or feeling associated with pain (Bateson 1991; Broom 2001). In respect to animals, “pain” has been defined as an “aversive sensation and feeling associated with actual or potential tissue damage” (Broom 2001). In humans and mammals, this pain experience resulting from nociception is created in the cerebral cortex, leading to learned avoidance and modified species-specific behaviors (Nieuwenhuys 2012). Although invertebrates do not possess a central nervous system with a well-described cortex or similar structure it has been shown that a nociceptive response is present in invertebrates (Kavaliers et al. 1983; Mather 2011; Smith & Lewin 2009). Various parts of the nociceptive system have been described and seem to be similar across the wide range of invertebrate taxa (Elwood 2011; Tobin & Bargmann 2004). Multi-dendritic polymodal nociceptive neurons with naked endings attached to epidermal cells (Goodman 2003; Hwang et al. 2007; Nicholls & Baylor 1968), and unmyelinated nociceptive fibers (Smith & Lewin 2009) similar to the C-fibers of vertebrates, are present. An upregulation of the nociceptive system after noxious stimulation resulting in long-term hypersensitization has been explained (Walters 1987).

Invertebrates do not possess a brain-like structure that is homologous to the human cortex, and wide

differences exist across the invertebrate phyla (Crook & Walters 2011; Elwood 2011). Nevertheless, many invertebrates have an incredible complex brain configuration that certainly is different from the mammalian brain, but is suspected to have structures that are analogous to a cortex with the ability to experience pain, sensory analysis, memory, and learning (Broom 2007; Elwood 2011; Smith 1991). Invertebrates that lack appropriate processing centers may only be capable of a rapid reflexive unconscious response to a noxious stimulus (Crook & Walters 2011). Further research is needed to give us a better understanding in this matter. Opioid receptor systems may have a functional role in invertebrate nociception (Fiorito 1986; Kavaliers 1988; Kavaliers & Hirst 1983; Kavaliers et al. 1983; Smith 1991), although there are controversial opinions (Crook & Walters 2011; Dores et al. 2002). The animals’ response to mechanical, chemical, and electrical stimulation is seen by withdrawal and escape behaviors (Elwood et al. 2009). This response is decreased or slowed when an analgesic is used (Kavaliers & Hirst 1983; Lozada et al. 1988; Maldonado & Miralto 1982). It is not yet clear if this decreased response is due to a sedative or an analgesic effect of the drug. Two interesting studies in fruit flies and glass prawns have addressed this problem by showing a change in behavior without the decrease in activity when an analgesic agent was administered (Barr et al. 2008; Maney & Dimitrijevic 2005).

Certain species (*Drosophila* sp., *Chasmagnathus granulatus*, *Pagurus clarkia*, and *Pagurus bernhardus*) expressed a learning of avoidance of noxious stimuli over various periods of time, which indicates ability for memory to decrease risk for potential future damage (Denti et al. 1988; Elwood & Appel 2009; Kawai et al. 2004; Yarali et al. 2008).

However, due to limited conclusive data, no definitive answer exists for the debate of whether invertebrates perceive pain and would suffer emotional stress from it. Evidence from behavioral studies that crustaceans and mollusks experience pain, or a “painlike state”, seem to be consistent (Crook & Walters 2011; Elwood 2011), but further research is necessary to confirm and clarify this.

Presently, there is an emerging interest in bringing more evidence to the debate of invertebrate pain and in particular animal welfare. For further review, the reader is referred to a special edition of the *Institute for Laboratory Animal Research Journal* (ILAR) (Smith 2011). In the United Kingdom, the octopus is covered under the same animal welfare act as vertebrates, due to the increasing evidence for pain perception found in cephalopods (Crook & Walters 2011).

Until the question of pain in invertebrates is clearly answered, it should be taken into account that some invertebrate species seem to have the capacity of a painlike experience, and an analgesic should be considered for any animal that is subjected to a painful

procedure. On the other hand, the use of analgesics in invertebrate species is not common, and little research has been done examining methods of administration of analgesics, dosing, and the effects and impact of the different analgesics on the patient, the anesthesia, and the recovery.

Until more research is published, drugs with analgesic properties are recommended to anesthetize invertebrates when invasive procedures are performed to avoid potential nociceptor activation and painlike sensation. Hypothermia and CO₂ do not possess analgesic properties and inhalant agents or MgCl₂ may be preferred. Although inhalant agents do not possess true analgesic properties, they do render mammalian patient insensible to painful stimuli when administered at sufficient anesthetizing doses. Unfortunately, the insensitivity to painful stimuli only lasts as long as the animal is anesthetized, so if the procedure is expected to be associated with significant postoperative pain, the administration of an analgesic is advisable. Different general options may include: the use of a local anesthetic, such as 2% benzocaine applied topically to a specific site (Barr et al. 2008) or diluted lidocaine (0.5–1 mg/mL) also for topical administration, and the use of an opioid and/or an nonsteroidal anti-inflammatory drug (NSAID).

EUTHANASIA

Invertebrates play an important role in laboratory research. Historically, no thorough guidelines or rules were available for euthanizing invertebrates, despite ongoing improvements in regulations for euthanasia in different vertebrate species (American Veterinary Medical Association [AVMA] Panel on Euthanasia 2000). Main reasons were primarily the fact that invertebrates are not covered by the U.S. laboratory animal guidelines and do not need an IACUP. Animal welfare has recently been an emerging topic in North America, following Europe's lead, and over the last few years, suggestions for euthanasia of invertebrates have been made throughout the literature (Battison et al. 2000; Hackendahl & Mashima 2002; Reilly 2001; Cooper 2012; Bennie et al. 2012; Pizzi 2012). Very recently, great progress has been made by including invertebrates into the "2013 Edition of the AVMA Guidelines for the Euthanasia" from the "Panel on Euthanasia" (AVMA 2013), with specific suggestions on euthanasia techniques.

Due to the wide variety of invertebrate species, anatomical differences and major difficulties to confirm death in these species, it is in general suggested to perform a two-step euthanasia protocol (AVMA 2013). This involves a chemical induction of anesthesia, commonly an overdose, that causes presumed death (step 1), followed by an additional physical or chemical method that causes destruction of the nervous system (brain or major ganglia) (step 2) (AVMA 2013). Acceptable step 1 methods for invertebrates are dependent on

the species and the effectiveness of a specific anesthetic agent. For aquatic invertebrates immersions into magnesium salts, eugenol, or ethanol are listed in the guidelines as acceptable step 1 methods (AVMA 2013). The adjunctive methods (step 2) in aquatic species can be physical (pithing, freezing, or boiling) or chemical (70% alcohol or 10% formalin) (AVMA 2013). It is explicitly stated that any method that is listed under acceptable step 2 techniques is not accepted as a sole method or as a first step method (AVMA 2013). The guidelines also state that any method, that does not cause rapid death, in particular hypoxia, anoxia, or death by caustic chemicals or traumatic injury without the loss of consciousness prior to it, is unacceptable (AVMA 2013).

For terrestrial invertebrates, an overdosing injection of pentobarbital into the circulating hemolymph or intracoelemic is recommended by the AVMA, when possible, and can be used as a single method.

Also acceptable is an overdose of inhalant anesthetics or CO₂ with adjunct methods, such as a physical or chemical destruction of the nervous system (AVMA 2013). It is important to keep in mind that the nervous system is different in every species, and that decapitation alone may be an unsuitable technique.

Battison et al. (2000) described the intracardiac injection of KCl in lobsters, which causes rapid immobilization and death. This method has been further developed by Bennie et al. (2012) in various anesthetized terrestrial invertebrate species. Bennie et al. injected KCl (100 μL/g) directly into the thoracic ganglion ("targeted hyperkalemia"), and achieved immediate paralysis and death. Centipedes seem to need a higher KCl concentration (20% v/w) than other terrestrial invertebrates (Bennie et al. 2012).

The new guidelines are a step further into the right direction, but there still is an enormous need for improvement and research to assure ethically acceptable ways to euthanize members of this diverse group of animals. More species-specific research is needed on this topic. As mentioned earlier, the ability of invertebrates to respond to noxious stimuli and show different types of stress responses is well recognized.

It should be our goal as veterinarians to treat every living creature with respect and promote the well-being of these animals and trying to provide a stress-free environment, even when the perception of pain is not fully understood. Animal welfare should have priority over the success of a research study, and euthanasia should be performed by a method that is effective, painless, and fast.

15 Bony Fish (Lungfish, Sturgeon, and Teleosts)

Natalie D. Mylniczenko, Donald L. Neiffer, and Tonya M. Clauss

INTRODUCTION

Do fish need to be anesthetized? Do fish feel pain? Fish welfare has become a hot topic for the last several years, in particular, the ability of fish to feel pain has come under considerable scrutiny. We need to consider this notion as it questions the need for anesthesia or analgesia altogether in this taxon. The previous version of this chapter as well as many recent publications (Braithwaite & Boulcott 2007; Posner 2009; Sneddon 2009) have thorough reviews on the subject. In brief, fish display robust, neuroendocrine and physiologic stress responses to noxious stimuli. Acute and chronic stress negatively affects fish health. Consequently, there is a need to identify and then reduce these stressors in individuals and groups.

Although examination and sample collection can be performed using manual restraint, for many minor procedures, chemical immobilization is safer for both fish and handler. In addition, many procedures are preferably performed out of water. In most fish, this stimulates struggling that requires restraint (Harms & Bakal 1995). That said, we will attempt to describe some methods in which fish can be restrained without anesthesia but with minimal restraint and stress.

Chemical immobilization is routinely utilized to reduce excitement and trauma related to hyperactivity that can occur during routine handling for vaccinations, hormonal implants or injections, roe or milt collection, sorting, tagging, and transportation of fish (Cooke et al. 2004; Harms 1999; Kumlu & Yanar 1999; Myszkowski et al. 2003; Ross 2001). In addition to acute trauma causing mortality and morbidity, integument damage results in acute to chronic osmoregulatory disturbances and increased susceptibility to pathogens (Kumlu & Yanar 1999; Ross 2001). Chemical

immobilization during transport reduces metabolism, leading to decreased oxygen demand and waste (i.e., CO₂ and ammonia) production (Cooke et al. 2004; Crosby et al. 2006; Guo et al. 1995; Ross 2001).

Major or surgical procedures require anesthesia to prevent movement and remove any doubt in the debate over pain (Harms & Bakal 1995; Myszkowski et al. 2003; Ross 2001). At the very least, movement and physiologic changes in response to nociception are minimized.

STRESS AND ANESTHESIA

Fish restraint activates the hypothalamo–pituitary–interrenal (HPI) axis, resulting in cortisol release causing various secondary stress responses (Bressler & Ron 2004; Myszkowski et al. 2003; Ross and Ross 2008; Small 2003; Small & Chatakondi 2005). Cortisol release suppresses feeding and immune function, and alters reproductive productivity (Bressler & Ron 2004; Iversen et al. 2003; Myszkowski, 2003; Small 2003; Small & Chatakondi 2005).

Although anesthesia minimizes handling stress, it is inherently stressful (Bressler & Ron 2004) and a strong potentiator of catecholamine release, especially in salmonids (Rothwell et al. 2005; Zahl et al. 2010). Anesthesia-associated catecholamine release is likely due to hypoxemia rather than acidemia or direct drug effects (Ross & Ross 2008; Rothwell et al. 2005). However, unbuffered inhalants (immersives) (e.g., MS-222) do induce a stress response. Hypoxemia is usually due to drug-induced hypoventilation (decreased buccal movement). In air-breathing fish, hypoxemia can be exacerbated by preventing anesthetized fish access to the water's surface (Rantin et al. 1993, 1998).

Hypoventilation with decreased water flow in the buccal cavity usually leads to reflex bradycardia and dorsal aortic hypotension producing a progressive hypoxemia (Ross 2001).

Despite the earlier-mentioned effects, chemical sedation or anesthesia produce a lower stress response when compared with drug-free handling and transport. This conclusion is based on comparison of circulating cortisol levels, as well as secondary indicators such as blood glucose, hematocrit (HCT), hemoglobin (Hgb), lactate, and osmolarity (Bressler & Ron 2004; Crosby et al. 2006; Hseu et al. 1996; Small & Chatakondi 2005).

Of the commonly used drugs, only metomidate consistently and significantly blocks HPI activation (Davis & Griffin 2004; Iversen et al. 2003; Zahl et al. 2010) in a broad range of species (e.g., red drum, *Sciaenops ocellatus*, Thomas & Robertson 1991; Atlantic salmon, *Salmo salar*, Iversen et al. 2003, Olsen et al. 1995; hybrid striped bass, *Morone chrysops* × *Morone saxatilis*, Davis & Griffin 2004; channel catfish, *Ictalurus punctatus*, Small 2003; and Atlantic cod and Atlantic halibut, Zahl et al. 2010).

The effect of clove oil (eugenol and isoeugenol) on cortisol secretion in fish is inconclusive. In channel catfish, no significant increase in cortisol concentrations were observed following 30 minutes of undisturbed clove oil anesthesia or when subjected to confinement and reduced oxygen levels while exposed to isoeugenol (AQUI-S™) (Small 2003, 2004; Small & Chatakondi 2005). However, in the same species anesthetized with AQUI-S and exposed to high unionized ammonia concentrations, cortisol was not suppressed (Small 2004). In Atlantic salmon smolts, clove oil and AQUI-S suppressed cortisol secretion while in adults only high dosages had the same effect (Iversen et al. 2003). In a different study, isoeugenol was found to have the same effect as MS-222 on stress but did not reach levels of cortisol as high as with MS-222 (Zahl et al. 2010). In seabream (*Sparus* sp.) exposed to clove oil (Bressler & Ron 2004) and rainbow trout (Small & Chatakondi 2005) exposed to both clove oil and AQUI-S, cortisol concentrations increased in response to handling. In gilthead seabream (*Sparus aurata*) exposed to clove oil (Bressler & Ron 2004) and hybrid striped bass exposed to both compounds (Davis & Griffin 2004), similar increases in circulating cortisol and glucose occurred. In red pacu (*Piaractus brachipomus*), exposure to eugenol increased glucose, HCT, and Hgb (Sladky et al. 2001) while in a related tropical freshwater species, tambaqui (*Colossoma macropomum*), no increase in glucose was noted (Roubach et al. 2005).

Except for low MS-222 dosages that depress (not block) the stress response in some fish (e.g., Chinook salmon, *Oncorhynchus tshawytscha*, and hybrid striped bass), immersive anesthetic drugs minimally inhibit the HPI response (Davis & Griffin 2004). Elevated cortisol and/or hyperglycemia occur in MS-222 exposed

channel catfish (Small 2003; Small & Chatakondi 2005), Atlantic salmon (Olsen et al. 1995), hybrid striped bass (Davis & Griffin 2004), and red drum (Thomas & Robertson 1991). Similar elevations occur in gilthead bream exposed to benzocaine (Bressler & Ron 2004). Increased cortisol, with or without hyperglycemia, has also been associated with quinaldine exposure in red drum (Thomas & Robertson 1991), channel catfish (Small 2003), and hybrid striped bass (Davis & Griffin 2004). In four marine teleost species, the physiologic effects of 2-phenoxyethanol varied between species with significant elevations of HCT in red snapper (*Lutjanus argentimaculatus*), Hgb in gray mullet (*Mugil cephalus*), and osmolarity of black porgy (*Acanthopagrus schlegeli*), but no changes in milkfish (*Chanos chanos*) (Hseu et al. 1996).

Limited information on the effects of injectable drugs on the HPI response exists. In bonito (*Sarda chilensis*), ketamine/medetomidine did not significantly alter HCT, Hgb, or glucose, although baseline values were not provided (Williams et al. 2004).

It has been argued that the stress-induced corticosteroid response is not harmful and is essential for recovery from severe acute or prolonged stressors. A transient, relatively small elevation of cortisol does not necessarily reduce immunocompetency, but may instead bolster it (Bressler & Ron 2004; Davis & Griffin 2004; Small 2003; Thomas & Robertson 1991). Based on this argument, drugs that suppress the HPI (e.g., metomidate) are contraindicated in fish. However, the contrary argument is that typical husbandry and handling procedures do not result in high stress levels associated with chronic immunosuppression (Bressler & Ron 2004; Davis & Griffin 2004; Small 2003; Thomas & Robertson 1991). For anesthetics that do not block the HPI, the intensity and duration of the stress response either depends on the duration of exposure or is drug, dosage, and species dependent (Bressler & Ron 2004; Gomes et al. 2001; Thomas & Robertson 1991).

In addition to affecting the stress response, some anesthetics are immunosuppressive. This effect may be caused by direct interaction with immune components or indirectly through the nervous system. For example, in gilthead seabream, both humoral and cellular immune responses were significantly depressed by benzocaine (Bressler & Ron 2004). However, clove oil does not cause significant immunosuppression in the same species demonstrating the variability between species and drug effects (Bressler & Ron 2004). Metomidate associated blockade of the HPI is thought to prevent immunosuppression (Davis & Griffin 2004).

TAXONOMY, ANATOMY, PHYSIOLOGY, AND BEHAVIOR

Fish number upwards of 30,000 species and comprise more than 40% of all extant chordates. Of these, tele-

osts (Teleostei: class Acinopterygii) comprise about 96% of living fish species. Other groups include other members of class Acinopterygii or ray-finned fishes (sturgeon, gar, bichir, paddlefish, and bowfin), class Sarcopterygii or lobe-finned fishes (lungfishes and coelacanth), class Agnatha or jawless fish (hagfishes and lampreys), and class Chondrichthyes (elasmobranchs and chimeras) (Bond 1996; Harms 2003).

The majority of immobilization studies involve only a handful of teleosts. Extrapolation to all species is potentially harmful and negligent without consideration of the wide range of anatomic, physiologic, and behavioral differences. For example, benzocaine kills cod (*Gadus morhua*) at the same dosage that is safe and effective in Atlantic salmon (Hansen et al. 2003; Mattson & Rippe 1989). Even within families, there can be marked variation in preferred environmental parameters. Consequently, knowledge of taxonomy and natural history is essential for developing anesthetic regimens in fish.

Respiration

All fish have gills though the degree of reliance on these structures for respiration varies across class, order, and family. Most fish force water over the gills through rhythmic movements of their lower jaw and opercula (buccopharyngeal respiration). However, some species utilize ram ventilation (forcing water over the fish gill by swimming through the water column) with minimal opercular movement. Some teleosts (e.g., tuna, family Scombridae, tribe Thunnini) are obligate ram ventilators, with gilling alone not providing sufficient ventilation to meet metabolic demands. These species swim forward continuously with mouth slightly agape to develop the pressure head necessary for sufficient water flow over the gills. Failure to perfuse the gills during anesthesia results in suffocation (Brill & Bushnell 2001; Bushnell & Jones 1994). Tuna also rely on constant forward speed to produce lift from their pectoral fins for hydrostatic equilibrium (Brill & Bushnell 2001). Consequently, during recovery of ram ventilating species, it is necessary to hold the fish with sufficient water flow over the gills via a pump mechanism until adequate voluntary forward motion of the sedated animal returns. Walking the animal or pulling the animal manually through the water to ventilate is a favored option among fish enthusiasts; however, this does not always provide adequate ventilation, and a pump is strongly encouraged to move water over the gills, particularly with pelagic fish species.

In responses to hypoxic environments or other selective pressures, many species have evolved anatomical, physiologic, and behavioral adaptations to meet their ventilatory needs (Graham 1997). In addition to elaboration of the basic gill design for improved oxygen extraction, a diverse array of accessory respiratory organs has evolved, with a number of species capable

of utilizing atmospheric air. For many, increased aerial gas exchange surface exists in portions of the alimentary canal (i.e., buccal and pharyngeal cavities) either as a direct proliferation of the respiratory surface in the lumen or as a single or a pair of pouches extending from it (Ishimatsu & Itazawa 1993). Alternatively, branchial diverticulae may develop as in anabantoids (gouramis, bettas, and climbing gouramis) (Graham 1997).

Many species take in atmospheric air with a behavior termed aquatic surface respiration (ASR). The fish position their mouths to skim the air/water interface that is richer in oxygen. Some species (e.g., pacu, *Piaractus mesopotamicus*) respond to hypoxic conditions by developing temporary dermal swellings of the lower jaw to facilitate ASR (Rantin et al. 1993, 1998). Others (e.g., channids [snakeheads] and anabantoids) employ alternate filling of an air-breathing chamber (larynx organ in anabantoids) with air and water during aerial ventilation (Ishimatsu & Itazawa 1993).

Lungfish (the sister group to tetrapods) and polypterids (bichirs and reedfish) possess true lungs with ventrally situated pneumatic duct openings in the alimentary canal instead of a traditional gas or "swim" bladder (Graham 1997). Of these, the African (*Propterus* sp.) and South American (*Lepidosiren* sp.) lungfish are obligatory air-breathers (Bassi et al. 2005; Graham 1997). The Australian lungfish possesses gills as well as a lung (Lenfant et al. 1966). Interestingly, unlike water-breathing fishes, the air-breathing lungfish will alter ventilation to compensate for metabolic acid-base changes, but there is likely an extrarenal component involved as with water breathing fish (Gilmour et al. 2007). Although anatomically challenging, it is theoretically possible to cannulate the pneumatic duct of lungfish for administration of inhalant anesthesia; this has been done experimentally with animals under controlled experiments (Pack, et al, 1992). Conceivably, chamber induction (while somewhat submerged) may be possible but has not been reported. Alternatively, sterile percutaneous trocharization of the lung could be attempted. The Australian lungfish is the only facultative breather in the group, but when placed in immersive anesthetics, will attempt to breathe air and not respire with its gills. However, immersion anesthesia with MS-222 has been accomplished in lungfishes and is a viable option if the animals are managed appropriately under anesthesia either by ensuring oxygenation once sedated via oxygen gas (or oxygenated water in animals with gills) and prevent drowning (DeLaney et al. 1976; Lenfant et al. 1966; N. Mylniczenko, pers. exp., 2004).

Understanding the range of fish respiration is important for anesthesia for two reasons. First, immersion uptake and induction rate is linked to oxygen demand. For fish that depend primarily or entirely on dissolved oxygen in water, induction rates are shorter compared

with those of air-breathing species. Responding to confinement or hypoxic anesthetic baths, the latter pull air from the water surface and reduce opercular movement. Some may temporarily stop opercular activity (Hseu et al. 1997). Decreased branchial contact with the water results in a slower rate of anesthetic uptake. For example, 2-phenoxyethanol induction in hypoxia tolerant tilapia (*Oreochromis mosambicus*) and molly (*Poecilia velifera*) is significantly longer than in black porgy (*Acanthopagrus schlegeli*) and Japanese sea perch (*Lateolabrax japonicus*) (Hseu et al. 1997). To circumvent this issue, injectable anesthetics can be used for induction of species capable of aerial respiration (e.g., anabantoids) (Bruecker & Graham 1993). Second, although many fish that utilize an accessory respiratory organ retain gills for aquatic gas exchange, effective gill tissue is so reduced in some species (e.g., channids, lepidosirenid lungfish, and clariids or walking catfish), they will succumb or “drown” if denied access to atmospheric air (Ishimatsu & Itazawa 1993; Peters et al. 2001). These species are maintained in very shallow water, or on a moist substrate, until capable of reaching the water: air interface regardless of anesthetic route used.

Arapaima and other osteoglossids are also obligate air breathing fishes that use a modified swim bladder for respiration (Brauner et al. 2004). Focused spraying of immersion drugs, such as benzocaine and eugenol, on the gills is an effective method of induction (Honzaryk & Inoue 2009, 2010). Researchers have used MS-222 at 25, 50, 75, and 100 mg/L in juveniles, finding that 100 mg/L concentration was ideal for their project (Hinostroza & Serrano-Martínez 2013). In a different study, chloroform was used via gas mask with rapid induction times, but longer than expected recoveries; regardless, the anesthesia was considered successful (Carreiro, et. al, 2011). One of the authors (Mylniczenko) has experiences using high dose MS-222 (1 g/L) over the gills to sedate larger species, as well as low dose immersion MS-222 (25 ppm) in combination with valium (1 mg/kg PO) for transport. Ketamine has shown to be successful orally in this species for transport (Raines & Clancy 2009). There is also concern that these fish are at high risk for not recovering their air-breathing reflexes once anesthetized (Chu-Koo et al. 2008), though the authors have not experienced this (Carreiro et al. 2011). Still, caution must be exercised as the arapaima are very sensitive species and can drown without air access. As described with the lungfish, intubation can be attempted in their swim bladders (Farrell 1978).

Although notable exceptions exist (e.g., tarpon, *Megalops atlanticus*), few marine species have evolved adaptations for hypoxic environments other than surface piping or migrating from the area. Consequently, marine species may be less tolerant of hypoxic conditions during anesthesia in comparison with the freshwater species discussed earlier (Rothwell et al. 2005).

Metabolism

Most fish are ectothermic with metabolism dependent on ambient temperature. Though exceptions exist for some cold-adapted species, lower temperatures are usually associated with prolonged induction and recovery times during either inhalant/immersion or parenteral anesthesia (Gelwicks & Zafft 1998). This effect is reversed at higher temperatures (Detar & Mattingly 2004; Gomes et al. 2001; Peters et al. 2001; Stehly & Gingerich 1999). During immersion anesthesia, this relationship is primarily related to altered respiratory rate. Blood acid–base status is temperature dependent. Increased temperature leads to acidemia and hypercapnia, which stimulate hyperventilation. This decreases induction and recovery times for drugs taken up or eliminated from the gills (Aguiar et al. 2002; Stehly & Gingerich 1999).

Some fish have evolved various degrees of endothermy. They have the capacity to conserve metabolic heat in slow-twitch muscle, viscera, brain, and eyes, and to elevate body tissue temperature above ambient (Bushnell & Jones 1994). The most studied are tuna (family Scombridae), which have many anatomical and physiologic adaptations that promote endothermy. Tuna gills have large surface areas and thin epithelia compared with other fish (Brill & Bushnell 2001; Bushnell & Jones 1994). For example, gill surface areas are approximately 7–9× larger and gill blood–water barrier thickness an order of magnitude less than those of rainbow trout (Brill & Bushnell 2001). The net result is enhanced oxygen uptake. Red cells with elevated hemoglobin are circulated by proportionally large hearts with high cardiac outputs (Blank et al. 2004; Bushnell & Jones 1994) to well vascularized tissues. High myoglobin levels and aerobic enzymes enhance tissue oxygen extraction. Enzyme activity is particularly high in muscle; aerobic oxidation rates are 3–5× greater than other teleosts (Bushnell & Jones 1994). Elevated enzymatic activity and counter-current heat exchangers raise muscle temperatures (Cooper et al. 1994). Endothermy leads to increased rate of anesthetic uptake and metabolism compared with similarly sized ectothermic species. More primitive Scombrids (e.g., bonitos, seerfishes, and mackerels) are not endothermic and lack physiologic characteristics of tuna, such as the vascular countercurrent heat exchange mechanism. However, aerobic enzyme activity is similar, and these scombrids represent a transition between ectothermy and tuna endothermy (Brill & Bushnell 2001; Williams et al. 2004).

All teleost fish have an anatomic separation between aerobic, slow-oxidative muscles (red muscle), and anaerobic, fast-twitch, glycolytic muscles (white muscle). In many species, a distinct pattern of highly oxygenated slow oxidative muscle runs along the midline of the body. Given the increased capillarization, injection of anesthetic agents into this region

may result in more rapid induction times compared with injections administered elsewhere (Williams et al. 2004), but in reality, this layer is very thin and has large variation in thickness and location, making consistent injections difficult.

Integument

Although most fish possess scales, marked variation in distribution and structure exist. This has implications for administration of parenteral drugs by hand and remote injection. Species (e.g., tarpon and arapaima) that have large, hard scales are difficult to dart or pole-syringe, while even large cobia (*Rachycentron canadum*) are relatively easy to inject.

For many fish, the skin is a respiratory organ, responsible in some species for up to 30% of oxygen uptake (Bruecker & Graham 1993). Most marine species have well vascularized skin capable of significant cutaneous gas exchange (Ishimatsu & Itazawa 1993). Though scaleless species (e.g., catfish, Siluriformes) are better designed for cutaneous respiration, capacity often varies with age class. Younger fish, regardless of size, tend to have thinner skin and less developed scalation favoring greater oxygen uptake (Myszkowski et al. 2003). Fish species that produce larvae lacking gills require skin respiration the first 9–15 days until full differentiation of secondary gill lamellae (Oikawa et al. 1994). Like other respiratory organs, skin is a route for immersion drug uptake and presumably excretion (Ferreira et al. 1984). The efficiency of uptake is dependent on scalation and, similar to gill tissue, lipid content of the skin. For example, some scaleless types of common carp (*Cyprinus carpio*) with high skin lipid content are much more efficient at cutaneous anesthetic uptake than rainbow trout with their small, densely packed scales and comparatively lower lipid content (Ferreira et al. 1984). In some instances, skin may actually be more efficient than other respiratory organs. For example, in the electric eel (*Electrophorus electricus*), quinaldine uptake across the skin was higher than the gills (Walsh & Pease 2002).

Size

Minimum effective anesthetic concentration is directly correlated with increasing body mass (Oikawa et al. 1994). This relationship is also true for toxic concentration. For example, MS-222 LC₅₀ increases with growth in rainbow trout (*Oncorhynchus mykiss*), brown trout (*Salmo trutta*), lake trout (*Salvelinus namaycush*), largemouth bass (*Micropterus salmoides*), and channel catfish (Oikawa et al. 1994).

ENVIRONMENTAL AND OTHER FACTORS

Temperature

In addition to metabolism, dissolved oxygen (DO) concentrations are influenced by temperature. At higher

temperatures, DO decreases exacerbating any anesthetic-induced hypoxia. Warmer temperatures also promote solubilization of immersion anesthetics while cooler temperatures promote precipitation.

pH

The pH of immersion solutions will influence efficacy, possibly by affecting the ratio of charged to uncharged molecules. In general, decreased efficacy is seen as the pH drops due to increased ionization that interferes with absorption. Unfortunately, most immersion anesthetics (e.g., MS-222 and quinaldine) in solutions are acidic, requiring buffering agents (e.g., sodium bicarbonate) to neutralize the pH. In addition to promoting immersion anesthetic efficacy (Ferreira et al. 1984), buffers prevent metabolic acidemia, a condition precipitated by anesthetic-induced hypoxemia and anaerobic metabolism. Saltwater, with its higher pH and greater natural buffering capacity compared with freshwater, may not require addition of buffering agents (Harms & Bakal 1995; Harms 1999; Oikawa et al. 1994; Ross 2001; Ross & Ross 2008). The greater efficacy and safety of immersion anesthetics in sea water was demonstrated in mullet (*Mugil cephalus*) (Sylvester 1975). For a given concentration of MS-222, decreased efficacy and increased toxicity was noted in freshwater acclimated compared with saltwater housed mullet. At some institutions, it is common practice to err on the side of caution and buffer marine water with sodium bicarbonate at a 2:1 ratio (2 parts bicarb, 1 part MS-222 based on weight). Alternatively, the pH of the anesthetic water can be measured and the pH adjusted accordingly. Regardless of the method used, one should keep in mind that pH shifts may potentially have metabolic effects on the fish not solely related to anesthetic efficacy especially if exposure is prolonged. That said, in an unpublished study (T. Clauss, pers. exp., 2011) with crevalle jacks, there was no significant short-term difference in blood gas values from fish anesthetized in buffered or unbuffered MS-222. Regardless, species differences exist and without a controlled study as this one, it is advised to buffer or measure water pH.

Nitrogenous Compounds

Build up of nitrogenous compounds, particularly ammonia and nitrite, can damage or induce changes in gill morphology that affect uptake and clearance of immersion anesthetics. In addition, compromised oxygen uptake affects metabolism, including that of parenteral and immersion anesthetic agents, and can lead to acidemia. Water that has an animal in it for a long period of time, or when immersion water is reused, has the risk of nitrogenous compound elevations; water changes during the procedure will ameliorate these effects; additionally, measuring the water's ammonia content during the procedure will remove all concerns.

Drug Concentration or Dosage

At a given temperature, higher concentration immersions or drug dosages generally decrease induction and increase recovery times. However, recovery time from some immersions is independent of concentration (Hseu et al. 1997, 1998).

Drug Exposure Time

Increased immersion anesthetic exposure time usually results in increased recovery time. This effect is often associated with progressive hypoxemia and metabolic acidemia due to prolonged hypoventilation. Some immersion drugs (e.g., MS-222) continue to increase in brain and muscle despite blood equilibration. Therefore, an initially satisfactory drug dosage can produce progressively deeper anesthesia and respiratory arrest, even during recovery when the fish is in anesthetic-free water (Ross 2001). Thus, using graded anesthesia, higher dose rapid induction and lower dose maintenance levels is a sound practice. This practice has shown to reduce overall levels of physiologic stress in some species (Matsche 2011).

VASCULAR ACCESS

Most fish fall under a similar body plan and accessing their blood vessels is fairly straightforward. In large fish, spinal needles might be required due to the depth of the vessels. The ventral tail vein is accessible on the ventral midline or laterally under the lateral line (Fig. 15.1a,b). Cardiac puncture is sometimes the only viable options in species, where the tail is either covered by large, thick scales (parrot fish, arowana, and arapaima) that prevent access without removal of scale or where removal would result in significant skin exposure (Fig. 15.2). Cardiac puncture can be achieved by moving the operculum and inserting the needle through the skin that is cranial to the bulbus arteriosus/ventricle or ventrally through the body wall. Access to the dorsal aorta is also available through the oral cavity, midline and immediately posterior to the hard palate (Fig. 15.3). In some fishes (e.g., Australian lungfish), there is a periorbital sinus that can also be reached through the oral cavity.

Catheterization of fishes is not a minimally invasive process and is not routinely utilized, but possible (Ostrander 2000). In certain settings, typically research, dorsal aorta cannulization can be performed, but requires anchoring specialized tubing through the roof of mouth and through the rostrum and affixation to the dorsal fin or muscle of the fish (Smith & Bell 1964; Sovio et al. 1972). The ventral aorta is cannulated in a similar fashion but using the lower jaw. The caudal vein has also been catheterized and uses similar tubing as with the earlier cannulas (Ostrander 2000). With either method, the tubing of the setup must be affixed to the animal in order to prevent slippage of the catheter. In

Figure 15.1. (a) Midline caudal tail venipuncture in a grouper (*Epinephelus itajara*) using an 18-gauge spinal needle and extension set. A chamois is placed on the tail to hold the animal in place within a sling during the venipuncture. (b) Lateral approach to caudal vein in a rainbow trout (*Onchorynchus mykiss*).

fast-moving fishes, maintaining such catheters is nearly impossible, therefore confinement may be necessary which carries its own obvious stressors (Sumpter et al. 1986). Additionally, anatomical features of some fishes make some of these approaches impossible.

IMMOBILIZATION METHODS AND TECHNIQUES

Manual Restraint

Manual restraint when used appropriately can be used for managing simple, short procedures or when preparing the animal for induction of anesthesia. For procedures lasting longer than several minutes, it is better to use chemical immobilization. Animals that are habituated or domesticated tolerate handling restraint better than nonacclimatized fish. See also the operant conditioning section in this chapter.

Considerations for human safety with manual restraint should include bites, stings, abrasions, and

Figure 15.2. Cardiac venipuncture in a grouper (*Epinephelus lanceolatus*) using a 16-gauge spinal needle.

Figure 15.3. Cannulation of the dorsal aorta in a rainbow trout (*Onchorynchus mykiss*).

physical trauma due to thrashing. Even with chemical immobilization, the following should be considered so that appropriate safety precautions are utilized. Venom can occur in the dorsal or pectoral spines of scorpionfish, toadfish, rabbitfish, and a number of other fishes (Williamson et al. 1996). Sharp spines or other protuberances, such as with the acanthuridae (tang and surgeonfish) or some tetraodontidae (porcupine pufferfishes), can cause significant damage without protective wear. Teeth have vast anatomic variety and can be crushing, puncturing, and macerating. In some species, pharyngeal teeth deep in the oral cavity can

cause trauma, particularly if the handler is unaware of their presence. Finally, there is the unique group of electric animals (electric eels, Mormyridiformes, and Gymnotiformes) that pose varying risks. An electric eel can produce 550 V (~1 amp) (Harms 2003), while the elephant nose mormyrids produce 500Hz (Von der Emde 1998). Wearing gloves that do not transmit electric current is beneficial.

In regard to animal safety, the tubular, soft bodied fishes are particularly challenging to hold without crushing them. Further, the mucus on the skin of fishes is very slippery and in some species, copious. This not only poses a risk for not being able to securely restrain but it can be a source of long-term negative consequences should the mucus be removed. Wearing latex gloves that have been rinsed free of powder (an irritant to fish) helps with minimizing damage to fish skin and mucus, but can make secure handling more challenging. Wet material, such as cloth diapers and chamois used for automobiles, are both soft and smooth and can be useful in restraining some fish without damaging or altering the skin and mucous layer. Some fishes are scaleless and require more delicate handling in order to avoid abrading the skin. Additionally, keeping the basic facts in mind, such as that fish lack eyelids, will help in avoiding simple mistakes.

Nets of varying sizes and configurations (dip, seine, and box) are the most obvious tool for catching and restraining many fishes. For delicate skinned fish, nets made of plastic or very soft fine mesh are needed, but alternately, clear plastic bags can be used. In some circumstances, as in large exhibits, even the hook and line approach has been successfully used; note, however, that as with wild fishes, hook traumas can be fatal, as can exhaustive exercise.

Animals that struggle should be sedated. The concept of “learned helplessness” as with mammals is not an appropriate parallel to draw. The fish that “gives up” is stressed and depleted of energy. Anticipation of how a fish will manage manual restraint is crucial.

Larger fish can also be netted and then slung, but need care when lifting; the integrity of the net must be solid. These animals should only be moved for purposes of sedation and no further manipulation due to human and animal safety concerns. One method of recent use in elasmobranch restraint (see Chapter 16) is also an effective method for larger teleosts, such as grouper. This entails the use of a large vinyl bag with a narrow end that is open to allow water flow and a larger opening to catch the animal; this technique is best used on partially sedated or sedated animal. At the Seas, Walt Disney World, Orlando, FL, a large grouper in a 6-million-gallon aquarium was presedated with oral valium, moved into the bag, and then further sedated with high doses of tricaine methanesulfonate and safely brought to the surface. The bag was borrowed from uShaka Marine World Durbin, South Africa

(G. Drysdale, pers. comm., 2013), where it is used predominantly in elasmobranchs.

An additional important consideration for manual restraint is time out of the water. In several studies, exposure to air increased mortality rates of angler caught fishes (Ferguson & Tufts 1992; Gingerich et al. 2007). In another study, while there were no mortality rates, there was significant morbidity (Schreer et al. 2005). Severity is species variable, as fishes that require oxygen-rich environments (e.g., trout) are more profoundly affected by air exposure and become acidotic with even short exposure times to air.

Operant Conditioning

Operant conditioning in fish is not a new concept (Couvillon 1984; Sison & Garlai 2010; Wright & Eastcott 1982), but the general trend of utilizing it for husbandry practices in aquaria has only gained popularity in the last few years. Many fish can be trained to move into certain areas of their enclosure, to swim into nets, crates or pools. The size of the animal is not a restriction, as schools of small fish can be as efficiently trained as large fishes. In larger animals, operant conditioning can be an invaluable tool to isolate animals for brief exams, treatments or for facilitating chemical administration for inducing anesthesia (Fig. 15.4a,b).

Methods for induction of anesthesia usually reduce the area where an animal can swim so that immersion anesthetics can be used in smaller volumes, injections are more achievable, or so that high dose inhalation agents (discussed later) can be administered with ease. Corraling animals into smaller areas with baffles, bringing them over slings (Fig. 15.5) and allowing the sling to come up around the animal's body, moving them into small inflatable pools, and finally, moving them into "squeeze" areas (Fig. 15.6) are all methods that facilitate examination, minor procedures (e.g., praziquantel immersion treatments), as well as anesthetic induction. Training animals to shift into containers like a PVC box or a trash bin are also good options to get closer contact.

Fish cognitive abilities allow individuals or groups to respond to visual, auditory or olfactory cues, and as such they can be trained much like you would train any higher vertebrate (Couvillon 1984; Sison & Garlai 2010; Wright & Eastcott 1982).

General Suggestions for Anesthesia

Before anesthetizing an unfamiliar species the anesthesiologist should perform a review of the available literature. Despite limited fish anesthesia publications, a literature search using the scientific name, along with words or phrases such as "physiology," "anatomy," "site fidelity," "fecundity," and "population assessment," will identify studies that required sedation or anesthesia. Table 15.1, while listing anesthetic regimens for representatives of many families, is far from exhaustive and was accomplished, in part, as suggested

Figure 15.4. (a) Operant conditioning of a cobia (*Rachycentron canadum*). Note the animal is targeting on a T-shaped piece of PVC. (b) Operant conditioning of a grouper (*Epinephelus itajara*). The animal swims into a PVC box, which can then be closed/secured to reduce the functional swimming space of the animal.

Figure 15.5. Sling designed to lift large aquatic animals.

Figure 15.6. Squeeze device designed from PVC and plastic mesh. To the left of the squeeze is a net that reduced the spaced of the tank. The animal was corralled into the right side of the PVC/mesh (the animal is in the far right bottom corner).

earlier. Careful review of age class and body size in the literature should be taken into account when using these dosages and regimens because many studies utilize young or small fish. For example, drug dosages used in salmon smolts may not be effective in ocean ranging adults.

Regardless of available information, the anesthetic regimen for an untested species should be tried through to recovery using one or a small group of fish. Start at the low end of the recommended dosage range and work up to the desired effect (Harms & Bakal 1995; Ross 2001; Stetter 2001). However, in a species whose anesthetic tolerance is known, use a high dosage for a smoother and more rapid induction. Once induced, a lower immersion maintenance dosage is usually appropriate (Harms 1999). Rapid capture or in-enclosure anesthesia will reduce stress and facilitate smoother inductions. As mentioned, utilizing graded anesthesia (high induction, low maintenance dose) is a stress reducing method of anesthesia (Matsche 2011).

Preanesthetic Preparations

Where possible, the following should be performed prior to induction:

1. Baseline behavioral parameters (i.e., ventilation, caudal fin stroke rate, and overall activity level) should be recorded for comparison during anesthesia.
2. Although aspiration pneumonia is not a concern, it is not uncommon for fish to regurgitate material

that clogs gill rakers and contributes to water quality degradation. Additionally, if the regurgitant is fine and covers the gill lamellae, then suffocation can theoretically occur (sestonosis). Fasting for 12–24 hours (one feeding cycle) limits regurgitation and decreases nitrogenous waste production (Harms & Bakal 1995; Stetter 2001).

3. Containers with adequate water for transportation, induction, maintenance, and recovery should be available (Harms 1999; Stetter 2001). This is particularly important when water is used for immersion anesthesia. If the procedure occurs next to the animal's tank, it can be used for recovery. This assumes monitoring is possible and other specimens will not traumatize or predate the fish during recovery.
4. The physical (e.g., temperature) and chemical (e.g., pH and salinity) variables of all water used must be matched to those of the fish's source water. It is important to remember that the typically smaller water volumes used for anesthetic procedures will warm or chill to the temperature of the room air, thus water temperature should be monitored during the procedure and maintained as consistently as possible. Dissolved oxygen is maintained >5 ppm (mg/L) with 6–10 ppm ideal (Harms 1999; Stetter 2001).
5. For out of water procedures, a plan is made to prevent drying of the skin, fins, and eyes. This can include coverage with clear plastic drapes, bubble wrap, soft cloth (chamois or microfiber), and regular rinsing of tissues with water from a syringe or a small portable atomizer (Harms 1999; Ross 2001).
6. Capture techniques should be considered and the procedure discussed with all staff involved especially with large fishes.

Immersion (Inhalant) Anesthesia

Inhalant anesthesia via immersion in the water is analogous to gaseous anesthesia in terrestrial animals. The anesthetic in solution is ventilated by the fish, enters the bloodstream through the gills \pm accessory respiratory organs \pm the skin and passes rapidly to the central nervous system. When returned to drug-free water, drugs or their metabolites are excreted mostly via the gills and presumably accessory respiratory organs. Some elimination also occurs through the kidneys, liver, and presumably the skin (Ross 2001; Walsh & Pease 2002). Unlike in terrestrial vertebrates, any water soluble drugs or metabolites excreted from fish will be continuously absorbed through the body surface and gills, while being simultaneously metabolized and eliminated (Oikawa et al. 1994). This is problematic for assessing dosage effects and performing pharmacokinetic studies, unless flowthrough systems or closed systems with inline carbon filters are utilized. This is significant when considering reusing the same water for multiple fishes; while it is unknown how much metabolism of drug occurs per volume of anesthetic water, it is in the

Table 15.1. Selected anesthetic agents used in selected bony fish (lungfish, sturgeon, and teleosts)

Class Osteichthyes Taxa	Drug	Dose	Route	Wt/Age	Temp (°C)	Comments	Reference
Subclass Sarcopterygii (coelacanth/lungfish)							
Order Ceratodontiformes							
Family Ceratodontidae							
<i>Neoceratodus forsteri</i> (Australian lungfish)	MS-222	100 mg/L	IM	Adult		Possess gills but may cease ventilation, may need to ventilate for the animal. Drowning is a potential hazard as this species has a single lung. Anesthetic induction is often long and may require some manual restraint until fully sedate.	N. Myinczenko, unpubl.
Order Lepidosireniformes							
Family Lepidosirenidae							
<i>Lepidosiren paradoxa</i> (South American lungfish)	Benzocaine	Induction: 1 g/L Maintenance: 0.25 g/L	IN	577 ± 12 g	25	Obligate air breathers—prevent drowning. Induction: within 10 minutes. Maintained by flushing 0.25 g/L solution over gills. Recovery within 1 hour.	Bassi et al. (2005)
Family Protoptenidae							
<i>Protopterus annectens</i> (West African lungfish)	Medetomidine plus Ketamine	0.053 mg/kg 5.26 mg/kg	IM	1.33 kg		Obligate air breathers—prevent drowning. Provided mild sedation, but not adequate for diagnostics without physical restraint. No reversal given. Recommend higher dose.	D. Neiffer, unpubl.
<i>Protopterus aethiopicus</i> (African lungfish)	MS-222	0.5%	IM	2–14 kg		Used for catheter placement into the branchial arch	DeLaney et al. (1976)
Subclass Actinopterygii							
Subdivision Chondrostei (sturgeons, paddlefish)							
Order Acipenseriformes							
Family Acipenseridae							
<i>Acipenser oxyrinchus desotoi</i> (Gulf of Mexico sturgeon)	Medetomidine plus ketamine Atipamezole	0.06 mg/kg 6 mg/kg 0.30 mg/kg	IM IM	4-year-old 3.6 ± 1.2 kg	21.6 ± 3.1	Light plane of anesthesia for minor diagnostic procedures within 10 minutes. Mild bradycardia and respiratory depression noted. Atipamezole administered 30 minutes after immobilizing agents. Full recovery by 30 minutes. No mortality.	Fleming et al. (2003)
	Propofol	6.5 mg/kg	IV	4-year-old 3.6 ± 1.2 kg	21.6 ± 3.1	Light plane of anesthesia for minor diagnostic procedures within 5 minutes. Mild bradycardia and respiratory depression noted, with the latter persisting for 60 minutes. Fish remained quiet and unresponsive for 40 minutes. At 60 minutes, 70% were fully recovered within 120 minutes. No mortality.	Fleming et al. (2003)

<i>Acipenser transmontanus</i> (white sturgeon)	Clove oil	50–100 mg/L	IN	206–363 g	Induction: 3–6 minutes. Exposed for 10 minutes. Recovery: 4.5–8.5 minutes. No mortality.	Taylor and Roberts (1999)
<i>Acipenser ruthenus</i> × <i>Huso huso</i> (hybrid Sterlet and Beluga sturgeon)	Ketamine	77–88 mg/kg	IM	5–7.7 kg	Induction: 4–7 minutes. Effect lasted 6 hours.	Williams et al. (1988)
	MS-222	100–125 mg/L	IN	1.36–2.34 kg	Variable effect from mild sedation to light anesthesia. N = 10.	D. Neiffer, unpubl.
Subdivision Teleostei Order Anguilliformes (eels)						
Family Anguillidae						
<i>Anquilla reinhardtii</i> (long-finned eel)	Benzocaine dissolved in ethanol (1:10)	60–80 mg/L	IN	Adults	Induction within 6 minutes.	Walsh and Pease (2002)
	Clove oil	100 mg/L	IN	Adults	Induction within 6 minutes. Recovery within 4 minutes.	Walsh and Pease (2002)
Moray eels	MS-222	90–100 ppm	IN			
<i>Anquilla rostrata</i> (American eel)	MS-222	75 mg/L	IN		Sedation rated excellent. Examination performed.	D. Neiffer, unpubl.
Family Muraenidae						
<i>Gymnothorax funebris</i> (green moray)	MS-222	50–100 mg/L	IN	Adults	Suitable for examination. Animals that gulp air at surface may take longer to induce. Make sure animal is enclosed in a confined area since prone to leaping.	E. Chittick, unpubl.
<i>Gymnothorax vicinus</i> (purplemouth moray)	MS-222	50–100 mg/L	IN	Adults	Suitable for examination. Animals that gulp air at surface may take longer to induce. Make sure animal is enclosed in a confined area since prone to leaping.	E. Chittick, unpubl.
Order Batrachoidiformes						
Family Batrachoididae						
<i>Opsanus beta</i> (Gulf toadfish)	MS-222	670 mg/L buffered with NaOH	IN	Sexually mature fish	Once fish was induced they were wrapped in anesthetic solution soaked paper towels for 30 minute surgical placement of venous cannula. Species considered tolerant of air exposure, and it was not necessary to irrigate gills. pH = 8	Gilmour et al. (1998)
<i>Opsanus tau</i> (oyster toadfish)	MS-222	50–250 mg/L	IN	Adults 675 ± 46 g	Slight sedation at 50 mg/L. Decreasing respiratory rate and ability to maintain equilibrium from 100–250 mg/L. Cessation of voluntary respiratory activity at 300 mg/L. These later fish resumed gilling 14 minutes after anesthetic withdrawal and all fish regained equilibrium within 23 minutes of anesthetic withdrawal.	Palmer and Mensinger (2004).

Table 15.1. (Continued)

Class Osteichthyes Taxa	Drug	Dose	Route	Wt/Age	Temp (°C)	Comments	Reference
Order Beryciformes Family Holocentridae <i>Holocentrus ascensionis</i> (longjawed squirrelfish)	MS-222	70–85 mg/L	IN	160–500 g		Variable sedation (mild to heavy) for examination.	D. Neffler, unpubl.
Bloodspot squirrelfish	MS-222	100 mg/L	IN				T. Clauss, unpubl.
<i>Myripristis jacobus</i> (blackbar soldierfish)	MS-222	50–100 mg/L	IN	140–390 g		Variable sedation (mild to heavy) for examination.	D. Neffler, unpubl.
Order Characiformes Family characidae <i>Brycon cephalus</i> (matrinxá)	MS-222 buffered with CaCO ₃	150 mg/L	IN	Juveniles 31.56 ± 8.08 g	25	Time to anesthesia: 5.62 ± 0.53 minutes. Anesthesia duration: 10 minutes. Recovery: 5.19 + 3.07 minutes. Mortality: 0% at 150 mg/L, 16.7% at 200 mg/L, and 33.3% at 300 mg/L. Pronounced stress response at 200 and 300 mg/L. pH = 6.3	Roubach et al. (2001)
<i>Colossoma macropomum</i> (tambagui [aka large or black pacu])	Benzocaine dissolved in acetone (10 g/100 mL)	100–150 mg/L	IN	Juvenile 9.32 ± 3.7 g	24	Induction: 0.11–1.01 minutes. Recovery following exposure for 10 minutes: 2.32–9.04 minutes. Recovery following exposure for 30 minutes: 30 ± 20 minutes. Fish exposed to ≥220 mg/L exhibited stress response. Mortality 30% at 350 mg/L. pH = 6.5	Gomes et al. (2001)
	Eugenol dissolved in alcohol to make 1:2 stock solution	65 mg/L 65 mg/L	IN IN	Juveniles 56.6 ± 7.7 g Sub-adults 1100 ± 90.7 g	26–27	Stage necessary for handling reached in 1.45 minutes and a surgical stage in 2.54 minutes. Recovery: 6.82 ± 3.73 minutes. Exposure for 30 minutes was not associated with mortality. Dose up to 100 mg/L considered safe.	Roubach et al. (2005)
	MS-222	30 mg/L	IN	Adult		Stage necessary for handling in 1.48 minutes and surgical stage in 3.77 minutes. Exposure for 30 minutes. Recovery: 3.79 ± 0.89 minutes. No mortality. Dose up to 100 mg/L considered safe.	N. Mylniczenko, unpubl.
	Medetomidine, Butorphanol, Midazolam	100 µg/mkg 1 mg/kg 1 mg/kg	IM	Adult		In-tank sedation then transport	N. Mylniczenko, unpubl.
						Used in combination prior to euthanasia with MS-222. Very light sedation.	N. Mylniczenko, unpubl.

<i>Piaractus brachipomus</i> (red pacu)	MS-222 buffered 1:1 with NaHCO ₃	100, 200mg/L	IN	4 years old adults 500–727 g	20–23	Induction: 100mg/L average 550 seconds; 200mg/L average 350 seconds. Recovery: 300–500 seconds. pH = 5.5 = 7.0	Sladky et al. (2001)
	Eugenol dissolved in 95% ethanol (1:9)	50, 100, 200mg/L	IN	4 years old adults 500–727 g	20–23	Induction: 50mg/L average 300 seconds; 100 and 200mg/L average 200 seconds. Recovery: 550–600 seconds. Resuscitation required in >50% fish exposed to 100–200mg/L. pH = 5.5–7.0	Sladky et al. (2001)
<i>Piaractus mesopotamicus</i> (pacu caranha)	Benzocaine (1 g dissolved in 0.1 liter ethanol.	99 mg/L	IN	Adults 315.2– 745.2g	15–35	Used for surgical implantation of ECG electrodes, buccal and opercular catheters. Sufficient level of anesthesia without interruption of spontaneous breathing.	Aguar et al. (2002) Rantin et al. (1998)
<i>Pygocentrus cariba</i> (cariba piranha)	MS-222	70–90mg/L	IN	Adult		Good anesthesia for mass removal, ocular aspirations and assist feeding	T. Clauss, unpubl.
<i>Pygocentrus nattereri</i> (red-bellied piranha)	MS-222	70–100mg/L	IN	Adult		Good anesthesia for minor and surgical procedures	N. Mylniczenko and T. Clauss, unpubl.
Family Erythrinidae <i>Hoplias lacerdae</i> (giant trahira)	Benzocaine (1g in 0.1-L ethanol)	50 mg/L	IN	Adults 375 ± 47 g	25 ± 1	Provided light anesthesia for brief procedures including ECG electrode and buccal catheter placement.	Rantin et al. (1993)
<i>Hoplias malabaricus</i> (tiger characin)	Benzocaine (1 gram in 0.1-L ethanol)	50 mg/L	IN	Adults 312 ± 47 g	25 ± 1	Spontaneous breathing present. Provided light anesthesia for brief procedures including ECG electrode and buccal catheter placement.	Rantin et al. (1993)
Order Cypriniformes Family Cyprinidae <i>Carassius auratus</i> (goldfish)	2-PE	0.25–0.35 mL/L 0.45 mL/L	IN	3.93 ± 1.99 g	24	Provided light sedation. Provided anesthesia with loss of equilibrium.	Kaiser and Vine (1998)
<i>Ctenopharyngodon idella</i> (grass carp)	MS-222	100mg/L for induction; 75 mg/L for maintenance	IN	1.0–2.5 kg	22	Induction within 5 minutes. Allowed for surgical implantation of radio transmitters. Recovery took 5–25 minutes. Mortality occurred with 100mg/L at temperatures >31°C.	Schramm and Black (1984)
	2-PE mixed with 500mL tank water and added to chamber.	0.2 mL/L 0.4 mL/L	IN	Brood stock 3–12 kg	25	Induction to light sedation in 2–3 minutes. Females stripped of ova with this dose. Induction to anesthesia in 5–10 minutes. Males stripped of milt with this dose.	McCarter (1992)

(Continued)

Table 15.1. (Continued)

Class Osteichthyes Taxa	Drug	Dose	Route	Wt/Age	Temp (°C)	Comments	Reference
<i>Cyprinus carpio</i> (koi/ common carp)	MS-222	100–200 mg/L	IN	123 ± 53 g	22–27	Utilized for exploratory celiotomy. pH = 6.9–7.5	Harms et al. (2005)
	MS-222 buffered with NaHCO ₃	200 mg/L	IN	144 ± 44 g	23–25	Induction within 2 minutes. Level sufficient for deep IM injection and phlebotomy. Recovery within 2 minutes. pH = 7.4–7.6	Yanong et al. (2005)
<i>Epalzeorhynchus bicolor</i> (red-tail black shark)	Alphaxalone-alphadolone (Saffan®)	0.3 mL/kg	IM	2 kg.		Sedation with partial loss of equilibrium. Able to be netted, but responsive	Harvey et al. (1988)
	MS-222	100 mg/L	IN	Juveniles 1.4 ± 0.4 g	25.5	Anesthesia sufficient for handling and vaccination. pH = 7.5	Russo et al. (2006)
<i>Hypophthalmichthys molitrix</i> (silver carp)	2-PE mixed with 500-mL tank water and added to chamber.	0.2 mL/L 0.4 mL/L	IN	Brood stock 3–12 kg	25	Induction to light sedation in 2–3 minutes. Induction to anesthesia in 5–10 minutes.	McCarter (1992)
	MS-222 buffered with NaHCO ₃	60 mg/L	IN	Adults and juveniles 0.35–4.46 g	11–21	Induction to total loss of equilibrium in 5–13 minutes. Recovery: <2 minutes with faster recovery at higher temperatures. Mortality: 0%.	Detar and Mattingly (2004)
<i>Phoxinus erythrogaster</i> (Southern redbelly dace)	Clove oil dissolved in ethanol (1:10)	40–60 mg/L	IN	Adults and juveniles 0.35–4.46 g	11–21	Induction to total loss of equilibrium within 3 minutes. Recovery: <5 minutes with faster recovery at higher temperatures. No mortality. pH = 7.0–7.9	Detar and Mattingly (2004)
	Clove oil	40 mg/L	IN	Adults and juveniles	4–19	Used for anesthesia in the field during elastomer tag placement and fin clipping.	Detar and Mattingly (2004)
<i>Phoxinus cumberlandensis</i> (blackside dace)	MS-222 unbuffered with significant pH drop.	300–500 mg/L	IN	Adults		Light anesthesia within 3 minutes. Allowed for handling. Recovery following 9 minutes exposure: 4–7 minutes. Exposure to this dose range beyond 15 minutes associated with mortality.	MacAvoy and Zaepfel (1997)
	Clove oil dissolved in 95% ethanol at 1:10 ratio.	4 mg/L	IN	71 grams	15	Provided sedation for 6 hours without loss of equilibrium at which time fish is removed from anesthetic. Considered useful for transport. No mortality.	Hoskonen and Pirhonen (2004)
<i>Rutilus rutilus</i> (roach)	2-PE	0.5 g dm ⁻³	IN	Juveniles 0.08–1.82 g	25	Induction time: 2.2–12.6 minutes. Recovery after 15 minutes exposure: 1.1–3.3 minutes. Recommended for short term anesthesia. pH = 7.5–8.0	Myszkowski et al. (2003)

Order Cyprinodontiformes Family Poeciliidae <i>Poecilia velifera</i> (sailfin molly)	2-PE	600mg/L	IN	Adults 1.56 + 0.27 g	23	Induction: 7.50 ± 11.97 minutes. Recovery (fish placed in fresh water immediately after induction): 1.28 ± 2.53 minutes. Provides light sedation.	Hseu et al. (1997)
<i>Xiphophorus maculatus</i> (southern platyfish)	MS-222	30 mg/L	IN	Adults 1.71 ± 0.36g		Provides light sedation.	Guo et al. (1995)
	Metomidate	1 mg/L	IN	Adults 1.71 ± 0.36g		Provides light sedation.	Guo et al. (1995)
	Quinaldine sulfate	10 mg/L	IN	Adults 1.71 ± 0.36g		Provides light sedation.	Guo et al. (1995)
	2-PE	220 mg/L	IN	Adults 1.71 ± 0.36g		Provides light sedation.	Guo et al. (1995)
Order Gadiformes Family Gadidae <i>Gadus morhua</i> (Atlantic cod)	MS-222	75 mg/L	IN	84 ± 5 g	8.4	Anesthesia within 4 minutes. Exposure time 2.8–3.4 minutes. Recovery time 3.7–7.1 minutes.	Mattson and Riple (1989)
	Benzocaine dissolved in ethanol.	40 mg/L	IN	101 ± 6 g	9.5	Anesthesia reached within 3 minutes. Exposure time 2.1–3.2 minutes. Recovery time 3.9–10.8 minutes. Mortality 50% at 75–100 mg/L.	Mattson and Riple (1989)
	Metomidate	5 mg/L	IN	101 ± 6 g	9.6	Anesthesia reached within 4 minutes. Exposure time 4.8–10.8 minutes. Recovery time 8.2–19.2 minutes. Used for sorting and handling broodstock.	Mattson and Riple (1989)
Order Gasterosteiformes Family Syngnathidae <i>Hippocampus erectus</i> (lined seahorse)	MS-222	60–100 mg/L	IN		Adult	Low-end dose adequate for radiographs and minimally invasive procedures	N, Mylniczenko and T. Claus, unpubl.
<i>Hippocampus reidi</i> (longsnout seahorse)	MS-222	25 mg/L	IN			Provided mild sedation.	D. Neiffer, unpubl.
		75–100 mg/L	IN		Adult	Good sedation for blood draw, assist feed and injectable treatments	N, Mylniczenko, unpubl.
<i>Phycodurus eques</i> (leafy seadragon)	MS-222	50–100 mg/L	IN		Adult	Under 60 mg/L very light sedation and not sufficient for assist feeding or oral examination. Above 80 mg/L occasionally noted longer recoveries. Same as above	N, Mylniczenko and T. Claus, unpubl.
<i>Phyllopteryx taeniolatus</i> (weedy seadragon)	MS-222	50–100 mg/L	IN				
<i>Syngnathus scovelli</i> (pipefish)	MS-222	75 mg/L	IN			Sedation rated as good. Topical treatments performed.	D. Neiffer, unpubl.

Table 15.1. (Continued)

Class Osteichthyes Taxa	Drug	Dose	Route	Wt/Age	Temp (°C)	Comments	Reference
Order Gonorhynchiformes							
Family Chanidae							
<i>Chanos chanos</i> (milk fish)	2-PE	400 mg/L	IN	23.99 ± 1.07 g	28	Provided total loss of equilibrium allowing phlebotomy.	Hseu et al. (1996)
Order Lophiiformes							
Family Antennariidae							
<i>Antennarius maculatus</i> (warty frogfish)		50–60 mg/L	IN			Heavy sedation for radiographs and swim bladder aspiration	T. Clauss, unpubl.
<i>Antennarius ocellatus</i> (ocellated frogfish)	MS-222	30–80 mg/L	IN	350–450 g		Sedation rated fair to excellent (higher doses better). Examination and topical treatments performed.	D. Neiffer, unpubl.
<i>Antennarius striatus</i> (striated frogfish)	MS-222 buffered with NaHCO ₃	100 mg/L	IN	Adults		Diagnosics performed.	Yanong et al. (2003)
<i>Histrio histrio</i> (sargassumfish)	MS-222	30 mg/L	IN			Sedation adequate for examination and injections.	D. Neiffer, unpubl.
Order Osteoglossiformes							
Family Mormyridae							
<i>Gnathonemus petersii</i> (elephantnose fish)	Alfaxalone-alfadolone	2 mg/L for induction 1.5 mg/L for maintenance	IN	Average 15 grams and 15 cm	23	Loss of equilibrium and cessation of opercular movement at 20 minutes. Recovery took average of 17 minutes following 2.5 hours exposure.	Peters et al. (2001)
Order Perciformes							
Family Acanthuridae							
<i>Acanthurus bahianus</i> (ocean surgeonfish)	MS-222	50–75 mg/L	IN			Sedation rated fair to good. Examinations performed.	D. Neiffer, unpubl.
<i>Acanthurus chirurgus</i> (doctorfish)	MS-222	50–75 mg/L	IN			Provided surgical anesthesia for enucleation.	D. Neiffer, unpubl.
<i>Acanthurus coeruleus</i> (blue tang)	MS-222	85 mg/L	IN			Sedation rated excellent. Examination and topical treatment performed.	D. Neiffer, unpubl.
<i>Acanthurus leucosternon</i> (powder blue surgeonfish)	MS-222	50–78 mg/L	IN			Sedation rated excellent. Diagnostic examination performed.	D. Neiffer, unpubl.
<i>Acanthurus sohal</i> (Sohal tang)	MS-222	50 mg/L	IN			Sedation rated good. Diagnostic examination performed.	D. Neiffer, unpubl.
Family Anarhichadidae							
<i>Anarhichas lupus</i> (Atlantic wolffish)	MS-222	50–75 mg/L	IN			Physical exam, blood draw	N. Myliczenko, unpubl.
<i>Anarhichthys ocellatus</i> (wolf eel)	MS-222	90–100 mg/L				Lower than 90 not adequate for blood draw	T. Clauss, unpubl.

Table 15.1. (Continued)

Class Osteichthyes Taxa	Drug	Dose	Route	Wt/Age	Temp (°C)	Comments	Reference
<i>Micropterus salmoides</i> (largemouth bass)	MS-222	50 mg/L for induction 25 mg/L for maintenance				Provided sufficient sedation for transport.	Cooke et al. (2004)
	Clove oil dissolved in ethanol (1:9)	5–9 mg/L 15–20 mg/L		fingerlings and subadults	21	Time to deep sedation: 368 seconds. Sufficient for transport (reduced activity while maintaining equilibrium). Recovery: 417 seconds Time to moderate anesthesia 651 seconds. Recovery: 1699 seconds	
Family Centropomidae <i>Centropomus undecimalis</i> (common snook)	MS-222	50–60 mg/L	IN			Provided mild sedation for diagnostic examinations.	D. Neiffer, unpubl.
<i>Lates calcarifer</i> (Asian sea bass)	Clove oil dissolved in boiled water	6–9 mg/L		42 ± 9.74 g	29–30	Induction: 1.8–4.5 minutes. Exposed to clove oil for 4 minutes. Recovery: 0.5–5.0 minutes. No mortality, though some distal gill filament necrosis noted with repeated exposure to 9 mg/L.	Affi et al. (2001)
Family Cichlidae <i>Amphitophus citrinellus</i> (<i>Cichlasoma citrinellum</i>) (Midas cichlid, red devil)	MS-222	150 mg/L for induction; 60 mg/L for maintenance.	IN	800 g		Induction in 8 minutes. Flow rate of maintenance solution = 3 L/min. Procedure duration (partial swim bladder resection) = 71 minutes	Lewbart et al. (1994)
	Ketamine	30 mg/kg	IV	206 ± 36 g	22 ± 2	Fish sedated first in buffered MS-222 (100–125 mg/L) for 8–10 minutes at which point fish became unresponsive. Fish removed to from bath and ketamine was injected. Induction: <10 seconds. In some fish, complete cessation of ventilation occurred while in other intermittent coughing or rapid ventilation was noted. Anesthesia lasted 1–41 minutes, with balance regained at 57–263 minutes.	Bruecker and Graham (1993)
<i>Oreochromis mossambicus</i> (Mozambique tilapia)	2-PE	600 mg/L	IN	Juveniles 3.83 ± 0.55 g	30	Induction: 7.43 + 13.25 minutes. Recovery (fish placed in fresh water immediately after induction): 1.38 + 1.77 minutes.	Hseu et al. (1997)
	MS-222	100 mg/L	IN	Juveniles and adults			N. Mylniczenko, unpubl.
(African cichlid)		110–150 mg/L	IN			Light sedation at low range	T. Clauss, unpubl.

Family Chaetodontidae													
<i>Chaetodon pelewensis</i> (Pelewensis butterfly)	MS-222	50–75 mg/L	IN	100 g								Sedation rated as good. Examination performed.	D. Neiffer, unpubl.
<i>Chaetodon semilarvatus</i> (red-lined butterflyfish)	MS-222	75–80 mg/L	IN									Provided mild to heavy sedation. Examination and topical treatments performed.	D. Neiffer, unpubl.
<i>Heniochus acuminatus</i> (black and white heniochus)	MS-222	90 mg/L	IN									Sedation rated as good. Diagnostic examination performed.	D. Neiffer, unpubl.
<i>Heniochus</i> sp. (bannerfish)	MS-222	90 mg/L	IN									Provided heavy sedation for diagnostic examinations.	D. Neiffer, unpubl.
Family Ephyppidae													
<i>Chaetodipterus faber</i> (Atlantic spadefish)	MS-222	50–100 mg/L	IN	0.22–2–.32 kg								Effect varied from mild sedation at lower doses to surgical anesthesia at 100 mg/L. N = 11.	D. Neiffer, unpubl.
Family Gobiidae													
<i>Afurcagobius tamarensis</i> (Tamar River goby)	Clove oil in ethanol at ratio 1:5	40 mg/L	IN		18							Induction within 3 minutes. Recovery within 5 minutes. Sufficient for handling and measurement.	Griffiths (2000)
<i>Bathygobius cocosensis</i> (Cocos frill-goby)	Clove oil in ethanol at ratio 1:5	40 mg/L	IN		18							Induction within 3 minutes. Recovery within 5 minutes. Sufficient for handling and measurement.	Griffiths (2000)
<i>Favonigobius lateralis</i> (goby)	Clove oil in ethanol at ratio 1:5	40 mg/L	IN		18							Induction within 3 minutes. Recovery within 5 minutes. Sufficient for handling and measurement.	Griffiths (2000)
Family Grammatidae													
<i>Pseudoanthias</i> sp. (<i>Anthias</i> sp.)	MS-222	77 mg/L	IN	Adult								Sedation rated excellent. Diagnostic examination performed.	D. Neiffer, unpubl.
<i>Gramma loreto</i> (royal gramma)	MS-222	65–90 mg/L	IN									Sedation rate as good. Diagnostic examinations performed.	D. Neiffer, unpubl.
Family Haemulidae													
<i>Haemulon chrysargyreum</i> (smallmouth grunt)	MS-222	100 mg/L	IN									Provided surgical anesthesia for kidney culture.	D. Neiffer, unpubl.
<i>Haemulon flavolineatum</i> (French grunt)	MS-222	100 mg/L	IN									Provided surgical anesthesia for enucleation and kidney culture.	D. Neiffer, unpubl.
<i>Haemulon plumieri</i> (white grunt)	MS-222	85–100 mg/L	IN									Sedation rated good. Examinations performed.	D. Neiffer, unpubl.
<i>Haemulon sciurus</i> (bluestripe grunt)	MS-222	30–90 mg/L	IN									Most sedations rated as good. Diagnostic examinations, injections, and enucleation (1 case) performed.	D. Neiffer, unpubl.
<i>Haemulon melanurum</i> (Cottonwick)	MS-222	80 mg/L	IN									Sedation rated as good. Examination performed.	D. Neiffer, unpubl.

Table 15.1. (Continued)

Class Osteichthyes Taxa	Drug	Dose	Route	Wt/Age	Temp (°C)	Comments	Reference
<i>Haemulon aurolineatum</i> (tomtate)	MS-222	100 mg/L	IN			Sedation rated good. Examination performed.	D. Neiffer, unpubl.
<i>Anisotremus virginicus</i> (porkfish)	MS-222	100 mg/L	IN			Provided surgical anesthesia for enucleation and kidney culture.	D. Neiffer, unpubl.
Family Kyphosidae <i>Girella elevata</i> (black drummer)	Clove oil in ethanol at ratio 1:5	40 mg/L	IN		18	Induction within 3 minutes. Recovery within 5 minutes. Sufficient for handling and measurement. Provide heavy sedation.	Griffiths (2000)
<i>Microcanthus strigatus</i> (convict tang)	MS-222	75 mg/L	IN				D. Neiffer, unpubl.
<i>Scorpius lineolatus</i> (silver sweep)	Clove oil in ethanol at ratio 1:5	40 mg/L	IN		18	Induction within 3 minutes. Recovery within 5 minutes. Sufficient for handling and measurement.	Griffiths (2000)
Family Labridae <i>Halichoeres radiatus</i> (puddingwife)	MS-222	50–100 mg/L	IN			Sedation rated as good. Diagnostic examinations performed.	D. Neiffer, unpubl.
<i>Thalassoma duperreyi</i> (saddle wrasse)	MS-222	90 mg/L	IN			Sedation rated as good. Diagnostic examinations performed.	D. Neiffer, unpubl.
<i>Cheilinus undulatus</i> (Napolean Wrasse)	MS-222	100 mg/L	IN			Induction at 100 mg/L, maintenance at 50 mg/L. Excellent for transport and physical exam.	N. Mylniczenko, unpubl.
Family Lateolabracidae <i>Lateolabrax japonicus</i> (Japanese seaperch)	2-PE	400 mg/L	IN	48.98 ± 3.47 g	29	Provided total loss of equilibrium allowing phlebotomy.	Hseu et al. (1996)
	2-PE	400 mg/L	IN	Juveniles, 4.4 ± 0.86 g	28	Induction: 2.13 ± 0.45 minutes. Recovery (fish placed in fresh water immediately after induction): 0.69 ± 0.15 minutes.	Hseu et al. (1997)
	2-PE	400 mg/L	IN	Juveniles, 4.8 ± 1.46 g	24	Induction: 1.75 ± 0.16 minutes. Recovery (fish placed in non-medicated water immediately after induction): 0.49 ± 0.08 minutes.	Hseu et al. (1997)
Family Lobotidae <i>Lobotes surinamensis</i> (triple tail)	MS-222	80–90 mg/L	IN			Sedation sufficient for examinations and jaw debridement (one individual).	D. Neiffer, unpubl.
Family Lutjanidae <i>Lutjanus apodus</i> (schoolmaster)	MS-222	125 mg/L	IN			Provided surgical anesthesia for kidney culture.	D. Neiffer, unpubl.
<i>Lutjanus</i> sp. (Snapper)	Metomidate	50 mg/kg	IM	14 kg		Anesthesia with marked depression of ventilation. Two or more darts used to deliver total.	Harvey et al. (1988)

<i>Ocyurus chrysurus</i> (yellowtail snapper)	MS-222	75–85 mg/L	IN	50–120 g	Effect varied from mild to heavy sedation. Examinations performed. $N = 17$.	D. Neffter, unpubl.
<i>Lutjanus argentimaculatus</i> (mangrove red snapper) Family Moronidae <i>Dicentrarchus labrax</i> (sea bass)	Medetomidine plus ketamine	1.1–1.7 27–42 mg/kg (ratio M:K averages 24:1)	IM	2.35–3.65 kg ($N = 6$)	All fish injected by dives using jab stick. Initial effect seen in 4–12 minutes. For complete injections, mild to moderate sedation achieved. Fish netted and transferred to MS-222 bath for phlebotomy. Fish culled as part of disease surveillance and thus no reversal agent given.	D. Neffter, unpubl.
	2-PE	400 mg/L	IN	39.21 ± 2.08 g	Provided total loss of equilibrium allowing phlebotomy.	Hseu et al. (1996)
	Quinaldine sulfate with diazepam	7.5 mg/L 2 mg/L	IN	Juveniles 8–9 g	Induction time 1–2 minutes. Recovery time 4–6 minutes. Provides deep anesthesia suitable for marking, surgery, and handling. ^a Note: quinaldine sulfate alone at 15 mg/L associated with 10% mortality and at 20–25 mg/L, associated with 30–100% mortality. pH = 7.9–8.2	Yanar and Kumlu (2001)
<i>Morone saxatilis</i> (striped bass)	Quinaldine sulfate with diazepam	5 mg/L 2 mg/L	IN	Juveniles 8–9 g	Induction time 1–2 minutes. Recovery time 3–5 minutes. Provides light anesthesia suitable for transportation. pH = 7.9–8.2	Yanar and Kumlu (2001)
	MS-222	20 mg/L	IN	Adult, 48–81 cm	Prior to placement in bath, gills were sprayed twice with MS-222 solution (3200 mg/L). Procedure: Mock intra-coelomic transmitter placement. Induction: 38–58 seconds. Recovery after 5 minutes exposure to drug: 156–272 seconds. No mortalities. ^a Note from author (DN): species appears to be sensitive to MS-222.	Jennings and Looney (1998)
<i>Morone saxatilis</i> (striped bass)	Benzocaine dissolved in 100% ethanol at 1 g/30 mL MS-222	55–80 mg/L 25 mg/L	IN	Juvenile and Adults 0.118–3.5 kg 87 ± 24.4 g	Induction in 3 minutes. Recovery in 1.5–14.25 minutes.	Gilderhus et al. (1991)
<i>Morone saxatilis</i> × <i>chrysops</i> (hybrid striped bass)	Clove oil	8 µl/L	IN	87 ± 24.4 g	Light sedation.	Davis and Griffin (2004)
	Isoeugenol (AQUI-S)	3.6 mg/L	IN	87 ± 24.4 g	Light sedation.	Davis and Griffin (2004)
	Quinaldine sulfate	8.3 mg/L	IN	87 ± 24.4 g	Light sedation.	Davis and Griffin (2004)
	Metomidate	1.5 mg/L	IN	87 ± 24.4 g	Light sedation.	Davis and Griffin (2004)

Class Osteichthyes Taxa	Drug	Dose	Route	Wt/Age	Temp (°C)	Comments	Reference
Family Mugilidae <i>Mugil cephalus</i> (gray mullet)	2-PE	400 mg/L	IN	38.49 ± 3.85 g	31	Provided total loss of equilibrium allowing phlebotomy.	Hseu et al. (1996)
<i>Myxus elongatus</i> (sand gray mullet)	Clove oil in ethanol at ratio 1:5	40 mg/L	IN		18	Induction within 3 minutes. Recovery within 5 minutes. Sufficient for handling and measurement.	Griffiths (2000)
Family Mullidae <i>Pseudupeneus maculatus</i> (spotted goatfish)	MS-222	30–50 mg/L	IN			Heavy sedation.	D. Neiffer, unpubl.
Family Tripterygiidae <i>Emmeopterygius rufipileus</i> (redcap triplefin)	Clove oil in ethanol at ratio 1:5	40 mg/L	IN		18	Induction within 3 minutes. Recovery within 10 minutes. Sufficient for handling and measurement.	Griffiths (2000)
Family Osphronemidae <i>Colisa labiosus</i> (thick-lipped gourami)	MS-222 buffered with sodium bicarbonate	200 mg/L for induction. 80 mg/L for maintenance.	IN	8 g		Induction: 90 seconds. Total anesthesia time = 47 minutes. Flow rate of maintenance fluid = 12.1 mL/min. Gill motion throughout procedure. Full recovery by 23 minutes. Surgical mass removal.	Harms and Bakal (1995)
<i>Trichogaster trichopterus</i> (threespot gourami)	MS-222 buffered with NaHCO ₃	400 mg/L 60 mg/L	IN	19 ± 3 g	23–25 28–29	Induction within 2 minutes. Level sufficient for deep IM injection and phlebotomy. Recovery within 2 minutes. pH = 7.4–7.6 Level sufficient to induce light sedation within 4 minutes.	Yanong et al. (2005) Crosby et al. (2006)
	Metomidate	0.8 mg/L	IN		28–29	Level sufficient to induce light sedation within 4 minutes.	Crosby et al. (2006)
	Quinaldine	5 mg/L	IN		28–29	Level sufficient to induce light sedation within 4 minutes.	Crosby et al. (2006)
Family Percidae <i>Perca fluviatilis</i> (European perch)	Clove oil dissolved in 95% ethanol at 1:10 ratio.	6 mg/L	IN	17 g	15	Provided sedation for 6 hours without loss of equilibrium at which time fish removed from anesthetic. Considered useful for transport. No mortality.	Hoskonen and Pirhonen (2004)
<i>Perca flavescens</i> (yellow perch)	Isoeugenol (AQUI-S)	20 mg/L	IN	Juveniles-young adults 126 ± 50.1 g	12 ± 2	Induction within 3 minutes. Total exposure time ≤15 minutes. Recovery within 8 minutes. Useful for basic handling procedures. pH = 8.1	Stehly and Gingerich (1999)
	Isoeugenol (AQUI-S)	20 mg/L	IN	Fry-fingerlings 1.1 ± 0.22 g	12 ± 2	Induction within 4.1 minutes or less. Total exposure time ≤15 minutes. Recovery within 5 minutes. Useful for basic handling procedures. pH = 8.1	Stehly and Gingerich (1999)

<i>Stizostedion vitreum</i> (walleye)	Isoeugenol (AQUI-S)	50 mg/L	IN	Juveniles-young adults 58.3 ± 12.2 g	12 ± 2	Induction averaged 4.3 minutes. Total exposure time <15 minutes. Recovery within 8 minutes. Useful for basic handling procedures. pH = 8.1	Stehly and Gingerich (1999)
	Isoeugenol (AQUI-S)	50 mg/L	IN	Fry-fingerlings 0.8 ± 0.16 g	12 ± 2	Induction averaged 3.9 minutes. Total exposure time <15 minutes. Recovery within 5 minutes. Useful for basic handling procedures. pH = 8.1	Stehly and Gingerich (1999)
Family Pomacanthidae							
<i>Centropyge bicolor</i> (bicolor angelfish)	MS-222	75 mg/L	IN			Sedation rated excellent. Diagnostic examination performed.	D. Neiffer, unpubl.
<i>Pomacanthus arcuatus</i> (gray angelfish)	MS-222	50–100 mg/L	IN	0.2–1.7 kg		Provided mild to heavy sedation with a few animals considered lightly anesthetized at 100 mg/L. Diagnostic exams and topical treatments performed. N = 16	D. Neiffer, unpubl.
<i>Pomacanthus paru</i> (French angelfish)	MS-222	50–80 mg/L	IN	0.40–1.95 kg		Provided mild to heavy sedation with a few animals considered excessively deep at 70–80 mg/L range. Diagnostic examinations performed. N = 8	D. Neiffer, unpubl.
<i>Pomacanthus semicirculatus</i> (Koran angelfish)	MS-222	60–85 mg/L	IN			Variable sedative effect (fair to excellent). Diagnostic exams and topical treatments performed. N = 2	D. Neiffer, unpubl.
Family Pomacentridae							
<i>Abudefduf saxatilis</i> (sergeant major)	MS-222	100 mg/L	IN			Provided surgical anesthesia for kidney culture.	D. Neiffer, unpubl.
<i>Amphiprion percula</i> (Percula clownfish)	MS-222	50–75 mg/L	IN			Provided mild to heavy sedation for examinations.	D. Neiffer, unpubl.
<i>Chromis cyanea</i> (blue chromis)	MS-222	75 mg/L	IN			Sedation rated as good. Examination performed.	D. Neiffer, unpubl.
<i>Chromis multilineata</i> (brown chromis)	MS-222	75 mg/L	IN			Sedation rated as good. Examination and transport.	D. Neiffer, unpubl.
<i>Dascyllus melanurus</i> (four-stripe damselfish)	MS-222	90 mg/L	IN			Sedation rated as good. Diagnostic examination performed.	D. Neiffer, unpubl.
<i>Dascyllus trimaculatus</i> (domino damselfish)	MS-222	50–75 mg/L	IN			Provided heavy sedation for examinations.	D., Neiffer, unpubl.
Family Rachycentridae							
<i>Rachycentron canadum</i> (cobia)	Medetomidine with Ketamine	0.122–0.240 mg/kg 6–13.5 mg/kg	IM	24–40 kg		Injected using spring-loaded pole syringe. Dose resulted in mild sedation. Supplemental dose of 0.100-mg/kg medetomidine and 2.8-mg/kg ketamine necessary for final capture. MS-222 at 50 mg/L has been used for maintenance during examinations, skin biopsies, and one enucleation. Reversal with atipamezole at 5 × total mg dose of medetomidine given IM.	D. Neiffer, unpubl.

Table 15.1. (Continued)

Class Osteichthyes Taxa	Drug	Dose	Route	Wt/Age	Temp (°C)	Comments	Reference
Family Scaridae							
<i>Scarus coelestinus</i> (midnight parrotfish)	MS-222	75 mg/L	IN			Provided light anesthesia for diagnostic examination.	D. Neiffer, unpubl.
<i>Scarus guacamaia</i> (rainbow parrotfish)	MS-222	50–75 mg/L	IN	2.03–7.45 kg		Effect varied from moderate sedation to light anesthesia. Diagnostic examinations performed. N = 4.	D. Neiffer, unpubl.
<i>Scarus vetula</i> (queen parrotfish)	MS-222	50–75 mg/L	IN			Provided mild to heavy sedation. Diagnostic examinations performed.	D. Neiffer, unpubl.
<i>Sparisoma aurofrenatum</i> (redband parrotfish)	MS-222	75 mg/L	IN			Provided surgical anesthesia for enucleation.	D. Neiffer, unpubl.
Family Sciaenidae							
<i>Sciaenops ocellatus</i> (red drum)	MS-222	80 mg/L	IN		26–27	Anesthesia induced in 2.5–6 minutes. Sufficient for handling and phlebotomy. pH = 7.7–7.8	Thomas and Robertson (1991)
	Metomidate	7 mg/L	IN		26–27	Anesthesia induced in 3–7 minutes. Sufficient for handling and phlebotomy. pH = 7.7–7.8	Thomas and Robertson (1991)
	Quinaldine sulfate	20 mg/L	IN		26–27	Anesthesia induced in 2–4 minutes. Sufficient for handling and phlebotomy. pH = 7.7–7.8	Thomas and Robertson (1991)
Family Scombridae							
<i>Sarda chiliensis</i> (bonito)	Ketamine plus Medetomidine Atipamezole	4 mg/kg 0.4 mg/kg 2 mg/kg	IM IM	2.7 ± 0.6 kg	19.5–20.5	Injections placed in red lateral muscle, immediately ventral to the lateral ridge below the lateral line, posterior and dorsal to the end of the pectoral fin. Induction: 8.9 ± 2.1 minutes. Anesthesia time: 19.0 ± 3.8 minutes. Recovery following injection of atipamezole: 7.7 ± 8.5 minutes. Mortality in fish receiving atipamezole dose <5× medetomidine dose. pH = 7.8–7.9	Williams et al. (2004)
<i>Scomber japonica</i> (Pacific mackerel)	Ketamine plus Medetomidine Atipamezole	53–228 mg/kg 0.6–4.2 mg/kg 5× Medetomidine dose.	IM IM	0.33–0.40 kg	19.5–20.5	Injected placed in red lateral muscle, immediately ventral to the lateral ridge below the lateral line, posterior and dorsal to the end of the pectoral fin. Induction: 4–21 minutes (mean = 9 minutes) for 37 fish; 45–56 minutes for 8 fish. Anesthesia time: 1–52 minutes (mean = 16 minutes). Recovery following atipamezole: 2–12 minutes (mean = 5 minutes). pH = 7.8–7.9	Williams et al. (2004)

<i>Thunnus thynnus</i> (bluefin tuna)	MS-222	90 mg/L	IN		Oxygenated water over gills at 12–20L/min following induction until recovery. Minor surgical procedures, ultrasonographic examinations, and serial blood sampling. Induction rapid and deep. For short procedures, fish captured and dosed in vinyl bag with supplemental oxygen provided. For longer procedures, fish captured in stretcher and transferred to large pool containing MS-222. Once induced, fish transferred to exam table with oxygenated anesthetic water directed over gills. In either case, recovery involved directing anesthetic free water over gills until fish capable of forward swimming motion.	Sylvia et al. (1994)
		75 mg/L	IN			Cooper et al. (1994)
Family Serranidae <i>Epinephelus itajara</i> (goliath grouper)	MS-222	75–95 mg/L	IN	7.7–106.2 kg	Provided mild to heavy sedation. Diagnostic examinations, injections, and topical treatments performed. <i>N</i> = 5.	D. Neiffer, unpubl.
		95–125 mg/L	IN	3.4–10 kg	Effect varied from heavy sedation to anesthesia (swim bladder surgeries and sampling). <i>N</i> = 6.	D. Neiffer, unpubl.
<i>Epinephelus lanceolatus</i> (Queensland grouper)	MS-222	1 g/L, 75 mg/L	IN	Adult	Induction with high dose power sprayer over gills, following by maintenance in lower dose	N. Mylniczenko, unpubl.
<i>Epinephelus ongus</i> (white-streaked grouper)	MS-222	80 mg/L	IN	610 g	Good for diagnostics (clips and scrapes)	T. Clauss, unpubl.
<i>Epinephelus polyphekadion</i> (camouflage grouper)	Clove oil	10 mg/L	IN		Suitable for sampling and for transportation.	Affi et al. (2001)
<i>Epinephelus morio</i> (red grouper)	MS-222	80 mg/L	IN	0.51–8.64 kg	Effect ranged from mild sedation to light anesthesia. Examinations performed. <i>N</i> = 7.	D. Neiffer, unpubl.
<i>Mycteroperca bonaci</i> (black grouper)	MS-222	80–100 mg/L	IN	183–800 g	Provided adequate sedation for examination. <i>N</i> = 5	D. Neiffer, unpubl.
<i>Mycteroperca venenosa</i> (yellowfin grouper)	MS-222	50 mg/L	IN		Provided adequate sedation for examination.	D. Neiffer, unpubl.
Family Siganiidae <i>Siganus lineatus</i> (rabbitfish)	Clove oil	100 mg/L	IN	Juveniles 7–39 g	Time to anesthesia <3 minutes. Time to recovery <5 minutes. Suitable for examination. No mortality observed.	Soto and Burhanuddin (1995)

Table 15.1. (Continued)

Class Osteichthyes Taxa	Drug	Dose	Route	Wt/Age	Temp (°C)	Comments	Reference
Family Sparidae <i>Acanthopagrus schlegelii</i> (black porgy)	2-PE	400 mg/L	IN	11.55 ± 3.47 g	29	Provided total loss of equilibrium allowing phlebotomy.	Hseu et al. (1996)
<i>Calamus pennatula</i> (pluma porgy)	MS-222	50–100	IN			Suitable for evaluation of exophthalmia though 100 mg/L excessive in one case.	D. Neiffer, unpubl.
<i>Chrysophrys auratus</i> (New Zealand snapper, squirefish)	Isoeugenol (AQUI-S)	120 mg/L for induction; 60 mg/L for maintenance.	IN	861.3 ± 64.6 g	11 ± 0.2	Time to surgical anesthesia was 20–25 minutes. During surgery (cannula placement) 60 mg/L oxygenated solution flushed continuously over gills. Poor survival with possible relation to prolonged surgery and/or hypoxemia.	Rothwell et al. (2005)
<i>Pagrus major</i> (red seabream, porgy)	MS-222	100 mg/L with no buffering 50 mg/L with no buffering	IN IN	595 days old, 320 g post-hatch larvae, 0.00022 g	20	Induction: 3–5 minutes. 100% recovery after 30 minutes exposure. Observations: maintained Stage III anesthesia; pH = 7.2 Induction: 3–5 minutes. 100% recovery after 30 minutes exposure. Note: no gills in this species at this age—all skin absorption. Maintained Stage III anesthesia; pH = 7.7	Oikawa et al. (1994)
<i>Rhabdosargus sarba</i> (<i>Sparus sarba</i>) (goldlined seabream)	MS-222	100 mg/L	IN	Juvenile 3.2 + 0.15 g	27–29	Induction: 1.31 ± 0.06 minutes. Recovery: 0.63 ± 0.03 minutes. No mortality. pH = 8.1	Hseu et al. (1998)
	Benzocaine dissolved in 95% ethanol	50 mg/L	IN	Juvenile 3.2 + 0.15 g	27–29	Induction: 1.94 ± 0.03 minutes. Recovery: 0.52 ± 0.04 minutes. No mortality. pH = 8.1	Hseu et al. (1998)
	Quinaldine dissolved in 95% ethanol	9 µL/L	IN	Juvenile 3.2 + 0.15 g	27–29	Induction: 1.19 ± 0.11 minutes. Recovery: 0.40 ± 0.03 minutes. No mortality. pH = 8.1	Hseu et al. (1998)
	Quinaldine sulfate	20 mg/L	IN	Juvenile 3.2 + 0.15 g	27–29	Induction: 2.40 ± 0.11 minutes. Recovery: 0.51 ± 0.02 minutes. No mortality. pH = 8.1	Hseu et al. (1998)
	2-PE	400 µL/L	IN	Juvenile 3.2 + 0.15 g	27–29	Induction: 1.25 ± 0.08 minutes. Recovery: 0.51 ± 0.04 minutes. No mortality. pH = 8.1	Hseu et al. (1998)
<i>Sparus aurata</i> (gitthead seabream)	Benzocaine dissolved in 100% ethanol (1:20)	22.5 µL/L	IN	220 ± 15 g	24 ± 0.5	Used for diagnostic sampling. Loss of sensation and equilibrium within 8 minutes. Recovery within 90 seconds of transfer to anesthetic free water. No mortality.	Bressler and Ron (2004)
	Clove oil dissolved in 100% ethanol (1:5)	44.5 µL/L	IN	220 ± 15 g	24 ± 0.5	Used for diagnostic sampling. Loss of sensation and equilibrium within 8 minutes. Recovery within 90 seconds of transfer to anesthetic free water. No mortality.	Bressler and Ron (2004)

Quinaldine sulfate (plus diazepam)	5 mg/L 1 mg/L 7.5 mg/L 1 mg/L 10 mg/L	IN IN IN	Juveniles 6-7 g Juveniles 6-7 g Juveniles 6-7 g	25-26	Use for light anesthesia and transportation. Induction: 1-2 minutes. Recovery: 2-4 minutes. Observations: opercular rate 150/min, which is less than opercular rate when quinaldine sulfate is used alone to reach the same level of anesthesia. Mortality 0%. pH = 7.9-8.2 Use for deep anesthesia, marking, handling and surgery. Induction: 0-1 minute. Recovery: 3-5 minutes. Observations: opercular rate 170/min, which is less than opercular rate observed when quinaldine sulfate is used alone to reach the same level of anesthesia. Mortality: 0%. pH = 7.9-8.2 Light anesthesia achieved. Induction: 0-1 minute. Recovery: 3-5 minutes. Observations: opercular rate 190/min. All fish remained sensitive to external stimuli. Mortality: 0% at light sedation dose, but 30-100% at deep sedation dose of 15-20 mg/L. In these cases, opercular rate increased to 190/min and then ceased. pH = 7.9-8.2	Kumlu and Yanar (1999)
MS-222	30 mg/L, 50 mg/L	IN	Adult		Lower dose for whole tank sedation, higher dose for transport. Once transported, blood was drawn from the animal. Excellent sedation for physical exam and treatments	N. Mylniczenko, unpubl.
MS-222	100 mg/L	IN	Juvenile			N. Mylniczenko, unpubl.
Benzocaine	20 mg/L	IN	682 ± 99 g		Used for sedation during transport	Kildea et al. (2004)
Clove oil	15 and 50 mg/L	IN	682 + 99 g		15 mg/L sufficient for light handling, tagging, and harvesting (exposure time 60 minutes). 50 mg/L produced anesthesia suitable for surgical procedures (exposure time 30 minutes). Sufficient for light handling, tagging, and harvesting (exposure time 60 minutes).	Kildea et al. (2004)
AQUI-S	15 mg/L	IN	682 + 99 g			Kildea et al. (2004)
MS-222	90-100 mg/L	IN				N, Mylniczenko and T. Clauss, unpubl.

Table 15.1. (Continued)

Class	Osteichthyes Taxa	Drug	Dose	Route	Wt/Age	Temp (°C)	Comments	Reference
Family	Zanclidae							
	<i>Zanclus cornutus</i> (Moonfish idol)	MS-222	75 mg/L	IN			Sedation rated as excellent. Examination performed.	D. Neiffer, unpubl.
Order	Pleuronectiformes							
Family	Paralichthyidae							
	<i>Paralichthys lethostigma</i> (southern flounder)	MS-222	75 mg/L	IN	2915 + 592 g	9–10	Provided adequate sedation for examination.	D. Neiffer, unpubl.
Family	Pleuronectidae							
	<i>Hippoglossus hippoglossus</i> (halibut)	MS-222	250 mg/L	IN	2915 ± 592 g	9–10	Induction to anesthesia = 250–282 seconds. Dose allowed for handling and phlebotomy. Recovery time 495–649 seconds.	Malmstrøm et al. (1993)
		Metomidate	20–30 mg/L	IN	2915 ± 592 g	9–10	Induction to anesthesia = 189–310 seconds. Dose allowed for handling and phlebotomy. Recovery time 220–320 seconds.	Malmstrøm et al. (1993)
			9 mg/L 3 mg/kg (50-mg/mL soln. diluted with 0.9% NaCl to 3 mg/mL)	IN IV	Age 12 months	10.3 ± 0.5	Though times not given, induction considered rapid and recovery prolonged. Respiration was depressed. See information on same study results in turbot (<i>Scophthalmus maximus</i>) in this table. No information on use, induction, or recovery, but good tissue distribution measured. No mortalities.	Hansen et al. (2003)
Family	Scophthalmidae							
	<i>Scophthalmus maximus</i> (turbot)	Metomidate	9 mg/L 7 mg/kg (concentration in a minced fish feed: cod liver oil emulsion delivered by gavage. 3 mg/kg (50 mg/mL solution diluted with 0.9% NaCl to 3 mg/mL)	IN PO IV	Age 8 months Age 8 months, 228 g Age 8 months, 228 g	18 ± 0.5	Induction: 0.28–1.83 minutes. Recovery following 10 minutes exposure: 19–38 minutes. Observations: opercular movement ceased 2.16–4.50 minutes into bath and resumed 0.63–2.98 minutes after placing in nonmedicated water. Heart rate was depressed. No mortality. Induction: 2.5–5 minutes. Recovery time 11–35 minutes. Observations: Induction based on loss of balance/motor control and inability to right self. Recovery considered complete when fish righted self. No mortalities. No information on use, induction, or recovery, but good tissue distribution measured. No mortalities	Hansen et al. (2003)

Order Salmoniformes Family Salmonidae <i>Oncorhynchus kisutch</i> (coho salmon)	Clove oil	25 mg/L	IN	5.47–12.72 kg	15	Induction: 2.5–3.5 minutes. Exposed for 10 minutes. Recovery: 7.5–13 minutes. No mortality.	Taylor and Roberts (1999)
	Ketamine	30 mg/kg	IV	1.857 ± 0.102 kg	15	Injected into dorsal aorta via cannula. Caused immediate cessation of ventilation for 10–300 seconds with loss of equilibrium. Ventilation rate recovered within 1–2 hours.	Graham and Iwama (1990)
<i>Oncorhynchus nerka</i> (sockeye salmon)	Alphaxalone-alphadolone (Saffon)	0.5–1.0 mL/kg	IM	2–3 kg		Sedation with partial loss of equilibrium. Able to be netted, but responsive.	Harvey et al. (1988)
	Clove oil	50 mg/L	IN	Adults	9–10	Fish could be handled within 3 minutes for measurement, esophageal implants, and fin clips. Recovery within 10 minutes following 15 minutes exposure.	Woody et al. (2002)
<i>Oncorhynchus tshawytscha</i> (Chinook salmon)	MS-222	100 mg/L with 300-mg/L NaHCO ₃	IN	844–1562 g	12.5 ± 2.5	Resulted in light anesthesia. Recovery following 5 minutes exposure occurred within 5 minutes.	Rothwell et al. (2005)
	MS-222 buffered 1:1 with NaHCO ₃	50 mg/L	IN	Juveniles 40.2 + 0.6 g		Provided deep anesthesia within 2 minutes.	Cho and Heath (2000)
<i>Oncorhynchus mykiss</i> (rainbow trout)	Benzocaine dissolved in ethanol at 1 g/30 mL	25–35 mg/L	IN	Juveniles 80 g	7–17	Induction: 1–3.25 minutes. Recovery following 15 minutes exposure: 2.25–18.5 minutes. Provided light to heavy sedation.	Gilderhus (1989)
	Clove oil in 1:10 ratio with 95% ethanol.	20 mg/L	IN	Juveniles 40.2 + 0.6 g		Provided deep anesthesia within 2 minutes.	Cho and Heath (2000)
<i>Oncorhynchus mykiss</i> (rainbow trout)	Isoeugenol (AQUI-S)	60 mg/L	IN	844–1562 g	12.5 ± 2.5	Sedation with partial loss of equilibrium. Suitable for handling.	Rothwell et al. (2005)
	Isoeugenol (AQUI-S)	120 mg/L	IN	844–1562 g	12.5 ± 2.5	Resulted in surgical anesthesia within 10 minutes for placement of vascular cannula. Recovery within 5–8 minutes.	Rothwell et al. (2005)
<i>Oncorhynchus mykiss</i> (rainbow trout)	Metomidate	42 mg/kg	IM	9 kg		Light sedation with partial loss of equilibrium. Directed net avoidance.	Harvey et al. (1988)
	Benzocaine	20 mg/L	IN	100–500 g	10	Provided adequate sedation within 30 seconds to permit weighing and injections.	Oswald (1978)
<i>Oncorhynchus mykiss</i> (rainbow trout)	Benzocaine dissolved in ethanol at 1 g/30 mL to make stock solution	25–40 mg/L 30–45 mg/L	IN	Juveniles 2–500 g Adults 0.68–2.04 kg	7–17	Induction: 1.25–5.5 minutes. Recovery following 15 minutes exposure: 4–16 minutes. Provided light to heavy sedation.	Gilderhus (1989)
						Induction: 2.25–4.5 minutes. Recovery following 15 minutes exposure: 5.5–13.5 minutes. Provided light to heavy sedation.

Table 15.1. (Continued)

Class	Osteichthyes	Taxa	Drug	Dose	Route	Wt/Age	Temp (°C)	Comments	Reference
			Clove oil dissolved in ethanol at a ratio of 1:10	2–5 mg/L	IN	Age 6 months 20.46 ± 0.73 g	9.1 ± 0.2	Recommended for sedation suitable for 6–8 hours transport. Provided deep anesthesia following 3–6 minutes exposure.	Keene et al. (1998)
				40–60 mg/L	IN				
			Isoeugenol (AQUI-S)	20 mg/L	IN	Juveniles-young adults 754 ± 145 g Fry fingerlings 4.1 ± 1.4 g	12 ± 2	Induction within 3 minutes. Total exposure time ≤15 minutes. Recovery within 8 minutes. Useful for basic handling procedures. pH = 8.1	Stehly and Gingerich (1999)
				20 mg/L	IN				
			Ketamine	50 mg/L	IM	100–500 g	10	Induction generally within 5–10 minutes. Anesthesia persisted for 20 minutes at 130 mg/ and 50–80 minutes at 150 mg/kg. Apnea requiring assisted ventilation occurred in 30% fish. Recovery took up to 90 minutes and was characterized by excitement and ataxia.	Oswald (1978)
			Ketamine	30 mg/kg	IV	365 ± 26 g		Injected into dorsal aorta via cannula. Caused immediate cessation of ventilation for 10–300 seconds with loss of equilibrium. Ventilation rate recovered to preanesthesia values within 1–2 hours.	Graham and Iwama (1990)
			Medetomidine	5–20 mg/L	IN	300–400 g	10 ± 0.2	Exposure for 10 minutes. Considered to be a good sedative, but not anesthetic. Exposed to atipamezole for 7–10 minutes. Exposure to 80 mg/L atipamezole resulted in panic-like reactions.	Horsberg et al. (1999)
			Atipamezole	30–80 mg/L (6× medetomidine dose)	IN				
			Alphaxalone-alphadolone (Saffan)	130 and 150 mg/kg	ICe or ⅓ ICe + ⅓ IM	100–500 g	10	Induction within 5–10 minutes. Doses of 18 mg/kg produced anesthesia. Lower doses only produced sedation. Recovery generally complete within 2 hours. Doses >18 mg/kg associated with apnea and prolonged recoveries (3–6 hours). 70–75 ppm provides excellent anesthesia for invasive procedures.	Oswald (1978)
			MS-222 buffered 1:1 with NaHCO ₃	50–100 mg/L	IN	Adult 0.6–2 kg		Induction in 2.5–3.9 minutes. Total exposure time ≤15 minutes. Recovery within 8 minutes. Useful for basic handling procedures. pH = 8.1	N. Mylnitszenko, unpubl.
			Isoeugenol (AQUI-S)	50 mg/L 20–50 mg/L	IN IN	Adult Juveniles-young adult 167–1399 g	12 ± 2	Induction in 2.5–3.9 minutes. Total exposure time ≤15 minutes. Recovery within 8 minutes. Useful for basic handling procedures. pH = 8.1	Stehly and Gingerich (1999)
			Benzoak (20% benzocaine)	30–100 mg/L	IN	31–44 g	15	Provided sedation for 6 hours without loss of equilibrium at which time fish removed from anesthetic. Considered useful for transport. No mortality.	Hoskonen and Pirhonen (2004)

<i>Salmo trutta</i> (brown trout)	Clove oil dissolved in 95% ethanol at 1:10 ratio.	5 mg/L	IN	31–44 g	15	Provided sedation for 6 hours without loss of equilibrium at which time fish removed from anesthetic. Considered useful for transport. No mortality.	Hoskoken and Pirhonen (2004)
	Clove oil dissolved in 95% ethanol at 1:10 ratio.	8 mg/L	IN	1-year-old smolts 44.7 ± 12.8 g	5.4 ± 0.2	Anesthesia attained in 2.2–8.1 minutes. Exposure to 100 mg/L for >6 minutes may result in cessation of voluntary respiration.	Iversen et al. (2003)
	Clove oil dissolved in ethanol at 1:10 ratio.	30–100 mg/L	IN	1-year-old smolts 44.7 ± 12.8 g	5.4 ± 0.2	Anesthesia attained in 2.2–8.1 minutes. Exposure to 100 mg/L for >6 minutes may result in cessation of voluntary respiration.	Iversen et al. (2003)
	Isoeugenol (AQUI-S)	30–100 mg/L	IN	1-year-old smolts 44.7 ± 12.8 g	5.4 ± 0.2	Anesthesia attained in 2.2–6.2 minutes.	Iversen et al. (2003)
	Metomidate	2–10 mg/L	IN	1-year-old smolts 44.7 ± 12.8 g	5.4 ± 0.2	Anesthesia attained in 3.0–17.4 minutes. Exposure to 100 mg/L for >6 minutes may result in cessation of voluntary respiration.	Iversen et al. (2003)
	Clove oil dissolved in 95% ethanol at 1:10 ratio.	8 mg/L	IN	100–500 g	10	Provided adequate sedation within 30 seconds to permit weighing and injections.	Oswald (1978)
	Benzocaine	50 mg/L	IN	100–500 g	10	Induction generally in 5–10 minutes. Anesthesia persisted for 20 minutes at 130 mg/kg and 50–80 minutes at 150 mg/kg. Apnea requiring assisted ventilation occurred in 30% of fish. Recovery took up to 90 minutes and was characterized by excitement and ataxia.	Oswald (1978)
	Ketamine	130 and 150 mg/kg	IM	100–500 g	10	Induction within 5–10 minutes. Doses of 18 mg/kg produced anesthesia. Lower doses only produced sedation. Recovery generally complete within 2 hours. Doses >18 mg/kg associated with apnea and prolonged recoveries (3–6 hours).	Oswald (1978)
	Alphaxalone-alphadolone (Saffan)	12–18 mg/kg	ICe or 2/3 ICe + 1/3 IM	100–500 g	10	Induction within 5–10 minutes. Doses of 18 mg/kg produced anesthesia. Lower doses only produced sedation. Recovery generally complete within 2 hours. Doses >18 mg/kg associated with apnea and prolonged recoveries (3–6 hours).	Oswald (1978)
	<i>Coregonus lavaretus</i> (whitefish)	Clove oil dissolved in 95% ethanol at 1:10 ratio.	3 mg/L	31–44 g	15	Provided sedation for 6 hours without loss of equilibrium at which time fish removed from anesthetic. Considered useful for transport. No mortality.	Hoskoken and Pirhonen (2004)

Table 15.1. (Continued)

Class Osteichthyes Taxa	Drug	Dose	Route	Wt/Age	Temp (°C)	Comments	Reference
<i>Anoplopoma fimbria</i> (sablefish)	Metomidate	62 mg/kg	IM	3 kg		Light sedation with partial loss of equilibrium. Directed net avoidance.	Harvey et al., (1988)
	Alphaxalone- alphadolone (Saffan)	0.3–0.4 mL/kg (need mg)	IM	3–5 kg		Light to heavy sedation with some fish exhibiting directed net avoidance. Recovery within 90 minutes.	Harvey et al., (1988)
Family Sebastidae <i>Sebastes caurinus</i> (copper rockfish)	Metomidate	100 mg/kg	IM	2 kg		Anesthesia with marked depression of ventilation. Recovery taking several hours.	Harvey et al., (1988)
	Gallamine triethiodide	1–4 mg/kg	IM	1–3 kg		Up to 2 hours until effect noted. Effect ranged from sedation (fish could be netted but were responsive) to anesthesia with marked depression of ventilation.	Harvey et al., (1988)
<i>Sebastes</i> sp.	MS-222	80–110 mg/L	IN			Good sedation for invasive procedures (ocular surgery)	N, Mylniczenko and T. Claus, unpubl.
Family Scorpaenidae <i>Pterois</i> sp. (dwarf lionfish)	MS-222	75 mg/L	IN			Sedation rated as good. Diagnostic examinations performed.	D. Neiffer, unpubl.
<i>Taenianotus</i> <i>triacanthus</i> (leaf scorpionfish)	MS-222	50–90 mg/L	IN			Provided mild to good sedation. Diagnostic examination performed. N = 3.	D. Neiffer, unpubl.
Order Siluriformes Family Clariidae <i>Clarias gariepinus</i> North African catfish	Alphaxalone- alphadolone	24 mg/kg	IM	Average 1150 g	24	Prenesthetized by squirting a few mL of 2-PE on gills, which induced almost immediate immobility. Once alphaxalone-alphadolone is injected, the gills were rinsed with fresh water. Surgical anesthesia at 26 ± 8 minutes. Artificial respiration required by pumping gills. If the investigators assured that either the fish could reach the water surface from time to time during recovery or the fish were placed in shallow water (≤15 cm), the fish survived. If these precautions were not taken, mortality occurred.	Peters et al. (2001)
Family Ictaluridae <i>Ictalurus furcatus</i> (blue catfish)	MS-222	60–120 mg/L	IN			Low range good for minimally invasive procedures	T. Claus, unpubl.
(<i>Ameiurus nebulosus</i>) (<i>Ictalurus nebulosus</i>) (brown bullhead catfish)	Alphaxalone- alphadolone	24 mg/kg	IM	56–255 g	18	Injection given just behind first dorsal fin. Induction: within minutes. Gradually lost balance and eventually ventilation ceased. Artificial respiration required by pumping water over gills at ~100 mL/min. Surgical anesthesia required on average 20 minutes. Time until recovery of opercular movements averaged 207 minutes.	Peters et al. (2001)

<i>Ameiurus melas</i> (<i>Ictalurus melas</i>) (black bullhead catfish)	Alphaxalone- alphadolone	IM	24 mg/kg	18	Injection given just behind first dorsal fin. Event very similar to brown bullhead above	Peters et al. (2001)
	MS-222	IN	100 mg/L	14.5	Anesthesia: 4.5 ± 0.8 minutes. Fish immediately transferred to anesthetic free water with recovery time of 1.7 ± 0.2 minutes. Survival 100% at 24 hours. Dose considered useful for basic handling procedures.	Small and Chatakondi (2005)
<i>Ictalurus punctatus</i> (Channel catfish)	Clove oil	Inhalant	100–150 mg/L (no ethanol added directly to water and aerated strongly prior to addition of fish).	23	Induction: Within 1 minute. Recovery: Following 10 minutes exposure to 100 mg/L, recovery occurred within 4 minutes. Recovery prolonged (>10 minutes) after exposure to 150 mg/L. Exposure to 100 mg/L for ≥20 minutes associated with increasing mortality. Exposure to 300 mg/L for 10 minutes resulted in 50% mortality. pH = 7.6	Waterstrat (1999)
	Isoeugenol (AQUI-S)	IN	2.5 mg/L	26	Sedation achieved in all fish. No mortality with exposure from 30 minutes to 24 hours. pH = 8.6	Small (2004)
Family Pangasiidae <i>Pangasius</i> sp. (Pangasius catfish)	Isoeugenol (AQUI-S)	IN	40–60 mg/L	14.5	Time to anesthesia: 3.7–3.9 minutes. Fish immediately transferred to anesthetic free water with recovery time of 2.8–5.3 minutes. Survival 100% at 24 hours. Dose considered useful for basic handling procedures.	Small and Chatakondi (2005)
	Metomidate hydrochloride	IN	6 mg/L	26	Induction: 0.46–2.31 minutes. Rapid recovery after 60 minutes exposure (2.01–2.52 minutes). Note: 65% mortality at 16 mg/L. pH = 8.6.	Small (2003)
Family Pangasiidae <i>Pangasius</i> sp. (Pangasius catfish)	Metomidate hydrochloride	IN	1.5 mg/L	26	Sedation achieved in all fish. No mortality with exposure from 30 minutes to 24 hours. pH = 8.6.	Small (2004)
	Isoeugenol (AQUI-S)	IN	20 mg/L 20 mg/L	12 ± 2	Induction in 5.3 minutes. Total exposure time ≤15 minutes. Recovery within 8 minutes. Useful for basic handling procedures. pH = 8.1. Induction within 4.1 minutes or less. Total exposure time ≤15 minutes. Recovery within 5 minutes. Useful for basic handling procedures. pH = 8.1.	Stehly and Gingerich (1999)

Class Osteichthyes Taxa	Drug	Dose	Route	Wt/Age	Temp (°C)	Comments	Reference
Family Siluridae <i>Kryptopterus bicirrhus</i> (Glass catfish)	Alphaxalone- alphadolone	4.8 mg/L for induction 2.4 mg/L for maintenance	IN	Check on age, but likely adults 2–7 g	23–27	Opercular movements disappeared after 5 minutes exposure at which time fish transferred to maintenance. Artificial respiration given by pumping water through mouth and across gills at 7–10 mL/min. Recovery in ~ 30 minutes after being placed in clean water.	Peters et al. (2001)
Order Tetraodontiformes Family Balistidae <i>Canthidermis</i> <i>maculata</i> (rough triggerfish)	MS-222	45–75 mg/L	IN			Provided mild to heavy sedation. Diagnostic examinations performed.	D. Neiffer, unpubl.
Family Diodontidae <i>Diodon holocanthus</i> (balloonfish)	MS-222	75–80 mg/L	IN	0.38–1.16 kg		Sedative effect rated fair to good. Diagnostic exams and topical treatments performed. N = 5.	D. Neiffer, unpubl.
<i>Diodon hystrix</i> (porcupinefish)	MS-222	75–80 mg/L	IN	0.38–0.42 kg		Provided surgical anesthesia for removal of fungal granulomas from integument and resection of coelomic musculature.	D. Neiffer unpubl.
Family Monacanthidae <i>Aluterus scriptus</i> (scrawled filefish)	MS-222	100–125 mg/L	IN			Mild to moderate sedation. Diagnostic examinations performed. N = 2.	D. Neiffer, unpubl.
<i>Meuschenia trachylepis</i> (filefish)	Clove oil in ethanol at ratio 1:5 MS-222	40 mg/L 50 mg/L	IN	0.44–2.35 kg	18	Sedation rated as good to excellent. Diagnostic examinations performed. Heavy sedation with cessation of gilling Induction within 3 minutes. Recovery within 5 minutes. Sufficient for handling and measurement.	D. Neiffer, unpubl. Griffiths (2000)
<i>Monacanthus tockeri</i> (slender filefish)	MS-222	70–75 mg/L	IN			Provided mild to heavy sedation. Diagnostic examinations performed. N = 3.	D. Neiffer, unpubl.
Family Tetraodontidae <i>Arothron</i> <i>nigropunctatus</i> (dogface puffer)	MS-222	100 mg/L	IN	360 g		Provided surgical anesthesia for removal of skin lesion.	D. Neiffer, unpubl.
<i>Spherooides testudineus</i> (checkered puffer)	MS-222	70–100 mg/L	IN	280–330 g		Variable effect from mild sedation to light anesthesia. Examinations and topical laser surgeries performed. N = 6.	D. Neiffer, unpubl.

Notes: Where possible, the most recently accepted scientific name is used. Anesthesia was not the focus of some articles, with only limited information provided. "IM, intramuscular; IN, inhalant/immersion; PO, orally; IV, intravenous; ICe, intracoelomic; 2-PE, 2-phenoxyethanol; MS-222, tricaine methanesulfonate.

authors' experience that with multiple animals, there is degradation of water quality and inductions are longer, but this is highly variable based on the number of fish and the volume of water used.

Immersion drugs must be water soluble or utilize a water-soluble solvent as a vehicle. For simple, short procedures, the required drug concentration is made up in an aerated container to which fish are transferred or drugs are added directly to the water containing the fish. In the latter situation, a buffer (e.g., sodium bicarbonate) is added. It is always preferable to use water from the fish's tank or pond to make the anesthetic solution prior to drug administration to minimize acute drops in pH (Harms 1999; Ross 2001). Ideally, spontaneous ventilation is maintained during short procedures.

For large fish, where immersion is impractical or dangerous to handlers, drugs may be applied directly to the gills. Inexpensive plastic pump spray bottles (e.g., unused bug sprayers) are ideal for this application (Fig. 15.7). When used by divers, the addition of a harmless dye (e.g., food coloring) helps identify distribution of the anesthetic.

Regardless of application, anesthetic solutions are most accurately made using a measured volume of a standard stock solution. However, preparing stock solutions of expensive powdered anesthetic drugs (e.g., MS-222) is uneconomical if used infrequently because potency decreases over time (Ross 2001). Alternatively, preweighed drug packets are recommended. Waterproof quick reference charts and known volume containers are useful for procedure set up. More importantly, they enable quick modification of drug dosage level.

Ventilation, even in animals that are apparently ventilating on their own, is an important tool to perform. It is akin to providing oxygen to mammals sedated with injectables. Simply, a syringe and plastic tubing can be utilized with care to ventilate each side of the animal's gills. With longer procedures (>10 minutes), debilitated fish, species that are slow to recover, and all but the shortest out-of-water proce-

Figure 15.7. A large grouper (*Epinephelus* sp.) being anesthetized using a pump sprayer to deliver concentrated MS-222 into the oral cavity of the animal.

dures, an artificial ventilation system can be used (Fig. 15.8). The animal is held in shallow water or placed on a fenestrated surface in lateral recumbency or in dorsal recumbency in a soft holder (foam, soft cloth, and sponge).

Aerated anesthetic solution is delivered across the gills from a bifurcated pipe or mouthpiece placed in the buccal cavity (Fig. 15.9). Nonrecirculating or recirculating systems can be used. In its simplest form, a nonrecirculating system uses an IV fluid bag and drip set. Resealable bags are easier for preparation, but used sealed bags with an opening cut in the end suffice. Flow rate is controlled by the drip set valve. Aeration of the anesthetic water with an air stone in the IV bag ensures

Figure 15.8. A simple recirculating system that enables delivery of anesthetic water from a reservoir to the gills and recycling of the effluent back to the fish by use of submersible pump.

Figure 15.9. A goliath grouper (*Epinephelus itajara*) positioned in dorsal recumbency in a foam holder during anesthesia with MS-222. Note the bifurcated mouthpiece being placed in the buccal cavity for delivery of oxygenated anesthetic water to both sets of gill arches, normograde.

near-saturation of oxygen and removal of dissolved CO₂. Used water is collected, but not recycled (Harms 1999; Ross 2001; Stetter 2001). This system is suitable for small- to medium-sized fish depending on reservoir volume, drip set tube diameter, and the rate at which fluid can be delivered.

Recirculating systems enable delivery of anesthetic water from a reservoir to the gills and recycling of the effluent back to the fish. This recycling is either done manually (refill elevated reservoir with collected effluent) or with a submersible pump. When using pumps electrical safety for the operator must be considered. Flow rate can be controlled by a valve on the tube leading to the mouth. Minimum effective flow rate during fish anesthesia has not been determined; 1–3L/min/kg are recommended. Low delivery rates fail to keep the gills on both sides wet, reducing gas exchange. High flow rates can result in alimentary anesthetic delivery and gastric dilatation, which may also occur due to depth of anesthesia and low sphincter tone. Both scenarios can be alleviated with the use of a “Y” or “T” plastic piece that equally distributes water over both gill arches. Oxygenation of the water should be provided. Recirculating systems are used in large fish where cost and waste water concerns make conservation of anesthetics and water paramount (Harms 1999; Ross 2001; Stetter 2001).

Regardless of method used, adjusting the delivered drug concentration in response to anesthetic depth is difficult. One option is to prepare measured volumes of anesthetic-free water and concentrations of anesthetic solution. These solutions are placed in separate bags or reservoirs and used in either recirculating or nonrecirculating systems. Alternatively, a syringe or turkey baster is used to rapidly deliver small amounts of fluid directly to the gills without disconnecting the fish from the system (Harms 1999).

The flow is usually normograde to achieve optimal gas and anesthetic exchange. During oral surgery, flow is reversed, if necessary, for surgical access. However, retrograde flow nullifies the normal countercurrent exchange mechanism and may damage the gills. The size or anatomy of some fish (e.g., filefish [Monacanthidae], triggers [Balistidae], or eels [Muraenidae]) (Fig. 15.10) make placement of a bifurcated buccal tube difficult. In these species, some retrograde flow is used to ensure all gill tissue is adequately perfused.

In some circumstances, whole tank anesthesia is required to move fishes out of their systems. When this occurs, sufficient supportive staff for induction, transport, and recovery will be necessary. Using lower doses that tranquilize the animals enough for safely moving into transports would be sensible versus full sedation, but this will be species specific as well as animal specific (individual temperament, disease state, and size). This method has shown to result in the least amount of stress when compared with capturing animals out of

Figure 15.10. Laced moray eel (*Gymnothorax favagineus*) receiving retrograde ventilation in preparation for an oral surgery.

the tank and transferring to an induction tank (Caamano Tubio et al. 2010).

Parenteral Anesthesia

In addition to inhalation, anesthetics are delivered orally, intravenously (IV), intramuscularly (IM), and intracoelomically (ICe). Oral administration is rarely used because precise dosing is difficult and the rate and degree of absorption is uncertain (Harms 2003). However, a few examples of successful oral drug use exist (Hansen et al. 2003; Harms & Bakal 1995; Harvey et al. 1988; Raines & Clancy 2009; Steers & Sherrill 2001). Intravenous injection is the fastest delivery method, with rapid induction and usually short duration of effect. However, this route has limited clinical use because it requires either manual restraint or prior administration of drugs by another route to allow IV access (Fleming et al. 2003; Hansen et al. 2003).

Intramuscular is the most common parenteral route. The major challenge with this route is that muscle is comprised of both red and white muscle with the white muscle taking up a majority of the muscle mass. In comparison with white muscle, the red muscle is aerobic and most likely the ideal set of muscles for appropriate metabolism and pharmacokinetics. However, because of location and low percentage of muscle mass, it is unlikely that an injection will be in the correct location, particularly if it needs to be administered quickly. Additionally, not all fish have both types of muscle, instead being composed of completely white muscle. ICe has an increased risk of visceral damage, and drugs must pass through the serosal surface, making induction time erratic. Both IM and

Ice routes are used in larger fish because many are kept in large volume aquariums or pens where adding waterborne anesthetics is impractical and because injection site trauma is less problematic in larger specimens (Harms 1999; Harvey et al. 1988; Williams et al. 1988). Injected fish will stop swimming and begin to drop through the water column with or without obvious gilling. However, when approached by divers with a net, they will often arouse and swim with directed movement. The diver retreats and allows the drugs more time to act and/or supplemental drug injections are made. Regardless of ease of capture, parenteral anesthetics are unpredictable and often do not provide adequate sedation or anesthesia, thus requiring supplemental inhalation anesthesia. Hypoxemia during the induction is a concern as ventilatory ability is compromised. Additionally, ventilatory support is necessary during maintenance of parenteral immobilization drugs, and particularly during recovery if prolonged (Harms 1999).

Injections are made by hand syringe, pole syringe (or modified pole syringe [Fig. 15.11]), or a darting system.

Examples of darting systems include a modified Hawaiian sling (Fig. 15.12), pneumatic spear guns, and a laser-aimed underwater gun (Harms 1999; Harvey et al. 1988; Williams et al. 1988).

The latter propels darts from a distance of 1- to 2-m (4–7 ft) that inject pneumatically upon impact and remain attached after jettisoning the lightweight spear shaft. The Hawaiian sling and pneumatic spear guns should be used with caution and are usually used for euthanasia as they are very powerful and it is hard to control the force of the impact on the animal. Both barbless and barbed needles are used for large active

Figure 15.11. Modified pole syringe system: a commercially available spring-loaded syringe capable of injecting 5 cc of solution is loaded and charge. The dart setup is backed into a syringe case taped to a PVC pipe, and the dart is taped with paper tape that can easily fall off when the animal is injected. Filtered food dye has been added to the contents of the syringe so injection success can be judged.

and heavily scaled or sluggish fish, respectively (Harvey et al. 1988). A complication of dart use is injection site trauma and scale loss, with some fish requiring local or systemic wound treatment. Intramuscular injections will often result in leakage of some injected drug as the needle falls out or is withdrawn and the surrounding muscles contract (Harms & Bakal 1995; Peters et al. 2001). Consideration to injection volume is important as fish cannot retain much fluid due to muscle inelasticity. A final thought is that when divers are underwater, there is refraction between the divers mask and the water, thus affecting the aim.

If the fish is in hand for injection, the needle is placed directly on dorsal midline between epaxial muscles, and then laterally inserted into a muscle bundle to reduce drug loss (Harms & Bakal 1995). Filtered food dye can be added to the contents of the syringe, so injection success can be judged. Alternatively, fluorescein stain or methylene blue dye is used (Harvey et al. 1988).

A first consideration when using parenteral anesthetics is human safety. The large dosages and drug volumes required make accidental injection a possibility for handlers (Harvey et al. 1988). The authors recommend reference to drug exposure protocols for hoofstock when using large enough doses that may adversely affect the handler.

MONITORING

Anesthetic Depth

Various schemes are used to describe anesthetic depth in fish with no consensus (Detar & Mattingly 2004; Myszkowski et al. 2003; Oikawa et al. 1994). This makes comparison of regimens between and within species difficult when reviewing the literature. Common criteria used in defining anesthetic depth or level include

Figure 15.12. An example of a Hawaiian sling. It is recommended that this only be used for long distances with skilled users or for euthanasia purposes due the power of the propulsion of the tip.

activity, reactivity to stimuli, equilibrium (righting reflex), muscle tone, and respiratory and heart rates. Broad stages include sedation, narcosis or loss of equilibrium, and anesthesia; each stage is further subdivided further into light and deep planes (Harms 2003; Stetter 2001). Depending on the species, drug, and dosage used, some stage components are unrecognized (Harms 1999; Stetter 2001). Conversely, some signs attributed to drug effect are instead responses to stress. For example, Gulf of Mexico sturgeon (*Acipenser oxyrinchus de soti*) often turns into a ventral/dorsal position when stressed (Fleming et al. 2003). Therefore, loss of the righting reflex is not used to determine anesthetic stage in this species.

For most fish, induction occurs in 5–10 minutes with immersion drugs, but can be prolonged using other routes. During induction swimming, respiratory rate and reaction to stimuli decreases. As the fish becomes anesthetized, there is loss of equilibrium and response to stimuli. At a surgical anesthetic plane, there is total loss of muscle tone and a further decrease, but not cessation, in respiratory rate. A firm squeeze at the base of the tail or insertion of a needle into the peduncle is used to determine response to stimuli; if the animal does not respond, general anesthesia has been achieved (Harms 2003; Stetter 2001; Storms & Mylniczenko 2004). Some species go through excitement during immersion induction and may traumatize themselves (Harms 1999; Stetter 2001).

Cardiopulmonary

Respiratory and cardiac rate changes are useful in assessing anesthetic depth. Both usually decrease with increased anesthetic dosage and anesthetic time. Respiratory rates are determined in the perianesthetic period by observing opercular movement (Harms 1999, 2003; Stetter 2001). However, in some species (e.g., scombrids), opercular movement is minimal to nonexistent, and potentially nondetectable in some species due to anatomy (frogfish, cowfish, etc). Additionally, passage of oxygenated water over the gills of any anesthetized fish with ceased opercular movement will maintain adequate ventilation, at least in the short term. This is accomplished because of the large differential between respiratory and cardiac arrest. The heart will still supply fresh arterial blood to the gills, allowing for adequate gas exchange.

In species with thin pliable body walls and proportionally large hearts, heart beats are observed directly, but for most, it is neither visible nor palpable (Harms 1999; Harms & Bakal 1995). In these species, heart rate is monitored using cardiac ultrasonography, Doppler flow probes, or electrocardiography (Harms 1999; Harms & Bakal 1995; Ross 2001). During cardiac ultrasonography, the probe is placed into the opercular slit of medium to large fish, or directly over the heart in smaller or small scaled/scaleless species (Fig. 15.13).

Figure 15.13. Ultrasonography is a useful tool for monitoring heart rate in fish. In specimens of sufficient size, the probe can be placed into the opercular slit as in this goliath grouper (*Epinephelus itajara*). Alternatively, the probe is placed directly over the heart in smaller specimens or small-scaled/scaleless species.

Figure 15.14. Doppler flow is also used for monitoring heart rate in fish with probes placed as described for ultrasonography. This figure demonstrates placement of the probe onto the area of the heart in a laced moray eel (*Gymnothorax favagineus*).

Doppler probes are placed in the same locations (Fig. 15.14). Regarding electrocardiogram, electrodes can be clamped lightly to the surface of the fins, with the pectoral and anal fins being a good combination (Ross 2001). Subcutaneous placement of needle electrodes minimizes skin trauma, reduces the chance of grounding out the ECG signal by contact with a wet external surface, and improves signal quality (Harms 1999). In

Figure 15.15. While not always practical, is it possible to monitor the ECG of fish, as with this laced moray eel (*Gymnothorax favagineus*). Note the retrograde placement of a ventilation tube in the opercular slit.

some species, use of human electrodes may work as well (Fig. 15.15). Pulse oximetry is not effective for measuring hemoglobin saturation in fish (Harms 1999; Ross 2001).

If the animal is stable, respiratory and heart rates are measured and recorded every 2–5 minutes. It is important to focus on trends because normal rates are not known for most species. Additionally assessing quality of the rhythm and if using ultrasound, contractility can be helpful, particularly if a baseline has been observed. Anesthetized fish generally have slower heart rates than terrestrial animals of similar size (Stetter 2001).

Other variables that are visually or palpably monitored include equilibrium, jaw tone, color of fin margin (pallor = hypoxemia, hypotension, or peripheral vasoconstriction), response to touch or surgical stimuli, and gill color (pallor = hypoxemia, hypotension, hypovolemia, or asystole) (Harms & Bakal 1995; Stetter 2001). Because of the relative low blood pressure of fishes, blood pooling can occur normally and occur in the dependent portions of the body, particularly when animals are not in the water where hydrostatic forces keep this pooling from occurring (Sandblom & Axelson 2007).

An effective way to monitor respiratory efficiency is periodic blood gas sampling to determine oxygenation, carbon dioxide, and pH. Venous samples are easier to collect, and useful information about physiological trends is obtained. Other blood variables used to assess metabolic status include HCT, glucose, and lactate. Lactate is a critical metabolite that has been instrumental in evaluating fish responses to hypoxia and exertion (Heming 1989; McDonald & Milligan 1992). There is

species variation in tolerance of both hypoxia and exertion that must be taken in account; regardless, changes in blood gas values indicate an unstable anesthetic event. Small size or debilitation may preclude collection of even a single sample from some individuals.

Water Quality

After cardiorespiratory function, water quality monitoring is critical to reducing anesthetic morbidity and mortality. Assuming aeration, DO, and temperature are appropriate and constant, ammonia concentration is of greatest concern. Ammonia concentrations will rise, and buffering capacity will decrease during prolonged procedures and when multiple fish are sequentially anesthetized in the same system. More alkaline water, as in marine systems, enhances ammonia toxicity. Ammonia concentrations are easy to measure with tank side kits. Alternatively, the handler uses other indicators of deteriorating water quality (e.g., surface foam formation due to increased protein from fish slime) (Harms 1999). Some species (e.g., Gulf toadfish, *Opsanus beta*) are facultatively ureotelic and ureogenic. In contrast to most teleosts that are obligate ammonio-tele, the toadfish switches to ureotelism in response to moderate stressors (e.g., anesthesia), excreting the majority of its nitrogenous waste as urea (Gilmour et al. 1998). Consequently, ammonia level measurement as a guide to water quality is inaccurate for this and similar species.

Declining water quality during anesthesia is corrected with a partial water change. The handler either adds water containing a known anesthetic concentration or, when reducing anesthetic depth, a known volume of clean water to the system.

RECOVERY

Recovery from immersion anesthesia begins when the fish is placed in drug-free water (Ross 2001). Even when using oral or parenteral drugs, moving to clean water is important, as some of these drugs and their metabolites may be excreted into the water and be reabsorbed across the gills and/or skin. The recovery water is aerated, with the fish's mouth oriented toward water flow. In an artificial ventilation system, clean drug-free water is passed over the gills until spontaneous ventilation returns. Alternatively, if the fish is not spontaneously ventilating, it is pulled forward through the water with its mouth open; however, assisted ventilation is preferred. Dragging the animal backwards through water may cause gill damage and should be avoided. Most fish fully recover within 5–15 minutes from immersion anesthetics, but this number can be highly variable. Recoveries extending >10 minutes indicate either excessive anesthetic dosage or a medically compromised animal (Ross 2001; Stetter 2001). In

comparison, recovery from oral and parenteral agents is often greater. The time is dependent on route, rate of drug metabolism, and if a reversal agent is used. As the fish recovers, respirations increase, muscle tone returns, fin movements start, and the fish swims with progressively less ataxia until full equilibrium is regained. Some fish go through an erratic porpoising phase and are prevented from escaping from tank (Harms 1999). Certain individuals may need to be manually restrained during this period to prevent damage to eyes and body.

RESUSCITATION

Marked hypoventilation or apnea is usually not alarming. If cardiac output is maintained and oxygenated water is flowing appropriately over the gills, tissue gas exchange is probably adequate. Decreasing the anesthetic concentration or moving the fish to anesthetic-free water until respirations resume (Stetter 2001) are recommended. If involved in a major procedure (e.g., exploratory coeliotomy), the latter is not advisable. In either scenario, the anesthetist takes advantage of the “buccal flow/heart rate” reflex; increasing water flow through the buccal cavity accelerates heart rate. The subsequent increase in gill blood flow more rapidly eliminates immersion drugs and hastens recovery. However, too rapid a flow may not allow adequate exchange, thus a balance must be achieved. Unresponsive fish are given standard mammalian emergency drugs, such as doxapram, corticosteroids, and fluids. The authors have observed positive response to doxapram administration (5 mg/kg IV, IM [or both at the same time], ICE or even over the gills) in several cases of erratic respirations or respiratory arrest. Controversy over the use of epinephrine versus norepinephrine in fish exists and is an area in need of further investigation. At this time, epinephrine appears to be an effective drug for critical situations.

ANESTHETIC DRUGS

General Comments

Of the definitions of “anesthesia,” the following is perhaps more acceptable given the controversy regarding pain perception in fish: “Anesthesia is a biological state induced by an external agent which results in the partial or complete loss of sensation or loss of voluntary neuromotor control through chemical or non-chemical means” (Bressler & Ron 2004).

Rather than listing a few cross taxa dosage recommendations for several commonly used drugs, the authors have taxonomically arranged cited and anecdotal dosages for representative species from most orders (Table 15.1). Some extrapolation is always necessary, but the more species-based data one can refer to, the more accurate the educated guess.

Inhalant (Waterborne or Immersion) Drugs

Tricaine Methanesulfonate (MS-222) Tricaine methanesulfonate (MS-222) is a benzocaine derivative with a sulfonate radical, which accounts for its water solubility and increased acidity over the parent compound (Harms 1999; Oikawa et al. 1994). It is absorbed across the gill epithelium (\pm skin) and biotransformed in liver and probably kidney. It is cleared primarily through the gills as free and acetylated forms, with additional metabolites eliminated in urine and bile (Harms 1999). Tricaine powder is directly mixed into the anesthetic chamber or administered as a stock solution of 10 g/L (10,000 mg/L). The latter is unstable in light and is kept in a dark container. Oily residues in buffered stock solutions indicate the presence of a desulfonation product and decreased potency.

MS-222 is acidic and is more effective and safe in its neutralized form. Solutions are buffered to the pH of the holding water before immersing the fish. Although sodium bicarbonate is primarily used, other buffers include imidazole, sodium hydrogen phosphate, sodium hydroxide, and calcium carbonate. Exact amounts are measured out or the powdered buffer is incrementally mixed into the anesthesia chamber until the solid no longer dissolves and saturation is reached (Harms 1999; Oikawa et al. 1994; Roubach et al. 2001; Stetter 2001).

There has been some dispute in the literature regarding the susceptibility of some sturgeon subspecies to MS-222, suggesting they are refractory to standard doses of MS-222 (Fleming et al. 2003); however, other groups have used MS-222 with no resistance at typical inductive doses (Hernandez-Divers et al. 2004; Feng et al. 2011; Matsche 2011). The reasons for this discrepancy can include subspecies variations and environmental parameters (e.g., temperature), which may affect metabolism. In one study of sturgeon anesthesia, it was found that when compared with medetomidine/ketamine and even clove oil, MS-222 resulted in much higher negative physiologic effects (Di Marco et al. 2011).

The margin of safety is narrower with young fish in warm, soft water, and there is species variation (Harms 1999; Roubach et al. 2001). In all age groups, MS-222 can be associated with hypoxemia resulting from drug-induced hypoventilation (Davis & Griffin 2004; Harms & Bakal 1995; Oikawa et al. 1994). MS-222 is a suspected carcinogen (Detar & Mattingly 2004) and in humans may cause reversible retinal deficits (Bernstein et al. 1997). A chronically exposed ichthyologist developed decreased vision, photophobia, and photopsia that resolved after terminating MS-222 contact for 7 months (Bernstein et al. 1997). While this article suggests that fish can have similar effects, a recent paper showed that koi carp exposed for 13 days to clinically relevant concentrations of MS-222 showed no changes in retinal structure or function (Bailey et al. 2013). Personnel with regular occupational exposure should

wear gloves to prevent systemic absorption of this retinotoxic drug.

MS-222 is the only FDA-approved anesthetic for fish and, consequently, is widely used in United States aquaculture. However, there is a 21-day withdrawal period prior to human consumption or release to the wild. This makes its use impractical or incompatible with some farming operations and field work (Detar & Mattingly 2004; Sladky et al. 2001; Waterstrat 1999).

Benzocaine Benzocaine, the parent compound to MS-222, is similar in pharmacology, but is much less water soluble. Consequently, a stock solution in ethanol or acetone (100 g in 1 L) or propylene glycol is prepared prior to its use. The stock solution is kept in a dark bottle and held at room temperature (Harms & Bakal 1995; Iversen et al. 2003) Its relative insolubility may account for its usefulness in species sensitive to MS-222. For example, striped bass (*Morone saxatilis*) are very sensitive to MS-222, but are effectively anesthetized in benzocaine solutions (55–80 mg/L) (Hseu et al. 1998).

Other advantages include low toxicity to humans at the concentrations used, and it can be removed from aquaculture facility effluents using activated carbon filtration. Even if not filtered, breakdown in water is approximately 4 hours, making it less likely to cause environmental contamination. Exposure also does not impair fish growth or reproductive capacity (Gomes et al. 2001; Hseu et al. 1998).

Efficacy and sensitivity to benzocaine is species and dosage related (Gomes et al. 2001; Heo & Shin 2010) and it can stimulate the stress response as discussed previously. The only other major concern is its fat solubility, which may result in prolonged recovery in older and gravid fish (Iversen et al. 2003). It is one of the few drugs shown to be effective for safe anesthesia of arapaima (Honczaryk & Inoue 2010). A recent paper in Crucian carp noted it to be a safe rapid agent with low increases in stress biomarkers (glucose and cortisol) (Heo & Shin 2010). In Atlantic cod, induction and recovery times were found to increase with increasing body weight. Additionally, it was found that recovery times were longer with benzocaine versus MS-222, even at half the dose of MS-222. In combination with metomidate though, induction times did decrease (but not as much as medetomidate and MS-222) (Zahl et al. 2009).

Clove Oil, Eugenol, Isoeugenol, and AQUI-S Clove oil is a mixture of compounds, of which the phenolic eugenol comprises 85–95%. Isoeugenol and methyleugenol make up the remaining 5–15% of active ingredients. Commercially available clove oil has approximately 84% eugenol, but it is possible to purchase 100%, even at local natural product stores. Clove oil and isoeugenol are “generally recognized as safe” (GRAS) by the FDA as a food additive for humans. Eugenol is similarly approved for use in animal feeds and is used in dental

cement for temporary fillings. (Harper 2003). AQUI-S contains primarily isoeugenol (Iversen et al. 2003; Kildea et al. 2004). Clove oil and/or AQUI-S are approved as legal anesthetics with no withdrawal period in Australia, Chile, Finland, New Zealand, and the Faroe Islands (Hoskonen & Pirhonen 2004), but neither clove oil, any component of clove oil, nor AQUI-S is approved for use as a fish anesthetic in the United States (Bressler & Ron 2004; Davis & Griffin 2004; Harper 2003; Stetter 2001). AQUI-S was under review as a possible approved drug for zero withholding days (Young 2009), but due to carcinogenic effects in mice, has been now strictly prohibited (<http://www.fws.gov/fisheries/aadap/aquis.htm>, accessed 5/7/2014). However, AQUI-S 20E is available in the United States under the Investigational New Animal Drug (INAD) program (Aquatactics Fish Health, Kirkland, WA).

Clove oil and eugenol are incompletely water soluble, particularly at cold temperatures. A 1:10 mixture of either in 95% ethanol yields a 100-mg/mL stock solution. Final concentrations of 40–120 mg/L are used for most species (the contribution of ethanol to the anesthetic effect is nil at these concentrations) (Harms 2003).

In addition to use in aquaculture, research, and aquaria, clove oil is regularly employed in marine field studies for sampling tide pool and tropical reef fish assemblages (Ackerman & Bellwood 2002; Griffiths 2000; Marnane 2000). For tide pools, the volume is estimated, and the drug is administered as in an anesthetic chamber. For reef surveys, a section is covered with mesh net covered in turn by a nylon cloak. A solution of clove oil mixed with ethanol is then pumped into the netted area to temporarily immobilize all fish (as a reminder, clove is not a U.S. approved drug). Rotenone, an effective and nonselective ichthyocide, has historically been utilized for this purpose, but is more controversial given increasing conservation and environmental concerns (Ackerman & Bellwood 2002). This application of clove oil may be of use in captive exhibits that often have elaborate rock or coral work, making removal of fish for medical or maintenance reasons difficult.

Compared with other immersion anesthetics, clove oil results in more rapid induction times and consistent anesthesia (Bressler & Ron 2004; Detar & Mattingly 2004; Sladky et al. 2001). However, isoeugenol (AQUI-S) is considered more effective (Ross 2001). Although clove oil recoveries are also consistent, they are longer compared with other drugs (e.g., MS-222) (Detar & Mattingly 2004; Sladky et al. 2001). Other claimed advantages include efficacy at a range of water temperatures, availability, lower expense, and handler safety (Bressler & Ron 2004; Detar & Mattingly 2004; Gladden et al. 2010). As mentioned previously, the effect of clove oil and its components on the stress response is variable with suppression in some cases and activation in others. Unlike metomidate, the mechanism of action remains unknown (Small & Chatakondi 2005).

Although increased safety compared with other immersion drugs has been claimed (Detar & Mattingly 2004), a narrow safety margin compared with MS-222 has been reported. In red pacu, most fish exposed to eugenol (100 mg/L) required resuscitation, and the risk of ventilatory failure increased with increasing dosages (Sladky et al. 2001). An explanation for ventilatory failure and medullary collapse in some fish is a neurotoxic or hepatotoxic effect similar to those described in mammals (Sladky et al. 2001). On the note of low safety margin, in a study on *Astyanax altiparanae*, concentrations of 50–150 mg/L were assessed, with the 50 mg/L concentration deemed as the most efficacious and safe for deep anesthesia with rapid inductions (1.5 minutes) but with mortalities of >80% at 75 mg/L (Pereira da Silva et al. 2009). Alternatively, it may be a function of the physical properties of eugenol oil or increased duration of exposure. As an oil, eugenol coats anatomic structures and its persistence on gill epithelia may block gaseous diffusion (Sladky et al. 2001). In addition, mild gill necrosis due to repeated exposure to low dose eugenol (9 mg/L) has been reported (Afifi et al. 2001). Along with safety concerns, some fish are very sensitive to small increases in concentration, acutely losing equilibrium. This is a problem when controlling concentrations in large tanks, and clove oil and its components may not be suitable as transport drugs in sensitive species (Hoskonen & Pirhonen 2004).

Clove oil at 18–20 μ L/L has also been used for long-term transports (up to 48 hours) in *Haplochromis obliquoidens*, with some mortalities at the higher end range (reiterating the narrow safety margin); additionally, ammonia levels were higher in those containers with anesthetized fish (Kaiser et al. 2006). In beluga, *Huso huso*, that were exposed to clove oil at doses of 500–3000 mg/L, it was noted that cortisol, glucose, and lactate levels were lower, at the higher dosages with faster inductions (Hoseini et al. 2010). In the authors' experience, this tends to be true with many anesthetics.

A more novel approach has been to utilize clove powder mixed in water rather than oil. In sturgeon, the powder has been used in juvenile great sturgeon from 175 to 350 mg/L, with negative side effects being limited to increases in hematocrit, hemoglobin, and total erythrocyte count, but with a return to normal within 24 hours (Mohammadzarejabad et al. 2010).

Although the analgesic effects of eugenol in humans result from the inhibition of prostaglandin H synthase (Keene et al. 1998), proof of analgesia in fish does not exist (Sladky et al. 2001). In red pacu, fish anesthetized with eugenol were more likely to react to a hypodermic needle puncture than fish anesthetized with tricaine methanesulfonate, raising the question of appropriateness of clove oil or related compounds for invasive or markedly noxious procedures.

In a recent examination of AQU-I-S in small freshwater *Melanotania australis*, 80 mg/L was most efficacious with rapid induction times (lower doses resulted

in long inductions and recoveries), but mortality rates increased after exposure times of >15 minutes. This concentration is higher than those used for other freshwater fish, which usually use 20–60 mg/L, but these fish were all coldwater animals (Young 2009). In koi carp, isoeugenol was used at 20, 40, 80, and at 500 mg/L, noting that mortalities occurred only at the high range, and even in those animals, no pathology was observed (Gladden et al. 2010).

Metomidate Metomidate is a nonbarbiturate imidazole. Available in Canada under the trade name Marinil, it is not licensed in the United States, but is available for investigational use (Harms 1999). It is readily water soluble and is stored in tight light protected containers. In addition to inhalation, the drug can be given orally (Hansen et al. 2003; Harvey et al. 1988).

Metomidate suppresses cortisol response to anesthesia. It blocks adrenocorticotrophic hormone stimulation of steroidogenesis, even when exogenous ACTH is injected intracoelomically. This occurs by a direct effect on the interrenal gland and the mitochondrial cytochrome P₄₅₀-dependent enzymes that catalyze the synthesis of cortisol (Davis and Griffin 2004; Iversen et al. 2003; Small & Chatakondi 2005). Cortisol synthesis blockade may cause the anesthetized fish to transiently turn very dark. This may be due to reduced cortisol production terminating the negative feedback loop on ACTH synthesis. As ACTH synthesis is linked to melanocyte stimulating hormone production, both compounds increase with the associated color change occurring (Harms 1999; Harms & Bakal 1995).

In addition to sedation and anesthesia for minor procedures, metomidate is useful for limiting transport trauma. Fish transported while immobilized are damaged by contact with the container sides and bottom. Metomidate dosages that suppress the cortisol stress response still allow maintenance of equilibrium (Davis & Griffin 2004; Harms 1999; Kilgore et al. 2009).

Metomidate is a hypnotic, inducing sleep rather than general anesthesia. This is reflected in maintenance of opercular respiration for twice as long at the effective concentration as other immersions (Mattson & Riple 1989). Additionally, muscle fasciculations occur at low dosages, indicating incomplete relaxation (Harms 1999). Metomidate is probably a poor analgesic and should not be used alone for major surgical or noxious procedures (Hansen et al. 2003; Harms 1999).

In some marine species, metomidate has a wider therapeutic range compared with benzocaine (Hansen et al. 2003). Among freshwater tropical fish, gouramis are very sensitive to metomidate, and its use in cichlids (Cichlidae) in water of pH < 5 is contraindicated (Harms 1999). In Atlantic cod, recovery times were found to increase with increasing body weight, but not induction times. When metomidate was used in combination with MS-222 or benzocaine, overall reduction of dose of both MS-222 and benzocaine were possible,

with marked reduction of both induction and recovery time (Zahl et al. 2009).

Quinaldine and Quinaldine Sulfate Quinaldine sulfate (QS) is a strongly acidic, highly water-soluble powder that must be buffered. Rather than adding powder directly to the water, QS is administered as a stock solution (10g/L). Its parent compound, Quinaldine, is a yellowish oily liquid and must be dissolved in acetone or alcohol prior to mixing in water. Due to high lipid solubility, quinaldine tends to accumulate in the brain more than QS (Harms 1999; Hseu et al. 1998; Ross 2001). Like MS-222 and most immersions, quinaldine and QS depress the CNS sensory centers. Unlike MS-222, neither drug is metabolized by fish and is excreted entirely unchanged (Harms 1999; Hseu et al. 1998).

Though not approved for use in the United States (Harms 1999), QS is common in aquaculture elsewhere because of its relatively low cost. This has also made quinaldine a popular tool for collection of fishes from tidal pools and small lagoons (Ross & Ross 2008). Other reported advantages include effectiveness at very low concentrations, purported low toxicity and wide safety margin, and short fish recovery time (Kumlu & Yanar 1999).

Despite claims of safety, mortality occurs in some species. For example, in gilthead seabream, low dosage QS (15–20 mg/L) resulted in 30–100% mortality (Kumlu & Yanar 1999). In addition, quinaldine can be an irritant and has caused corneal damage in salmonids (Harms & Bakal 1995; Ross and Ross 2008). Also of importance are studies that demonstrate that fish exposed to quinaldine or QS alone retain a strong reflex response to being touched, even when they have totally lost equilibrium and are deeply anesthetized. This, along with the potential lack of analgesia, makes them inappropriate for transportation, handling, and surgical or similarly noxious procedures (Cullen 1996; Harms 1999; Kumlu & Yanar 1999).

To reduce toxicity, and increase efficacy and analgesia, some researchers have combined diazepam with QS. As demonstrated in gilthead seabream, sea bass (*Dicentrarchus labrax*), and cichlids (*Cichlasoma nigrofasciatum*), addition of diazepam to the QS bath results in fish entering a deeper anesthetic plane at lower QS dosages. This occurs with lower to no mortality, improved muscle relaxation, and reduced excitement in confined spaces (e.g., transport boxes) (Bircan-Yildirim et al. 2010; Kumlu & Yanar 1999; Yanar & Kumlu 2001). Nondepolarizing neuromuscular blocking agents (gallamine triethiodide, tubocurarine chloride, and pancuronium bromide) IM eliminate the reflex responses in fish anesthetized by quinaldine alone (Kumlu & Yanar 1999). However, these combinations do not provide analgesia.

2-Phenoxyethanol 2-phenoxyethanol (2-PE) is a clear or straw-colored oily liquid. It has a faintly aromatic odor and is moderately water soluble. 2-PE was used

initially in aquaculture to treat ichthyophoniasis and other fungal, bacterial and parasitic diseases. Less expensive than many anesthetics, 2-PE has been widely used for sedation, particularly in fish transportation, as well as general anesthesia (Hseu et al. 1996, 1997; Ross 2001). Another advantage is that it causes no pH change when added to sea water (Hseu et al. 1998).

2-PE produces hypoventilation and has poor analgesia (Oswald 1978). Also, sustained and regular exposure to 2-PE solution causes a neuropsychological syndrome in some handlers (Hseu et al. 1998). Additionally, 2-PE may not completely cease involuntary movements, so muscle twitching is possible. Other negative aspects to the drug include no block of the stress response and cardiovascular activity is significantly reduced (Fredricks et al. 1993; Molinero & Gonzalez 1995).

In a recent article, over 102 species (30 families) of a variety of sizes and ages were moved from one aquarium to another using 2-PE exclusively at an average dosage of 0.15 mL/L with maintenance in the immersion for up to 330 minutes. In general, the procedure was smooth, with very little (mostly none) excitation noted in most of the species (Vaughan et al. 2008). Due to the numbers of animals, they are not all included in the table in this chapter and the reader is referred to the original paper. Similarly, at Ocean Park, Hong Kong (K. Larson, pers. comm., 2011) 2-PE has become the anesthetic product of choice for their anesthetic events, and as earlier, they also use it to catch fish out of large aquaria with divers in the water.

Isoflurane There are limited published studies evaluating chlorofluorocarbon-based anesthetics in fish, and care is exercised in their use. Isoflurane is considered safe and effective in freshwater and marine fish at concentrations ranging from 0.4 cc to 0.75 cc isoflurane/L H₂O for induction and 0.25 cc isoflurane/L H₂O for maintenance (Stetter 2001). Isoflurane liquid is vaporized and bubbled through the water or is directly added to the anesthetic chamber. The latter involves spraying the drug through a 25-gauge needle beneath the surface of the anesthetic chamber. This allows small drug droplets to be distributed in the water (Stetter 2001). Anesthetic depth is difficult to control and, due to insolubility in water, localized areas of higher concentrations may occur, resulting in overdosage. In addition, volatilization and difficulty in scavenging waste gas is a hazard to personnel (Harms 1999; Ross 2001). This is addressed, to some extent, by attaching a funnel system to a standard scavenging system and placing it immediately above the anesthetic chamber (Stetter 2001). Given the disadvantages associated with its use, a number of researchers and clinicians recommend the use of isoflurane or similar drugs only as a last-resort anesthetic, for euthanasia, or not at all (Harms 1999; Ross 2001). A recent paper rejuvenated interest in this drug for fish anesthesia, utilizing it in combination with MS-222 which resulted in safer anesthetics for zebrafish, which

have high mortalities with long MS-222 sedations (Huang et al. 2010).

Ketamine and Xylazine Traditionally used intramuscularly or intravenously, the drugs ketamine and xylazine can also be used as an immersion. In a study utilizing these drugs in various combinations as a bath for carp (*Cyprinus carpio*) resulted in smooth inductions with sufficient anesthetic time to perform minor procedures (Al-Hamdani et al. 2010).

Medetomidine One novel use of this drug is as an anti-fouling agent used for barnacle control. The drug is incorporated into marine paints and prevents the settling of barnacle and tubeworm larvae on surfaces coated with the paint. To assess the potential for effects on nontarget species in the vicinity of such paints, studies have been performed with low dose long-term immersion baths. In one of these studies 0.5- to 50-nM medetomidine baths were used; mostly fry were affected, and side effects noted were body paleness, decreased oxygen consumption, and decreased respiratory (Lennquist et al. 2010). Sedative effects were not noted, as it was not the scope of the study, but all the side effects were reversible when animals were removed to clean water. In rainbow trout it produced sedation but not analgesia. Bradypnea was observed during immobilization with an increase in respiration occurring after addition of atipamezole to the recovery water at 6× the medetomidine concentration (Horsberg et al. 1999).

Carbon Dioxide Carbon dioxide for immobilization is obtained from three sources: CO₂ gas, sodium bicarbonate (NaHCO₃), or carbonic acid (H₂CO₃) (Gelwicks & Zafft 1998; Prince et al. 1995). Use of carbon dioxide gas involves diffusing compressed CO₂ gas through air stones into water. The NaHCO₃ (baking soda) method involves mixing a specific amount of the drug with water to release CO₂. Carbonic acid immobilization involves mixing equal volumes of sulfuric acid (H₂SO₄) and NaHCO₃ solutions in water to form carbonic acid and liberate CO₂ (Gelwicks & Zafft 1998; Prince et al. 1995).

Carbon dioxide gas and NaHCO₃ methods are popular, but cumbersome for many field applications (Gelwicks & Zafft 1998; Prince et al. 1995). In comparison, the materials needed for carbonic acid immobilization are compact, and concentrations are easily controlled, making it more applicable to field work (Gelwicks & Zafft 1998). The carbonic acid method has its own disadvantage in that NaHCO₃ and H₂SO₄ solutions are designed to react completely, and accuracy is essential. If one solution is mixed incorrectly, water chemistry (i.e., pH) will be significantly affected. Safe handling of concentrated H₂SO₄ requires protective gloves, clothing, and glasses and work under a fume

hood (Gelwicks & Zafft 1998). The acid is added to the water, not the reverse.

Regardless of method, CO₂ use has many disadvantages. Concentrations in water are difficult to control and oxygen must be maintained at high levels. Blood gases and acid–base balance are markedly altered (Harms 1999; Prince et al. 1995). To address the latter concern, some handlers use NaHCO₃ with CO₂ gas for its buffering effect (Prince et al. 1995). Alternatively, some handlers mix NaHCO₃ with glacial acetic acid to yield carbon dioxide concentrations sufficient for immobilization while limiting acid-base shifts (Prince et al. 1995).

Following immersion in water with a high CO₂ concentration, there is a rapid decrease in blood pH and increase in blood CO₂ concentration. Low blood pH results in less efficient oxygen transport to tissues, including the brain. The resulting cerebral hypoxia causes an overall inhibition of spontaneous activity of the CNS and the observed “anesthetic” effect (Gelwicks & Zafft 1998; Harms & Bakal 1995). When fish are returned to freshwater, CO₂ diffuses out of the gills, blood pH rapidly returns to normal levels, and fish recover. One may expect these changes in blood pH and subsequent cerebral hypoxia to produce morbidity. However, rainbow trout appear tolerant of these changes in blood pH. Recent studies provide conflicting evidence regarding effectiveness and safety of carbonic acid (Gelwicks & Zafft 1998).

Although touted to decrease the stress response, CO₂ has questionable analgesia (Prince et al. 1995; Ross 2001) and is not appropriate for invasive procedures.

In the United States, the primary advantage of using CO₂ is that it is “generally regarded as safe, and there are not restrictions on its use which is appealing to both aquaculture and field work” (Gelwicks & Zafft 1998; Harms 1999). However, many handlers feel it should be used for immobilization or euthanasia as a last resort (Harms 1999).

Other Immersion Agents There are more esoteric drugs that have been tried in fishes, usually in an effort to find an inexpensive and easy-to-use drug with no tissue residues. They include tobacco (nicotine) (Agokei 2010), menthol (Simoes & Gomes 2009), avocado pear (Adebayo et al. 2010), and crotoalaria, among others (Ramanayaka & Atapattu 2006). To obtain details on the use of these drugs, the reader is referred to the original papers.

Of additional interest is also the use of diazepam as an immersion, and while not overtly sedative, it does show evidence of an anxiolytic effect, which may prove useful in other combinations. Zebrafish, in particular, are used as a model for behavioral pharmacology research, as anxiety behaviors have been described in this species with amelioration after exposure to anxiolytic drugs. Clonazepam, bromazepam, diazepam, and ethanol significantly reduced shoal cohesion and tank

exploration. These benzodiazepines and buspirone, as well as ethanol also increased time spent in light versus dark areas (and thus less “hiding”). Whereas propranolol and chlordiazepoxide had no effects (Bencan et al. 2009; Gebauer et al. 2011). Nicotine, which has anxiolytic effects in rodents and humans, showed similar responses in the zebrafish. Different dosages of these drugs provided little to no sedation, with the exception of 20 mg/L of chlordiazepoxide (Bencan et al. 2009; Gebauer et al. 2011).

Some historical drugs include chloral hydrate, urethane, chlorobutanol, and diethyl ether, none of which are recommended for use in fish any longer (McFarland & Klontz 1969).

Oral Anesthetics

Metomidate In addition to being used as an immersion, metomidate has been administered orally by high pressure syringe as a supplement in fish partially immobilized by remote injection (Harvey et al. 1988) and to turbot (*Scophthalmus maximus*) via stomach tube for rapid and complete immobilization (Hansen et al. 2003).

Diazepam In addition to being combined with QS for immersion anesthesia (Yanar & Kumlu 2001), diazepam impregnated pellets have been fed to American shad (*Alosa sapidissima*), resulting in a slow anesthetic induction (Harms & Bakal 1995). The authors regularly use oral diazepam as an oral presedative in larger fishes at dosages of 0.5–1.5 mg/kg, with higher dosages likely being necessary. This is an area requiring much more investigation on efficacy and safety in its use in fishes.

Ketamine Ketamine, when gavaged orally to goldfish (*Carassius auratus*) and hybrid striped bass (*Morone saxatilis*), showed notable sedative effects and animals allowed themselves to be netted; further, an arapaima sedated by this method tolerated slinging (Raines & Clancy 2009).

Tiletamine-Zolazepam Though designed to be used as an injectable drug combination, successful sedation and translocation of >70% of a population of captive yellowtail jacks (*Seriola lalandi*) was performed using tiletamine-zolazepam (TZ) powder packed in gelatin capsules placed in food items. Mortalities were attributed to anesthetic overdose from fish consuming greater than one medicated food item (Steers & Sherrill 2001).

Injectable Anesthetics

Ketamine Hydrochloride Ketamine is used alone or in combination with alpha₂-agonists (Harms 1999). Intramuscular injection is the most common route and requires high dosages in teleosts and sturgeons when used alone (Bruecker & Graham 1993; Fleming et al. 2003; Williams et al. 1988). When available in the lyophilized form, a concentrated solution permitting a

smaller volume IM injection can be prepared (Oswald 1978). IV administration, though rarely reported, uses dosages 1/3 to 1/2 of those used IM. Ketamine has been used for capture and manipulation of a number of marine and freshwater species (Williams et al. 1988) and for short-duration procedures and transport (Bruecker & Graham 1993; Oswald 1978). Ketamine IV in coho salmon (*Oncorhynchus kisutch*), rainbow trout, and Midas cichlids (*Heros citrinellum*) reduces the oxygen demand during handling (Bruecker & Graham 1993; Oswald 1978).

Regardless of administration route, ketamine alone has a species-specific effect in fish often characterized by incomplete anesthesia, periods of apnea, and prolonged recovery with excitement when used (Bruecker & Graham 1993; Graham & Iwama 1990; Oswald 1978). To reduce dosage and apnea, and improve anesthesia, ketamine is often combined with the reversible alpha-2-adrenergic agonist, medetomidine. This combination provides safe and effective anesthesia in some species (Williams et al. 2004), but respiratory depression, bradycardia (Fleming et al. 2003), and incomplete immobilization is noted in others. For the latter reason, either ketamine or a ketamine/medetomidine (K/M) combination is more appropriate as an aid to restraint rather than a substitute for immersion anesthesia during major procedures. One of the authors (Neiffer) has found K/M particularly useful in capture of fish from large-volume aquaria. Following sedation or slowing down with K/M, staff is able to net the fish and transfer them to an MS-222 bath for maintenance and evaluation. In sturgeon (*Acipenser* hybrids), IV medetomidine 0.04 mg/kg and ketamine 4 mg/kg had slower inductions and longer recoveries than MS-222 or clove oil, but interestingly had fewer physiologic effects than the MS-222 or clove oil (DiMarco 2011).

Medetomidine Medetomidine is usually combined with ketamine and reversed with atipamezole. One of the authors (Mylniczenko) found that in black pacu, medetomidine (100 µg/kg IM) in combination with midazolam (1 mg/kg IM) and butorphanol (1 mg/kg IM), did not produce adequate anesthesia to result in ataxia or allow any invasive testing or significant animal manipulation, but did allow sedation for removal into a small transport and then for euthanasia with MS-222.

Xylazine In rainbow and brown trout, the lowest effective dose of xylazine (100 mg/kg) consistently produced apnea. Convulsant activity occurred during induction and recovery, making it difficult to ensure artificial ventilation because the convulsions frequently dislodged the water supply. In addition, gross ECG disturbances were detected. Consequently, xylazine is not recommended in salmonids (Oswald 1978). Given the proven usefulness of medetomidine in other teleost

species, xylazine is not the preferred α_2 -agonist for any fish.

Tiletamine-Zolazepam IM administration of TZ was used in one study at dosages of 5–20 mg/kg in multiple saltwater species (not noted in the abstract). Even at dosages of 60 mg/kg, this group did not experience any mortalities. At higher dosages, animal did have prolonged recoveries, some up to 72 hours (Garcia-Parrage et al. 2007). The greatest advantage of using TZ was lower volumes of drug required as the drug is purchased as a powder and can be reconstituted to high concentrations with good effect and no supersaturation.

Propofol Propofol IV has been used successfully for rapid induction in Gulf of Mexico sturgeon, but caused significant respiratory depression. This complication was addressed by passing oxygenated water across gills. In addition to respiratory depression, uncomplicated bradycardia was noted (Fleming et al. 2003). At one facility (Neiffer), propofol in an African lungfish (*Protopterus annectens*) was associated with mortality. It is not certain if this was directly drug related or due to an obligate air-breathing fish being recovered in water that was too deep to allow surface access.

Alfaxalone-Alfadolone A combination steroid anesthetic, alfaxalone/alfadolone (A/A), mainly depresses CNS activity while leaving the integumentary sensory system operational. This makes it very valuable for research in sensory physiology including mechanoreceptors (Peters et al. 2001). However, it is no longer marketed in the United States. An advantage of A/A is its cardiac chronotropic and inotropic stimulatory effect with vasodilation of the gill capillaries. This seems to ensure adequate oxygenation of the blood compared with many other anesthetics (Oswald 1978). As with all drugs, species differences are seen. In a collection of marine and freshwater species A/A was effective, but not consistent for capture of free swimming individuals (Harvey et al. 1988). In several catfish species, A/A provided surgical anesthesia lasting several hours (Peters et al. 2001). In rainbow and brown trout, A/A produces similar long sleep times, but it is difficult to give a dose that simultaneously abolishes locomotion yet preserves ventilation (Oswald 1978).

Lidocaine Lidocaine yields variable results as an immersion anesthetic. However, it is effective as an injectable local anesthetic in fish, alone or in combination with other drugs (Harms & Bakal 1995; Park et al. 2011).

Miscellaneous Drugs Galamine triethiodide IM has been used for capture and handling of large tank fish, providing a smooth induction of paralysis following injection (Harvey et al. 1988). It is worth considering for noninvasive procedures or as an adjunct to anesthetic

agents. A combination of etorphine-acetylpromazine (Large Animal Immobilon™) has been used in trout for anesthesia, but given the human accidental exposure risks (Oswald 1978) and availability of other agents, its use is not recommended. Ethanol is an anesthetic of last resort. Anesthetic depth is variable and difficult to control. However, in nonclinical situations or for euthanasia, ethanol is sometimes available when other drugs are not (Harms & Bakal 1995).

NONCHEMICAL ANESTHESIA

Electroshock is a common fisheries tool for group immobilization to tag, survey, or remove animals from an area. It is often coined “electroanesthesia”; however, this is a misnomer, as animals are not truly anesthetized. The process results in electronarcosis or stunning, but when the intensity of the current is too high, it can result in severe muscle tetany and spinal injuries (Schreck et al. 1976). While this method can be used appropriately and there are reports that when done properly there are few deleterious effects, one author (Mylniczenko) has experienced long-term immunocompromise and resulting secondary infections in animals collected by this manner. Additionally, the acute effects can be very dramatic and mimic exhaustive exercise. Finally, this method does not have much practical application for the aquarium but may be a tool used to collect specimens coming into quarantine or utilized during field work. There should be caution for human safety when using electricity in water and for collateral damage of nontarget animals in the vicinity of the shock.

Hypothermia is not an appropriate method of anesthesia but had been used historically to induce light anesthesia and for transport; the physiologic effects are too great for its consideration as an anesthetic.

ANALGESIA

Most sources define analgesia as the absence of pain in the presence of stimuli that would normally be painful without the loss of consciousness. The less used definition seems more universally acceptable, as it includes absence of noxious stimulation as well as pain in the definition (Blood & Studdert 1988; Thurmon et al. 1996). Numerous contemporary articles exist on the topic of analgesia in fishes (Neiffer & Stamper 2009; Sneddon 2009; Weber 2011). Putting aside the question of pain perception, fish have μ and κ opiate receptors throughout the brain, making it reasonable to expect some effect of opioid treatments in fish experiencing noxious stimuli (Harms et al. 2005).

Despite increased interest, limited information on the use of analgesics in fish exists. In one of the earliest studies, the lips of juvenile rainbow trout were injected with 0.1-mL acetic acid. This resulted in a marked

increase in opercular rate compared to controls, and anomalous behaviors including rocking from side to side and lip rubbing against the gravel and tank sides. Administration of high morphine dosages significantly reduced the opercular rate and the noxious stimulus-related behaviors. These fish also returned to normal eating behavior faster. Thus, morphine appears to act as an analgesic or at least antinociceptive in this and presumably other teleost fish (Sneddon 2003; Sneddon et al. 2003). In a later study, koi carp (*Cyprinus carpio*) underwent exploratory celiotomy and were treated with butorphanol, ketoprofen, or saline. Only koi injected with butorphanol exhibited no significant differences between pre- and postsurgery caudal fin beat frequency and vertical position in the water column. This suggests a mild behavioral sparing effect compared with the ketoprofen-treated and saline control groups (Harms et al. 2005). Fish can become tolerant of morphine, and naloxone reduces its effects (and presumably butorphanol) (Rose 2002). Regardless of the pain perception controversy, it appears that analgesic drugs have application in reducing stress associated with noxious stimuli in teleosts and presumably other bony fish. Additionally, some drugs that attain immobility are devoid of analgesic effects and should not be used alone for surgical or similarly noxious procedures.

In trout treated with ketoprofen or butorphanol, the amount of MS-222 needed for antinociception was lower using the drugs than without; this technique was modeled after the MAC (minimal alveolar concentration) sparing studies performed in mammals (Davis et al. 2006; Mylniczenko 2012). Not only was there an anesthetic sparing effect occurring, but there were dose-dependent responses as well.

EUTHANASIA

When necessary, overdosage of immobilization drugs is an acceptable means of euthanasia (Harms & Bakal 1995). Inhalant (immersion) drugs at 5–10× the anesthetic concentration for a particular species are usually chosen, although injectable agents can also be used (Ross and Ross 2008). MS-222 is most often used. However, many fish in large exhibits require induction first with parenteral drugs (e.g., medetomidine/ketamine), then euthanasia in an MS-222 bath. Alternatively, in fish too large for a bath, inhalant (immersion) is poured directly over the gills (Harms & Bakal 1995). Cessation of opercular movements sometimes indicates a fish has expired, but is not definitive and should not be used as the sole parameter for confirmation of death. Cardiac asystole usually lags behind brain death since fish myocardial cells utilize local glycogen stores for energy and do not need blood glucose (Stetter 2001). Use of Doppler flow probes, ultrasonography, or electrocardiography is recommended to confirm asystole. To be certain, additional anesthetic

drug or pentobarbital are administered IV into the heart or caudal vein (Ross 2001). Alternatively, cranial concussion, decapitation, spinal transection, or exsanguination is performed once the fish is deeply anesthetized (Harms & Bakal 1995). While euthanasia with baking powder or Alka-Seltzer™ tablets has been utilized and is considered an acceptable euthanasia method, MS-222 is the quicker and has less physiologically altering technique. The reader is directed to review euthanasia principles for fish as outlined by the American Veterinary Medical Association (AVMA) and by Yanong et al. (2009). Unacceptable methods of euthanasia include asphyxiation and hypothermia.

FIELD IMMOBILIZATION

Immobilization of fishes in the field is a fairly commonplace event. Considerations for immobilizing fish in remote areas include having portable equipment that can connect to car batteries or portable generators/batteries. It is important to consider guidelines for approved drugs (U.S. Fish and Wildlife Service, The Aquatic Animal Drug Approval Partnership 2010) and to observe withdrawal periods. Alternately, there are tags available that state “do not consume” that are affixed to the fish.

Typically for field procedures, unless invasive, animals are not anesthetized with chemicals. Hook and line, net, trawl, and electroanesthesia fishing are methods used to capture free-range fish, each technique carrying its own risk to the animal from hypoxia, trauma, exhaustion, and major physiologic disturbances. These must be considered for long-term management or survival of the animals.

When using source water, clarity must be considered as some water bodies may have turbid water, algal blooms, or high tannins. This can complicate visualization of induction or recovery in these animals. Temperature shifts throughout the course of the day will greatly modify temperatures in holding vats.

POSTANESTHETIC CHALLENGES

Once animals are placed into recovery water, ensuring adequate ventilation is critical. The authors prefer using an electronic pump to facilitate oxygenated water flow, but many aquarists prefer moving the animal through the water column (see previous section on this topic). Determining when to release the animal requires skilled staff that is aware of normal swimming behavior. Staff should be prepared to retrieve the animal if rather than swimming away it falls to the bottom of the water column (or if agressed upon). Observation of the animal for the next 24–48 hours is recommended for observing any morbidity or mortality associated with the procedure. As with all anesthetic procedures in animals, restraining a compromised animal with

either manual or chemical methods carries a risk for increased morbidity or mortality.

ACKNOWLEDGMENTS

Special thanks to Charlene Burns, Dr. M. Andrew Stamper, Jane Capobianco, DeAnne Fanta, and Dr. Beth Nolan from Walt Disney World, Orlando, FL, and Lynda Leppert from the Georgia Aquarium, Atlanta, GA for their assistance with chapter preparation.

16 Elasmobranchs and Holocephalans

Natalie D. Mylniczenko, Tonya M. Clauss, and M. Andrew Stamper

INTRODUCTION

The class Chondrichthyes is comprised of nearly 1200 extant species worldwide (Compagno 1999) belonging to two subclasses, Elasmobranchii and Holocephalii. They are probably the most successful of all fishes based on historical endurance in the fossil records (Grogan & Lund 2004). Elasmobranchs (sharks and batoids) represent 96% of the cartilaginous fishes, while the Holocephalans (chimeras and elephant fish) represent only 4% (Compagno 1999), and as such, elasmobranchs are the primary focus in this chapter. With so many different species and such variety of anatomical and physiological characteristics among them, immobilization and anesthesia can be challenging. Additionally, much of the information relied upon for anesthesia in cartilaginous fishes has been anecdotal.

Due to the variable and often inconsistent reactions to drugs intra- and interspecies, extrapolation of drug doses between species is often difficult and unpredictable. Growth of the aquatic animal medicine field has resulted in a greater breadth of clinical experience with teleost and elasmobranch fishes. This has led to some generalities that can be applied to facilitate safe and effective immobilization and anesthesia.

Various situations arise that require fish to be immobilized, including research and clinical procedures, as well as field activities. As mentioned in Chapter 15, however, the debate over the necessity for chemical immobilization and anesthesia in fish continues. Elasmobranchs do possess opioid receptors and receptor-like DNA sequences and cyclooxygenase. There is, however, histological evidence some axonal layers are missing from the spinal cords of some species. This suggests transmission of pain to the central nervous system is either limited, not possible or at the very least

different from pain transmission in “higher” animals (Davis et al. 2006; Rose 2002; Snow et al. 1993). Regardless of this neuroanatomical evidence, these animals (unless behaviorally conditioned) often respond negatively to even mildly invasive stimuli, such as injections. Decisions on whether to manually or chemically immobilize an animal should be based on the invasiveness of the procedures planned, the duration of time the animal will need to be immobilized, experience and capabilities of staff involved, and human and animal safety. When chemical immobilization is deemed necessary, determination of what drug or drug combination should be used depends on the level and duration of sedation or anesthesia desired, method and feasibility of delivery of the drug, and ability to safely support and monitor the animal through recovery.

ANATOMY AND PHYSIOLOGY

A full discussion of the anatomy and physiology of the cartilaginous fishes is outside the scope of this chapter, and has been well described in detail in other texts (Carrier et al. 2004, 2011; Hamlett 1999; Oetinger & Zorzi 1995; Smith et al. 2004). Some of their unique characteristics, however, should be taken into account when considering immobilization and anesthesia as they may have a direct impact on the outcome of a procedure. The stress response is one such factor.

As with teleost fish, elasmobranchs possess a functional hypothalamic-pituitary-interrenal (HPI) axis based on the presence of adrenocorticotrophic hormone (ACTH), which regulates interrenal production of 1 α -hydroxycorticosterone (1 α -OHB), a primary corticosteroid, which is produced only in elasmobranchs and which is currently difficult to study since there are no

available assays for its measurement (Anderson 2012; Idler & Truscott 1966, 1967, 1968, 1969; Truscott & Idler 1968, 1972). Comparatively, cortisol is not present in elasmobranchs, while it is the primary corticosteroid in teleost fish (Skomal & Bernal 2011). Corticosterone (CS) is also found in measurable concentrations in some elasmobranch species (Rasmussen & Crow 1993; Rasmussen & Gruber 1990, 1993; Snelson et al. 1997), but 1α -OHB has been shown to be the dominant hormone. It is likely that early reports of cortisol and CS levels were due to interference with the 1α -hydroxycorticosterone under certain assays (fluorimetric). CS assays are currently being used as an indirect measure of 1α -OHB. However, CS also shows elevations with the reproductive cycle. Interpretation of the results of CS assays must, therefore, take these effects into account (Anderson 2012; Skomal & Bernal 2011).

There are few studies of the role of the HPI axis in regulating the elasmobranch primary stress response. Catecholamines increase immediately after a stressor and peak after the cessation of the event (Randall & Perry 1992). Manire et al. (2007) found both a short and long-term CS response to capture and handling stress in bonnethead sharks (*Sphyrna tiburo*). These reports suggest a relationship between stress and the activity of the interrenal gland. The secondary stress response has been studied more than the primary response; receiving a lot of attention in the last several years (Adrian Van Rijn & Reina 2010; Frick & Reina 2009; Karsten & Rice 2004; Mandelman & Farrington 2007; Mandelmann & Skomal 2009; Marshall et al. 2012; Naples et al. 2012; Renshaw et al. 2012). This information can be very useful in assessing elasmobranchs, and clinical applications will be discussed later in this chapter.

Chemical immobilization and anesthesia can decrease the stress response associated with handling, as well as decrease the chance of injury to the people, animals, and equipment involved. An adequately anesthetized fish is easier to handle and manipulate, providing more diagnostic opportunities.

The response to a drug is dependent on many factors including drug receptor type and tissue distribution, method of administration, body temperature, hepatic biotransformation, blood distribution, renal function, and respiratory mechanism and function. These, among other factors, explain the frequent variation of drug effect seen in elasmobranchs both within and between species. Drug-binding sites are molecular locations on target tissues. The use of mammalian anesthetic drugs in elasmobranchs may result in several possible outcomes: (1) they may bind to the same active binding site and produce the desired effect; (2) there may be a chemically similar binding site, but one that triggers a different physiological function resulting in a completely different response; (3) there may be a

lower number of binding sites resulting in a weakened response or conversely, there may be more binding sites thus requiring more drug to fill these sites; (4) the binding site may be slightly different in anatomy resulting in the inability to bind; or (5) there may be no binding sites at all resulting in no effect. Drugs can also bind with blood proteins or other nontarget tissue, thus altering the amount of drug available and the effect on target tissue.

Drug administration in elasmobranchs may be via inhalation/immersion, injection (intravenous, intramuscular, and intracoelomic) or orally. Some drugs that produce a notable response when administered intravenously may produce little to no response when delivered intramuscularly or orally (Clauss et al. 2011; Mylniczenko, pers. exp.). Drugs delivered intramuscularly may produce variable responses dependent upon the injection site on the animal's body. As with some teleosts, sharks have red and white muscles (Fig. 16.1a). In most sharks, the red (myotomal) muscles are located more laterally along the body of the fish and are aerobic versus the more predominant anaerobic, white muscle. Injection into white muscle is most likely since it is the predominant anaerobic muscle type. Anesthetic injections in the red muscle may result in more rapid induction times as has been noted in some teleosts (Williams et al. 2004). Due to the variable density of vasculature associated with myotomal muscle bodies (Bernal et al. 2001; Bernal & Graham 2001; Totland et al. 1981), however, drug uptake can still be relatively unpredictable.

Active sharks (e.g., hammerhead [*Sphyrna mokkaran*] and blacktip [*Carcharhinus limbatus*]) have a higher percentage of myotomal muscles (up to 22%) than less active sharks (e.g., nurse shark [*Ginglymostoma cirratum*] and epaulette [*Hemiscyllium ocellatum*]) (Bone 1999). The even more active sharks from the Lamnidae (e.g., porbeagle [*Lamna nasus*], mako [*Isurus oxyrinchus*], white [*Carcharodon carcharias*]) family, and the common thresher shark from the Alopiidae family have a similar muscular plan, except that the myotomal framework is unique and similar to that of scombrid teleosts (e.g., tuna and mackerel). In these species, the red muscle is condensed into a solid piston-like muscle mass that is found closer to the vertebrae (Bernal et al. 2001; Carey et al. 1985; Graham & Dickson 2000, 2001; Graham et al. 1983; Sepulveda et al. 2005). In these highly active elasmobranchs, the vascular supply to this red muscle is through a set of lateral vessels that give rise to a counter-current heat exchange system (retia mirabilia). This allows conservation of metabolically derived heat, giving these sharks some endothermic abilities. The red muscle temperature may be elevated significantly above ambient (Bernal et al. 2003; Bone & Chubb 1983; Carey et al. 1971) and produce regional endothermy. Environmental temperature may have little to no impact on the metabolic rates of these endothermic sharks. Ambient

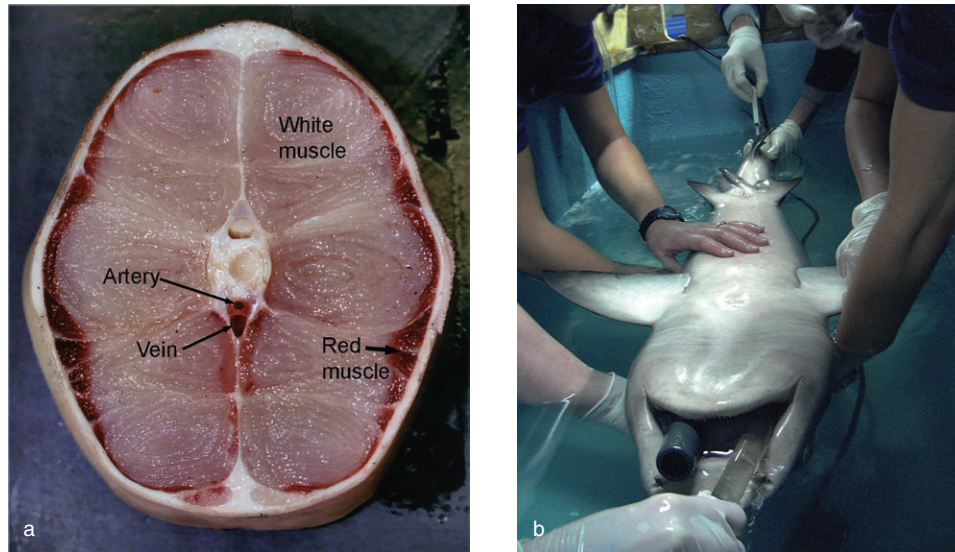

Figure 16.1. (a) Cross section of the tail of a blacktip reef shark (*Carcharhinus melanopterus*) demonstrating the more vascular or “red” muscle in comparison with the “white” muscle. Note the location of the artery and vein in comparison to the vertebral column. (b) Assisted ventilation in a sandbar shark (*Carcharhinus plumbeus*). There is a PVC tube in place to keep the mouth open. A continuous flow pump is used to direct oxygenated water over the gills. Water flow out of the gill slits determines appropriate positioning.

temperature, however, plays a major role in controlling the metabolic rates of the majority of elasmobranchs, which are ectothermic. Body temperature, therefore, must be considered as it impacts metabolic rates, determines enzyme activity, and may influence drug elimination and duration of effect.

In most studied animals, the liver metabolizes certain drugs to either active or inactive forms. Elasmobranch liver size and composition is species dependent, but is overall larger than other animals and more lipid rich. In the normal animal, it can account for up to 23% of body weight and as much as 80% may be lipid (Holmgren & Nilsson 1999). The pharmacodynamics of drugs are dependent, in part, on their lipophilic or lipophobic solubility, as well as the amount of hepatic cellular exposure. This adds an additional layer of complexity to drug metabolism in elasmobranchs. Unfortunately, there is very little pharmacokinetic data in elasmobranchs, especially with regard to anesthetics.

The kidney is very different to that of mammals, having a higher filtration rate and different selectivity (Lacy & Reale 1999). These differences may influence drug elimination rates. Like reptiles and other nonmammals, elasmobranchs have a renal-portal system that allows blood from the caudal half of the animal to drain directly into the kidneys. Historically, injections in the caudal half of the body were avoided in reptiles and fish as theory suggested the renal portal system may enhance the nephrotoxicity or influence renal excretion of drugs. Studies in reptiles, however, found no significant difference in drug metabolism when injections were given in the fore or hind limbs suggesting the renal portal system

has little, if any, negative influence on drug metabolism (Beck et al. 1995; Holz, 1999; Holz et al. 2002). Based on the studies in reptiles, it is unlikely the renal portal system poses a threat to drug action or metabolism in elasmobranchs.

The basic function of the respiratory system is the exchange of gases (oxygen, pH, and carbon dioxide). While simplistic in theory, elasmobranchs manage their metabolic exchange of these gases differently. The elasmobranchs can be classified into categories based on their methods of respiration: pelagic (open water), intermediary, and benthic. Examples of these include: (1) pelagic: black tip (*C. limbatus*) and blue shark (*Prionace glauca*); (2) intermediate: sand tiger shark (*Carcharhinus taurus*) and brown shark (*Carcharhinus plumbeus*); (3) benthic: Japanese wobbegong (*Orectolobus japonicus*) and the nurse shark (*G. cirratum*). Many pelagic elasmobranchs rely on ram ventilation, forcing water over their gills by swimming constantly. The nonpelagic animals are able to pump water over their gills and can rest on the bottom for extended periods of time. These animals tend to have a higher tolerance for lower oxygen environmental conditions (Mylniczenko et al. 2007). The nonpelagic animals can further be divided into intermediate or benthic respirators. Benthic animals are those that spend much of their active time on the sea bottom, while the intermediates swim more than they rest. The classifications are not strict. In general, benthic animals are able to buffer acidemia and/or manage hypoxemia more efficiently. This is critical because activity (such as capture) will significantly affect elasmobranch blood gases and physiologic

status. In general, there are few obligate ram ventilators in aquaria, but these animals need additional care during anesthesia and recovery to ensure adequate ventilation.

Most benthic sharks and batoids have an additional respiratory feature, the spiracle, located dorsally behind the eyes. This opening may serve as an alternate route for channeling water over the gills when the mouth of these elasmobranchs is in contact with the sediment or substrate. It is suggested that the spiracle function is voluntary to prevent sand entry into the gills (Butler 1999). During anesthesia, ventilation may occur either via the mouth or through the spiracles. The advantage to ventilation via the mouth is flow may easily be directed over both gill sets simultaneously (Fig. 16.1b). Specific modifications are necessary to achieve simultaneous flow over both gill sets when water is directed through the spiracles.

Other physiological or anatomical factors that may influence drug response include gill surface area to body weight ratio, lipid content, stress, health status, and body condition changes associated with age, season, sexual maturity, and nutrition. There are, therefore, many variables that need to be considered when anesthetizing elasmobranchs.

CAPTURE

Many elasmobranchs housed in public aquaria share large systems with mixed species. Catching these animals can be challenging and even dangerous to both the people and animals involved. Retrieving these animals may be done either by using behavioral conditioning, manually using a variety of techniques or with chemical immobilization. Regardless of the method used, minimizing distress and maintaining safety should be primary goals. Elasmobranchs are very responsive to behavioral conditioning and training techniques. The benefits of animal training programs include enrichment, better animal control and monitoring, reduced stress during handling, implementation of advanced husbandry techniques, enhanced education programs, and positive associations between animals and caretakers (Baker 1991). Operant conditioning is a process by which a subject produces a behavior in the presence of a cue on the condition of achieving desirable outcomes or avoiding undesirable consequences. A number of facilities have achieved impressive results through operant conditioning and behavioral modification (Fig. 16.2a,b).

Behaviors as seemingly simple as target training or station feeding can be invaluable. Staff from the International Zoological Applications at Parque Nizuc, Cancun, Mexico successfully trained a group of nurse sharks (*G. cirratum*), southern stingrays (*Dasyatis americana*) and chupare stingrays (*Himantura schmardae*) to do a number of advanced husbandry and veterinary

Figure 16.2. (a) A sandbar shark (*Carcharhinus plumbeus*) target feeding during a training session. (b) An eagle ray (*Aetobatus narinari*) targeting over a stretcher in a training session. (c) Behaviorally conditioning a manta ray (*Manta alfredi*) to swim into and through a stretcher (photo credit: Georgia Aquarium).

procedures, including shifting areas of the exhibit, stretcher training, and layouts for ultrasound examination (Sabalones et al. 2004). Animal care staff at the Georgia Aquarium, Atlanta, GA,, conditioned four manta rays (*Manta birostris*) to swim into and through

Figure 16.3. A partially deflated swimming pool in a larger medical pool used to corral a sandbar shark (*Carcharhinus plumbeus*) into a smaller area for anesthesia. The pool was measured for volume when fully inflated and in the water in order to provide accurate dosing with immersion anesthesia.

a stretcher to enable physical examinations and collection of morphometric data (Fig. 16.2c). Similarly, at the John G. Shedd Aquarium, Chicago, IL, sharks and sawfish were trained to swim into a deflated swimming pool (which is then inflated once the animal is captured) or into a chute/restraint device for induction of anesthesia (Fig. 16.3). Behavioral management in some of the larger elasmobranchs is arguably a necessity as manually catching and restraining can be difficult, if not impossible, and has the potential to cause significant stress and possible injury to the staff and animal(s).

When animals are not conditioned to present behaviorally for exams or other procedures, more invasive capture techniques must be used and may or may not involve administration of drugs. Staff at the Melbourne Aquarium in Melbourne, Australia routinely caught four adult broadnose sevengill (*Notorynchus cepedianus*) sharks out of the “Oceanarium” for ultrasound examination using a 300-cm, clear vinyl bag with Velcro® closures. The narrow end of the bag was covered with a nylon mesh to enable water flow to be directed at the head of the shark. Three divers operated the bag, one at the closed end and two at the entrance. A fourth diver guided the nonanesthetized shark into the bag. The bag and shark were then brought into a holding area for the procedures (Daly et al. 2007). A similar set-up is used at uShaka Marine World Durbin, South Africa for the capture of their animals. They utilize the device, however, only for sedated animals due to the species they regularly work with (Fig. 16.4a). At the Georgia Aquarium in Atlanta, Georgia, staff periodically catch unanesthetized large batoids (e.g., bowmouth (*Rhina ancylostoma*) (Fig. 16.4b) and giant guitar fish (*Rhynchobatus djiddensis*), sawfish (Fig. 16.4c–e),

and pink whiprays (*Himantura fai*) from a 6.4 million gallon exhibit using a large box net. The square PVC frame and attached knotless net is sunk to the exhibit floor. Divers in SCUBA corral the target animal over the net and people at the surface then haul the net up rapidly. The animal may then be restrained manually or chemically. Smaller sharks, such as bonnetheads and blacktips, may be caught via a hoop net when they approach a feeding station. Though this technique has proven successful much of the time, care should be taken not to over use this technique as the behavior of showing up to station for feeding may be broken if a negative event occurs frequently.

In some cases, a net draped across the width of a tank and pushed across the length of the enclosure can be used to both encourage animals into a medical pool and to limit the overall size of the area animals need to be captured in. This technique also allows the possibility to significantly reduce the depth of the area by bringing the bottom of the net to a more comfortable depth (Fig. 16.4f,g). Disadvantages include the amount of staff/divers required to execute a “catch up” as well as catching multiple animals and nontarget animals. Animals such as sawfish in these situations are difficult to manage and need to be excluded.

Drugs may also be used to assist in retrieving elasmobranchs from an exhibit or holding system. Immersion anesthetics are often impractical (but possible) due to tank size and presence of other animals. However, divers may spray very concentrated immersion agents such as tricaine methanesulfonate (MS-222) or eugenol directly over the gills of an animal to sedate it long enough to gain physical control. Injectable drugs may be delivered while the animal is swimming. This is usually done intramuscularly, but intravenous anesthetics have been delivered to a variety of rays and whale sharks by staff at the Okinawa Churaumi Aquarium in Okinawa, Japan (Yanagisawa, pers. comm., 2011) and to whale sharks at the Osaka Aquarium KAIYUKAN in Osaka, Japan (Ito, pers. comm., 2011). When dealing with the more active or aggressive animals, diligent care must be taken when administering drugs via pole syringe, nearby darting apparatus, and especially when hand injecting. Animals, when surprised, even if partially sedated, may turn around on a diver and inflict harm in their effort to ward off a threat. The speed of the animal and the trauma from their teeth or skin cannot be underestimated. Oral medications may also be delivered if the animal in question is target or station trained. Oral doses required to sedate elasmobranchs are often quite high and the amount of drug required may be volume limiting or cause the animal to regurgitate the food item it is delivered in. As with injectable agents, the response to oral anesthetics is often unpredictable. Anesthetics and sedation will be discussed in greater detail later in this chapter.

Figure 16.4. (a) A clear vinyl bag (a round hoop at the wide end and a narrower hole, to allow for water flow, at the distal portion of the bag) used to guide a shark into the bag for transport to the surface of the water and further restraint into a sling (photo credit: Gavin Drysdale, uShaka Marine World Durbin, South Africa). (b) Restraint of a bowmouth guitarfish (*Rhina ancylostoma*) in a partially submerged boxnet (photo credit: Georgia Aquarium). (c, d, and e) Retrieval of a largetooth sawfish (*Pristis microdon*) from an exhibit utilizing a boxnet. SCUBA divers corral the animal over the submerged net which is then quickly hoisted to the surface (photo credit: Marj Awai, Georgia Aquarium). (f) A metal bridge across an enclosure with a net (wall-to-wall) that extends to the depth of the tank. The bridge and net can move across the entire tank to isolate animals or push them from one end to the other. (g) The same net as in Figure 16.4b with an underwater view of divers maneuvering the net over coral heads in the enclosure's bottom.

PHYSICAL RESTRAINT

Tonic immobility (TI) or hypnosis is one form of physical restraint used in a variety of elasmobranchs. Tonic immobility is induced by placing an animal in dorsal recumbency. Though these animals, especially batoids, may go through a period of marked excitability during the initial catch and handling, once in this hypnotic state, they are subdued. The level of restraint and duration of effect is highly variable between species. This technique has been reported in a variety of elasmobranchs, including the clearnose skate (*Raja eglanteria*), cownose ray (*Rhinoptera bonasus*), southern stingray (*D. americana*), blacktip reef shark (*Carcharhinus melanopterus*), Caribbean reef shark (*Carcharhinus perezii*), leopard shark (*Triakis semifasciata*), swellshark (*Cephaloscyllium ventriosum*), whitetip reef shark (*Triaenodon obesus*), and shovelnose guitarfish (*Rhinobatos lentiginosus*). When immobilized with TI, the blood pressure and heart rate of *C. melanopterus* decreased significantly. Branchial irrigation improved blood pressure in these animals, but heart rate was unchanged (Davie et al. 1993; Henningsen 1994). This indicates a vagal nerve response with the ability to have physiologic shifts based on ventilator support. Some aquaria report that pinching the dorsal fin will have a calming effect on some species, akin to reptile ocular–vagal responses; however this is anecdotal and not recommended as a stand-alone method of restraint.

Manual restraint in species that do not experience TI or when it is unsuccessful can be challenging and induce stress responses in the animal. Even when not utilizing manual restraint for an entire procedure, it is often necessary at the onset of a chemical immobilization. In those cases, rapid restraint either by netting or by hand is recommended if it can be done safely. Pursuing animals for prolonged periods frequently results in rapid elevations of lactate and acidemia. Only experienced staff should be involved with manual restraint of elasmobranchs. Even some of the smallest species are extremely strong, thus increasing the chances of injury to people and animals. Some additional human safety factors to consider include (1) abrasions from the placoid scales in sharks, (2) sharp teeth, spines, or crushing plates in the oral cavity, (3) barbs on stingrays, and in some of the freshwater ray species, the surrounding epidermal bumps are venomous (Mylniczzenko 2010). To mitigate these issues, under dangerous situations, it is advisable to utilize baffles made of mesh and PVC or some other shielding device (Fig. 16.5), to wear appropriate gloves that prevent bite and crush injuries (e.g., Kevlar gloves), and in some circumstances, to wear suits that prevent bodily injury (e.g., chain mail suits specifically designed to work with dangerous aquatic animals). Ideally, in case of traumatic injury, there should also be an emergency diver evacuation plan in place and access

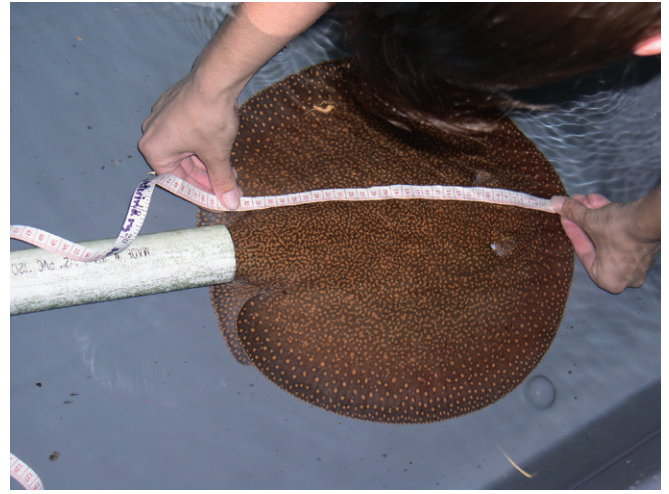

Figure 16.5. A PVC safety tube placed over the tail of a freshwater stingray (family Potamotrygonidae).

to first aid either by trained personnel or a nearby emergency response unit.

Chimaerids offer unique handling challenges in that they are soft-skinned and have ambient light restrictions (because they have an all-rod retina they must minimize the amount of light that enters the retina). These animals should be handled with soft mesh or plastic nets and corralled under water as they are very sensitive to net trauma. Ideally, procedures should be conducted in low light. They have a spine that precedes the first dorsal fin that contains weak venom, therefore staff should handle cautiously.

VASCULAR ACCESS

Access to elasmobranchs vasculature is often determined by the size and position of the animal rather than which vessel is most ideal. The largest blood vessel accessible with the animal in dorsal recumbency, in both sharks and rays, is the artery or vein that lies along the midline just ventral to the vertebral column (Fig. 16.1 and Fig. 16.6a). These vessels are located by placing the needle just posterior to the base of the trailing edge of the first or second anal fins in sharks or just caudal to the vent in rays. The needle is directed anteriorly at an angle of 30–90°, relative to the body, and inserted until the needle tip meets cartilage (approximately 4 cm for a 10 kg shark) to penetrate the vessel (Stoskopf et al. 1984). In large-bodied species and mature animals, needles may become plugged during penetration of the cartilage wall protecting the vessel. A spinal needle (with a removable stylet protecting the needle aperture) is used in these larger animals. However, longer needles may be difficult to place accurately on midline, therefore careful threading is necessary.

Figure 16.6. (a) Collection of blood from a ventral tail vessel in a whitetip reef shark (*Triaenodon obesus*). (b) Collection of blood from the dorsal sinus in a zebra shark (*Stegostoma fasciatum*). (c) Underwater collection of blood from the pectoral fin vasculature of a whale shark (*Rhincodon typus*) under behavioral control using a specialized feeding technique (photo credit: Georgia Aquarium). (d) Collection of blood from the wing vessel in an eagle ray (*Aetobatus narinari*).

There is a vascular plexus associated with the dorsal fins that is commonly referred to as the “dorsal sinus” (Fig. 16.6b). The first and second dorsal fins have this plexus and it can be found in most shark species as well as numerous batoids. It is a viable access port for blood collection as well as drug administration and is considered an access point to the secondary circulatory system. The reader is cautioned with interpretation of blood work from this site as it does have variations compared to the central vasculature system (Mylniczenko et al. 2006). Regardless, various species have been successfully anesthetized using this route.

The pectoral fin vasculature in large sharks, such as whale sharks, as well as wing vessels in rays, can be used for either blood collection or administration of intravenous drugs (Fig. 16.6c). The wing vessel in rays can be found by palpating the cartilaginous rays and then placing the needle in front of the cartilage, advancing the needle slowly with slight negative pressure in the syringe until a flash is obtained (Fig. 16.6d).

Catheterization of the ventral coccygeal vein or dorsal sinus is possible, but difficult to maintain. When successful, it permits medications to be given in a direct, consistent manner over a long period of time.

PREANESTHETIC CONSIDERATIONS

Ideally, preanesthetic assessment will include a thorough history of the fish, information on water quality conditions and husbandry practices, remote observation (preferably in the original habitat) and familiarization with any unique characteristics of the species or individual. Fish often present to the clinician when they are already systemically ill. This represents an anesthetic risk, particularly since the etiology will likely be unknown until an examination is conducted.

Determining if water quality conditions may be a contributing factor in a disease process is important, and evaluation prior to sedation can be helpful. If the fish has been transported to the clinician, the water quality variables of the transport vessel should be tested

as well. Observation of fish in their primary habitat or even in a transport or holding vessel is useful for assessing swim patterns, posture, general appearance and demeanor, as well as obtaining respiratory rates.

Even minimal handling can be stressful to healthy fish. A full clinical examination or blood work prior to anesthesia may, therefore, not be feasible or reasonable. The stress and potential trauma associated with manual restraint for diagnostics and morphometrics may be more risky than anesthetizing a fish without that information. When the body weight cannot be safely obtained prior to anesthesia, other methods exist for estimation, such as the length-to-weight ratio data exist for some species. When this information is not available, blind estimates may have to be made if oral or injectable anesthetics are used. However, this may greatly affect the quality and depth of the anesthesia. If this is the case, a weight and fork length should be taken and documented for future work.

As with most other animals, it is preferable fish be fasted prior to anesthesia so the anesthetic water and/or the procedure container are not fouled if regurgitation or elimination occurs. Caretakers should be instructed to bring additional water with them that may be used if the transport water is fouled and/or for recovery from anesthesia.

Once an animal is removed from its primary habitat, all actions associated with transport, handling, and anesthesia should be swift and precise to minimize the stress response. Ideally, a preanesthetic meeting is conducted to ensure animal and human safety by outlining the goals of the capture, procedure, and recovery process, as well as identifying the responsibilities for each person that is partaking in the event. Thorough preparation prior to an anesthetic procedure is essential in providing fish with the best opportunity for a full recovery.

CHEMICAL IMMOBILIZATION

The use of chemical restraint can provide a safer, less stressful procedure for the fish and staff involved. Minimization of movement and the ability to perform procedures with a fish out of the water often reduces handling time. Some diagnostic techniques and procedures cannot be adequately performed when animal movement occurs (e.g., magnetic resonance imaging, computed tomography, and standard radiography), and thus chemical immobilization is essential. The authors have compiled cited and anecdotal dosages of anesthetics used in various species of elasmobranchs (Table 16.1). Anesthetics may be delivered via inhalation, injection or per os.

Immersion (Inhalation) Anesthesia

Waterborne or immersion anesthesia is still the most widely used method for sedating or anesthetizing elas-

mobranchs and holocephalans. The chemical in aqueous solution is ventilated by the fish, passes into the blood via the gills, and is delivered to the central nervous system. An extensive discussion of immersion anesthetics, including delivery techniques, mechanisms of action, metabolism and clearance, as well as advantages and disadvantages, can be found in Chapter 15. The same principles used in boney fish also apply to elasmobranchs and holocephalans. Immersion anesthetics are most commonly administered with the fish submerged in a specified concentration of the drug. Depending on clinician preference, a higher concentration of a drug may be used to induce anesthesia, with a lower concentration being used to maintain the preferred plane of anesthesia. These chemicals have the advantage of being relatively safe to deliver, and the concentration can be modified by addition or dilution of the solution. One disadvantage of immersion medications is the large amount of drug needed when immobilizing animals in large bodies of water, such as those many captive elasmobranchs inhabit. As previously mentioned, some waterborne anesthetics may be delivered in high concentration via direct administration to the gills. Gilbert and Kritzler (1960) anesthetized large sharks and rays with MS-222 (1 g/L) delivered through a hand pump sprayer while animals were free swimming. Care must be taken with this approach, as some of these larger specimens are predatory and delivery requires the anesthetist to be in very close proximity to the mouth of the animal. An alternative that facilitates the use of immersion anesthetics is training or conditioning fish to shift into smaller bodies of water, such as secondary systems or smaller containers. An example of the latter is an inflatable pool submerged partially deflated in the main tank (Fig. 16.3). Air is then added to fully inflate the pool once the water is in the body of the pool. In large elasmobranchs, even after an animal is moved to a smaller container, the volume of drug needed for adequate immobilization can still be great. The technique of applying high concentrations of the anesthetic over the gills via the gill slits or through the spiracles, if present, can further reduce the volume of drug needed (Fig. 16.7a–c).

Tricaine Methanesulfonate (MS-222) This water-soluble, benzocaine derivative is used at a range of 50–150 mg/L to anesthetize both sharks and batoids (Larid & Oswald 1975). The concentration is varied with species and procedures performed. If delivering via a hand pump, even higher concentrations will likely be necessary for induction (1–2 g/L). One author (Stamper) has used up to 25 g/L. The drug is acidic and requires buffering. Sodium bicarbonate is the most commonly used buffering agent and is usually mixed at a ratio of two parts buffer to one part drug based on weight. Cavin and Innis (pers. comm.) have modified their protocols to an effective concentration of 5–6 g/L

Table 16.1. Anesthetic and immobilization drugs used in elasmobranchs

Species	Common Name	Drug	Dose or Dosage	Route of Administration	Body Wt (kg)	Population	Age Class	Water Temp (C°)	Comments	Reference
<i>Squalus acanthias</i>	Spiny dogfish	Hexobarbital	20 mg/kg	IV					Recovery of righting reflex—3 hours.	Adamson and Guarino (1972)
<i>Squalus acanthias</i>	Spiny dogfish	Sodium pentobarbital	20 mg/kg	IV					Recovery of righting reflex—6–8 hours.	Adamson and Guarino (1972)
<i>Squalus acanthias</i>	Spiny dogfish	Thiopental	20 mg/kg	IV					Recovery of righting reflex—3 hours.	Adamson and Guarino (1972)
<i>Carcharhinus plumbeus</i>	Sandbar shark (brown shark)	Dexmedetomidine + ketamine	0.03 mg/kg + 2 mg/kg	IM	21	0.1.0	3 years		Added saline to make a 1mL injection. Purpose of exam: mass removal.	Boylan, pers. comm.
<i>Carcharhinus plumbeus</i>	Sandbar shark (brown shark)	Dexmedetomidine + ketamine + midazolam	0.036 mg/kg + 7 mg/kg + 0.5 mg/kg	IM					Able to swim animal into a net	Boylan, pers. comm.
<i>Carcharhinus taurus</i>	Sand tiger shark	Medetomidine + diazepam + ketamine	0.5 mg + 7.5 mg + 50 mg	IM		1.0.0				Boylan, pers. comm.
<i>Carcharhinus taurus</i>	Sand tiger shark	Medetomidine + midazolam	0.5 mg + 7.5 mg	IM		1.0.0				Boylan, pers. comm.
<i>Ginglymostoma cirratum</i>	Nurse shark	Quinoline salts	0.075–0.1 mM	Immersion	4.0/21.0/4.5	1.2.0			Blood levels reached fairly constant value within 15 minutes	Brown et al. (1972)
<i>Negapion brevirostris</i>	Lemon shark	Quinoline salts	0.075–0.1 mM	Immersion	5.7 / 7.0	1.1.0			Blood levels reached fairly constant value within 15 minutes	Brown et al. (1972)
<i>Negapion brevirostris</i>	Lemon shark	Quinoline salts	0.15 mM	Immersion	5.7/7.0/4.1	3.0.0	young	26.5	Quickly produced anesthesia; drug enters brain rapidly	Brown et al. (1972)
<i>Squalus acanthias</i>	Spiny dogfish	Medetomidine + ketamine	200 µg/kg + 4 mg/kg	IM		0.0.15			Adequate for sedation, not for surgical anesthesia	Cavin et al. (2007)
<i>Squalus acanthias</i>	Spiny dogfish	Propofol	5 mg/kg	IV		0.0.15			Good for surgical anesthesia	Cavin et al. (2007)
<i>Carcharhinus taurus 1</i>	Sand tiger shark	Dexmedetomidine + ketamine	0.05 mg/kg + 10 mg/kg	IM		1.0			Induction. Used repeatedly (some dosage variation) with varied results, some recoveries rapid, some prolonged (days).	Cavin and Innis, pers. comm.
<i>Carcharhinus taurus 1</i>	Sand tiger shark	MS-222	90 mg/L	Immersion		1.0			Maintenance; plan to reduce to 70 mg/L MS-222	Cavin and Innis, pers. comm.
<i>Carcharhinus taurus 1</i>	Sand tiger shark	MS-222	12.5 g/L	Spray to gills		1.0			35 minutes after injection	Cavin and Innis, pers. comm.

<i>Carcharhinus taurus 2</i>	Sand tiger shark	Dexmedetomidine + ketamine	0.03 mg/kg + 3 mg/kg	IM	1.0	Induction for transport. Slightly reactive and ventilating well. Intermittent and prolonged periods of resting on the bottom. Technique performed underwater by divers, not sprayed directly onto the gills. This concentration is highly acidic; currently used at 5–6g/L buffered 4:1 with bicarb (20–24 g/L). Rapid induction within 11 minutes with minimal respiration	Cavin and Innis, pers. comm.
<i>Carcharhinus taurus 2</i>	Sand tiger shark	MS-222	12.5 g/L	Spray to gills	1.0	Maintenance (very short period of time)	Cavin and Innis, pers. comm.
<i>Carcharhinus taurus 3</i>	Sand tiger shark	Dexmedetomidine + ketamine	0.03 mg/kg + 3.3 mg/kg	IM	0.0.1	Rapid induction within 11 minutes with minimal respiration	Cavin and Innis, pers. comm.
<i>Carcharhinus taurus 3</i>	Sand tiger shark	MS-222	70 mg/L	Immersion	0.0.1	Maintenance (very short period of time)	Cavin and Innis, pers. comm.
<i>Carcharhinus taurus 4</i>	Sand tiger shark	Dexmedetomidine	0.03 mg/kg	IM	0.0.1	Good sedation—removed from tank after 20 minutes	Cavin and Innis, pers. comm.
<i>Carcharhinus taurus 5</i>	Sand tiger shark	Dexmedetomidine + Ketamine	0.03 mg/kg + 3.3 mg/kg	IM	0.1	Rapid induction within 11 minutes with minimal respiration	Cavin and Innis, pers. comm.
<i>Carcharhinus taurus 5</i>	Sand tiger shark	MS-222	70 mg/L	Immersion	0.1	Maintenance; increased to 90 mg/L due to mild arousal	Cavin and Innis, pers. comm.
<i>Carcharhinus taurus 6</i>	Sand tiger shark	Dexmedetomidine	0.03 mg/kg	IM	0.1	Good sedation—removed from tank after 20 minutes	Cavin and Innis, pers. comm.
<i>Carcharhinus taurus 6</i>	Sand tiger shark	MS-222	50 mg/L	Immersion	0.1	Transport bin	Cavin and Innis, pers. comm.
<i>Ginglymostoma cirratum 2</i>	Nurse shark	Dexmedetomidine	~0.03 mg/kg	IM	0.1	Induction; minimal sedation after 30 minutes	Cavin and Innis, pers. comm.
<i>Ginglymostoma cirratum 2</i>	Nurse shark	MS-222	25 g/L	Spray to gills	0.1	20 minutes of spraying (in tank) before sedated enough	Cavin and Innis, pers. comm.
<i>Ginglymostoma cirratum</i>	Nurse shark	MS-222	20 g/L	Spray to gills	0.1	5 minutes of spraying in stretcher	Cavin and Innis, pers. comm.
<i>Ginglymostoma cirratum 1</i>	Nurse shark	Dexmedetomidine + ketamine	0.05 mg/kg + ~9 mg/kg	IM	0.1	Induction	Cavin and Innis, pers. comm.
<i>Ginglymostoma cirratum 1</i>	Nurse shark	MS-222	90 mg/L	Immersion	0.1	Maintenance	Cavin and Innis, pers. comm.
<i>Trygonorrhina fasciata</i>	Fiddler ray	MS-222	90 mg/L	Immersion		Blood and morphometrics	Claus and Hatcher, pers. comm.

(Continued)

Table 16.1. (Continued)

Species	Common Name	Drug	Dose or Dosage	Route of Administration	Body Wt (kg)	Population	Age Class	Water Temp (C°)	Comments	Reference
<i>Pristis microdon</i>	Large-tooth sawfish	Propofol	2.0–3.0 mg/kg	IV dorsal sinus	64.7–112.5	4.1	adult		2–8 min initial effect; 45–63 min full recovery; good for animal moves, exam, debridement of wounds	Claus and Hatcher, pers. comm.
<i>Taeniura meyeni</i>	Blotched fantail ray	Propofol	3 mg/kg	IV	57	0.1	adult		Hook removal from esophagus; 2 min initial effects; top up with 1.5 mg/kg at 36 min due to increased GVR & resistance to manipulation; 88 min recovery	Claus and Hatcher, pers. comm.
<i>Carcharhinus melanopterus</i>	Blacktip reef shark	Propofol	3 mg/kg	IV dorsal sinus	17.5	0.1	adult		<1 min initial effect; 40–60 min swimming; endoscopy of uterus	Claus and Hatcher, pers. comm.
<i>Carcharhinus melanopterus</i>	Blacktip reef shark	Propofol	2.5 mg/kg	IV	22.6	0.1	adult		Pregnant; good plane at 4 min; 50 min swimming	Claus and Hatcher, pers. comm.
<i>Sphyrna tiburo</i>	Bonnethead shark	Propofol	4 mg/kg	IV dorsal sinus	1.4–4.65	1.3	adult		1–3 min initial effect; 48–64 min swimming	Claus and Hatcher, pers. comm.
<i>Carcharhinus taurus</i>	Sand tiger shark	Propofol	2.56–3.77 mg/kg	IV dorsal sinus	85–116.5	3.3	adult		4–6 min adequate plane; 2–4 hour swimming	Claus and Hatcher, pers. comm.
<i>Urogymnus asperrimus</i>	Porcupine ray	MS-222	80 mg/L	Immersion	89	0.1	adult		Ultrasound, blood, endoscopy	Claus and Hatcher, pers. comm.
<i>Notorynchus cepedianus</i>	Broadnose sevengill shark	None—dorsal recumbancy		Tonic immobilization		0.4.0	adult	17–22.5	10-minute ultrasonography exams	Daly et al. (2007)
<i>Dasyatis violacea</i>	Pelagic Stingray	MS-222	80–100 mg/L	Immersion	50		2–6 years	20		Ezcurra, pers. comm.
<i>Squatina californica</i>	Angel shark	MS-222	80–100 mg/L	Immersion				10–14		Ezcurra, pers. comm.
<i>Torpedo californica</i>	Pacific electric ray	MS-222	80–100 mg/L	Immersion	0.5 kg		Adult	10–14		Ezcurra, pers. comm.
<i>Rhinoptera bonasus</i>	Cownose stingray	Eugenol	25–75 mg/L in 50% ethanol	Immersion					Deep sedation not achieved at 25 mg/L. Recovery times longer than with MS-222	Grusha (2005)
<i>Aetobatus narinari</i>	Spotted eagle ray	Alphaxalone-alphadolone (Saffan)	0.35 mL/kg	IM	54	0.0.1			Achieved the deepest state within 1 hour with disorientation, slowed swimming, bumping into tank walls, net avoidance	Harvey et al. (1988)

<i>Carcharhinus limbatus</i>	Blacktip shark	Alphaxalone- alphadolone (Saffan)	0.4 mL/kg	IM	21	0.0.1	Harvey et al. (1988)	Achieved deepest state within 1 hour, partial loss of equilibrium, settling or rising to surface, allowed netting but still responsive to touch
<i>Dasyatis alta</i>	Brown stingray	Alphaxalone- alphadolone (Saffan)	0.2–0.3 mL/kg	IM	15	0.0.2	Harvey et al. (1988)	Deepest state within 1 hour: partial loss of equilibrium, settling or rising to surface, allowed netting but still responsive to touch
<i>Dasyatis alta</i>	Brown stingray	Alphaxalone- alphadolone (Saffan)	0.85 mL/kg	IM	18	0.0.1	Harvey et al. (1988)	Deepest state within 1 hour: disorientation, slowing of swimming, bumping into tank walls, net avoidance
<i>Raja binoculata</i>	Skate	Alphaxalone- alphadolone (Saffan)	0.25 mL/kg	IM	50	0.0.1	Harvey et al. (1988)	Deepest state within 1 hour: partial loss of equilibrium, settling or rising to surface, allowed netting but still responsive to touch
<i>Squalus acanthias</i>	Spiny dogfish	Alphaxalone- alphadolone (Saffan)	0.3–0.5 mL/kg	IM	3/2	0.0.2	Harvey et al. (1988)	Deepest state within 1 hour: disorientation, slowing of swimming, bumping into tank walls, net avoidance
<i>Squalus acanthias</i>	Spiny dogfish	Alphaxalone- alphadolone (Saffan)	1.5 mL/kg	IM	4	0.0.2	Harvey et al. (1988)	Deepest state within 1 hour: complete loss of equilibrium and cessation of swimming, no response to touch, marked depression of ventilation
<i>Squalus acanthias</i>	Spiny dogfish	Metomidate hydrochloride	30 mg/kg	IM	3	0.0.1	Harvey et al. (1988)	Deepest state within 1 hour: disorientation, slowing of swimming, bumping into tank walls, net avoidance
<i>Ginglymostoma cirratum</i>	Nurse shark	Medetomidine + ketamine	70–100 µg/kg + 8–10 mg/kg	IM			Kilbourn, pers. comm.	Poor to mild sedation; often ketamine was repeated at 5 mg/kg doses and medetomidine at 30 mcg/kg
<i>Hemiscyllium ocellatum</i>	Epaulette shark	Tiletamine + zolazepam	20 mg/kg	IM			Kilbourn, pers comm.	Allowed some manipulation (rolling over) but could not perform invasive procedures

(Continued)

Table 16.1. (Continued)

Species	Common Name	Drug	Dose or Dosage	Route of Administration	Body Wt (kg)	Population	Age Class	Water Temp (C°)	Comments	Reference
<i>Carcharhinus taurus</i>	Sand tiger shark	Medetomidine + butorphanol	0.1 mg/kg + 0.3 mg/kg	IM	160	1.0	Adult		Swimming more deeply in 4 minutes after injection. Able to guide shark for transport after 12 minutes. Sternal recumbancy and ideal for transport in 20 minutes. Sedated for radiographs	Larson, pers. comm.
<i>Chiloscyllium spp.</i>	Bamboo shark	2-Phenoxyethanol	0.02 ml/L	Immersion		0.0.1			Spontaneous gill movement ceased at 3 minutes, returned at 55 minutes. Spontaneous movement at 148 minutes, full recovery at 153 minutes.	Larson, pers. comm.
<i>Orectolobus japonicus</i>	Japanese wobbegong	Propofol	2.2 mg/kg	IV		0.0.1			Spontaneous gill movement ceased at 3 minutes, returned at 55 minutes. Spontaneous movement at 148 minutes, full recovery at 153 minutes.	Larson, pers. comm.
<i>Pristis microdon</i>	Largetooth sawfish	2-Phenoxyethanol	0.1–0.17 mL	Immersion		0.0.6			0.1 ml/L not adequate for transport; 0.0145 ml/L markedly sedate, full recovery 90 minutes later.	Larson, pers. comm.
<i>Raja erinacea</i>	Little skate	2-Phenoxyethanol	0.11 mL/L	Immersion		0.0.1			Deep sedation for minor surgical procedure. Excellent sedation, fast recovery.	Larson, pers. comm.
<i>Rhina ancylostoma</i>	Bowmouth guitarfish	Propofol	2.22 mg/kg	IV		0.0.1				Larson, pers. comm.
<i>Rhinoptera bonasus</i>	Cownose stingray	2-Phenoxyethanol	0.2 mL/L	Immersion		0.0.2			Sedated for ultrasound	Larson, pers. comm.
<i>Squalus acanthias</i>	Spiny dogfish	Azaperone	4 mg/kg	Spray on gills	1–5	10.11.0			Ideal for capture & confinement; still exhibit normal swimming	Latas (1987)
<i>Carcharhinus plumbeus</i>	Sandbar shark (brown shark)	Etomidate	40 mg + 40 mg 15 minutes later	IM	~45	1.0.0	20 years	23–27	Procedure for diagnostics; induced TI at 29 minutes	Lécu et al. (2011)
<i>Carcharhinus plumbeus</i>	Sandbar shark (brown shark)	Eugenol 99%/ethanol (1:8)	30 mg/L	Immersion	40	1.0.0	20 years	23–27	Hook removal; stage II at 5 minutes, stage III at 10 minutes	Lécu et al. (2011)
<i>Aetobatus narinari</i>	Spotted eagle ray	MS-222	75 mg/L	Immersion	14.5–82	0.0.6			Average to good sedation	Mylniczenko, pers. comm.

<i>Aetobatus narinari</i>	Spotted eagle ray	MS-222	40 mg/L	Immersion			Slightly light sedation	Myliczenko, pers comm.
<i>Aetobatus narinari</i>	Spotted eagle ray	MS-222	50 mg/L	Immersion	avg 2.2; 1@40	0.0.8	Good	Myliczenko, pers comm.
<i>Aetobatus narinari</i>	Spotted eagle ray	MS-222	60 mg/L	Immersion			Good to deep sedation	Myliczenko, pers comm.
<i>Carcharhinus acronotus</i>	Blacknose shark	Medetomidine + Ketamine	0.07–0.1 mg/kg + 5.5–8.8 mg/kg	IM	15-Oct		Variable effects but did not achieve more than light sedation without supplementation of the same drugs. One animal death.	Myliczenko, pers comm.
<i>Carcharhinus acronotus</i>	Blacknose shark	MS-222	150 mg/L	Immersion	6.9		Good	Myliczenko, pers comm.
<i>Carcharhinus falciformis</i>	Silky shark	MS-222	100 mg/L	Immersion	9.5		Fair	Myliczenko, pers comm.
<i>Carcharhinus plumbeus</i>	Sandbar shark (brown shark)	Medetomidine + Ketamine	0.1 to 0.12 mg/kg + 5–7 mg/kg	IM	26–65			Myliczenko, pers comm.
<i>Carcharhinus plumbeus</i>	Sandbar shark (brown shark)	MS-222	100 mg/L	Immersion	9.5		Good	Myliczenko, pers comm.
<i>Carcharhinus taurus</i>	Sand tiger shark	Medetomidine + Ketamine	0.1 mg/kg + 5–8 mg/kg	IM	110		Variable effects from very light sedation to heavy sedation.	Myliczenko, pers comm.
<i>Carcharhinus taurus</i>	Sand tiger shark	MS-222	85 mg/L	Immersion	avg 92		Good	Myliczenko, pers comm.
<i>Chiloscyllium spp.</i>	Bamboo shark	MS-222	60 mg/L	Immersion	0.17–2	0.0.4	Good	Myliczenko, pers comm.
<i>Chiloscyllium spp.</i>	Bamboo shark	MS-222	60 mg/L	Immersion	2.344		Good	Myliczenko, pers comm.
<i>Dasyatis americana</i>	Southern stingray	MS-222	50 mg/L	Immersion	11.7–28.48	0.0.7	Good	Myliczenko, pers comm.
<i>Dasyatis americana</i>	Southern stingray	MS-222	55 mg/L	Immersion		0.0.4	Average to good sedation	Myliczenko, pers comm.
<i>Dasyatis americana</i>	Southern stingray	MS-222	60 mg/L	Immersion	4.66–43.31	0.0.28	Good	Myliczenko, pers comm.
<i>Dasyatis americana</i>	Southern stingray	MS-222	70 mg/L	Immersion	13.1	0.0.3	Good	Myliczenko, pers comm.
<i>Dasyatis americana</i>	Southern stingray	MS-222	75 mg/L	Immersion	9.98–45.83		Good	Myliczenko, pers comm.
<i>Dasyatis americana</i>	Southern stingray	MS-222	80 mg/L	Immersion	5.29–25.8	0.0.3	Good	Myliczenko, pers comm.

Table 16.1. (Continued)

Species	Common Name	Drug	Dose or Dosage	Route of Administration	Body Wt (kg)	Population	Age Class	Water Temp (C°)	Comments	Reference
<i>Hemiscyllium ocellatum</i>	Epaullette shark	MS-222	75 mg/L	Immersion					Good	Mylniczenko, pers. comm.
<i>Rhinobatos spp.</i>	Guitarfish	MS-222	75 mg/L	Immersion	0.5–1.1	0.0.6			Good	Mylniczenko, pers. comm.
<i>Rhinoptera bonasus</i>	Cownose stingray	MS-222	50 mg/L	Immersion	2.39–21.9	0.0.12			Light to good	Mylniczenko, pers. comm.
<i>Rhinoptera bonasus</i>	Cownose stingray	MS-222	55 mg/L	Immersion	17.95	0.0.2			Slightly light	Mylniczenko, pers. comm.
<i>Rhinoptera bonasus</i>	Cownose stingray	MS-222	60 mg/L	Immersion	2.39–24.36	0.0.8			Consider higher dose for longer/invasive exam	Mylniczenko, pers. comm.
<i>Rhinoptera bonasus</i>	Cownose stingray	MS-222	65 mg/L	Immersion	10.11	0.0.2			Slightly light	Mylniczenko, pers. comm.
<i>Rhinoptera bonasus</i>	Cownose stingray	MS-222	70 mg/L	Immersion	2.39–24.36	0.0.13			Deep	Mylniczenko, pers. comm.
<i>Rhinoptera bonasus</i>	Cownose stingray	MS-222	75 mg/L	Immersion	2.2–10.05	0.0.10			Average to good	Mylniczenko, pers. comm.
<i>Rhinoptera bonasus</i>	Cownose stingray	MS-222	80 mg/L	Immersion	2.28 to 13.5	0.0.15			Recovery tends to be a bit slow, but otherwise normal	Mylniczenko, pers. comm.
<i>Rhinoptera bonasus</i>	Cownose stingray	MS-222	83 mg/L	Immersion					Good	Mylniczenko, pers. comm.
<i>Rhinoptera bonasus</i>	Cownose stingray	MS-222	85 mg/L	Immersion	4.3–20.9	0.0.10			Average to good	Mylniczenko, pers. comm.
<i>Rhinoptera bonasus</i>	Cownose stingray	MS-222	88 mg/L	Immersion					Good	Mylniczenko, pers. comm.
<i>Rhinoptera bonasus</i>	Cownose stingray	MS-222	90 mg/L	Immersion	4.3				Slightly light	Mylniczenko, pers. comm.
<i>Rhinoptera bonasus</i>	Cownose stingray	MS-222	93 mg/L	Immersion	4.3				Prolonged recovery; average good	Mylniczenko, pers. comm.
<i>Rhinoptera bonasus</i>	Cownose stingray	MS-222	95 mg/L	Immersion	avg 20				In recovery, breathing was slightly shallow and rapid	Mylniczenko, pers. comm.
<i>Rhinoptera bonasus</i>	Cownose stingray	MS-222	100 mg/L	Immersion	avg 8				Good to deep	Mylniczenko, pers. comm.

<i>Sphyrna tiburo</i>	Bonnethead shark	MS-222	50 mg/L	Immersion	0.9-3.4	0.0.16	Good; maintenance	Mylniczenko, pers. comm.
<i>Sphyrna tiburo</i>	Bonnethead shark	MS-222	100 mg/L	Immersion	0.9-3.4	0.0.16	Good; induction	Mylniczenko, pers. comm.
<i>Stegostoma fasciatum</i>	Zebra shark	MS-222	60 mg/L	Immersion	34.47		Good	Mylniczenko, pers. comm.
<i>Taeniuria lymna</i>	Blue spotted or ribbontail stingray	MS-222	50 mg/L	Immersion	2.05	0.0.3	Slightly light	Mylniczenko, pers. comm.
<i>Taeniuria lymna</i>	Blue spotted or ribbontail stingray	MS-222	60 mg/L	Immersion	avg 2.2		Slightly light	Mylniczenko, pers. comm.
<i>Taeniuria lymna</i>	Blue spotted or ribbontail stingray	MS-222	65 mg/L	Immersion	2.178		Good	Mylniczenko, pers. comm.
<i>Taeniuria lymna</i>	Blue spotted or ribbontail stingray	MS-222	70 mg/L	Immersion	1.2-2	0.0.2	Good to deep	Mylniczenko, pers. comm.
<i>Taeniuria lymna</i>	Blue spotted or ribbontail stingray	MS-222	50 mg/L	Immersion			Good	Mylniczenko, pers. comm.
<i>Taeniuria lymna</i>	Blue spotted or ribbontail stingray	MS-222	70 mg/L	Immersion			Good	Mylniczenko, pers. comm.
<i>Taeniuria lymna</i>	Blue spotted or ribbontail stingray	MS-222	60 mg/L	Immersion	0.129		Good	Mylniczenko, pers. comm.
<i>Triakis semifasciata</i>	Leopard shark	MS-222	60-65 mg/L	Immersion	5-8.86	0.0.4	Good	Mylniczenko, pers. comm.
<i>Urobatis halleri</i>	Haller's round ray	MS-222	60-70 mg/L	Immersion	0.3-1.2	0.0.2	Good	Mylniczenko, pers. comm.
<i>Urobatis halleri</i>	Haller's round ray	MS-222	60 mg/L	Immersion	0.875		Slightly light	Mylniczenko, pers. comm.

(Continued)

Table 16.1. (Continued)

Species	Common Name	Drug	Dose or Dosage	Route of Administration	Body Wt (kg)	Population	Age Class	Water Temp (C°)	Comments	Reference
<i>Urobatis jainacensis</i>	Yellow stingray	MS-222	50 mg/L	Immersion	0.914				Dose should be increased for more invasive procedures; average good	Mylniczenko, pers. comm.
<i>Urobatis jainacensis</i>	Yellow stingray	MS-222	60 mg/L	Immersion	0.87				Good	Mylniczenko, pers. comm.
<i>Urobatis jainacensis</i>	Yellow stingray	MS-222	65 mg/L	Immersion	1				Good to deep	Mylniczenko, pers. comm.
<i>Urobatis jainacensis</i>	Yellow stingray	MS-222	70 mg/L	Immersion	0.5-1	0.0.8			Good to deep	Mylniczenko, pers. comm.
<i>Carcharhinus taurus</i>	Sand tiger shark	Diazepam	0.1 mg/kg	IM			Adult		High individual variability. 20 minutes for induction, assessment by pulling the tail or dorsal fin. If not too active, place into a stretcher and into a transport container. If after about 30 minutes the animal is still too active, then inject about 20% more. We found the drug lasts for at least 5 hours.	McEwan, pers. comm.
<i>Ginglymostoma cirratum</i>	Nurse shark	Medetomidine + ketamine	75 µg/kg + 7.5 mg/kg	IM	20 kg		Juvenile			Mulican, pers. comm.
<i>Carcharhinus melanopterus</i>	Blacktip reef shark	Midazolam hydrochloride	0.05-0.1 mg/kg	IM					Used as a premedication administered immediately after netting appeared to decrease stress or hyperexcitability during induction followed by MS222 staged anesthesia.	Mylniczenko, pers. exp.
<i>Carcharhinus plumbeus</i>	Sandbar shark (brown shark)	Diazepam	1.2-1.6 mg/kg	PO						Mylniczenko, pers. exp.

<i>Carcharhinus plumbeus</i>	Sandbar shark (brown shark)	Midazolam hydrochloride	0.05–0.1 mg/kg	IM			Premedication administered immediately after netting as animals became larger and more difficult to handle to decrease stress during induction	Mylniczenko, pers. exp.
<i>Carcharhinus plumbeus</i>	Sandbar shark (brown shark)	MS-222	50–125 mg/L	Immersion		24–25.5	High dose induction around transport, then switched to a manageable transport for exam to the low dose. Usually 100 mg/L to 50 mg/L.	Mylniczenko, pers. exp.
<i>Chiloscyllium punctatum</i>	Brownbanded bamboo shark	Medetomidine + Midazolam hydrochloride + Butorphanol	0.1 mg/kg + 1 mg/kg + 1 mg/kg	IM + IV		Adult	No response from IM doses, IV dosages produced light sedation that allowed handling and minor procedures (transponder, blood draws, pin prick to evaluate).	Mylniczenko, pers. exp.
<i>Dasyatis americana</i>	Southern stingray	Guaifenesin	10–40 mg/kg	IV		Adult	Initial induction with MS-222, then increased sedation with increasing dosage of guaifenesin to stage 2; notable period of asystole at onset of injection with rapid return to normal rhythm.	Mylniczenko, pers. exp.
<i>Dasyatis americana</i>	Southern stingray	Isoeugenol	15–30 mg/L	Immersion		Adult	Habituated rays that are often handled needed the lower doses for good effect. These animals at 30 mg/L showed dramatic decreased ventilations, improved at lower doses.	Mylniczenko, pers. exp.
<i>Himantura granulata</i>	Mangrove whipray	MS-222	125 mg/L	Immersion		2.2		Mylniczenko, pers. exp. (Continued)

Table 16.1. (Continued)

Species	Common Name	Drug	Dose or Dosage	Route of Administration	Body Wt (kg)	Population	Age Class	Water Temp (C°)	Comments	Reference
<i>Hydrolagus collia</i>	Spotted raffish	MS-222	125 mg/L	Immersion		1.1			Induction	Mylniczenko, pers. exp.
<i>Hydrolagus collia</i>	Spotted raffish	MS-222	100 mg/L	Immersion		1.1			Maintenance	Mylniczenko, pers. exp.
<i>Potamotrygon castexi</i>	Vermiculate river stingray	MS-222	125 mg/L	Immersion		0.1				Mylniczenko, pers. exp.
<i>Potamotrygon menchacai</i>	Tiger ray	MS-222	125 mg/L	Immersion		4.1				Mylniczenko, pers. exp.
<i>Pristis zijsron</i>	Green sawfish	Diazepam	0.4 mg/kg	PO					Premedication 1 hour prior to any attempted handling because the animal was considered dangerous to handlers	Mylniczenko, pers. exp.
<i>Pristis zijsron</i>	Green sawfish	MS-222	125 mg/L	Immersion		0.1			Induction	Mylniczenko, pers. exp.
<i>Pristis zijsron</i>	Green sawfish	MS-222	100 mg/L	Immersion		0.1			Maintenance	Mylniczenko, pers. exp.
<i>Taeniura lymna</i>	Blue spotted or ribbontail stingray	Butorphanol	0.2 mg/kg	IM						Mylniczenko, pers. exp.
<i>Aetobatus narinari</i>	Spotted eagle ray	MS-222	125 mg/L	Immersion		2.2			Induction	Naples et al. (2012)
<i>Aetobatus narinari</i>	Spotted eagle ray	MS-222	100 mg/L	Immersion		2.2			Maintenance	Naples et al. (2012)
<i>Carcharhinus melanopterus</i>	Blacktip reef shark	MS-222	50–125 mg/L	Immersion				24–25.7	High dose induction around transport, then switched to a manageable transport for exam to the low dose. Usually 100 mg/L to 50 mg/L.	Naples et al. (2012)
<i>Carcharhinus melanopterus</i>	Blacktip reef shark	MS-222	125 mg/L	Immersion		15.3			Induction dose	Naples et al. (2012)
<i>Carcharhinus melanopterus</i>	Blacktip reef shark	MS-222	100 mg/L	Immersion		15.3			Maintenance dose	Naples et al. (2012)

<i>Carcharhinus plumbeus</i>	Sandbar shark (brown shark)	MS-222	100 mg/L	Immersion	3.3	Maintenance	Naples et al. (2012)
<i>Cephaloscyllium ventriosum</i>	Swell shark	MS-222	50–125 mg/L	Immersion	14	High dose induction around transport, then switched to a manageable transport for exam to the low dose. Usually 100 mg/L to 50 mg/L.	Naples et al. (2012)
<i>Cephaloscyllium ventriosum</i>	Swell shark	MS-222	125 mg/L	Immersion	1.1	Induction	Naples et al. (2012)
<i>Cephaloscyllium ventriosum</i>	Swell shark	MS-222	100 mg/L	Immersion	1.1	Maintenance	Naples et al. (2012)
<i>Chiloscyllium plagiosum</i>	White spotted bamboo shark	MS-222	125 mg/L	Immersion	6.7	Induction	Naples et al. (2012)
<i>Chiloscyllium plagiosum</i>	White spotted bamboo shark	MS-222	100 mg/L	Immersion	6.7	Maintenance	Naples et al. (2012)
<i>Heterodontus francisci</i>	Hornshark	MS-222	50–125 mg/L	Immersion	14	High dose induction around transport, then switched to a manageable transport for exam to the low dose. Usually 100 mg/L to 50 mg/L.	Naples et al. (2012)
<i>Heterodontus francisci</i>	Hornshark	MS-222	125 mg/L	Immersion	1.1.1	Induction	Naples et al. (2012)

<i>Chiloscyllium plagiosum</i>	White spotted bamboo shark	MS-222	50 mg/L	Immersion				25.0–26.68	Light anesthesia	Zimmerman et al. (2006)

Figure 16.7. (a) Target training a green sawfish (*Pristis zijsron*) to swim over a foldable restraint device. (b) The same animal, within the folded restraint device, now in the shape of a prism with the animal's head at the far end of the photo. Divers are administering high dose MS-222 over the gills of the animal through the device. (c) The same animal, fully anesthetized and pulled from the water, ready for examination.

MS-222 buffered 4:1 with sodium bicarbonate (20–24 g/L). When the same anesthetic water is used to anesthetize multiple animals, it is necessary to monitor the pH as shifts may occur. The authors recommend monitoring water quality or changing water after every third animal.

A direct linear relationship exists between MS-222 concentration and time to muscular relaxation (Dunn & Koester 1990). A wide variety of elasmobranch species will achieve a surgical plane of anesthesia (i.e., stage 3) using MS-222 (75–95 mg/L), but species-specific responses are common (Dunn & Koester 1990). Many sharks have been anesthetized using a low concentration (50 mg/L) as a “preanesthetic” dose followed by higher concentrations (≤ 85 mg/L) for maintenance (Davis, pers. comm. 2006). This “preanesthetic” concentration is reported to reduce the excitement phase and lower overall maintenance level of MS-222. Conversely, the authors prefer high dose induction (150 mg/L), especially in pelagic animals, with removal to a lower maintenance dose (50–75 mg/L). This regimen has resulted in rapid anesthesia, decreased excitement phase, better blood gas measurements, and better planes of anesthesia.

Gilbert and Wood (1957) describe a field technique of bringing large lemon sharks (*Negaprion brevirostris*)

up to the water surface with a hook and line and then applying a high concentration of MS-222 (1 g/L) with a pump hand sprayer. Effects were noted within 15 seconds, and the animals were anesthetized within 1 minute. It is recommended the patient's head remain out of water, and only buffered MS-222 be applied to the gills if utilizing this technique.

MS-222 excretion in the piked dogfish (*Squalus acanthias*) is primarily through the gills and is a function of cardiac output (Maren et al. 1968). Elimination of MS-222 into the water can result in a positive feedback of increasing anesthetic concentration if the heart slows, resulting in a possible overdose if the animals are not closely monitored. Utilizing a system, such as the drip system described in Chapter 15, whereby the drug is administered, and then discarded, can prevent an overdose problem. MS-222 anesthesia is the preferred anesthetic for holocephalans. In the authors' experience, 80–110 mg/L buffered MS-222 provides excellent anesthesia and good recovery.

Clove Oil (Eugenol), AQUI-S™/AQUI-S 20E™ (Isoeugenol) The active ingredient in clove oil is a phenolic compound, eugenol. It is commercially available and inexpensive. The active ingredient in AQUI-S™/AQUI-S

20E™ is isoeugenol. This anesthetic is commercially produced by Aqui-S New Zealand LTD and Aqui-S 20E is available in the United States under the INAD (Investigation New Animal Drug) program (Aquatactics Fish Health, Kirkland, WA).

The use of eugenol and isoeugenol is well established in teleosts (see Chapter 15), but controlled studies in elasmobranchs are limited. Clove oil (25–50 mg/L) was used to anesthetize epaulette sharks (*H. ocellatum*) and shovel nose rays (*Rhinobatus typus*) without complication (Grusha 2005). Grusha (2005) performed controlled studies with cownose rays (*R. bonasus*) using eugenol (25, 50, and 75 mg/L) dissolved in 50% ethanol, as well as MS-222 (100 mg/L). Effects were similar for all four treatment groups. The animals anesthetized with 25 mg/L eugenol, however, did not reach a plane of deep sedation. Recovery times were generally longer for the animals anesthetized with 50 and 75 mg/L eugenol compared with the rays anesthetized with MS-222. In a recent study with southern stingrays (*D. americana*) eugenol (20 mg/L), isoeugenol (15.7 mg/L), and MS-222 (55–65 mg/L) were compared. Induction-associated excitation was observed in all three groups, with a lower percentage observed with eugenol. Animals anesthetized with isoeugenol had a greater number of animals that didn't respond to stimuli. Cardiac rates were stable and similar for all regimens. Median time from placement in recovery water to release was 9 minutes for the MS-222 group and 12 minutes for both the eugenol and isoeugenol groups. Minor variations were noted, but overall, all the agents provided adequate anesthesia for short-term immobilizations and minor procedures (Neiffer et al. 2009). Similarly, one author (Mylniczenko, pers. exp.) has used this drug at doses from 15 to 30 mg/L. Higher doses produced hypoventilation and apnea in some animals, especially habituated or frequently anesthetized animals. Recoveries at higher dosages were also prolonged. Excitation seemed to be less or absent compared with MS-222 induction. Aqui-S foams the water, causing decreased patient visibility. There is a commercially available product designed to mitigate this issue (AQUI-S antifoam, Aquatactics Fish Health, Kirkland, WA). Lécu et al. (2011) anesthetized a male sandbar shark (*C. plumbeus*) with eugenol 99% and ethanol (1:8 respectively) at 30 mg/L for a laparotomy procedure to remove a hook from the coelom. Stage 2 anesthesia was reached in 5 minutes, and stage 3 anesthesia was reached within 10 minutes. The shark was maintained at 30 mg/L for 40 minutes and was then reduced to 15 mg/L for the remaining 46 minutes of anesthesia. The recovery period was prolonged, potentially due to the combination of tonic immobility and chemical immobilization, but consistent autonomous swimming resumed just over 3 hours after the procedure was concluded and the shark was returned to the main exhibit.

2-Phenoxyethanol (2-PE) 2-Phenoxyethanol, a glycol ether, is a clear or straw-colored oily liquid. It has a faintly aromatic odor and is moderately water soluble. 2-PE was used initially in aquaculture to treat ichthyophoniasis and other fungal, bacterial, and parasitic diseases. Less expensive than many anesthetics, 2-PE has been widely used for sedation, particularly in fish transportation, as well as general anesthesia (Hseu et al. 1996, 1997; Ross 2001). Another advantage is it causes no pH change when added to sea water (Hseu et al. 1995).

At uShaka Marine World in Durban, South Africa, 2-PE was mixed with tap water in plastic containers and poured directly into the water of two aquatic systems in an effort to translocate all of the teleost and elasmobranch fishes to new exhibits. Concentration increments of 0.05 mL/L were added every 30 minutes to the exhibit to a final concentration of 0.150 mL/L. Excitation events were recorded, and the fishes were removed according to their effective induction to anesthesia based on loss of equilibrium. No excitation was noted in the eight sand tiger sharks (*C. taurus*), but excitation was noted at 0.100 mL/L in the two Zambezi sharks (*C. leucas*). Members of both species were guided into stretchers at the first signs of anesthesia to prevent physical injury due to collision with walls or viewing windows. Anesthesia at 0.150 mL/L lasted 70 minutes in both species. All sharks recovered well (Vaughan et al. 2008).

According to Oswald (1978), 2-PE may cause hypoventilation, and it has poor analgesic properties. Sustained regular exposure can cause a neurophysiological syndrome in some individuals, thus staff handling 2-PE are advised to wear personal protective gear, such as gloves and masks (Hseu et al. 1995).

Metomidate and Etomidate Etomidate and metomidate are GABA agonists and provide a more rapid induction and recovery than MS-222. Etomidate is more effective in alkaline water and higher water temperature, but is not affected by total hardness. In adult sandbar sharks (*C. plumbeus*), 10 mg/L of either drug induced stage II anesthesia in approximately 2–4 minutes. This stage was characterized by an absence of response to positional changes, decreased respiratory rate to approximately normal, total loss of equilibrium, no righting response, decreased muscle tone, some response to strong tactile and vibrational stimuli, and adequate restraint for external sampling (e.g., gill biopsy). Increasing the dose to 20 mg/L reduced induction time to ≤ 1 minute, but anesthetic depth was more difficult to control. Although etomidate is considerably more potent than metomidate in freshwater teleosts, this difference was not observed in sandbar sharks. Recovery from stage II plane 2 took approximately 3–5 minutes for metomidate. Recovery from deeper planes

was considerably prolonged (>1 hour), possibly due to decreased cardiac output (Stoskopf 1986).

Halothane/Oxygen/Nitrous Oxide Halothane (2-bromo-2-chloro-1,1,1-trifluoroethane) is an inhalation anesthetic typically used in air breathing animals, including previous use in humans. Dunn and Koester (1990) used halothane (1.5% for induction, then 0.5–0.8% for maintenance) in nitrous oxide (100–200 mL/min) and oxygen (200–300 mL/min) for anesthesia of guitarfish (*Rhinobatas* sp.) and skates (*Raja* sp.). A precision vaporizer was used to add halothane to a mixture of nitrous oxide and oxygen which was then introduced into the water through an aerator. This combination provides easy control of anesthetic depth, shorter recovery and a very high survival rate. A major disadvantage is contamination of the working environment room with halothane and nitrous oxide. Isoflurane (1-chloro-2,2,2-trifluoroethyl difluoromethyl ether) and sevoflurane (fluoromethyl 2,2,2-trifluoro-1-(trifluoromethyl) ethyl ether) can be used in the same manner. The advantages and disadvantages of isoflurane and sevoflurane are similar to those noted for halothane and, hence, use of anesthetics requiring gas vaporizers is not common practice in fish medicine.

Oxygen The use of oxygen for sedation (hyperoxia or hyperoxygenation) is common practice in aquaria, but its use is largely anecdotal with scant available references. This oxygen narcosis is used for transport or minor procedures. Hyperoxygenated (>100%, usually 120–180%) water is flushed across the gills via a power head or ventilation system. Reported signs of oxygen sedation include depressed respiratory effort, behavioral changes, and in some cases, loss of equilibrium (Stamper, pers. exp.). Since the oxygen is not provided under pressure, “gas bubble disease” does not occur.

Prolonged exposure to elevated oxygen will depress ventilation and produce hypercapnia (likely the cause of narocosis) and potentially life-threatening acidemia (Spotte 1992). The use of oxygen narcosis for immobilization, therefore, should be limited in duration, and monitoring of blood gas variables is recommended. Hyperoxygenation, even in short bursts, can also result in elevated plasma cortisol levels (Sundh et al. 2009). Chronic exposure in fish also increased permeability of cell membranes and pathogen susceptibility (Sundh et al. 2009). Oxygen toxicity, when administration of oxygen levels exceeds biotransformation and clearance, can occur (Manning 2002). Consequently, the positive and negative aspects of hyperoxygenation must be considered in balance.

Injectable Anesthesia

Injectable anesthetics are an alternative when waterborne anesthesia is impractical due to large water volume, or as mentioned previously, when sedation is

Figure 16.8. An underwater dart system with laser apparatus (AQUADART, Harvey et al. 1988).

necessary to safely capture animals from primary exhibits. The popularity of injectable anesthesia has grown as more controlled studies offer clinicians a better understanding of the effects the drugs may have on various species. Intramuscular (IM) delivery is the most common, however, intravenous (IV) and intracoelomic (ICe) administration are used in some situations.

Delivery IM is typically achieved by hand injection, pole syringe, Hawaiian sling (Chapter 15), or remotely through either an underwater laser aimed dart gun (Fig. 16.8), (AQUADART, Harvey et al. 1988) or other similar remote injection devices.

A newer “homemade setup” is described for immobilizing large fishes and may prove useful for large elasmobranchs as well (Garcia-Parrage et al. 2007). When setting up a dart on a pole or extension, an air-charged dart as used in zoo practice (Chapter 11) is placed against a barrier at the caudal end. This is then attached to a sturdy pole (Chapter 15). Whether an animal is free swimming or manually restrained, IM injections should be delivered quickly, ensuring reduced contact or handling time. This in turn reduces the chance of injury to the animal and people involved. The safety precautions taken when injecting free swimming animals are described earlier. Challenges of underwater darting include judgment of distance, refraction from the facemask (making targeting less accurate), and getting a full discharge of darts under water (reduces gas pressure in the dart) is less reliable than on land. Increased water depth markedly changes these parameters. With the earlier-mentioned laser aimed dart gun these issues are reduced. The cost and availability of this unit, however, make it impractical for use (Harvey, pers. comm., 2012).

As mentioned previously, many sharks have both red and white muscle (Fig. 16.1). The red, oxidative myotomal muscles usually comprise less than 10% of the body mass and consist of relatively small, well-vascularized, myoglobin-rich fibers. White myotomal muscles comprise approximately 50% of body mass and consist of less vascularized, myoglobin poor fibers. In fishes, other than the scombrids, lamnid sharks, and the common thresher shark, the red muscle usually occurs as a relatively thin layer directly beneath the

Figure 16.9. Intramuscular injection into the dorsal saddle just ventrolateral to the first dorsal fin in a giant guitarfish (*Rhynchobatus djiddensis*) (photo credit: Georgia Aquarium.)

skin, gradually becoming more abundant in the posterior regions of the body (Greer-Walker & Pull 1975). Injection into different muscles will theoretically affect drug absorption. Some of the variability in response to IM drugs within a species may be due to this anatomical variation in blood supply.

The recommended site for IM injection is the dorsal saddle (Fig. 16.9). This area surrounds the first dorsal fin and extends laterally to just above the lateral line, from the posterior gill slit caudal to a point halfway between the first and second dorsal fins (Stoskopf et al. 1984). The protective denticles and epidermis make needle penetration of the integument difficult and often require the use of a heavy needle (20–22 gauge in small species, 16–18 gauge in larger species) for IM injections. Unfortunately, shark skin does not have a great degree of contractibility and muscle is at a positive resting potential. Injection site leakage is, therefore, a problem in many injections (Stamper, pers. exp.). To minimize leakage, it is recommended the needle be angled either anteriorly or posteriorly, depositing the drug away from the injection site. If remotely injected darts are used to administer a drug, the dart should be left in the animal until it has become sedated, thus preventing drug leakage. Barbed or collared needles can be used, but they result in more skin/muscle trauma. Additionally, if the animal is not sedated sufficiently it may remain in the skin/muscle for a long period of time. In some situations, bone wax (mix of beeswax and isopropyl palmitate), Ilex[®] skin protectant paste, or other water-insoluble substances may be used to cover or plug the injection site when the needle is removed. In rays, the volume of drug to be administered must be considered as the musculature and cartilaginous rays prevent retention of high volumes. In one of the authors experience (Stamper), higher

volumes resulted in slow absorption or increased leakage of drug. This can be mitigated by using dyes to detect leakage.

Skeletomuscular movement helps blood and lymph circulate (Gruber & Keyes 1981) and has a direct impact on IM drugs, which may not be adequately absorbed in sedentary animals. Anesthetic induction time may be erratic or delayed in these animals, and injection of large volumes of drugs may form a sterile abscess (Tyler & Hawkins 1981).

Intravenous injection is the most reliable anesthetic delivery route, providing more rapid induction and often a shorter duration of effect. Locations for vascular access are described above. Walker (1972) calculated a circulation time of 1–2 minutes for indigo cyanine green injected in the caudal tail vein of nurse sharks (*G. cirratus*). Slow circulation in elasmobranchs may delay the onset of effect of an IV drug when compared with onset times of other classes of animals. The main disadvantage with IV administration is most animals must be appropriately restrained for drug delivery. Some exceptions were previously described in which a diver swims next to an animal while administering a drug via the vasculature associated with the dorsal or pectoral fins.

ICe (into the body cavity) injection is an additional option. It requires drugs to pass through the serosal membranes of the coelomic cavity organs, making anesthetic induction time erratic. Needle insertion at an acute angle directed anteriorly to the pelvic girdle on the right side of the abdominal wall minimizes the possibility of puncturing any internal organs, particularly the liver, which is easily damaged. In addition to unpredictable induction times and the possibility of organ puncture, other disadvantages of ICe administration include risk of peritonitis, as well as the need to place an animal in dorsal recumbency to administer the injection.

Injectable Anesthetics

No published reports were found on batoid injectable anesthesia; however, recent procedures using a combination of midazolam, medetomidine, and butorphanol were successful in producing sedation adequate for minimally invasive procedures (Neiffer, pers. comm. 2011). The protocol included initial immersion in isoeugenol (15.7 ppm), followed by midazolam (0.2–0.3 mg/kg IV), medetomidine (0.035–0.05 mg/kg IV), and butorphanol (0.2–0.3 mg/kg IV), and immediate transfer to isoeugenol-free saltwater for the remainder of the anesthetic event. Recovery was complete after administration of reversal with flumazenil (0.01 mg/kg IV), atipamezole (0.228 mg/kg IV), and naltrexone (0.280 mg/kg IV).

Acepromazine Intrasinus administration of acepromazine (0.5 and 4 mg/kg), a phenothiazine derivative, in *S. tiburo* resulted in no clinical responses (Clauss, pers. exp.).

Alfaxalone-Alfadolone Alfaxalone-alfadolone (Alfathesin[®]) is a steroid anesthetic (no longer marketed in the United States) that had been used in the piked dogfish (1.5 mL/kg), the brown ray (*Raja miraletus*) (0.2–0.3 mL/kg), the skate (*Dipturus batis*) (0.2 mL/kg), the blacktip shark (*C. limbatus*) (0.4 mL/kg), and the spotted eagle ray (*Aetobatus narinari*) (0.3 mL/kg) (Harvey et al. 1988). The anesthetic response was highly variable from minimal effect in the eagle ray to immobilization in the dogfish.

Azaperone Azaperone, a butyrophenone, reduces response to environmental stimuli without motor impairment or sedation. Preliminary studies in piked dogfish (*Squalus acanthias*) showed the most efficacious application of azaperone is directly over the gills rather than by injection. No effect was noted when animals were injected with the drug IM. However, an effect was observed when the drug (4 mg/kg) was deposited on the gill filaments and the animal held out of water for several seconds (Latas 1987). At 4 hours, drugged animals, compared with control animals, showed no flight response. Blood glucose levels were unaffected. Tranquilized animals were more likely to feed compared with control animals that exhibited several days of anorexia after blood collection. They were capable of negotiating tank walls and returned to normal behavior within 24 hours. The advantages of using azaperone include uninterrupted swimming patterns, normal gill ventilation, and normal cardiovascular function (Latas 1987).

When administered intraspinally to *S. tiburo*, a range of responses were seen. These include variable induction times (10–40 minutes), ability to handle animals, and highly varied recovery times. At the higher dosages, bottom settling was noted as well as a slow, coordinated swim pattern with obstacle avoidance. If given IM, there were no responses at 12 mg/kg, but higher dosages were not tried (volume limiting) (Clauss, pers. exp.).

Carfentanil Citrate Carfentanil citrate, an ultrapotent opioid, failed to achieve any effect in a nurse (*G. cirratum*) and a lemon shark (*Negaprion brevirostris*) at a dosage of 0.25 mg/kg (normal hoofstock dosages are 1–6 µg/kg) (Stoskopf 1986, 1993). This seems unusual as sharks do possess µ opioid-like receptors and peptides (Li et al. 1986; Lorenz et al. 1986). It is conceivable that as with amphibians (Wright & Whitaker 2001), the amount of receptors binding requires much higher amounts than those published in other animals.

Chloral Hydrate Chloral hydrate is a hypnotic sedative whose mechanism of action is not well understood. When given intraspinally to bonnethead sharks (*Sphyrna tiburo*) at 60–80 mg/kg, reactions were variable from intermittent uncoordination with little obstacle avoidance to settling on the bottom and tolerance of han-

dling. Additionally, the drug caused minor skin reaction at the injection site (Clauss, pers. exp.).

Detomidine Hydrochloride Dormosedan[®] (detomidine hydrochloride) is an α₂ agonist. Two trials using relatively high amounts of detomidine (115 µg/kg IM)/ketamine (4.5 mg/kg IM) in a single bull shark (*Carcharhinus leucas*) showed little effect (Clauss, pers. exp.). Atipamezole was given in equal volumes to the detomidine (5× times the microgram dose) for reversal.

Dexmedetomidine This α₂ agonist is gaining more popularity since medetomidine can now only be purchased at compounding pharmacies in concentrated form. It has been used in *C. plumbeus*, *C. taurus*, and *G. cirratum* at dosages of 0.03 mg/kg alone and in combination with ketamine. See also the comments on medetomidine and ketamine combinations and their side effects.

Diazepam Diazepam in sand tiger sharks, *C. taurus* (0.1 mg/kg IM) provided satisfactory sedation in one institution, but more research is indicated to define dosages (McEwan, pers. comm., 2011). The authors feel diazepam does not provide sufficient sedation despite use at multiple dosages.

Etomidate Etomidate (0.4–1.3 mg/kg IM) has been used as an induction agent for *C. taurus* and *C. plumbeus* by either darting or by pole syringe. The higher dosages resulted in more rapid induction. The drug formulation is very thick and can result in leakage from the injection site. Anesthetic effects were noted as variable, but resulted in animals that would allow manual restraint and tonic immobility. Ultrasound assessment of these animals noted no cardiac effects (Lecu, pers. comm., 2012).

Guaifenesin The mechanism of guaifenesin is unknown but is believed to depress or block nerve impulse transmission and has sedative qualities. It is commonly used for continuous rate infusions in hoofstock species to maintain muscle relaxation and offer rapid recoveries. Guaifenesin IV was used in *D. americana* after 5–10 minute induction in buffered MS222 (50 ppm), which was enough to allow turning the animal over for IV administration of the drug (Mylniczenko, pers. exp.). The drug was given as a bolus at dosages of 10–40 mg/kg to observe effects in hopes of identifying a continuous rate infusion dose for longer procedures. At the low dosages, this drug provided very little sedative effect and only showed sedation (stage 2) at the higher dosages, with rapid recoveries at all dosages. The only negative effect was a brief cessation of cardiac rhythm, asystole (identified by continual observance via ultrasound), which rapidly returned to a normal rhythm. One other institution has used the drug (20 mg/kg) in a bowmouth guitarfish (*Rhina ancylostoma*) for treatment of a suspected muscular condition and showed

minor sedative effects as well (Naples, pers. comm., 2011).

Haloperidol Haloperidol lactate is a neuroleptic butyrophenone used as a tranquilizer in mammals. It is used to facilitate transports of flighty animals and to decrease stress. Its calming effects make it a possible desirable drug for elasmobranchs. During trials in bonnethead sharks (*Sphyrna tiburo*), using the lactate form (2–10 mg/kg) intrasinus, only one animal out of five showed a response (incoordination and hyperexcitability) at the higher dosage. There was also considerable skin reaction to the drug. In general, haloperidol was not considered successful for sedation or adequate tranquilization at the dosages tested (Clauss, pers. exp.). The use of haloperidol decanoate has not been documented in elasmobranchs.

Ketamine Hydrochloride Ketamine hydrochloride is an analgesic and cataleptic cyclohexamine. Ketamine provides good peripheral analgesia (pain relief) in mammals through suppression of dorsal horn cell activity in the spinal cord, but provides little visceral analgesia. Seizure-like muscle spasms due to spinal reflex firing are occasionally noted in elasmobranchs (Stoskopf 1993). For these reasons, it is preferably used in combinations with other anesthetics, but has been used alone at very high dosages (50–80 mg/kg). Recovery is often prolonged and animals are disoriented for long periods of time (another reason to use in combination with reversible anesthetics).

Medetomidine Medetomidine has been used in combination with ketamine in several shark species, including sand tiger shark (*C. taurus*), blacknose shark (*Carcharhinus acronotus*), sandbar shark (*C. plumbeus*), and nurse shark (*G. cirratum*) to ameliorate muscle spasms that can occur with ketamine alone (Snyder et al. 1998; Tuttle & Dunn 2003). See medetomidine/ketamine combinations for effects. Atipamezole is used as the reversal agent at standard mammalian dosages.

Midazolam As a benzodiazepine receptor agonist, midazolam can result in sedation and anxiolytic activity. When used at dosages of 1–5 mg/kg IM as a sole agent in *S. tiburo*, *C. melanopterus*, and *C. plagiosum* the authors have not found the drug to be useful. However, when used in combination with other drugs, induction times do seem to decrease as does the physical excitement phase (Mylniczenko, pers. exp.). When administered intrasinus in *S. tiburo*, there was notable hyperexcitability and ataxia at 4–5 mg/kg in two animals, while at 8 mg/kg death occurred in one animal (Clauss, pers. exp.).

Propofol Propofol is a sedative-hypnotic (Miller 2001; Mitchell et al. 2001) and has been administered at 2.5 mg/kg IV over 30 seconds to spotted bamboo sharks

(*Chiloscyllium plagiosum*), achieving a surgical anesthetic level by 5 minutes. Righting response returned within 60 and 75 minutes in four and two of the sharks, respectively. Respiration and heart rates remained stable throughout the anesthetic period. Using the drug at 1–2 mg/kg IV in *C. plagiosum*, *D. americana*, and *O. japonicas*, inductions were very smooth and provided long sedations, but recoveries were prolonged (>30 minutes) (Mylniczenko, pers. exp.). When used intrasinus in *S. tiburo*, at 2.5 mg/kg, slight incoordination was noted but no anesthesia. At 5 mg/kg, however, induction was rapid, a surgical plane of anesthesia was achieved, and marked respiratory suppression occurred with return to gilling >35 minutes post induction. The animals returned to swimming >65 minutes after induction, which is not practical for ram ventilators (Clauss, pers. exp.). In the spiny dogfish (*S. acanthias*), a minimum of 5 mg/kg IV was necessary to achieve a surgical stage of anesthesia (Cavin et al. 2007). With *C. limbatus*, 2.5–3.0 mg/kg delivered intrasinus resulted in rapid induction (<1 minute) and a surgical plane of anesthesia with persistent shallow, irregular spontaneous ventilation. Sharks returned to normal gilling 35–45 minutes post induction and normal swimming in 55–75 minutes (Clauss, pers. exp.).

Sodium Pentobarbital Sodium pentobarbital (10 mg/kg) produced satisfactory general surgical anesthesia in nurse sharks (*Ginglymosoma cirratum*) when administered rapidly IV (Walker 1972). Slow injection resulted in an erratic response. Intraperitoneal absorption was slow and response was variable, while IM injection resulted in only slightly improved response. Serum half-life was approximately 15 seconds with a second half-life of several days, due to an inability of the animals to excrete the drug through their gills or kidneys. An anesthetic IV dose (10 mg/kg) resulted in loss of ventilatory movements (gilling) within 1 minute. Gilling returned after 10 minutes and a weak righting response was observed at 3 hours. A higher IV dose (20 mg/kg) resulted in a rapid loss of gilling that did not return by 3 hours. A weak righting response was only observed after 5 hours. A high IV dose (60 mg/kg) resulted in death. Larger, more active sharks require smaller doses per kilogram than smaller, sedentary specimens. For example, sandbar and bull sharks (6 mg/kg IV) responded similarly to the nurse shark (10 mg/kg IV) (Walker 1972).

Tiletamine/Zolazepam Tiletamine/zolazepam (12 mg/kg) administered to a lemon (*Negaprion brevirostris*) and a sand tiger (*C. taurus*) shark produced irritability, rapid swimming, and unrestrained biting (Stoskopf 1986, 1993). Dosages of 5–20 mg/kg IM in *C. plagiosum* showed very little response even at the high dosage (some animals allowed being turned over for a few seconds) (Kilborne, unpubl. data, 1999).

Xylazine Xylazine in bony fish (teleosts) is a convulsant and causes major changes in the electrocardiogram (Oswald 1978). Used in combination with ketamine (12 mg/kg), xylazine (6 mg/kg) in sand tiger shark (*C. taurus*), lemon shark (*Negaprion brevirostris*), sandbar shark (*C. plumbeus*), and nurse shark (*Ginglymosoma cirratum*) variably ameliorated the muscle spasms that can occur with ketamine alone (Stoskopf 1993). Yohimbine hydrochloride administered IV to a nurse shark immobilized with xylazine/ketamine caused arousal (Stoskopf 1986).

Injectable Anesthetic Combinations

Several drug combinations have been or are currently being investigated for immobilization or anesthesia of elasmobranchs. Stoskopf (1986) showed xylazine (6 mg/kg) and ketamine (12 mg/kg) satisfactorily immobilized (between stage I and III) sand tiger (*C. taurus*) ($n = 4$), lemon (*N. brevirostris*) ($n = 4$), sandbar (*C. plumbeus*) ($n = 9$), and nurse sharks (*G. cirratum*) ($n = 5$). Andrews and Jones (1990) also found xylazine (7.5 mg/kg) and ketamine (16.5 mg/kg) produced light anesthesia adequate for the safe transport of adult sandbar sharks (*C. plumbeus*).

One popular combination is IM medetomidine and ketamine at varying dosages (see Table 16.1). General dosages range from 90–100 µg/kg medetomidine and 4–5 mg/kg ketamine. Usually initial effects take 20–40 minutes, but results can be erratic. These effects vary from complete anesthesia with recumbency (some within 5 min), animals showing partial signs with no recumbency (despite additional dosing), and animals showing almost no sedative effects. There also appears to be a great variation between species in their responses to similar dosages under the same conditions. Additionally, recoveries are highly variable, with reports of immediate recoveries to some deaths several days later. Anorexia is a common complaint post procedure. Cavin and Innis (pers. comm.) sedated three adult sand tigers with variable inductions and recoveries. Recoveries of 6–10 hrs with one not swimming until 24 hrs; all swam abnormally slowly and did not eat for 2–3 weeks after the exam.

Penning and his team (2012) have successfully used medetomidine and butorphanol for multiple procedures in several elasmobranchs. Medetomidine (0.1 mg/kg IM) and butorphanol at (0.65 mg/kg IM) proved very successful with several *Carcharinus* species. Moderate success was achieved with giant guitarfish (*R. djiddensis*) by increasing the butorphanol dosage to 1 mg/kg. Inductions started at approximately 20 minutes, but animals were not handled until 45 minutes, considered a minimum time to avoid stimulation for successful sedation. The animals were then guided into a plastic sock (described above) and transported. In some instances, the sharks lay on the bottom of the tank, while others continued to glide very slowly. Reversals were given for rapid and full recoveries. The team noted

the addition of ketamine seemed to increase the frequency of phantom biting or biting at the stimulating activities. In these situations, they offered a bite stick for the animal to hold onto (Penning, pers. comm.).

In bamboo sharks (*C. plagiosum*), midazolam (1–5 mg/kg), medetomidine (80–90 µg/kg), and butorphanol (0.5–1 mg/kg) had little to no effect IM, but minor sedative effects IV. With the latter route, the animals tolerated being turned over and stayed dorsally recumbent for several seconds to several minutes (Mylniczenko, pers. exp.).

Oral (PO)

Oral sedation of elasmobranchs is not widely practiced and rarely reported (Clauss et al. 2011; Raines & Clancy 2009). It holds potential for management of animals in large aquaria and for improving capture of animals for further immobilization. In one study, four ocellated river stingrays (*Potamotrygon motoro*) were offered ketamine-injected earthworms at a dosage of 20 mg/kg; within 15 minutes, the animals were easily netted and placed into dorsal recumbency, but did not reach anesthetic depths (Raines and Clancy 2009). In a different study, multiple sedatives were used with bonnethead sharks (*S. tiburo*), comparing oral (via capsule in food) and IV injectable drugs (Clauss, pers. exp.). The oral drugs produced little effect, even at doses considered high for other species. These drugs included chloral hydrate (no sedative response at 300 mg/kg), ketamine (no sedative response at 30 mg/kg), and haloperidol lactate (no sedative response at dosages up to 50 mg/kg). Haloperidol showed no sedative effects at 10 mg/kg in *Triakis semifasciata*, but did show behavioral modifying effects (decreased stereotypy) (Mylniczenko, pers. exp.). The authors have also used diazepam at dosages from 1 to 40 mg/kg (most at the 1–10 mg/kg range) with variable anxiolytic effects or appetite stimulation effects. There were no overt sedative effects in a variety of species: sawfish (*Pristis zijsron*), brown sharks (*C. plumbeus*), blacktip reef shark (*C. melanopterus*), leopard (*Triakis semifasciata*), blotched fantail ray (*Taeniura meyeni*), bowmouth (*Rhina ancylostoma*), and whale sharks (*Rhincodon typus*). More research is indicated to evaluate the usefulness of oral sedation in elasmobranchs.

Nonspecific “Reversal” Drugs

Doxapram Hydrochloride Doxapram hydrochloride has been noted to produce dramatic arousal and stimulation in anesthetized elasmobranchs and should be used with caution because animals can become extremely excited and dangerous (Stoskopf 1986).

MONITORING

In captive animals, a quiet environment without predatory tank mates should be used for anesthetic induction and maintenance. Several baseline physiological

variables should be monitored. Ventilation rates are recorded if the animal is actively pumping water through the gills and not ram ventilating (i.e., using forward motion to force water through the gills). Caudal fin strokes are measured to determine the onset of drug effect; this activity is usually the first to be reduced.

After an animal becomes ventrally recumbent, the righting reflex, respiration, and heart rate should be closely monitored. Although animals may appear to be ventilating well, bradycardia and an increased resistance to gill capillary flow (as erythrocytes accumulate within the capillary bed and become swollen) has been noted to possibly cause hypoxemia (Tyler & Hawkins 1981). Therefore, the authors strongly advise assisted ventilation even with voluntary gill movement. Gill ventilation rate and rhythm can be monitored visually. If respiration becomes erratic, slows significantly, or ceases, the animal must be manually ventilated by directing water flow over the gills. Respiratory effectiveness is best assessed with periodic blood gas analysis to determine oxygenation, carbon dioxide, pH, and lactate levels. Large changes in blood chemistry can occur during the stress of capture and handling elasmobranch fishes (Frick & Reina 2009; Mandelmann & Skomal 2009; Naples et al. 2012). Respiratory, metabolic, and lactic acidosis are common. In elasmobranchs, lactic acid is produced in large quantities during hyperactivity and the resultant acidemia is usually corrected by hydrogen ions buffering or through gill excretion (a much slower process). This is why lactate levels will continue to rise in elasmobranchs for up to 12 hours after the inciting event (Piiper & Baumgarten 1969). Experiments with larger spotted dogfish (*Scyliorhinus stellaris*) indicated PaCO₂ was increased immediately after exercise, but returned to baseline within 1 hour. The pH gradually decreased, reaching a minimum in the second hour and returned to baseline within 8 hours. Lactate concentrations increased slowly to very high levels reaching a maximum of 220 mg% within 6–8 hours after exercise (Piiper & Baumgarten 1969). The pH may, therefore, correct itself in an animal that has sufficient buffering capacity, but this is largely determined by the animal's respiratory mode and method of oxygen metabolism (Chapman & Renshaw 2009; Cliff & Thurman 1984; Frick & Reina 2009; Manire et al. 2001; Piiper & Baumgarten 1969). Benthic animals tolerate and correct acidemia more readily than pelagic.

Handheld analyzers offer rapid analysis at poolside or on a boat and some automatically adjust calculations for lower body temperature. If they do not, then correction for ambient water temperature is necessary, or alternately, evaluation or trends should be followed rather than actual values. The pH appears to be a critical variable to monitor. For the authors, animals with corrected values under 7.0 are unlikely to recover, even

when chemical restraint is not utilized. A temperature corrected pH of 7.2 is usually associated with imminent recovery from anesthesia. Lactate levels are useful for anticipating problems that may occur later or for evaluating handling/anesthetic events. Further investigation is needed to determine lactate values that would indicate that an animal is at increased risk. These values vary by species. Under circumstances of continued pH decline and/or lactate elevation, the authors have treated animals with fluids solely or in combination with sodium bicarbonate and/or sodium acetate therapy.

Another factor to consider when evaluating blood gas variables is the location used for blood collection. In larger specimens, the dorsal sinus is often used for blood collection due to ease of access. Several variables, however, have been shown to be inaccurate for the animal's baseline state. Not only is hematocrit lower at this site compared with the tail (Mylniczenko et al. 2006), blood gas values are also different. In particular, pH and lactate are not accurate or "real-time" when measured in blood samples collected from the dorsal sinus (Naples et al. 2012). The collected sample from the tail is likely to be arterial if the needle tip is moved just off the cartilage as the vessel abuts the vertebrae.

Heart rate is monitored using either an ultrasound or Doppler flow detection probe placed over the heart. It is located along the ventral midline just caudal to the gill openings (Fig. 16.10). The heart rate will vary between species and in response to stress and temperature. Most unanesthetized fish will have a heart rate between 30 and 70 beats per minute, depending on animal size, species, and condition (Lewbart 2001). In addition to heart rate, the contraction quality and rhythm are critical to examine. Changes, such as weak

Figure 16.10. Cardiac ultrasound of a whitetip reef shark (*Triacodon obesus*).

contractions and dysrhythmias, may indicate the animal is doing poorly under anesthesia and must be recovered. If contractions appear to be weak, then evaluation of the animal's calcium is warranted, particularly ionized calcium, which can be monitored with a handheld analyzer. Normally, this value is greater than the readable limit of some portable units (>2.5 mmol/L). If it is reading below this value, and the animal has weak contractions, then the animal should be recovered and/or calcium administered to manage the relatively lower calcium levels (Mylniczenko, pers. exp.).

Anesthetic stages in elasmobranchs are similar to mammals and teleost fish (Chapter 15). Stages are gauged by activity, reactivity to stimuli, equilibrium, muscle tone, respiratory rate and heart rate (Ross & Ross 2008). The period between respiratory and cardiac arrest, however, is greater because the respiratory capillaries are able to exchange oxygen and carbon dioxide when water flow over the gills is maintained via assisted ventilation. Stages of anesthesia are highly variable between animals (both intra and interspecies) and between drugs.

During an immobilization procedure, it is also important to monitor and control the water quality of the anesthesia or restraint system as poor or altered water variables may negatively impact the animal(s). Temperature fluctuations may also occur if the water volume is small and should be controlled. Hyper or hypothermia can impact metabolism and recovery. Dissolved oxygen should be maintained close to 100% and may require the addition of supplemental air stones with or without supplemental oxygen. If animals have not been adequately fasted, buildup of nitrogenous waste due to elimination may result, requiring water changes or chemical additions. Waterborne anesthetics, in particular MS-222, can lower the pH of the water and will require buffering.

RECOVERY CONSIDERATIONS AND POSTANESTHETIC CHALLENGES

All safety precautions exercised for induction and maintenance should continue to be a priority during recovery from anesthesia. An isolated environment is preferable. Ideally, the recovery container or tank will be easily accessible for the staff but will also be large enough to allow the animal space to swim as it progresses through stages of recovery. Water in recovery containers should be well aerated. The water flow should be aimed toward the fish's mouth if the animal is respiring spontaneously. Assisted ventilation directly over the gills may be necessary if the fish is not respiring, if the respiration rate is slow or irregular, or if the animal is still sedate from anesthesia. An alternative to using the ventilation system is pulling the fish forward

through the water with its mouth open. However, in the authors' experience, this method is inferior to the use of a ventilation system.

Animals should continue to be monitored carefully during recovery. Care should be taken when monitoring requires any touching or handling as some fish may exhibit erratic behavior to this stimulus. If a fish is respiring spontaneously and attempting to regain normal posture in the water column, it is often best left untouched to avoid erratic movements and added stress. However, if an animal is in danger of injuring itself due to erratic movements, restraint may be necessary (Harms 1999). Additionally, if animals are released prior to being able to maneuver in the water column, they may swim briefly and then fall to the bottom of the recovery pool. This is not an issue with buccopharyngeal breathers, but can be problematic with pelagic animals; the animal must be retrieved and continue to be supported through recovery. It is important to have experienced personnel involved when making judgment calls of this nature. As a fish recovers from anesthesia, the respiratory rate should increase and the rhythm should stabilize. Muscle tone and fin movements should return followed by progressively less ataxia. Careful observation is important, and staff should be readily available to intervene if the fish becomes distressed or the recovery process halts.

Recovery from immersion anesthesia begins when the fish is placed in anesthesia-free water. With most immersion anesthetics, the authors find that time to full recovery is seldom greater than 10 minutes. During the recovery process, the water in the tank may need to be changed as anesthetics and their metabolites may be excreted from the fish into the water and potentially reabsorbed. The same process is theoretically possible with oral or parenteral drugs as they, too, may be excreted into the water and reabsorbed. Recovery from oral or parenteral anesthetics technically begins after the drug is administered and fully metabolized. Faster recovery in some cases is facilitated by administering reversal agents. However, there is no reversal for some drugs, and in those situations, it is up to the fish to fully metabolize and clear the drug(s) for full recovery to occur. Recovery time from oral and parenteral agents is dependent on the route of administration, rate of metabolism, use of reversal agents, health status of the patient, and the species. As has been mentioned previously, the response to anesthetics and associated recoveries varies considerably both within a species and between species of elasmobranchs.

Extended recovery periods may occur with excessive anesthetic dosage, in a medically compromised animal or for unknown pharmacokinetic reasons. Due to the tremendous variation in response to anesthesia, extrapolation of doses is challenging and can potentially

result in prolonged recoveries or other unpredictable scenarios. At the New England Aquarium, two sand tiger sharks (*C. taurus*) anesthetized with dexmedetomidine (0.03 mg/kg) and ketamine (3.0 mg/kg), followed by MS-222 (70–90 mg/L) immersion, had markedly different recovery times. Even after reversal with atipamezole, one shark did not begin to swim until 6 hours after reversal and return to the exhibit tank. The other shark did not begin to swim until 24 hours after reversal (Cavin and Innis, pers. comm., 2011). At the Living Seas with Nemo and Friends® (Walt Disney World, Orlando, FL), highly variable responses to a similar drug combination were noted and ranged from no response to rapid induction; recoveries were also highly varied, such as a quick return to normal versus different degrees of abnormal behavior, including swim gait abnormalities, anorexia, and prolonged lethargy for up to 7 days in the same species.

Care should be taken not to abandon recovery or resuscitation attempts prematurely in apneic fish as respiratory arrest may precede cardiac arrest by extended periods of time. In the authors' experience, anesthetics such as propofol may produce respiratory arrest for periods in excess of 30 minutes followed by full recovery when the sharks are artificially ventilated. Four bonnethead sharks (*S. tiburo*) at the Georgia Aquarium were anesthetized with propofol (5.0 mg/kg) administered into the first dorsal sinus. Spontaneous respirations ceased within three minutes. The sharks were artificially ventilated with a submersible pump and monitored closely. Gilling resumed in all four animals within 36–52 minutes after propofol administration. Fish with persistent apnea or bradypnea that also experience bradycardia, abnormal blood gases, or other physiological challenges may be given doxapram. The authors have observed positive response to doxapram (5 mg/kg IV, IM, ICo, or over the gills) in several cases of respiratory arrest. Caution should be used when administering doxapram as it may cause hyperexcitability, especially in sharks.

In some situations, it may be necessary to provide supportive care and/or emergency drugs, such as atropine, corticosteroids, fluids, or other therapeutics. In cases of shock or physiological collapse, corticosteroids, such as methylprednisolone, prednisolone, or dexamethasone, may be given with the caveat that it is unknown if steroid therapy is effective in elasmobranchs. In the authors' experience, corticosteroid administration has been subjectively helpful in some cases and no adverse effects have been noted.

Emergency fluid therapy should take into account the animal's osmotic balance as well as any imbalances or deficiencies that may be present. Elasmobranchs are hyperosmotic to their environment with urea, NaCl, and trimethylamine oxide being the major osmoregulatory plasma components (Olson 1999). Elasmobranch Ringers, a balanced salt solution, is made by adding

NaCl (8 g/L) and urea (21 g/L) to phenol red-free Hank's balanced salt solution (Andrews & Jones 1990). Alternatively, if Hank's balanced salt solution is not available, 0.9% NaCl or Normosol R with of additional NaCl (8 g/L) and urea (21 g/L) may be used. Thorough summaries on the osmoregulation of elasmobranchs as it is currently understood can be found in the literature (Anderson et al. 2007; Hammerschlag 2006). Greenwell et al. (2003) provides an overview of the clinical implications involved with elasmobranch osmoregulation including additional guidelines on the principles of fluid administration. The fluids are ideally administered through a needle or catheter placed in the caudal vein or the dorsal sinus, but may also be administered intracoelomically or orally. No rates of fluid administration have been published based on scientific studies, but the authors use maintenance doses of 7–10 mL/kg. Fluid volumes reportedly as high as 66 mL/kg/d have been given following surgical procedures and routine handling (Greenwell et al. 2003). Some elasmobranchs appear to respond to oral freshwater administration at 1–3% body weight in less severe situations. When metabolic acidemia occurs, if the fish is unable to compensate and does not respond to increased oxygen supplementation and fluid therapy, it may be beneficial to administer an alkalinizing agent such as sodium bicarbonate or sodium acetate. Care should be taken not to over correct causing an alkalosis or electrolyte imbalance.

As with other classes of animals, administration of emergency medications varies by case and should be governed by individual animal needs. Table 16.2 lists emergency and supportive care therapeutics the authors have used that has been valuable when working with elasmobranchs and holocephalans.

FIELD IMMOBILIZATION

Immobilization of elasmobranchs in the field has been in practice for many years. Live release biological assessments and subsequent tagging and tracking provide valuable information on factors such as population dynamics, spatial patterns, foraging behavior, and health status of free ranging animals. These activities have become increasingly common practice as scientists try to understand the causes and significance of changing or declining populations and relationships to ocean health.

Generally, animals are manually restrained after hook and line, long line, or trawl net capture, but other techniques may be employed as warranted. In these situations, naïve animals are being placed under the rigors of extreme exercise and are particularly vulnerable to exertional rhabdomyolysis (Chapter 12), hypoxemia and lactic acidemia, hook and handling trauma, and stomach eversion. Pelagic (ram ventilating) species are especially susceptible to stress and exhaustion and

Table 16.2. Drugs used for emergency and supportive care in anesthetized elasmobranchs

Elasmobranch and Holocephalan Emergency Medications			
Drug	Dosage	Route	Indication
Atropine	0.02–0.2 mg/kg	IV, IM, IP	Bradycardia, arrhythmia, organophosphate poisoning
Glycopyrrolate	0.01 mg/kg	IV, IM	Bradycardia, arrhythmia
Epinephrine	0.2 mL/kg	IV, IM, IP	Bradycardia, cardiac arrest
Doxapram	2–10 mg/kg	IV, IM, over gills; may cause hyperexcitability	Apnea, respiratory arrest
Furosemide	2–3 mg/kg	IV, IM, IP	Excessive coelomic fluid, generalized edema
Dexamethasone	1–2 mg/kg	IV, IM, IP	Stress, shock, trauma
Methyl-prednisolone acetate	30 mg/kg initial, 15 mg/kg follow-up		
Prednisolone sodium succinate	5–30 mg/kg		
Midazolam	0.5 mg/kg	IV, IM	Seizures
Diazepam	1–2 mg/kg		
Calcium gluconate	0.2–1.5 mL/kg	IV, IP	Muscle fasciculations, tetany, dysrhythmias, decreased myocardial contractility
Calcium lactate/calcium glycerophosphate	10 mg/kg	IV, IM, IP	
Sodium bicarbonate	0.5–1 mEq/kg	IV, IM, IP	Acidosis
Sodium acetate	1 mEq/kg diluted ~ 1:10 with fluids	IV, IP	
Hank's balanced salt solution + 8 g/L NaCl and 21 g/L urea	7–10 mL/kg	IV, IP, PO	Dehydration, shock, fluid loss, hypovolemia, hypotension
0.9% NaCl + 8 g/L NaCl and 21 g/L urea	7–10 mL/kg		

can have a poor chance of survival; however, this is highly species dependent (Mandelman & Skomal 2009). Location of release may also have an impact on survivability. Predatory fish, including other elasmobranchs, may take the opportunity to predate a tired, recently released animal, particularly if the area has been chummed to attract additional specimens for capture. Often, however, there is no control in the matter as the animals are mainly caught and released in open water. Capture–release scenarios that result in the least impact to the animal are imperative.

Experienced handlers are required as the space on a boat or dock is limited, areas on deck are potentially unstable, or wet and animals are strong and often very agitated (see previous comments in this chapter about manual restraint and safety). If the animals will be out of the water for any length of time, it is advised to safely ventilate them with the water they were just pulled from. If animals are to be maintained in live wells, consider the time in the well, volume of water, oxygen delivery to the water, swim-glide pattern (usually nonexistent under these circumstances), and number of animals in the well (more animals means more consumption of oxygen, crowding, and excretion of biological end products).

In some scenarios with animals too large to be hauled onto the deck, they must be restrained in the water along the side of the boat or dock (Fig. 16.11). Under these circumstances, even more expertise and potentially specialized equipment is important for

Figure 16.11. Collection of blood from a free-ranging sand tiger shark (*Carcharias taurus*) during a population health assessment project in Delaware Bay (photo credit: Georgia Aquarium).

human and animal safety. Though rare, when capture and immobilization involves extremely large specimens, such as white sharks, whale sharks, or manta rays, specialized water craft is also necessary.

It is rare to use anesthesia for field immobilization procedures for a number of reasons: speed, efficiency, space, and most importantly regulations governing

using drugs in potential food fish (U.S. Fish and Wildlife Service, The Aquatic Animal Drug Approval Partnership 2010). It is important to note that if elasmobranchs are to be retained in captivity for extended periods of time, there may be restrictions against release or there may be special permitting required, but this is highly variable by state in the United States.

When health assessments occur during field immobilization projects, additional considerations include having portable equipment that can connect and operate on generators, batteries, or plugged into the vessel's electrical, as well as having adequate, safe storage and preservation capacity for biological specimens. Weather and water conditions may change rapidly and in turn may complicate sample collection, processing, and safe handling. Having seaworthy staff, experienced in biological sample processing is beneficial.

With any field immobilization technique, speed and precision is essential to reduce the stress on the animal and improve viability on release. Ultimately, limited handling or limited time in a live well is best. Some researchers have developed techniques for collecting samples and attaching tracking or identification devices without physically restraining the animals. These methods usually involve less stress or physical exertion for the animal, but may present a different set of safety hazards for the people involved.

Some studies have assessed the impacts of catching elasmobranchs for science, sport or accidentally as by-catch. Blood acid-base status can be utilized to gauge the magnitude of the stress response, which is dependent on the nature of the capture and the metabolic capacity of the animal in question (Mandelmann & Skomal 2009). Changes in blood glucose, electrolytes, osmolality, and hematocrit have also been documented in various species of elasmobranchs after capture (Wells et al. 1986; Wendelaar Bonga 1997; Hoffmayer & Parsons 2001; Manire et al. 2001; Moyes et al. 2006). Regardless of collection technique, captured fish experience distress caused by the cumulative impacts of physical trauma and physiological stress (Skomal 2007). The importance of swift and meticulous capture, handling, and release cannot be underestimated and can greatly improve survivability in field immobilization activities.

EUTHANASIA

The goal of euthanasia should be the rapid loss of consciousness. This can be accomplished by an overdose of immobilization drugs. Inhalant (immersion) drugs at 5–10× the anesthetic concentration for a particular species can be chosen (Ross & Ross 2008). Elasmobranchs, however, may require sedation first with parenteral drugs then euthanasia with a drug such as

pentobarbital, following all of the previously stated techniques. Use of Doppler flow probes, ultrasonography, or electrocardiography is recommended to confirm asystole. Severing the spinal cord at the brain stem (decapitation) or exsanguination are alternatives to chemotherapeutic euthanasia and can be performed once the fish is anesthetized. The reader is directed to review euthanasia principles for fish as outlined by the American Veterinary Medical Association (AVMA). Unacceptable methods of euthanasia include asphyxiation and hypothermia.

ACKNOWLEDGMENTS

Portions of this chapter have previously been published in Smith M, Warmolts D, Thoney D, Hueter R. (eds.) 2004, The elasmobranch husbandry manual: captive care of sharks, rays and their relatives (a special publication of the Ohio Biological Survey). The authors would like to thank Mike Walsh, Ilze Berzins, Lisa Naples, Don Neiffer, Lynda Leppert, Nicholas Parnell, and Nicole Hatcher for their assistance in preparing the manuscript.

17 Amphibians

Eric Baitchman and Mark Stetter

INTRODUCTION

Amphibians are native to all continents, except Antarctica, and are routinely maintained in captive situations as pets, in laboratories, and in zoos. They reside in a wide variety of habitats including aquatic, semi-aquatic, and terrestrial. Amphibians are found from the equatorial rainforest to Canada, where they may remain frozen through the winter. There are more than 6000 species, including frogs, toads, salamanders, newts, and caecilians (IUCN 2008). There is significant concern about worldwide amphibian declines and its implications for global ecosystem health.

Veterinarians are most likely to be involved with captive anurans (frogs and toads) or caudates (salamanders and newts). It is not uncommon for amphibians to require sedation or anesthesia for diagnostics, surgery, or research.

ANATOMY AND PHYSIOLOGY

Amphibians have several unique and clinically relevant anatomical characteristics. The first is they go through metamorphosis and change from strictly aquatic larval forms (i.e., tadpoles) to terrestrial adults. These metamorphoses include dramatic anatomical changes; growth of legs, loss of gills, resorption of tails (anurans), and formation of lungs. As a completely aquatic tadpole with gills, they have very similar respiration to fish.

The respiratory physiology of amphibians is unlike that of any other animal taxa. Four different types of respiration are employed, including branchial, cutaneous, pulmonary, and buccopharyngeal. All species utilize branchial respiration (gills) as larvae, and some pedomorphic species, such as axolotl (*Ambystoma mexicanum*), mudpuppies (Proteidae), and sirens (Sirenidae),

retain gills as adults (Duellman & Trueb 1994). All adult amphibians utilize cutaneous respiration to varying degrees that can account for a significant portion of the animals' total oxygen exchange. The largest family of salamanders, the Plethodontidae or lungless salamanders, perform nearly all of their respiration via cutaneous gas exchange (Duellman & Trueb 1994). In species that possess lungs, however, the majority of oxygen intake is usually via pulmonary exchange, while the cutaneous route still accounts for the majority of carbon dioxide exchange (Duellman & Trueb 1994; Hillman et al. 2009). Lungs are inflated by positive pressure ventilation achieved through buccal pumping. Small amounts of gas exchange may also occur across buccopharyngeal mucus membranes. Central respiratory drive to increase respiratory frequency, or tidal volume is stimulated by either decrease in PO₂ or increase in PCO₂ (Branco & Glass 1995; Fonseca et al. 2012; Hillman et al. 2009).

Amphibian skin is highly permeable and well vascularized. In addition to respiratory gas exchange, it is the primary route of water exchange and also actively participates in electrolyte balance. Smooth-skinned animals, adapted to moister environments, have higher permeability and are susceptible to dehydration through insensible water loss. In most species, the ventral pelvic region, often referred to as the pelvic patch or drink patch, is the area of highest water uptake. It is especially well developed in terrestrial species, showing increased surface area and vascularity in this region (Fig. 17.1).

VASCULAR ACCESS

Vascular access is limited by animal size. Fine-gauge needles or catheters (24 gauge or smaller) work best in

Figure 17.1. Ventral pelvic region of a gray tree frog, *Hyla versicolor*. Note the verrucae hydrophilicae, or granular sculpturing of the skin, providing increased surface area for water absorption. This region can have application for drug absorption as well.

animals that are large enough. Useful sites include the ventral abdominal vein on the caudal ventral midline (Fig. 17.2), femoral vein behind the stifle, axillary venous plexus (Fig. 17.3), sublingual plexus, and ventral tail vein in caudates. Other sites may be possible, such as the brachial vein or lateral abdominal veins in larger species. Transillumination is a useful technique for highlighting the pathways of major vessels (Fig. 17.4).

GENERAL ANESTHETIC CONSIDERATIONS

The aquatic nature and skin permeability of amphibians makes topical use of anesthetic agents a convenient means of achieving systemic effects. Amphibian anes-

thesia is very similar to fish anesthesia in methodology and drugs used (Stetter 2001). The anesthetic compounds are most commonly delivered in water and absorbed across the animal's skin or gills. Inhalant anesthetic agents may be used either topically or in solution. When gas anesthetics are delivered into a chamber or bubbled through water, induction can be prolonged or unsuccessful. Some amphibians can be intubated awake and administered an inhalant anesthetic for induction. Parenteral or injectable anesthetics are often unreliable, have a very low margin of safety, may be associated with a prolonged recovery, and dosages are very species specific (Crawshaw 2003; Stetter 2001; Wright & Whitaker 2001).

Aquatic amphibians can be kept out of water for extended periods of time if the skin is kept moist to prevent damage or dehydration, and ensure dermal respiration is maintained (Wright & Whitaker 2001). When working with entirely aquatic species (e.g., African clawed frog, *Xenopus laevis*), tank water from the animal's environment is used. This reduces exposure to abrupt environmental changes (i.e., temperature and pH). All water used for anesthesia is tested using standard reagent test kits to ensure there are no elevated deleterious variables, such as ammonia (Wright & Whitaker 2001). Toxin-free (dechlorinated) water within the animal's preferred body temperature range (usually 15–23°C, 59–73°F) is used (Wright & Whitaker 2001). Bottled spring water at room temperature is often a convenient standard for use, or amphibian Ringer's solution may be prepared.

Whatever container is used for an anesthetic chamber must be thoroughly cleaned and rinsed. Since amphibians absorb chemicals across their skin, cleaning solutions or other chemicals left in a container can be toxic. In addition, some amphibians secrete toxins from their skin, and it is important to rinse containers well between patients. Sealable plastic bags are an efficient container for anesthetic bath induction chambers and can be discarded when administration is complete. Other potential induction chambers include small plastic containers with lids, or small fish aquariums. Many amphibians exhibit an excitement phase during induction, making it important to have an enclosed container to prevent the patient leaping out and the interior should be smooth and padded if possible, to prevent injury (Crawshaw 2003; Stetter 2001; Wright & Whitaker 2001). When a water bath is being used for anesthetic application, there should be an interface with the air at the surface (i.e., do not fill the container completely to the lid). Animals with lungs are removed from the water after induction and positioned with nostrils elevated to ensure against aspiration.

When using a bath solution to induce anesthesia, the induction dose received is dependent on the surface area of the animal. That is, smaller animals with greater surface area are being exposed to larger amounts of anesthetic than larger animals with smaller surface area relative to body size. Consideration should be given to adjusting solution concentrations based on body size (Goulet et al. 2010, 2011).

Moistened gloves are worn when handling amphibians, to protect their skin, as well as to protect the handler from potentially toxic secretions in some species (Crawshaw 2003; Stetter 2001; Wright & Whitaker 2001). Rinsed nonlatex, nonpowdered gloves are recommended for handling adults, due to potential species sensitivities, and only washed vinyl gloves have been found safe for handling amphibian larvae. Mortality was seen in tadpoles exposed to latex, nitrile, and unwashed vinyl gloves (Cashins et al. 2008; Gutleb et al. 2001).

Amphibians are not commonly fasted prior to anesthesia. Their larynx remains tightly closed even under general anesthesia and the chance of aspiration is very low (Wright & Whitaker 2001). Regurgitation or gastric prolapse, however, has been reported in studies using isoflurane or eugenol in *X. laevis* or eugenol in *Rana pipiens* (Goulet et al. 2011; Lafortune et al. 2001; Smith & Stump 2000). While no lasting adverse effects were appreciated in those animals, consideration might be given to fasting for 24 hours when feasible, particularly if the amphibian's diet includes large prey items or if the anesthetic procedure is to include celomic surgery.

Respiratory ventilation is usually reduced or absent during amphibian anesthesia. The dermis is kept moist to allow for efficient dermal respiration. Cutaneous oxygen exchange, however, may be low in some species (Hillman et al. 2009), and supplemental oxygen should be considered to avoid hypoxemia and acidemia (Andersen & Wang 2002). While some amphibians can sustain anoxia for long periods, reoxygenation is a significant stress and risks free-radical injury to tissues (Bickler & Buck 2007). For long surgical procedures, the patient can be placed in a shallow water bath with oxygen bubbled into it. Intubation is also a safe option to provide supplemental oxygen (G. Crawshaw and D. Mader, pers. comm., 2013). Small species may be intubated with modified intravenous catheters or non-cuffed Cole tubes may be used in larger species. The larynx is usually tightly closed, even in anesthetized animals, and the tube may need to be gently forced (G. Crawshaw, pers. comm.). The trachea is very short and the tube is placed just past the larynx (Stetter 2001). Amphibian lungs are composed of thin-walled membranes and manual or mechanical ventilation is done gently. Larger species can be ventilated at a pressure of 5 cm H₂O, with a breath every 10 seconds (D. Mader, pers. comm.).

MONITORING

The skin under the mandible and along the ventral cervical region is the gular region; movement in this area is a primary means of respiration. As a patient becomes anesthetized, gular respirations decrease, and there is a diminished withdrawal reflex (Crawshaw 2003; Stetter 2001; Wright & Whitaker 2001). Light anesthesia is associated with loss of righting reflex and an absence of abdominal respirations. Surgical anesthesia is indicated by a loss of withdrawal reflex and cessation of gular respiration (Crawshaw 2003; Stetter 2001; Wright & Whitaker 2001). When the patient has ceased movement and appears to be anesthetized, the animal may be placed on to dorsal recumbency to see if the amphibian has lost its righting reflex. For procedures requiring light anesthesia (e.g., blood sampling, radiographs, and physical examinations), the patient is

removed from the container and quickly rinsed with anesthetic-free water before the procedure begins. If surgical anesthesia is required, an aggressive toe pinch of the rear leg will help determine if there is loss of the withdrawal reflex and nociception.

Anesthetized amphibians usually become apneic; abdominal and gular respirations cease. This can be very disconcerting for the anesthetist who relies on respiratory rate for assessing anesthesia. Consideration should be given to intubation or other means of supplementing oxygen, as discussed above.

Heart rate is a more useful indicator for anesthetic monitoring (Crawshaw 2003; Wright & Whitaker 2001). In most anesthetized patients in dorsal recumbency, the heart is seen contracting on the midline just caudal to the shoulders. Direct visualization, a Doppler monitor, or ultrasound is used to measure heart rate (Crawshaw 2003; Stetter 2001; Wright & Whitaker 2001). Although normal heart rates for species are not extensively published, a significant decrease in baseline heart rate is of concern and indicates excessive anesthetic depth. Pulse oximetry has not been validated in amphibians, but may show trends in hemoglobin saturation for long procedures and can assist with monitoring pulse (Fig. 17.5). Intermittently monitoring withdrawal reflex will determine if the patient is transitioning from surgical to light anesthesia. A patient that regains its withdrawal reflex, or gular respirations, requires supplementation if a surgical plane of anesthesia is still required. For supplementation, a 50% concentration of the induction solution is applied topically via syringe or partial water bath. When the animal reaches an adequate level of anesthesia, the application is discontinued.

During recovery, animals should be kept moist and well oxygenated, preferably at the preferred optimal temperature for the species. Full recovery is considered when the animal is responsive, respiring normally, and has regained all reflexes (Wright & Whitaker 2001).

ANALGESIA

Excellent discussions on nociception in amphibians can be found in Machin (1999), and Stevens (2011). Amphibians share the same array of nociceptive afferent nerves, spinal cord neurotransmitters, and endogenous opioid peptides as mammals. While the perception of pain in an amphibian is unknown, all of the same nociceptive pathways are conserved as in higher phylogenetic classes of vertebrates. Analgesia should be considered for any noxious procedures in amphibians. Drugs and dosages are summarized in Table 17.1.

Opioids

All mammalian opioid receptors: mu, delta, and kappa, are present in the central nervous system of amphibians. While receptor selectivity is less than in mammals, the relative analgesic potency $\mu > \delta > \kappa$, is the same (Stevens 1996, 2004). Dosages tend to be much

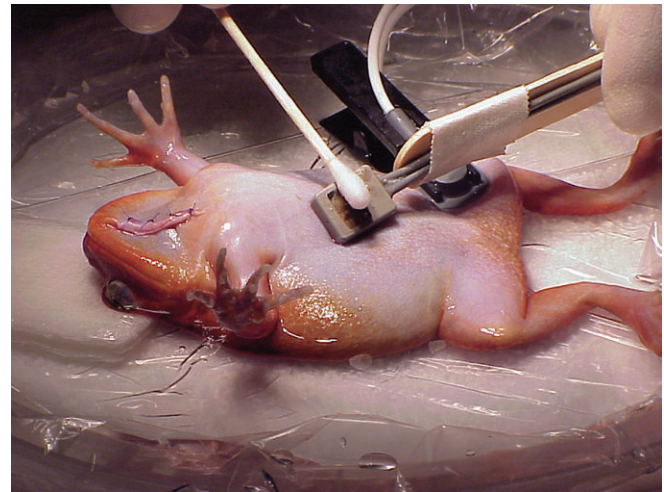

Figure 17.5. A tomato frog, *Dyscophus insularis*, under surgical anesthesia in a liquid anesthetic bath, being monitored by Doppler and pulse oximetry. Note the nostrils are elevated above the water line with gauze pads.

Table 17.1. Analgesic drug dosages for amphibians

Drug	Dosage	Route	Duration	Comments
Fentanyl	0.3–0.8 mg/kg	SC	>4 hours	ED ₅₀ = 0.5 mg/kg in <i>Rana pipiens</i> ^a
Morphine	18–33 mg/kg	SC	>4 hours	ED ₅₀ = 25 mg/kg in <i>Rana pipiens</i> ^a
Buprenorphine	27–79 mg/kg	SC	>4 hours	ED ₅₀ = 50 mg/kg in <i>Rana pipiens</i> ^a
	50 mg/kg	IC	NE	Shortened time to normal behavior following surgery in <i>Notophthalmus viridescens</i> ^b
Butorphanol	0.5 mg/L	72-hour bath	NE	Shortened time to normal behavior following surgery in <i>Notophthalmus viridescens</i> ^b
Dexmedetomidine	120 μg/kg	SC	>8 hours	<i>Rana pipiens</i> ^c
Meloxicam	0.1 mg/kg	IM	NE	Reduced PGE ₂ in <i>Rana catesbeiana</i> ; analgesic effect not examined ^d

^aStevens et al. (1994) (ranges based on 95% confidence interval of ED₅₀).

ED₅₀, effective dose in 50% of test subjects; NE, not examined.

higher in amphibians compared with mammals and onset to peak analgesic effect is longer at 60 minutes or greater when given systemically (Stevens et al. 1994). Planning analgesia for procedures should take this delay of onset in to account.

α-2 Adrenergic Agonists

Administration of α-2 adrenergic agonists to amphibians provides analgesia without sedation. Normal movement, including righting, corneal, and hind limb withdrawal reflexes, all remain intact. Onset of effect is rapid and long lasting, with peak effect occurring by 60 minutes and lasting for 6–8 hours or more (Brenner et al. 1994).

Nonsteroidal Anti-Inflammatory Drugs (NSAIDs)

Little good data exist using NSAIDs as analgesia in amphibians. Flunixin meglumine is reported to provide significant analgesia. The dosages used in two studies, however, are extremely high (25 mg/kg) compared with typical doses in other taxa, and one animal that died during the trial had histopathologic evidence of renal congestion and inflammation (Coble et al. 2011). Meloxicam reduced circulating prostaglandin E2 in *Rana catesbeiana*, implying it can suppress the inflammatory response and may, therefore, provide an analgesic effect (Minter et al. 2011). No significant effect was seen, however, when using meloxicam in analgesic trials with *X. laevis* (Coble et al. 2011). Mild analgesia is reported from a study with two uncommon NSAIDs, indomethacin and ketorolac (Stevens et al. 2001).

ANESTHETIC DRUGS

Anesthetic drugs and dosages are summarized in Table 17.2.

Tricaine Methanesulfonate (MS-222 or Finqel®)

This is the most commonly used anesthetic for amphibians (Cooper 2003; Crawshaw 2003; Downes 1995; Stetter 2001; Wright & Whitaker 2001). It is effective

in all species, with all developmental stages of amphibians, and it has a wide margin of safety. It is also the only FDA-approved anesthetic in fish and can be acquired through aquaculture distributors (Wright & Whitaker 2001).

Tricaine methanesulfonate is a white powder that easily dissolves in water. Its mechanism of action, similar to other local anesthetics, is as a sodium channel blocker inhibiting nerve conduction. Used systemically, it creates anesthesia via central nervous system depression (Cakir & Strauch 2005). In aqueous solution, it is very acidic, especially at higher concentrations and with waters that have a low buffering capacity (Crawshaw 2003; Downes 1995; Stetter 2001; Wright & Whitaker 2001). This acidic solution is not only irritating to the patient, but the drug is also in a more ionized form and, therefore, less effective as an anesthetic at low pH levels. It is important to buffer the solution to keep the pH at 7.0–7.4 (Crawshaw 2003; Downes 1995; Stetter 2001; Wright & Whitaker 2001). This is easily accomplished by adding sodium bicarbonate to the mixture. Common baking soda (powdered sodium bicarbonate) is added to the solution until saturation (powder no longer dissolves) is achieved. Because the patient is being induced in an anesthetic water bath, rather than a dosage based on body weight, the anesthetic solution concentration is determined by the level of sedation or anesthesia required along with relative life stage (larvae vs. adult) or species of amphibian (Crawshaw 2003; Downes 1995; Stetter 2001; Wright & Whitaker 2001). In general, much lower concentrations are required for younger larval stages, species with external gills, and for the more aquatic frogs compared with the terrestrial toads. Refer to Table 17.1 for general recommendations of concentrations.

For a desired volume of solution, the exact amount of tricaine methanesulfonate is weighed out, dissolved in water, and the buffer is added until neutral pH is achieved. The solution is not stable over long periods of time and is discarded after each use. A portion of anesthetic solution is added to the induction chamber (a sealed plastic bag or container) at a level sufficient to cover approximately half of the patient’s body. A

Table 17.2. Anesthetic drug dosages for amphibians

Drug	Dosage	Route	Comments
Tricaine methanesulfonate	0.2–0.5 g/L	Bath	Add buffer until neutral pH whenever using tricaine
	1.0–2.0 g/L	Bath	Larvae and paedomorphic species
Eugenol	350 μL/L	Bath	Adults
Isoflurane	2–3 mL/L	Bath	Using 99% pure eugenol oil; see chapter text for comments using clove oil
	0.025–0.035 mL/g BW	Topical gel	3 mL isoflurane, 1.5 mL water, 2.5 mL water-based gel
Benzocaine	0.03–0.06 mL/g BW	Liquid	Use absorbent pad with plastic backing to apply to dorsum
	0.2–0.3 g/L	Bath	Pure benzocaine will require dissolution in ethanol first, up to 1% ethanol in final solution.

BW, body weight.

further portion of the remainder of solution can be diluted to half the induction concentration, to be used as a maintenance solution to drip on the patient as needed for longer procedures.

Although induction times are variable, initial effects can be seen within a few minutes, with surgical plane of anesthesia in up to 30 minutes. General comments in the earlier sections apply to induction and monitoring in tricaine anesthesia. Loss of gular respiration is expected at a surgical plane of anesthesia and excessive anesthetic depth will cause cardiac depression on a dose-dependent basis (Cakir & Strauch 2005).

Eugenol

Eugenol is the active compound in clove oil, wherein eugenol concentration can vary widely, from 47% to 88% (Chaieb et al. 2007). It is worth noting that when dosing clove oil, the percentage of eugenol may not be known, nor is the possible composition of other active or inactive compounds present. Interpretation of published dosages of clove oil as an anesthetic should take this variability in to consideration. Simple side-by-side comparison of protocols using clove oil is not straightforward. Purified eugenol can be obtained for use as an anesthetic, which has the advantage of a known single concentration for more accurate and consistent dosing. As more published reports using purified eugenol are produced, species and dosage comparisons can be made more easily. The terms “clove oil” and “eugenol” are not used interchangeably in this chapter.

Eugenol has been used as a topical anesthetic in humans, as well as a general anesthetic in invertebrates, fish, and amphibians. Its mechanism of action is as a local anesthetic, creating analgesia and anesthesia by blocking sodium voltage-gated channels as well as vanilloid receptor TRPV1 and activating inhibitory GABA_A receptors (Goulet et al. 2010).

Eugenol or clove oil induction is most effective via an immersion bath solution, as with tricaine methanesulfonate, and is prepared in a similar manner. Eugenol solutions do not need to be buffered. Surgical anesthesia has been reliably achieved in multiple reports with *R. pipiens* and *X. laevis*. Regurgitation or gastric prolapse has been observed in these studies as a fairly common side effect during induction or recovery, though apparently without adverse consequence (Goulet et al. 2011; Guenette et al. 2007; Lafortune et al. 2001). Clove oil anesthesia has been reported in one caudate species, *Ambystoma tigrinum*, where a surgical plane of anesthesia was achieved in 67% (8/12), at a higher dose than required for *R. pipiens* (Mitchell et al. 2009).

Toxicity studies in *Xenopus* indicate that smaller animals have a higher incidence of toxic effect. Smaller animals have a higher surface area and, therefore, likely absorb anesthetic at a higher dosage per body weight relative to larger animals in the same bath concentration. Smaller *Xenopus* are also less mature than larger

animals, so the mechanism of toxicity could be either dose or age dependent (Goulet et al. 2010, 2011). Histopathologic findings in small animals (28.2 ± 13.7 g) 24 hours after receiving anesthetic doses ($350\mu\text{L/L}$) of eugenol included apoptosis of distal tubular cells in the renal medulla, followed by regeneration 1 week after anesthesia. Animals that received daily anesthesia for three consecutive days had tubular apoptosis ranging from mild to severe, followed by tubular regeneration, massive hepatic necrosis, and hemorrhage of celomic fat bodies 1 week later (Goulet et al. 2011). Large female *Xenopus* (111.7 ± 18.3 g) showed no histopathologic abnormalities 24 hours after anesthesia in the same bath concentration (Guenette et al. 2007). Cardiovascular depression is also seen with smaller animals in a surgical plane of anesthesia, but not in larger animals (Goulet et al. 2010; Guenette et al. 2007). Cutaneous necrosis has been reported with topical application in *Xenopus* at eugenol concentrations of 60mg/mL or greater (Ross et al. 2006).

Isoflurane

Isoflurane is a safe and effective anesthetic in amphibians and may be familiar and useful to the practitioner who does not keep tricaine methanesulfonate in stock (Stetter 2001). Topical applications of liquid isoflurane or bath immersion in isoflurane solution are the most reliable means of induction. Isoflurane gas can also be delivered in the traditional vaporized form via a chamber or by bubbling vaporized isoflurane and oxygen from an anesthetic system into a water bath (Crawshaw 2003; Stetter 2001; Wright & Whitaker 2001). In both cases, a sealed container is used to minimize human exposure and increase isoflurane concentrations in the air chamber. While these methods can be effective in some cases, they are associated with slow induction times and rapid recoveries once the patient is removed from the chamber. Frogs in a gas induction chamber can cease ventilation, thereby significantly increasing induction times (Barter et al. 2007). The aquatic frog *Xenopus* was not anesthetized by bubbling vaporized isoflurane in to a water chamber (Smith & Stump 2000). Intubation and maintenance of large amphibian patients with isoflurane gas may be performed with an uncuffed endotracheal tube (Wright 2006).

The most effective and longest lasting methods of isoflurane anesthesia are application of concentrated liquid isoflurane to the skin or immersion in an isoflurane bath solution (Stetter 2001). For the immersion bath, a syringe is used to add the liquid isoflurane directly into the water through a needle. The needle tip is placed below the surface of the water and the isoflurane liquid is injected and mixed into the bath. A concentration of 2–3mL/L is most commonly used (Crawshaw 2003; Stetter 2001).

When applying concentrated liquid isoflurane directly to the skin, a carrier solution or barrier is created

to increase dermal contact time prior to the isoflurane evaporating. A gel mixture is created using 3 mL of liquid isoflurane, 1.5 mL of water, and 3.5 mL of K-Y® Jelly (Stetter 2001). These three items are placed into a 10 mL empty serum vial and vigorously shaken until a uniform gel is established. This isoflurane gel can now be administered to the patient's dorsum at dosages of 0.025–0.035 mL/gram body weight (Stetter 2001). Lower dosages are used for more aquatic species and higher dosages for thicker skinned terrestrial species (e.g., toads). After the isoflurane gel is mixed in the vial, the indicated volume is withdrawn through a syringe and needle and the gel deposited on the patient's dorsum. Once applied, the patient is placed in a small sealed container until induction is complete. After induction, the anesthetic gel preparation should be rinsed from the patient's skin. Patients anesthetized with topical isoflurane gel will remain under anesthesia for 45–80 minutes. Shorter anesthetic times with a more rapid recovery are seen with the liquid isoflurane in water method (Stetter 2001), or the isoflurane and water solution can be dripped on the skin at a rate needed to maintain anesthetic depth, similar to the method for maintenance with tricaine methanesulfonate.

Topical application of concentrated isoflurane liquid was successful for anesthetizing *Xenopus* frogs using an absorbent pad with a plastic backing. Isoflurane at 0.03–0.06 mL/gram body weight is used to saturate the absorbent pad, cut to size to cover the animals' dorsum, and placed against the skin with the plastic backing facing up (Smith & Stump 2000).

It is possible sevoflurane can be used in amphibians, but no anesthetic studies have been published. Sevoflurane liquid mixed with either sterile lubricant or pluronic/lecithin organogel have shown good absorption across frog skin in *in vitro* experiments (Ardente et al. 2008).

Adverse complications are few when using isoflurane by the earlier-described methods. *Xenopus* frogs fed within 1 day of isoflurane induction tended to regurgitate. Injectable administration of isoflurane (intracelomic, subcutaneous, or intramuscular) is not recommended due to variable results and high mortality (Smith & Stump 2000).

Human exposure to vaporized isoflurane is of concern during protocols involving isoflurane liquid. Procedures should be performed within a fume hood or beneath an active scavenging system.

Miscellaneous Topical Anesthetic Drugs

A variety of drugs traditionally used for local analgesia in mammals have been evaluated for general anesthetic use in amphibians. Benzocaine has been used most widely with good results in a variety of anuran and caudate amphibians (Andersen & Wang 2002; Cakir & Strauch 2005; Crawshaw 2003; Wright & Whitaker 2001). Benzocaine powder is not readily soluble in

water and should be dissolved in ethanol first. The volume of ethanol in final anesthetic solution should not exceed 1% (Wright & Whitaker 2001). A commercially available topical gel product, Orajel®, containing 10–20% benzocaine has been successfully utilized in caudates and anurans topically in its original form and in solution as an immersion bath (Brown et al. 2004; Cecala et al. 2007; Guenette & Lair 2006). At least one study found unexpected mortality in *Bufo fowleri* with a 1 g/L Orajel® bath (equivalent to 0.2 g/L benzocaine; Cecala et al. 2007). No mortality, however, was seen in another bufonid, *Bufo marinus*, using 1 g/L pure benzocaine dissolved in ethanol and water (Andersen & Wang 2002).

A topical xylocaine spray (10% solution) produced satisfactory anesthesia in two *Rana* species (Garcia Aguilar et al. 1999). High mortality was seen in *R. pipiens* exposed to a commercial product containing lidocaine 2.5% and prilocaine 2.5% cream (Guenette & Lair 2006).

Injectable Anesthetic Drugs

Propofol is a short-acting intravenous anesthetic in mammals and reptiles that potentiates γ -aminobutyric acid (GABA) receptors. In amphibian species, intravenous administration is a challenge, and its effects when given by alternate routes are highly variable. In *R. pipiens*, 10 mg/kg perivascularly in the sublingual plexus produced brief and light anesthesia following a short induction time (Lafortune et al. 2001). *Xenopus laevis* were induced to a brief light anesthesia in an 88 mg/L immersion bath, while all animals died when exposed to bath concentrations of 175 mg/L or higher (Guenette et al. 2008). Surgical anesthesia was not achieved in either of these studies. Intracelomic administration of 35 mg/kg in *Ambystoma tigrinum* did produce very brief surgical anesthesia after prolonged induction times (Mitchell et al. 2009). Given the variability of reported dosages and routes of administration, and potential mortality at higher concentrations, specific recommendations for its use in amphibians are not possible. Differences in GABA receptor density between species may introduce further variability of propofol effect among amphibians (Guenette et al. 2008).

Another GABA agonist anesthetic, alfaxalone, is described for surgical anesthesia in a single case report with an axolotl. Induction in a 5 mg/L immersion bath was followed with maintenance by irrigation of the external gills with the same solution, supplemented as necessary with additional drops of 10 mg/L solution (McMillan & Leece 2011).

Alpha-2 adrenergic agonists, such as medetomidine and dexmedetomidine, do not produce sedation in amphibians. A related drug, etomidate, did produce anesthesia in *Xenopus laevis* tadpoles (Paris et al. 2007).

A variety of other injectable anesthetic agents, including ketamine, tiletamine/zolazepam, and various

barbiturates, have been used. These agents are not recommended, as they are less reliable than the topical and inhalant anesthetic agents. They are associated with large species variability in effect and produce significantly higher mortality rates.

18 Crocodilian Capture and Restraint

Kent A. Vliet

INTRODUCTION

Anesthesia and chemical immobilization of crocodilians usually requires some form of confinement and physical restraint for safe drug administration and to prevent them from seeking refuge in their aquatic environment. Anesthesia and immobilization are discussed in Chapter 20. The following is a description of capture and restraint techniques that minimize the potential for injury to handlers and animals.

Crocodilians are dangerous; they are capable of injuring, scarring, maiming, and even killing handlers. This is not to imply they are bad, loathsome, or evil. It is simply the result of being large, tremendously powerful, predatory, agile, and adaptable. No one can safely work with these animals until this is fully comprehended. Further, you must remind yourself of this every time you work with them; complacency is our greatest threat.

There are many ways to safely capture and restrain even very large crocodilians. There are a greater number of incorrect ways. Each capture is different and always has the potential to go wrong. There are many variables that must be taken into account in successfully capturing and restraining a crocodilian.

Ultimately, no amount of detail in this chapter, training, or experience will guarantee no harm to those working with these animals. If you cannot personally accept this liability, you should neither attempt any of the techniques discussed in this chapter nor should you work with crocodilians. Accepting this liability is part of the commitment necessary to work with these magnificent animals.

For larger captive crocodilians, the trend is to reduce contact with the keeper staff by providing shift enclosures and training the animals to use them. This is

much preferred over physically capturing and restraining an animal. While the former (shifting) is strongly encouraged, the latter (capture and restraint) will form the body of this chapter.

Few publications describe techniques for the safe capture, restraint, and handling of captive crocodilians. Most descriptions are of free-living species: for example, the American alligator (*Alligator mississippiensis*) (Chabreck 1963; Forster 1991; Joanen & Perry 1972; Jones 1965; Jones & Hayes-Odum 1994; Murphy & Fendly 1974; Wilkinson 1994); the American crocodile (*Crocodylus acutus*) (Mazzotti & Brandt 1988); the Nile crocodile (*Crocodylus niloticus*) (Hutton et al. 1987; Kofron 1989; Pooley 1984); and the saltwater crocodile (*Crocodylus porosus*) (Walsh 1987; Webb & Messel 1977). While useful insights and methods are gleaned from these articles, most describe traps that are of little practical application in the captive environment. A detailed list of equipment and techniques used in alligator research is found in McDaniel and Hord (1990). Fowler (1978) makes brief mention of restraint of smaller captive crocodilians. Almandariz (1986) describes physical restraint techniques of reptiles, including crocodilians. The most comprehensive reference is that of Wise (1994). This article contains many pertinent and useful insights that serve as a valuable reference for anyone interested in developing the skills necessary to safely work with these animals. The following discussion builds on and expands the contributions of the earlier-mentioned references.

This chapter does not detail all of the possible techniques for capture and restraint. The author has included those he is experienced with, accustomed to, and which he believes provide enhanced safety. The author has had the opportunity to capture all 23 crocodilian species during several thousand captures over 20

Table 18.1. Suggested standard list of materials used for crocodilian capture and restraint

1. Capture ropes (different diameters relative to animal sizes)
2. Restraint ropes
3. Jaw ropes
4. Defensive poles
5. Catchpoles
6. Mouth poles
7. Tape
A. Duct tape
B. Electrical tape
8. Rubberized shelf mat
9. Cable straps
10. Eye cloth
11. Eye covers (gauze or paper towel)
12. Hooks
A. Stump ripper
B. Livestock hook
C. Python hook
13. Restraint equipment (ladder, crate, etc.)
14. Knives and wire cutters
15. Trauma kit

years, in both captive and free-living situations. Techniques evolve, and new, better practices come into use. Others may have different, and even better, methods than those presented here.

CAPTURE EQUIPMENT

Crocodilians frequently damage and destroy capture equipment. Consequently, restraint is either an expensive exercise or one develops sets of equipment that are easy and inexpensive to manufacture. The latter allows an adequate supply of equipment to always be available. The standard equipment the author and the staff of the St. Augustine Alligator Farm and Zoological Park use for crocodilian capture and handling is described in Table 18.1.

Ropes

Capture Ropes Ropes are essential for most captures; they are used to gain a hold on, to restrain, and for the safe release of animals. Several ropes are always available for any capture. The size used depends on the crocodilian to be captured. Smaller specimens require smaller diameter ropes, while larger animals necessitate thicker and stronger ropes. Too small ropes may cinch too tightly on the animal or burn into a keeper's hands during a struggle. Ropes of too great a diameter will not close tightly enough over the neck or jaws, allowing the animal to work itself free.

For adult animal captures, the author uses either 1.3 cm (1/2 in) or 1.6 cm (5/8 in) ropes. They can be sisal (hemp), nylon, cotton, or a mixture. Ropes have different tensile strengths; it must be adequate for the size and mass of the animal to prevent breakage and animal escape. Nylon ropes are generally the strongest.

Cotton and sisal work well for many purposes, but rot if not allowed to dry after use. This leads to problems during captures of large animals; the rope may separate under tension, allowing the animal to go free and the keepers to fall back and possibly injure one another. Woven or braided ropes are less likely to kink or fail than twisted ropes. Many ropes float on the water surface preventing their placement under the head of a submerged crocodilian. Consequently, ropes are assessed before purchase and use for their ability to sink when soaked. The best ropes the author has used are those designed for arborists. They are soft and pliable yet strong, and they do not tend to "burn" hands when jerked by a crocodilian. However, they are also expensive.

Rope length depends on the intended use. Excessive length makes it difficult to gather and control during hectic moments in captures. The author frequently lassos crocodilians from a distance. For large crocodilians, several people are needed to pull a roped animal from the water or to a position where it can be safely secured. For these purposes, the author uses 8–9 m (25–30 ft) ropes.

Restraint Ropes Smaller diameter and shorter ropes are ideal for restraint. Ropes of 0.6 (1/4) or 1 cm (3/8 in) diameter are used to tie the legs off of the ground to prevent movement, or tie down an animal to a ladder or platform.

Jaw Ropes Jaw ropes are used to tie the jaws shut or remove the tape off of an animal's jaws as it is being released. These are generally small diameter, 0.3 (1/8) to 0.5 cm (3/16 in), and shorter, 3 (10) to 3.7 m (12 ft), ropes. Cotton clothes line works well for this purpose.

Poles

Defensive The primary use of a defensive pole is for protection of the handler(s). They must be of sufficient diameter and heft to maintain a safe distance between the holder and crocodilian during capture. When charged or lunged at by an overly enthusiastic animal, block the animal's advance and move to the other side of the pole.

These poles serve many other purposes. Animals can be discouraged from advancing toward a handler by lightly laying the pole on the soft tissues of its nostrils, or against its earflap. Similarly, animals are encouraged to move out of the way, allowing access to a particular animal for capture. In addition, the pole is used after capture to manipulate and position the animal (e.g., move legs, lift jaws, and force the jaws shut) without getting too close.

Defensive poles are generally wooden; if they are bitten by an animal they do not cause significant damage to the teeth. The author uses a heavy, large

diameter length of bamboo approximately 1.5 (5) to 1.8m (6ft) in length.

Poles greatly increase safety while working in close proximity to crocodilians. However, care must be taken when using them with larger crocodilians. Poles can become dangerous to personnel if grabbed and held in the crocodilian's jaws. When the animal swings its head from side to side, the pole may strike and injure a person. Care must also be taken when recovering a pole from a crocodilian.

Catch A variety of catchpoles are used to grab and hold. They all include a long rod with a noose or snare at one end. For larger animals (>2m), poles are designed so the noose and rope attachment separates from the rod. Commercial catchpoles are used when no other poles are available. They are sturdy and give very good control over the animal. However, even relatively small crocodilians (≥ 1.5 m) roll or spin violently enough during capture to twist and kink the cable snare, thereby destroying it. Further, during a struggle, the metal rotating cuff adjacent to the snare will push into the animal's head and neck and cause injury. Frequent use of commercial catchpoles is not recommended because of initial purchase cost, and the expense and time of repeated repair and maintenance.

Alternatively, it is easy, quick, and very inexpensive to make catchpoles. There are three commonly used, simple designs. The preferred is a "break-away" rope noose secured to the end of a pole with electrical tape. Once the rope is placed over the head and neck of the animal, the pole is pulled free and removed from the capture area. Recommended poles for this design are long (3–5 m), 3- to 4-cm (1 1/2 in) diameter wooden rods or lightweight aluminum electrical conduit. Swimming pool net poles also can be used; they are lightweight, long, and extensible.

Schedule 40 PVC pipes can also be used to make other catchpoles. Snares are made of twisted metal cable and affixed to the end (Fig. 18.1). The snare is attached by a metal swivel coupled to an eyebolt through an end cap. The cap is glued onto the end of the PVC pole (Fig. 18.1). An advantage of this design is that snares of different diameter, or that have become damaged during a capture, can be rapidly exchanged during a capture. A small wire is attached to the snare base to keep it open until in place on the animal. Surprisingly, jacketed cables with plastic coverings cause more skin damage than exposed metal cables.

The simplest homemade catchpole for animals ≤ 2 –3 m (8 or 9 ft) consists of a nylon or cotton rope run through a length of 1.5–2 cm (1/2 to 3/4 in) PVC pipe (Fig. 18.2). The rope is secured through a hole drilled in the pipe wall close to the end, then run out of the pipe and back in again, to form the noose, and then down the length of the PVC. When the noose is placed around the animal, the rope extending from the

Figure 18.1. A homemade cable snare used for catching small- to medium-sized crocodilians. The catchpole is made of PVC piping.

Figure 18.2. A homemade rope snare used for catching small- to medium-sized crocodiles. It can also be used as a jaw noose; the rope is placed around the upper and lower jaws and either twisted or the rope pulled at the distal end to tighten. The pole is made of PVC piping.

back end of the pole is pulled tight and bent back against the pole for added friction. PVC pipes bend and fracture if they are used to lift animals. Once secured with the noose, the restrainer pulls back in line with the direction of the pipe to pull the animal for positioning and restraint.

Mouth A short version of the noose design works exceedingly well as a mouth pole for closing and securing the jaws of captured crocodilians prior to taping or

tying. The noose is placed over the jaws and tightened. Once the jaws are shut, the pole is twisted several times to add more tension to the noose. A person then steps in to quickly secure the jaws.

Tape

Tape is essential after capture and during restraint; jaws can be safely secured and heavier tapes are used to immobilize legs to prevent movement. The most commonly used are silver duct and black PVC electricians tape. Always have a sufficient amount on-hand.

Cable Straps

Nylon cable straps (zip ties) are very useful for securing the jaws of some crocodilians (i.e., narrow-jawed species) even before one captures the animal. These come in various lengths and tensile strengths; the largest can resist a force of 100kg.

Shelf Mat: Rubberized

Shelf mats are made of rubber-coated, woven fabric. They are used as non-skid shelf coverings and are readily purchased. The mats are cut into 5 to 10 cm (2 to 4 inch) wide strips to wrap around the snout or the entire head. They are used for this purpose because they do not slip in a wet environment. The crocodile jaws are held shut with a mouth pole or by hand, wrapped with the mat and then taped over. The sponginess of the mat prevents the tape from binding too tightly. Also, the nonslip nature of this material prevents jaw tape from slipping forward and covering the nostrils during transport.

Eye Cloth

The eyes are covered before or after capture with a cloth, towel, burlap bag, or an old T-shirt. This has a calming effect on the animals and likely reduces stress during the capture period. The blinded crocodilian is much less likely to avoid capture and to struggle following capture. Additionally, if the animal does attempt to strike, it is undirected and less likely to injure. Eye cloths are safely and gently placed over the eyes using a hook. The cloth is soaked before placement so it will more completely cover the eyes of the partially submerged crocodilian.

Eye clothes are secured with a couple of wraps of duct tape. Crocodilian eyes can be voluntarily withdrawn down into the skull, but some caution must be used when taping the eye cloth. Do not press the eyes too hard or apply too much pressure with the tape. If the eyes are to be covered for an extended period, gauze pads or a folded paper towel are placed over them before taping.

Hooks

Hooks are absolutely essential tools when working with crocodilians. They facilitate work around the animals

by allowing placement of ropes, manipulation of legs, and so on, without bringing human appendages within striking range. Several different hook types have been used by the author. Heavy snake hooks (e.g., python hooks) are sufficiently robust for positioning ropes around a crocodilian's head, lifting legs, lifting the jaws, and so on. Hooks are also useful for removing and retrieving ropes during release.

The author also uses long, very lightweight fiberglass hooks designed for livestock showing (Fig. 18.2). These break fairly easily, but are also inexpensive. They are not substantial enough to manipulate an animal, but are excellent for rope noose placement and positioning. When capturing a submerged crocodilian, it is often possible to carefully position a rope noose over and around the head with these hooks without disturbing the animal and causing it to move.

Restraint and Transport Devices

Once captured and the jaws secured, there are many ways to confine or restrain a crocodilian (e.g., bags, buckets, ice chests, shipping crates, ladders, platforms, and cargo nets or marine mammal slings). The restraint technique and equipment selected depends on (1) animal size, (2) duration of confinement, and (3) distance to be transported. A more detailed discussion of these devices is given later.

Knives and Other Tools

Cutting implements are always available during a capture. Knives are used to cut tape, frayed rope, and so on. Wire cutters are used to cut through cable straps when used on the snouts of some specimens.

Trauma Kit

If the capture techniques described in this chapter are followed, the risks to personnel are minimized. However, the capture team should always be prepared for someone being injured during restraint. This includes having a well stocked trauma kit on hand to provide immediate aid.

TO CATCH A CROCODILIAN

As described above, crocodilians can be massive, powerful and often react violently to physical restraint. During capture safety of personnel is paramount, followed closely by the welfare of the animals. The techniques favored by this author restrain the animals completely to limit the possibility of self-injury to the animal and personnel injury. The essential components of successful capture are planning, communication, caution, and knowledge of the animals.

Planning and Preparation

Capture and restraint of small specimens is usually routine and does not necessitate much planning or

preparation. This is absolutely not the case when attempting to capture and restrain a larger specimen (i.e., $\geq 2\text{m}$, 6 ft in total length). Preparation includes careful planning, discussion, and oversight. One person (the team or crew leader) is designated “in charge,” and he or she directs everyone else what to do, where to be, and so on. Each person’s role or roles is discussed and clearly understood before the operation commences.

However, many plans are quickly rendered moot if the capture subject is uncooperative. Each capture experience is different; it is not possible to foresee all of the variables likely to be encountered. Flexibility and strategy, the ability to change capture plans in mid-course while still maintaining a safe working environment, are essential. As handlers become more experienced with captures, they develop a greater repertoire of techniques to apply to specific situations.

Communication is essential before, during, and after a capture to insure the safety of the staff and the animal. Each team member must listen for, and continue to receive instructions from, the team leader throughout the procedure. The team leader must also continually look out for crew safety, make sure staff is in their proper positions, performing their assigned roles, everyone is outside of the strike zone of the animal, and escape routes are kept clear at all times.

Environmental Assessment

The first stage of preparation is assessment of the capture environment. If the animal is in a simple off-exhibit enclosure, this may be fairly straightforward. However, an animal on display in a complex habitat full of obstacles and possibly with other enclosure mates requires more forethought. It is important to answer several questions when assessing the capture environment.

Where Are the Escape Routes? This is perhaps the most important question. More than one route is preferred, but often not available. All team members must be aware of these routes, and they are left clear at all times during the capture.

What Is Physically Possible? The geography of an enclosure will determine access and the capture technique used. For example, low overhanging vegetation, large amounts of vegetation, and logs or rocks in a pool make it difficult to get a rope on an animal.

Is the Animal Trained to Shift? Many institutions provide off-exhibit shift areas, similar to those used for mammalian carnivores or large hoofed stock. Crocodilians can be rapidly trained with food to utilize these shifts, and even to move into transport crates. This training facilitates working with these animals and reduces the need for stressful and potentially injurious captures.

Will the Animal Be Caught in Water or on Land? The habitat is assessed to determine whether staging the capture on land or in the water is best and safe. In many enclosures, land surface is insufficient or too crowded with vegetation and furniture to allow a well-coordinated capture. Similarly, some water features make it difficult to gain access to the animal. If the plan is to catch in the water, will the staff be on shore or down in the pool or both?

The characteristics of any water feature must be known to make a proper assessment of its utility in catching an animal. Important variables to know include total pool area, the water depth, whether the water can be lowered without emptying the pool, the slope of pool sides, and whether staff can easily get out of it.

Land capture requires sufficient space for both the team and the animal, and must allow the staff to stay safely outside the strike zone. If the animal is on land, the plan should include a contingency for capturing it in the water. Unless caught immediately, crocodilians will seek refuge in water. If either land or water offer ample opportunity for capture, consider choosing to catch in the water. On land, crocodilians feel threatened and cornered. Water is a natural refuge and they often lay more passively, allowing easier placement of the rope and positioning of personnel.

Where Will the Animal Be Restrained? In some situations, the crocodilian is removed from the enclosure to provide enough space to safely work around the animal. In other situations, the jaws are secured while the animal is in the exhibit, then it is removed from the habitat before full restraint or loading into a crate.

Are There Other Animals Present? Other crocodilians obstruct access or pose a significant and potentially serious threat to staff and the animal to be captured. If possible, these animals are shifted out of the way before beginning. Additional staff may be needed to fend them off during capture; these animals may become involved as the animal and catch team move about the enclosure. The heightened stress or anxiety in the enclosure associated with the capture may cause these animals to strike out. Care is taken to avoid injury to the animal being caught up and the staff members involved.

Animal Assessment

Not all techniques are appropriate for all species or size class. It is useful to have knowledge of the animal to be captured; crocodilian species are known for differences in temperament and their capabilities. Saltwater crocodiles (*C. porosus*) and Cuban crocodiles (*Crocodylus rhombifer*) are especially dangerous; they may charge and are powerful and agile jumpers. However, this does not imply other species are less dangerous. There are

also individual animal differences; some usually mild-mannered species can be unexpectedly belligerent. Ideally, all crocodylians are approached with the same degree of caution. There must be a healthy understanding and respect for the physical abilities of these animals.

Other aspects of the animal's biology, particularly snout morphology, are also considered when preparing for a capture. Slender-snouted species are more prone to serious snout damage during capture than are species with broader, more robust snouts. As a result, special precautions are necessary in preparing for capture of these more fragile species. Protecting the jaws prior to capture with cable straps may reduce disfiguring injuries. Conversely, exceptionally robust or broad-snouted species (e.g., the broad-snouted caiman, *Caiman latirostris*) are often difficult to safely secure because there is relatively little purchase area for hands or mouth-poles.

The "toothiness" of the animal to be captured is noted. Protruding teeth cause damage, or even serious injury, when accidentally caught on a hand or arm or forcefully slammed into a team member during a struggle. This danger persists even after the jaws have been secured. Many captive crocodylians have abnormal tooth development, resulting in misaligned teeth protruding from the jaws. In some species (e.g., the false gharial, *Tomistoma schlegelii*), the teeth are long, slender, sharp, and naturally interdigitate, making them very difficult to handle. In these animals, it is necessary to wrap the entire jaw line in tape, or with a bath towel, rubberized shelf mat, or other material to prevent injury.

CAPTURE AND HANDLING BASICS

Strike Zones

The crocodylian head is its most dangerous part. Many people unfamiliar with these animals believe the tail is the main area to be avoided. While it is true the tail can cause injury, it is the head that has a mouth full of 70–80 teeth and a very high bite force.

The stocky body form and heavily ossified skin of crocodylians limits their flexibility. However, they can and will strike sideways with exceptional speed. In most crocodylians lying on the ground, the strike zone is defined by the arc of the head swinging from side to side. It is, therefore, much safer to approach an animal, secured by a rope around its neck, from the front than the side.

In the process of swinging its large, massive head rapidly to the side, a crocodylian generally swings or slaps with its tail. The tail is solid and strong and can knock a person off his or her feet or knock them toward the jaws. Consequently, the tail arc must also be avoided by catch personnel.

Roping

Captures generally begin with the securing of a snare or rope noose to the animal. There are two basic variations of this procedure.

Neck Noosing This technique involves placing the rope over the head and cinching it around the neck. It is usually used for alligator, caiman, and heavy-bodied crocodiles. These animals have fairly large jowls at the back of the head behind that the rope noose can take hold. Crocodylian necks are thick, heavily muscled, and usually capable of enduring without injury the forces that occur during struggling. In captivity, where it is often possible to carefully place the rope before closing the noose, some prefer to also hook the noose under one forelimb so it does not cinch tight around the neck. This technique is necessary in very large, heavy specimens that have to be pulled up and over a steep bank or the lip of a pool. This is to prevent too much force being applied to the neck and spine.

Top Jaw Noosing Top-jaw noosing is used in species with body profiles too slim to allow a neck noose. The rope is caught in the teeth and held firmly. It is of a narrower diameter (≤ 1.3 cm, 1/2 in) allowing it to bind more closely around the upper jaw.

A clear advantage of this technique is the greater control of the head, since there is restraint of the snout. However, a major disadvantage is that when the crocodile jerks, twists, or shakes, which they do with tremendous force and speed, all of the force is transmitted through the rope into the hands of the holder. Those who use top-jaw noosing usually secure the jaws with a narrow rope. Two people stand on either side of the head, outside of the strike zone, with the rope stretched between them. This is placed under the lower jaw, and then the ends of the jaw rope are wrapped around one another and exchanged. As the rope is pulled, the jaws are forced together. One person then steps in and holds the knot while the second ties a securing knot. A safer alternative is the use a mouth pole.

Securing the Jaws

Depending in part upon the size of the crocodylian, the jaws can be secured with a variety of materials.

Tape Once the jaws have been closed (by hand in very small specimens or a mouth pole in larger animals), their jaws are usually taped. The standard used on larger crocodylians is silver, fabric duct tape. It has reasonably good adhesion to itself, but animals otherwise unrestrained are usually able to work it off of their jaws within a few hours. A major advantage is it has very little stretch, making it difficult to apply too tightly.

This author uses black PVC electrician's tape to secure the jaws of crocodylians ≤ 3 m (10ft) for short periods of time. It is very quick to apply and sticks well

to itself. Most other tapes do not adhere well to crocodilians, especially when wet. During application, the tape must be wrapped around the snout and taped to itself to provide a good hold. A general rule is one wrap of electrical tape for each foot (0.3 m) of animal (i.e., for a 5-ft or 1.6-m alligator, wrap the tape five times around the snout).

Do not leave a crocodilian taped for more than a few hours. Electrical tape has a lot of stretch and can be applied with enough force to block blood flow to the skin. If it remains in place for too long, it will cause ischemic skin damage resulting within a few days in scabbing, sloughing, and scarring.

The author has also used the heavy, bright red, tape used for drywall seams. This has excellent adhesive force and a small amount of stretch. However, it does not tear readily, making it necessary to cut with a knife. The great advantage of this tape is that it is highly visible, making it immediately obvious when an animal has thrown its tape and its jaws are unsecured. This is an added safety measure, especially when transporting several animals at once.

Always create a tab when taping an animal; fold back the end so that it is easy to see and grasp. This facilitates removal of the tape during the release.

Cable Straps Cable straps (zip ties) are frequently used on slender-snouted species (e.g., *Tomistoma*, *Gavialis*, *Crocodylus intermedius*, and *Crocodylus johnsoni*). There is an increased risk they will damage or even break their snout/lower jaw during capture. This often happens when the animal bites on something in the exhibit and then rolls, applying torsion to the jaws. Securing the jaws shut before a capture reduces the chances of injury. The captures also move more rapidly; staff can restrain the animal in a shorter period of time, further reducing chances of injury.

To use cable strap, first make a noose by inserting the tip of the strap through the locking mechanism. Then, drill or punch a small hole through the tip of the strap and thread a string, wire, or monofilament line through and tie it. The string and the tip of the cable strap noose are then run through a length of 0.6 (1/4) to 1.3 cm (1/2 inch) PVC pipe to serve as a catchpole. The noose can be accurately placed over the jaws without touching them. A rapid tug on the string will close the noose and pin the jaws shut, often without disturbing the animal. Alternatively, the cable strap noose is suspended from the string and lowered into a position around the jaws. A swift jerk tightens the strap around the jaws.

This technique is also used with other crocodilian species, but it is more difficult to zip-tie the jaws of broad-snouted species. However, in many species, there is a notch or depression in the jaw (e.g., behind an enlarged tooth) into which the cable strap can take hold and tighten down onto the snout.

Caution must be used with nylon straps. Do not trust them; they often are not affixed tightly and can easily slip, releasing the jaws. They also become more brittle with time and prone to breakage; buy new ones before each capture.

Other Binds Less frequently, jaws are bound with rubber bands or heavy cord. Strong, heavy, rubberbands made by cutting tire inner tubes into rings can be used for animals ≤ 3 m (10 ft) in length.

Eye Coverage

Cover the eyes whenever restraining a crocodilian. Use an eye cloth or, if the animal is fully restrained, cover with your hand. During a capture, drop an eye cloth in place with a hook. This prevents the animal from seeing your movements, makes it less likely the animal will become unruly and prevents the animal from directing a strike toward a capture team member. Covering the eyes also keeps the animal quieter and may reduce the stress of the experience for the animal.

Go to the Bathroom

There is no delicate way to state this and it seems an odd thing to mention in a discussion of catching crocodiles but, before beginning any major catch up operation, make sure each person on the catch team has visited the restroom. These operations can be time consuming and can be tense for the staff involved. The necessities of bodily functions can arise making a team member uncomfortable and distracted. This can result in actions being rushed or mistakes being made.

CAPTURE AND RESTRAINT

Hatchling/Juvenile (≤ 1 m)

Hatchling and small juvenile-sized crocodilians can still inflict a painful bite, so caution is still necessary when working with these animals. Biting a keeper is also stressful to the animal and may damage teeth or jaw structures. Also, the animals are small enough that no matter where you grab them, you're never very far from the mouth.

This size animal is easily grasped by hand. Approach from behind and grab and hold firmly by the neck, over the shoulders or on the front half of the torso (Fig. 18.3). To reduce the chance of a bite, use a hook, a small stick or rod, or even a broom to push the head away from the hand and block as the animal is picked up. Pillstrom tongs, a standard tool for most herpetologists (Chapter 21), do not work well with crocodilians. The bony armor on the neck and dorsum prevents the tongs from gaining a firm purchase and the animals can twist, roll, and wrest themselves free. There is also a natural tendency to squeeze the tongs more firmly to prevent this resulting in injury to the animal.

Figure 18.3. Physical restraint of a small crocodilian (*Crocodylus mindorensis*). Note the electrician tape placed around the jaws and the hand grasping the neck and forelimbs.

Once the animal is in hand the jaws must be secured. The animal is held firmly around the neck with one hand, and the other hand is advanced from behind, keeping it close to the body. It is placed around the neck and slowly slid forward while gently squeezing. As it moves up onto the head, it will slowly close the jaws. The eyes are covered and the head held with this hand. The jaws are then secured shut with tape (even transparent tape will work on this-sized animal, a rubber band, or a short length of cotton clothesline) (Fig. 18.3).

Subadults (≤ 2 m)

Subadult crocodilians or the adults of smaller species (e.g., Chinese alligator, *Alligator sinensis*; African dwarf crocodile, *Osteolaemus tetraspis*; both species of the caiman genus *Paleosuchus*) are perhaps the most difficult size class to capture and handle safely. These animals are large and powerful enough to provide a large struggle, yet still agile and quick enough to turn rapidly and snap.

The tool of choice for these animals is the catchpole made by running a loop of rope through a length of PVC pipe. The loop is placed over the animal's head and around the neck and pulled tight. The rope is bent back against the PVC pipe for added friction. PVC does have some flexion so the animal is not completely controlled. However, the animal can easily be dragged and positioned with this device. Greater control of the animal is achieved if a second person grabs the tip of the tail and pulls the animal. This stretches the animal between the catchpole and the second handler. Maintaining pressure on the tail prevents the animal from twisting or turning to bite. A mouth pole is used to close and secure the jaws. With the animal still controlled by the catchpole, the mouth-pole is placed over

the snout and the rope pulled tight. It is preferable to stand at the side and slightly behind the animal's head when doing this. The jaws are closed with pressure applied by pulling the rope. When the jaws are completely shut, the mouth pole is twisted several times to add pressure to the jaws. When the jaws are secure and the mouth pole is holding, another crew member steps in and tapes the jaws.

Adult (≥ 2 m)

Capture and restraint of larger crocodilians is as much a matter of manpower and logistics as it is of proper procedure and safety. A sufficient number of staff is a necessity for a safe and efficient operation. Two people are plenty for a 2-m (6-ft) specimen. Generally, it is best to have at least three or four team members for a 2.5–3 m (8–9 ft) animal. Four or even more people are needed for specimens greater than 3 m (10 ft).

Not to belabor the point, it is ideal for working with these large specimens that they be trained to shift and, even better, into a crate. This provides substantial daily or weekly safety benefits to keeper staff and removes most of the trauma and anxiety of a physical capture. If this is not an option, or if the animal fails to shift when needed, than one may have to proceed with a capture.

As described earlier, before beginning capture of a large crocodilian, make sure ropes that are not frayed or worn and have been soaked are available. Wet ropes not only sink better to position them around an animal, but they do not burn the skin of the animal as dry ropes often will during a struggle.

Catching Adult Crocodilians in Water If the plan is to catch the crocodilian in the pool, the following are some suggestions for techniques to use. If it is possible to lower the water, drop it to a level that just covers the back of the animal (approximately 25 cm, 10 in). This depth limits the animal's mobility within the water feature while still allowing it to submerge its head. It also provides better visibility of the animal and any obstacles. It is important to keep enough water in the pool for the animal to remain submerged. As long as it can keep its eyes underwater, it is much less likely to become violently defensive.

There are various means of securing an animal in this situation. Most commonly, a rope is placed around the head and neck, and possibly one of the forelimbs. Hooks greatly facilitate safe rope placement and positioning of the noose. Alternatively a wide lasso is thrown over the head, or a break-away noose or a cable snare catchpole are used to get a line on the animal. If the animal is slender-snouted, or if there are many obstacles in the environment on which the animal might injure itself, the jaws are first secured with a cable strap.

If the team is familiar with the temperament of the animal and it is not reacting violently, it is often possible to manipulate the animal when the water is shallow. Large nets or marine mammal slings may be used to slide under the animal, envelop it, and lift it out of the pool area, greatly reducing the animal's struggles and chances for injury. Animals may also be able to be pushed or herded into a crate or a large-diameter PVC pipe that has been placed in the pool (Saumure et al. 2002).

A common disadvantage of catching in the water is most pools are hard-sided. They are generally constructed of concrete or gunite and readily damage the side of the head of a struggling crocodilian. Attempt to keep the animal away from the pool sides as it struggles, and move it past these structures as rapidly as possible. Sealed foam rubber gym mats or other shock-absorbing materials can be placed against the side of a pool to protect the animal.

Catching Adult Crocodilians on Land Once the rope is placed on a crocodilian on land, there will be a struggle. They are able to generate a tremendous amount of resistance with their short legs forced into the ground. It is best to have sites already identified where one can tie off the rope (fence posts, trees, etc). Trees must be of sufficient diameter to resist the force of the animal; larger crocodilians will uproot a small tree. Tying off the rope restricts the animal's movements, facilitates repositioning of the handlers to provide further restraint and, perhaps most importantly, saves energy. Tired or exhausted catch crews are more likely to make mistakes. Successful techniques used for capture of crocodilians on land include the following sections.

The use of a rope to secure a hold on the animal is most common. Rope lassos can be tossed over the head or the rope is placed with a hook or catchpole. Once the rope is secure, the crocodilian is pulled to the designated work area. The animal is tied to a tree or post. Most carefully prepared capture plans unravel when the crocodilian begins to roll. This tangles ropes, scatters equipment, moves the animal into areas that compromise it or the catch staff and, generally, messes up an otherwise well-organized process. Catch leaders must recognize and concede when a plan has been disrupted. Most often, it is best to pause momentarily, regroup, reorganize, and then begin again. Once an animal is tied off, it may be possible to cinch a second rope to the tail. Stretch the animal and tie off the second line. This may help prevent the animal from rolling. Once the animal is restrained, a mouth pole is used to close and secure the jaws.

If there is a tree or post within the area, try to pull the animal up to it so that the head is pulled up against the tree. This acts as a stubbing post and can greatly restrict the movement of the head, making it safer to work around the animal.

Most crocodilians, when roped, will pull against the rope in an attempt to escape. A few may be more bold or aggressive and lunge at the staff on the other end of the rope. If this appears to be a potential, either control the animal by catching it up with a rigid catchpole, or place a second rope over the head and stretch the animal between them.

Mounting There are situations in which it is necessary to straddle over or "mount" a large crocodilian. With caution, procedure, and experience, this is a fairly safe technique. However, the level of security it offers personnel is much less than that of other methods recommended in this chapter (i.e., shifting, working at a distance with hooks and poles, or physical restraint on a backboard). If any of these other methods satisfy the purpose, use them instead.

Mounting allows one person to control the animal and its head, take blood or other samples, and facilitates measurement. Once in position on top of the animal, the handler is relatively safe. Even with vigorous twists from side to side, the animal should be unable to bite. Care is taken to prevent the animal from rolling. The best technique to prevent this is for other catch crew to keep the tail straight and pull the hind limbs back and off the ground. Some species (especially caiman) are quite capable of and prone to snapping their heads straight up as a handler leans over them. This is extremely dangerous and can cause serious injury; sit up straight while straddled on the animal.

To attain this position, the handler must move into the animal's strike zone, hence the danger of this technique. To do this safely, the animal must be tightly roped and the rope tied securely in front of the head. This prevents the animal from twisting back on the restrainer. The handler moves up along the axis of the animal's body, essentially straight up the tail and the back. Stay as close to the body as possible. If the animal thrashes unexpectedly, this will reduce the impact and help maintain your balance. The author finds it useful to nudge the animal with his foot before he proceeds. This tests whether the animal is ready to burst into a struggle. When ready to mount, move forward quickly and deliberately. Place one foot against the base of the tail just behind a hind limb. Move forward rapidly, place the other foot against the other side of the torso at midbody, and quickly drop into a seated position on its back, with knees planted behind the forelimbs of the animal. Cover the eyes with your hand, and keep your other hand on the top of the head and snout. Do not let fingers trail off the side of the face as this might elicit a snap to the side.

When ready to "dismount," make sure the path behind is clear and quickly step back off of the animal in the same manner you approached; place your feet against the body and step back along the body axis.

RESTRAINT AND TRANSPORT

Once the crocodilian is captured and the jaws safely secured, the techniques for safely and efficiently move it vary. The method of transport depends, obviously, on the size of the specimen and the distance it must be transported. For transport within the institution, smaller specimens are simply carried or placed in a bag, pillow case, duffel bag, bucket, or ice chest. However, even small crocodilians can deliver a painful slap with the tail. This is prevented by placing the tail underneath the arm while holding the animal around the neck and supporting its weight on your arm.

Larger specimens can be heavy, at least unwieldy if not often combative, and difficult to lift and carry. There is a natural tendency to try to lift these specimens by their legs. This can be injurious and must be avoided. The shoulder and hip joints of crocodilians are relatively shallow. It is not difficult to pull a limb out of the joint when lifting its leg. If an animal must be lifted, reach underneath and support it from below the torso and tail. However, crocodilians are not accustomed to being off of the ground; they will often struggle, twist, and attempt to roll. The head must always be controlled. Even with the jaws taped shut, it is dangerous. Always keep it directed away from others and keep your head away from it.

Ideally, larger crocodilians are either placed into a shipping crate or strapped to a backboard, platform, or aluminum ladder for transport (Fig. 18.4). They must

Figure 18.4. Physical restraint of large crocodilian (*Crocodylus novaeguinae*) with a restraint board. Cargo straps are used to tie the animal to the board. A towel covers the eyes to reduce struggling.

be thoroughly restrained to prevent them from struggling to free themselves and potentially injure themselves or the capture team. Although harsh, it has many benefits to the animal as well as to personnel. Some crocodilians will continue to struggle for long periods after capture. This increases their stress and exhausts them. Very large saltwater crocodiles (*C. porosus*) are known to struggle to such an extent that they build up dangerously high levels of lactic acid in their bloodstream (Seymour et al. 1987). This can result in severe acidosis and death. Crocodilians that are completely restrained on a board or platform usually cease to resist. Without the continued struggle, there is little chance of the animal seriously compromising itself physiologically.

Restraint can be in the form of nylon cable straps (for smaller specimens), ropes, or cargo straps. The platform can be lifted easily and can be placed on a cart or truck for transport. Straps are placed in several places along the body: over the neck, across the shoulders just behind the forelimbs, across the center of the torso, just in front of the hind limbs, on the base of the tail just past the pelvis, and one or more wraps across the anterior half of the tail (Fig. 18.4). The head is also secured. If the animal is restrained on an aluminum ladder, it is possible to run the rope through the hollow rungs of the steps to completely secure it to the structure. Cargo straps can be purchased in a variety of widths and strengths. It is best to use those that have a wrenching action to tighten the strap after it is attached.

It is possible to physically restrain even the largest of crocodilians in this manner assuming the platform and straps are sufficiently strong. However, it can be difficult to release the grip on the buckle of very large cargo straps. A heavy hook is useful for this purpose. For transport to other institutions, crocodilians are generally confined to a shipping crate.

RELEASE TECHNIQUES

Releasing an animal that has been captured poses as many safety concerns as the initial capture. One must be concerned not only with the safety of the staff, but also with risks to the animal being released or its enclosure mates.

There is a real possibility the animal may attempt to turn and bite after its jaws have been unbound. Methods should be utilized to put distance between the catch personnel and the animal being released. One such method is the use of a jaw rope. A length of narrow rope is passed underneath the tape or rubber-band holding the jaws shut. It is passed from the front to the back so there is no danger of accidentally causing the binds to slip and release the jaws prematurely. The rope is then tied off so that it will grip the binds. With the animal in position, all other restraints are removed, taking care not to trip on or

accidentally pull the jaw rope. When all restraints are free, and all personnel are well away from the animal, a hard tug on the jaw rope will pull the bindings from the jaws, freeing the animal.

In cases where the animal has been "top-jaw roped," it serves as the jaw rope. With the jaws still firmly taped or tied, the noose of the top-jaw rope is opened. The length of rope still firmly held in the crocodile's jaws is then used to make several wraps around the snout. This then serves to secure the jaws while the other bindings are removed. When all other restraints are removed and everyone is safely away, the top-jaw rope is unwrapped from the snout. The animal will open its mouth and release the rope.

A rope noose catchpole or mouth pole is ideal for assisting release. The animal is restrained by the catchpole while the jaw bindings are removed. The pole prevents the animal from moving toward the catch team member holding it. When everyone is safely back from the animal, the catchpole is removed.

Immediately after release, crocodilians may be highly agitated. If there are other enclosure mates, there is a possibility of displaced aggression, leading to injury of one or more of the other animals. Before releasing a crocodile, make sure it is positioned at a distance from others.

If it is suspected aggression will occur, it is possible to release an animal with its jaws still bound and remove the bindings later. Retape the jaws and insert a piece of rope or a metal ring under the tape. The rope should float and have a large loop tied in its free end. Once the animals have had sufficient time to calm down after release, a long-handled hook is used to catch the loop in the rope or the metal ring and pull the tape from the jaws.

19 Crocodilians (Crocodiles, Alligators, Caiman, and Gharial)

Gregory J. Fleming

INTRODUCTION

Crocodilians are one of the oldest living groups of reptiles and by their sheer size and character are popular exhibit animals in zoos. Many of the 23 crocodilian species are endangered, and conservation programs, in both zoos and in situ, are increasingly making higher demands for safe and effective chemical immobilization and anesthesia.

PHYSIOLOGY AND ANATOMY

Crocodilians spend much of their time entirely submerged except for their eyes and nares. Each nostril acts as a waterproof valve that is closed with a muscular flap during submersion. This reflex may be obtunded by immobilizing agents that relax the muscles of the nostril, allowing water into the respiratory tract (Fleming 1996). An additional respiratory valve is formed by the soft palate and gular fold. The elongated soft palate presses down against the gular fold, which protrudes from the floor of the mouth. This seal allows the crocodilian to open its mouth underwater without water rushing into the internal nares and the glottis. The gular fold may need to be displaced to visualize the glottis for endotracheal intubation (Fig. 19.1).

Crocodilians possess a pair of well-developed lungs (Klide & Klein 1973). The primary respiratory muscle groups are the intercostal and two transverse membranes, the postpulmonary and posthepatic. These membranes are comprised primarily of fibrous tissue with a muscular component (Van der Merwe & Kotze 1993). The postpulmonary membrane separates the lungs from the liver, and the posthepatic membrane is attached to a sheet of muscle that inters at the ospubis. These two membranes act as a diaphragm. Ventilation

is achieved by expanding the intercostal muscles, and then membranes pull the liver in a caudal direction, creating a negative pressure around the lungs. The lungs then expand and the air is drawn through the nostrils into the lungs. The glottic valve is then closed, holding the air in the lungs. Once the glottal valve relaxes, air in the lungs is expelled passively via the elastic recoil of the intercostal muscles and the postpulmonary/posthepatic membranes and lung tissue.

The air flow in the lungs of alligators has been shown to be unidirectional, passing through parabronchi similar to birds (Farmer & Sanders 2010). The significance for anesthesia is unknown.

Cardiovascular System

Crocodiles are the only reptiles that possess four-chambered hearts (Murphy 1996). The heart functions like a mammal's, with the exception of anatomical adaptations for an aquatic lifestyle. These include the foramen of Panizzi, an opening between the left and right ventricle, the subpulmonary conus situated in the pulmonary outflow tract of the right ventricle, and the aortic anastomosis that connect the two aortic arches just posterior to the heart (Axelsson 2001). In addition, crocodilians have a left aorta that arises from the right ventricle, which allows blood to bypass the lungs and be recirculated into the systemic circulation (Axelsson 2001).

The foramen of Panizza is a small window located between the intraventricular septum at the confluence of the left and right aortic arches (Millchamp 1988). It acts as a pressure valve allowing blood to flow between the venous and arterial systems. This flow from high pressure to low pressure results in venous admixture. When the animal is breathing, left ventricular pressure

Figure 19.1. View of the gular fold of a Chinese alligator (*Alligator sinensis*) being depressed with a tongue depressor to access the epiglottis. Note the oral speculum constructed of a piece of PVC pipe wrapped with tape.

is greater, allowing a small amount of oxygenated blood to flow through the foramen of Panizza into the venous blood supply (Millchamp 1988). When the crocodilian submerges, air held in the lungs restricts blood flow through the pulmonary capillary beds, resulting in pulmonary hypertension, which increases right ventricular and pulmonary arterial pressures. As a result, blood flows from right to left through the foramen of Panizza. Deoxygenated blood is diverted away from the lungs through the left aortic arch to organs that are not sensitive to low levels of oxygen (e.g., liver and stomach) (Grenard 1991). Oxygenated blood is diverted to oxygen-sensitive organs (i.e., the heart and brain). A combination of blood shunting and anerobic metabolism may allow an inactive crocodilian to stay submerged for 5–6 hours (Lane 1996).

This right to left shunt through the foramen of Panizza may have clinical implications during anesthesia when the crocodilian does not have ventilatory support or is apneic. Shunting of blood away from the lungs will delay inhalant anesthetic uptake and removal. This emphasizes the importance of assisted ventilation.

Renal Portal System

Crocodilians possess a renal portal system composed of the renal portal vein arising from the epigastric and external iliac veins (Millchamp 1988). These vessels drain blood from the dorsal body wall, the cloaca, sex organs, and the bladder. Drugs injected into the caudal half of the body, base of the tail and hind legs, may be cleared by the kidneys prior to reaching the systemic circulation. In other reptile species, such as the red-eared slider, studies have showed a significant a hepatic first-pass effect following hind limb drug administra-

tion (Holz 1997). A study comparing front leg versus hind leg injections of buprenorphine resulted in a 70% decrease in the bioavailability of buprenorphine when injected in the hind end (Kummrow et al. 2008). Thus, care should be taken when administering nephrotoxic drugs in the hind legs, and when possible, inject anesthetic drugs in the front legs until further research can be completed on crocodilian vascular anatomy (Mosley 2011).

Physiologic Reference Ranges

Obtaining heart and respiratory rates is very difficult in awake crocodilians. In one study, juvenile American alligators (*Alligator mississippiensis*) and smooth-sided caimans (*Caiman sclerops*) were implanted with monitoring equipment and isolated from human contact for 12–20 hours before measuring cardiac and respiratory rates. Normal respiratory and heart rates at 22°C were 0.6 and 11.6 beats per minute, and 1.6 and 14.2 beats per minute, respectively. Following visual contact with humans, both heart and respiratory rates doubled to 30 beats per min and 6 breaths per min (Huggins et al. 1969). Consequently, most captured crocodilians are likely to be tachycardic and tachypneic. In general, heart and respiratory rates vary inversely with the size of the animal, but are affected by environmental temperatures. In Nile crocodiles (*Crocodylus niloticus*), heart rates increased as temperatures increased from 1 to 8 beats per minute at 10°C up to 24 to 40 beats per minute at 28°C. Prolonged exposure to high temperatures above 40°C will cause irreversible cardiac damage. Heart rates as high as 55 beats per min at 29°C have been recorded in Nile crocodiles caught in traps (Klide & Klein 1973; Loveridge 1979).

Thermoregulation

Crocodilians are poikilothermic, regulating their body temperatures by using external environmental heat sources. They also operate at a preferred optimum body temperature (POBT) similar to mammalian internal body temperatures. For captive crocodilians, a good range for environmental temperatures is 25–35°C (Bennet 1996). Given a selection of temperatures, they are able to select the POBT for their metabolic needs.

Temperatures below and above POBT interfere with digestion and immune function. American alligators take twice as long to digest food at 20 than 28°C, while smooth-fronted caimans digest food three times faster at 30 than 15°C (Coulson & Hernandez 1983; Diefenbach 1975). However, experimental infection of American alligators kept at 30°C demonstrated the greatest white blood cell response to infection and survival of the infection, while alligators held above the POBT at 35°C succumbed to infection in 3 weeks (Glassman & Bennet 1978).

Crocodilians under general anesthesia should be kept at temperatures near their POBT or around 29.5°C

(Bennet 1996). Environmental temperatures below POBT decrease metabolism and thereby prolong clearance of injectable drugs, resulting in delayed recoveries. Induction may also be prolonged because of slowed absorption and circulation times. For example, large Nile crocodiles induced with the neuromuscular blocker, gallamine, took twice as long to become recumbent at 14°C (40 minutes) than at 26°C (20 minutes) (Fleming 1996).

RESTRAINT TECHNIQUES

All crocodilians are capable of inflicting serious damage by ether biting or lashing out with tails. For this reason, a number of restraint techniques have been developed for wild and captive crocodilians (Loveridge & Blake 1972; Wallach & Hoessle 1970; Walsh 1987). The goal of physical restraint is to be able to administer injectable anesthetics quickly and safely.

Successful restraint must be safe for both the handlers and the crocodilian. Reported injuries associated with physical restraint include fractured bones, damaged eyes, and drowning (Walsh 1987). Prolonged struggling will result in marked lactic acidemia, with pH levels dropping to 6.6–6.8 (normal range 7.2 ± 0.2) (Seymore et al. 1987). Like other reptiles, crocodilians take a prolonged period of time to recover from elevations in lactic acid, which have been implicated fatalities post restraint (Webb & Messel 1977). Captured crocodilians may become unconscious and drown if not allowed to rest after prolonged physical restraint (Sedgwick 1986). A variety of capture techniques have been described using scoop nets, squeeze cages, tongs, harpoons, rope traps, snares, box traps, and tubes, all with varying success (Blake 1993; Fowler 1985, 1986; Jones & Hayes-Odum 1994; Wallach & Hoessle 1970). Physical restraint of crocodilians is described in Chapter 20.

DRUG DELIVERY

The goal of drug delivery is to get close enough to the animal to administer the anesthetics safely. In most cases, this entails using injectable agents.

Darts

Darting can be a satisfactory method of delivering immobilizing agents to crocodilians. However, they have several major disadvantages to their use in these animals: (1) it is difficult to get an accurate shot while the crocodilian is in the water; (2) it is difficult to determine if the dart has fully discharged; (3) the osteoderms covering most of the dorsal surfaces of crocodilians may deflect the dart; and (4) once the animal is darted, if unrestrained, they may submerge, become immobilized, and drown. In captivity, in controlled situations (i.e., a dry enclosure), a dart may be

an appropriate way to deliver drugs remotely; however, in the field, darts are rarely used (Blake 1993; Flammard et al. 1992).

Hand Syringe

The hand syringe has the advantage that it can be accurately placed and the rate of injection can be controlled. However, the animal must be secured for safe injection. This technique can be used for smaller crocodilians that are hand-restrained and for administering reversal agents to larger specimens. Both intramuscular and intravenous routes can be used as described later.

Pole Syringe

The advantage of a pole syringe is that crocodilians can be injected while unrestrained in a shallow pool, net, or a snare. The main disadvantage is that the injector must be within 2.5 m of the animal, and injection volumes are limited to 10–15 mL. If the anesthetic agent is not administered fast enough, the pole syringe and handler may be damaged by the animal.

Injection Sites

The base of the tail just caudal to the hind legs has been a common area for intramuscular injections in crocodilians (Jacobson 1984). This area is composed of many layers of muscle, with the vertebrae located deep within the muscle, and there is no risk of injecting into any internal organs when using a pole syringe. The main disadvantage is in obese animals; there may be a layer of fat, which if injected, could delay drug absorption. Another factor to consider is the possibility of a significant hepatic first-pass effect following hind limb drug administration (Mosley 2011). When possible, IM injections into the front legs may be a more efficacious route of drug administration. In any case, care must be taken to direct the needle between the scutes to assure a complete drug delivery. Intravenous injections are best accomplished by accessing the lateral coccygeal vein or the ventral tail vein (Wellehan et al. 2004). This site can be used to obtain blood samples, inject intravenous drugs, or for intravenous catheter placement (Fig. 19.2).

Handling

Once the immobilizing drug has taken effect, it is prudent to use a pole or stick to stimulate the crocodilian a number of times to ensure there is no response. Once this is accomplished, the eyes should be covered with a damp towel and the jaw should be taped shut. Care must be taken to avoid taping the nostrils shut.

The crocodilian can then be rolled onto a stretcher or a large tarp. Care must be taken not to pull and tug on the legs of the animal. Large crocodilians may weigh up to 500 kg, and pulling on legs to move them or lift them may result in fractures or luxations (Blake 1993). To accommodate lifting a crocodilian out of shallow

Figure 19.2. Intravenous blood draw via accessing the lateral coccygeal vein. The needle is inserted at a 90° angle at the lateral midline of the tail, just beneath the lateral spinus process of the vertebral body. This same approach may be used to complete intravenous injections of anesthetic drugs such as propofol.

water, 1 m lengths of flat 2-in commercial crane slinging can be placed under the chest and hind legs. By using the slings to lift, animals can easily be picked up and moved without pulling on the legs (Fleming 1996).

If the animal is to be intubated, a mouth gag, made of a steel ring, polyvinyl chloride (PVC) pipe, or a wood block should be used to prop open the mouth. Depending on the size of the animal, steel tubing (in varying diameter and width) can be cut and wrapped with several layers of tape or leather so as not to damage the teeth. A hole in the middle of the gag allows for the passage of anesthetic tubes or endoscopic equipment.

MONITORING

Physiologic monitoring can include the use of stethoscope, pulse oximeter, Doppler blood flow transducer, electrocardiography (ECG), ultrasound, or blood gas analysis. Anesthetic depth is evaluated using the withdrawal reflex of limbs, increasing or decreasing cardiac rates, righting response, bite and corneal reflexes (Bennet 1996; Heaton-Jones et al. 2002; Neill 1971).

The electrocardiogram and reference values have been described for the American alligator (Heaton-Jones 1996). The ECG leads are attached to 2.5-cm needles passed through the skin. Although pulse oximetry may be used to assess heart rate, it does not appear to accurately calculate oxygen saturation in reptiles (Mosley et al. 2004). Crocodilian skin thickness and pigmentation may further hamper measurement with the transmission probe, whereas a reflectance probe in the cloaca may improve the signal achieved. Blood gas measurement in crocodilians may be difficult to

interpret because numerous variables, such as temperature, feeding, and sample site (arterial, venous, or a combination of both), may influence the results. American alligators have the ability to reduce the affinity of hemoglobin to reduce blood oxygen affinity at certain pH levels. This allows for more oxygen to be released from the hemoglobin under certain condition, such as acidemia, increasing the total amount of oxygen available to tissues (Busk et al. 2000).

Doppler blood flow transducer appears to a very reliable method of obtaining heart rate (Bennet 1996; Neilson 1996). The probe is placed over the heart or a large blood vessel, such as the ventral coccygeal, brachial, or femoral artery. Blood flow in the optic arteries may be detected by placing the probe against the globe with the eye lid or third eye lid closed. Alternatively, a dorsally directed probe placed in the cloaca may detect arterial blood flow.

ANALGESIA

Information on the use of analgesics in reptiles and specifically crocodilians is limited. As is common in exotic animal medicine, extrapolation of drug doses from similar species is needed to develop effective analgesia. The use of butorphanol as an analgesic in reptiles has been promoted for years based on research in birds (Paul-Murphy et al. 1999). However, multiple studies in other reptilian species, such as green iguanas and red-eared sliders, revealed that butorphanol at higher doses may result in sedation, but does not itself result in analgesia (Baker et al. 2011; Fleming & Robertson 2006; Mosley 2011; Mosley et al. 2003; Sladky et al. 2007, 2008). Until further analgesic trials with butorphanol in crocodilians are completed, the author does not advocate its use as an analgesic.

The use of opioids such as morphine at (0.8mg/kg) and meperidine (pethidine) (2mg/kg) in juvenile salt-water crocodiles showed evidence of analgesia as measured with thermal antinociception (Kanui & Hole 1992). In red-eared sliders, using infrared thermal latency testing, morphine dosed at 1.5 and 6.5 mg/kg IM resulted in analgesia, but caused long-lasting respiratory depression at higher doses (Sladky et al. 2007). Using the same methodology, morphine at 10 and 20 mg/kg IM in bearded dragons resulted in analgesia, but was delayed until 8 hours after administration (Sladky et al. 2008). In a recent study in red-eared sliders, tramadol (5 mg/kg PO every 5 days) induced analgesia via both opioid and nonopioid pathways (Baker et al. 2011). The author has used tramadol in numerous reptilian species at 5 mg/kg PO with good anecdotal success.

The use of meloxicam (0.2mg/kg PO, IM, IV) has been reported in reptiles, and administration either intravenously or orally resulted in the same bioavailability. (Hernandez-Divers et al. 2004; Wellehan 2006;

Whiteside & Black 2004). This author has used meloxicam (0.1 mg/kg orally once a day for 14 days) in two adult Nile crocodiles with traumatic foot lesions. The day following treatment, both crocodiles showed marked improvement in ambulation, with no evidence of lameness. After a single dose of ketoprofen at 2 mg/kg, IV and IM, in green iguanas, the terminal half-life was greater than that of dogs, suggesting dosing intervals for ketoprofen in reptiles should be longer than in mammals (i.e., >24 hours) (Tuttle et al. 2006).

TRANQUILIZERS AND SEDATIVES

Diazepam hydrochloride (0.22–0.62 mg/kg), administered 20 minutes prior to succinylcholine, resulted in a smoother induction and lower doses in American alligators (Loveridge & Blake 1972). Heart rates were decreased, respiration was maintained, and recovery for most was within 3 hours. Ketamine and diazepam have also been resulted in recovery times of 6 hours (Frye 1991). An alternative is zolazepam combined with tiletamine (Telazol).

Reversal/Recovery Reversal of benzodiazepine tranquilizers in mammals with flumazenil has been achieved in dogs at a ratio of 1:13, flumazenil to diazepam, or at 1:20, flumazenil to zolazepam (Lang 1987; Terpin et al. 1978). Without a reversal agent, recovery times of up to 6 hours in reptiles have been recorded (Frye 1991). Flumazenil is very expensive, making its routine use, particularly in larger reptiles, prohibitive.

LOCAL ANALGESIA

Local anesthetics are indicated for minor surgical procedures, such as skin lacerations or abscess removal (Burke 1986; Jacobson 1984). Toxic lidocaine doses have not been established for crocodilians.

A nerve locator can be used to assist in the accurate placement of local anesthetic around nerves (Wellehan 2006). Nerve locators use a pulsatile electric current passed through a needle in contact with the motor nerve (e.g., mandibular nerve) that innervates and thus stimulates an identifiable muscle (e.g., digastric muscle). Local anesthetic (e.g., 2% mepivacaine, 1 mg/kg) injected down the needle blocks nerve conduction. This technique has been used to provide analgesia in the mandible of American alligators, dwarf crocodile (*Osteolaemus tetraspis*) and Yacare caiman (*Caiman yacare*) (Wellehan 2006).

IMMOBILIZING DRUGS

Muscle Relaxants

Muscle relaxants do not provide analgesia for painful procedures, and auditory, visual, and tactile stimulation must be minimal. (Huggins et al. 1969) They have

been utilized historically in Africa for transportation and capture of wild crocodilians (Fleming 1996).

Gallamine Triethiodide The short-acting nondepolarizing neuromuscular blocking agent gallamine triethiodide produces flaccid muscle paralysis (Loveridge 1979; Woodford 1972). Even though paralyzed, the crocodile is fully conscious and aware of auditory, visual, and tactile stimulation, which may result in increased heart and respiratory rates (Lloyd et al. 1994). The eyes of immobilized crocodilians should be covered and all external stimuli (i.e., noise) kept to a minimum. Gallamine may cause the mouth to open as the muscles relax, commonly referred to as the flaxidil reaction (Blake 1993). Gallamine has been the drug of choice in South Africa, where it has been used for immobilization of Nile crocodiles for over 25 years in both the field and in captivity (Loveridge 1979; Webb & Messel 1977).

A wide range of dosages have been reported, 0.6 mg/kg IM in a 312-kg Nile crocodile to 4 mg/kg IM in a 9.7-kg crocodile (Loveridge 1979). An additional study of 38 adult Nile crocodiles reported effective dosages of 1–2 mg/kg IM (Fleming 1996). Larger crocodiles over 3 m were immobilized with dosages of 1.1 mg/kg IM, while smaller crocodiles less than 3 m were immobilized with a dosage of 2 mg/kg IM. Gallamine overdose may result in bradycardia, gastrointestinal hypermotility, increased salivation, mydriasis, and respiratory muscle paralysis and death (Blake 1993; Lloyd et al. 1994). Faster induction times (15–30 minutes) were reported with higher environmental temperatures (30°C). Cuban crocodiles have also been successfully immobilized, with gallamine at doses of 0.64 to 4 mg/kg IM (Lloyd 1999). Gallamine (1 mg/kg IM) has a low therapeutic index in American alligators and may cause death (Jacobson 1984). Deaths in false gharials (*Tomistoma schlegelii*) have also been reported (Frye 1991; Lang 1987).

Reversal/Recovery Crocodilians immobilized with gallamine recover within 12–24 hours without reversal. Recovery appears to be due to renal excretion of the unchanged drug (Flammard et al. 1992). Farmed Nile crocodiles are routinely left to recover without reversal in a shaded area with no access to water for 24 hours, until they walk (Flammard et al. 1992; Webb & Messel 1977). Accidental drowning may occur in partially recovered animals.

Neostigmine methylsulphate (0.03 to 0.06 mg/kg) antagonizes the effects of gallamine in the Nile crocodile (Flammard et al. 1992; Fleming 1996; Jacobson 1984). Recovery occurs within 5–40 minutes depending on dose and temperature. Redosing may rarely be necessary (Pleuger 1973). It is advisable to reverse the crocodile several meters from water and allow it to get up and walk into the water to assure that it has

recovered (Fleming 1996). Side effects reported in mammals, but not crocodilians, include those of a cholinergic crisis (vomiting, diarrhea, salivation, and bradycardia) (Schumacher 1996).

Succinylcholine Chloride Succinylcholine, unlike the other muscle relaxants, produces depolarization before muscle relaxation. This depolarization can produce acute hyperkalemia, lactic acidemia, extreme muscle pain, and phallus prolapse in males. Since there are better alternatives to its use, it is not recommended for the immobilization of crocodilians.

Succinylcholine has been used alone and in combination with other drugs for many years in numerous crocodilian species (Blake 1993, Flammerd 1992; Jacobson 1984, Klide & Klein 1973, Loveridge & Blake 1972; Millchamp 1988; Spiegel et al. 1984). American alligators >1.5 m are immobilized at 0.4 mg/kg. Smaller alligators require a larger dose (1 mg/kg IM), with recumbency in 5 minutes and recovery in 1.5 hours (Jacobson 1984). Higher dosages (3–5 mg/kg IM) also produced rapid recumbency within 4 minutes, but prolonged recovery (up to 7–9 hours) may occur (Brisaben 1966). The combination of succinylcholine (0.37 mg/kg IM) and diazepam (0.24 mg/kg IM) successfully immobilized adult American alligators (Loveridge & Blake 1972). The diazepam, administered 20 minutes before the succinylcholine, reduced stress and the succinylcholine dose. All animals were completely recovered within 3 hours. Juvenile caiman (*Caimen crocodylus*) are immobilized at dosages of 0.33–2.2 mg/kg IM, with recovery in 5–40 minutes (Johnson 1991).

Both freshwater (*Crocodylus johnsoni*) and saltwater crocodiles (*Crocodylus porosus*) have been immobilized successfully (Loveridge & Blake 1972). Saltwater crocodiles required a higher dosage of succinylcholine (2.2–5 mg/kg) than freshwater crocodiles (0.8 mg/kg to 0.3 mg/kg) at 5- and 35-kg, respectively. The dosage for both species was inversely related to weight. Immobilization was achieved at 5–7 minutes and up to three times the therapeutic dosage resulted in no deaths (Loveridge & Blake 1972).

Reversal/Recovery There is no reversal for succinylcholine; recovery is dependent on metabolism and renal excretion (Pleuger 1973). Severe liver disease will limit metabolism and prolong recovery. At preferred optimum body temperature, recovery takes 30 minutes to several hours depending on the dose administered (Jacobson 1984; Lloyd et al. 1994).

Atracurium Besylate In American alligators, atracurium besylate (15 mg/kg IM) 15 minutes after diazepam (0.4 mg/kg IM) induced loss of righting reflex within 40 minutes and recovery by 6 hours (Clyde et al. 1990). Five of eight animals became severely apneic (<1 breath/min), and were manually ventilated with room

air for up to 5 hours. With safer, more effective drugs available, its use is not recommended in crocodilians.

Reversal/Recovery Neostigmine methylsulfate (0.05 mg/kg IM) and atropine sulfate (0.01–0.02 mg/kg IM) reversed the muscle relaxation induced by atracurium (Clyde et al. 1990).

Opioids

Etorphine Hydrochloride Effective etorphine dosage varies considerably between and within crocodilian species. For example, American alligators weighing 1.6–3.9 kg required a dose of 1.3–3.1 mg/kg, while larger alligators weighing 39.5–68.0 kg required only 0.03–1.3 mg/kg (Hinsch & Gandal 1969). American alligators administered 0.29–0.51 mg/kg IM were immobilized within 20–25 minutes and were recovered in 60–180 minutes with no reversal drug (Hinsch & Gandal 1969). A 0.11-kg caiman administered the larger dosage of 44 mg/kg was immobilized at 11 minutes and recovered by 40 minutes (Thurmon et al. 1996). Intraperitoneal administration is effective, reducing induction times while having a similar duration of effect compared with IM administration. However, in Nile crocodiles, dosages as high as 8 mg/kg IM were ineffective and only produced pupillary dilatation (Loveridge 1979).

Reversal/Recovery Without administration of reversal drugs, crocodilians recover within 1–3 hours (Lang 1987). There is no report of using either naloxone or naltrexone to reverse etorphine in crocodilians.

Dissociative Anesthetics

Ketamine Hydrochloride Ketamine alone has variable immobilization or anesthetic effect. It has been used to anesthetize spectacled caiman (44–50 mg/kg), juvenile American alligators (11–12 mg/kg) (1 hour induction) (Beck 1972; Stoskopf 1993), and adult American alligators (45–70 mg/kg) (20 minutes induction) (Stoskopf 1993). Additional trials in American alligators at 50 mg/kg were reported to be successful, whereas 30 mg/kg had variable results (Heaton-Jones 1996; Loveridge 1979). Ketamine at 18–45 mg/kg in Nile crocodiles had little effect, while doses at 59–110 mg/kg caused death in three animals (Loveridge 1979). Dosages of ketamine in the range of 110 mg/kg have caused bradycardia and respiratory arrest in other reptile species (Burke 1986).

Recovery/Reversal There is presently no reversal agent for ketamine and recovery times vary with dose, taking up to several hours.

Tiletamine and Zolazepam Tiletamine/zolazepam (15 mg/kg IM) in American alligators did not produce complete immobilization (Jacobson 1984). Palpebral reflexes were unaffected; hind limb withdrawal was slow, and episodes of paddling were noted. Righting

reflex was achieved 3 hours post injection; however, with higher doses, reversal times may be prolonged.

Reversal/Recovery Partial reversal of tiletamine/zolazepam has been reported by using flumazenil at 1 mg per 20 mg of zolazepam (Lang 1987). Flumazenil has a high affinity for benzodiazepine receptors and competes with zolazepam resulting in a rapid reversal of the tiletamine in 2–4 minutes in mammals (Neilson 1996). Flumazenil, however, is seldom indicated in partially reversing Telazol because it is very expensive, and reversing the zolazepam will leave the tiletamine on board, which may result in seizures.

Barbiturates

The first reported use of pentobarbital was an oral dose of 200 mg/kg, followed by 15 mg/kg IP, in a Nile crocodile for removal of a gastric foreign body (Page 1996). It was later demonstrated in this species a dose of 28 mg/kg had an induction time of 2 hours and a recovery of 12 days, and 53 mg/kg could cause death (Loveridge 1979). Pentobarbital administered to spectacled caiman at 8.8–15.4 mg/kg IM resulted in induction times of 30–45 minutes and recovery times of 1–5 days. The use of barbiturates in crocodilians for immobilization is, therefore, not recommended.

Alpha-2 Agonists

Xylazine has been used with variable success in Nile crocodiles. Used alone at 3–11 mg/kg it had no observable effect. A combination of xylazine at 1–2 mg/kg IM, followed 30 minutes later by 20 mg/kg IM of ketamine, resulted in effective surgical anesthesia for 50 minutes with a 3–4 hour recovery. (Idowu & Akinrinmade 1986)

Medetomidine has been used in American alligator at 131–220 µg/kg in combination with ketamine 7.5–10 mg/kg, with juvenile alligators requiring the higher dose (Heaton-Jones et al. 2002). Mean induction time for juveniles was 19.6 minutes, and in adults was 26.6 minutes. Total anesthesia times were 61–220 minutes, with any procedure over 120 minutes receiving supplemental inhalant anesthesia. Doses of medetomidine of 150 µg/kg resulted in bradycardia and bradypnea (Smith et al. 1998a, 1998b, 1998c).

Relative high dosages (500–750 µg/kg IM) of medetomidine were required to immobilize juvenile (>3 kg) estuarine and freshwater crocodiles (Olsson & Phalen 2012a). The freshwater crocodiles required the higher dosage for immobilization.

Medetomidine (130–170 µg/kg) successfully immobilized four large (150–370 kg) estuarine crocodiles (*Crocodylus porosus*) (Olsson & Phalen 2012b) approximately 30 minutes after hand injection into the triceps muscle. The dosage appeared inversely related to body-weight. Reversal occurred within five minutes after IM administration of atipamezole.

Dexmedetomidine, an isomer of medetomidine, is approximately 1.6× as potent as medetomidine. Given the concentration of the commercially available formulation (0.5 mg/mL) and the high dosages required for immobilization, dexmedetomidine is only used in relatively small crocodilians.

Reversal/Recovery Yohimbine hydrochloric acid is used at a dose of 0.1 mg/kg IM to reverse the effects of xylazine. If reversal agents are not used, recovery times are variable, depending on dose, and may last 3–12 hours (Frye 1991; Lang 1987). Reversal of medetomidine in reptiles with atipamezole, a selective alpha-2 adrenergic antagonist, at five times the dose of the medetomidine given IM provides reversal. For reversal of dexmedetomidine, the dosage of atipamezole is 10 times. Reversal times vary with dose and body temperature, but in the earlier study with alligators, this was achieved in 35–37 minutes (Dennis & Heard 2002; Heaton-Jones et al. 2002).

OTHER INJECTABLE AGENTS

Tricaine Methanesulfonate (MS-222)

Tricaine methanesulfonate (MS-222) has been used at 88–99 mg/kg IM in juvenile American alligators, producing immobilization in 10 minutes and recovery in 9–10 hours (Brisabem 1966). A higher dosage of 150 mg/kg anesthetized an American alligator for 30 hours (Coulson & Hernandez 1983). Tricaine has also been used in spectacled caiman at 110–154 mg/kg IM with no effect (Johnson 1991). Unbuffered MS-222 is highly acidic and will cause tissue necrosis. There is also no commercially available approved parenteral form of MS-222. For reasons outlined earlier, it is not recommended for use in crocodilians.

Propofol

Propofol is an excellent induction agent and a single injection may give 15–25 minutes of surgical anesthesia, with righting reflexes returning after 25–40 minutes. It can be used as a continuous infusion to maintain surgical anesthesia (Divers 1996; Schumacher 1996). Its major disadvantage is that it must be injected IV, limiting its use in large crocodilians unless they are restrained. Dosages in reptiles from 10 to 15 mg/kg IV have been reported. It is the author's opinion, however, that dosages as low as 1–2 mg/kg in large animals may be enough to allow for intubation, while 5–6 mg/kg is appropriate for small or juvenile crocodilians (Dennis & Heard 2002). A butterfly needle, or extension set, may be used allowing the needle to be left in the vein for additional propofol to be titrated to effect. Due to its short duration of effect, propofol is best used in combination with an inhalant anesthetic for maintenance. Propofol is the author's most popular choice for induction of all reptilian species, including

crocodilians, where IV access can be obtained. Even large crocodilians trained to station in a restraint box may be induced with an IV injection of propofol with little stress or danger to the animal or the handlers.

Alfaxalone

The short-acting steroidal alfaxalone was previously available commercially in combination with alfadolone and solubilized with cremophor EL, which produced sometimes severe allergic reactions in mammals. A new commercial preparation contains alfaxalone alone bound to cyclodextrine to provide water solubility. Although marketed for IV use, it has been used IM in small domestic mammals without evidence of pain or tissue damage. The low concentration (10 mg/mL) or the commercial preparation, however, precludes its IM use in medium to large animals due to volume.

Alfaxalone (4 mg/kg IV, dorsal cervical sinus) provided 40–60 minutes of surgical anesthesia for implantation of radiotransmitters in 5- to 10-kg Johnson River crocodiles (*Crocodylus johnstoni*) (Franklin et al. 2009). A similar dosage (3 mg/kg IV) was used in 0.5-kg estuarine crocodiles (*Crocodylus porosus*) (Seebacher & Franklin 2004). Respiratory support was provided using an endotracheal tube and Ambu bag.

INHALANT ANESTHESIA

Endotracheal intubation and assisted respiration are recommended for inhalant anesthesia (Schumacher 1996), since aquatic species are capable of long periods of apnea. Injectable anesthetics are used for induction to allow safe access for intubation. Crocodilians have complete tracheal rings and cuffed endotracheal tubes, if overinflated, may cause avascular necrosis of the mucosa. To place the endotracheal tube, the snout should be grasped with two hands and the head and neck flexed 90° into a dorsal position. The mandible and maxilla can then be separated and a block of wood, speculum, can be placed (Fig. 19.1).

Positive pressure ventilation (PPV) at a rate of two breaths per minute or less is adequate for crocodilians (Schumacher 1996). Once the surgical or painful part of the procedure is completed, PPV can be switched from oxygen to room air and an Ambu bag. This will negate the negative respiratory effect of 100% oxygen, and a decreased respiration rate will allow an increase in systemic CO₂ levels to stimulate breathing. In the author's experience, this works very well for all reptilian species. In large crocodilians, a double-demand valve (Horne et al. 2001) can be used with pressurized room air (scuba tank) to achieve the same results.

For crocodilians weighing <5 kg, a nonrebreathing system is indicated with a flow of 300–500 mL/kg/min. For crocodilians >5 kg, a circle system 1–2 L/min for maintenance is recommended (Bennet 1996). This may be lower than in mammals of comparative size, but

oxygen requirements for crocodilians is much lower (Coulson & Hernandez 1983; Coulson et al. 1989).

Isoflurane provides fast induction, good muscle relaxation, and rapid recovery. Isoflurane is not metabolized, but is eliminated exclusively by the lungs so it can be used in compromised patients (Bennet 1996; Schumacher 1996). Induction is accomplished at a rate of 4–5% at 2–4 L/min; maintenance rates of 1–4% will vary depending on the injectable pre-anesthetic agent used. Recovery should take 10–60 minutes depending on the depth of anesthesia and type of premedication agent.

Halothane has also been used with good success in reptiles; however, induction and recovery times are prolonged when compared to isoflurane (Bonath 1979; Neilson 1996). Although the use of sevoflurane in crocodilians has not been reported, it has been used in a number of other reptilian species and does produce faster induction and recovery times than isoflurane with minimal cardiopulmonary effects (Bertelsen et al. 2005; Chittick et al. 2002; Rooney et al. 1999).

Nitrous oxide is an underutilized gas anesthetic and can be used in combination (1 part oxygen to 1–2 parts nitrous oxide) with isoflurane, sevoflurane or halothane (Neilson 1996). This gas is rapidly taken up and removed from the lungs, reduces inhalant anesthetic requirement, and produces added analgesia during painful procedures (Atkinson et al. 1977; Bertelsen et al. 2005).

ANESTHETIC PROTOCOLS

In designing an anesthetic protocol for a crocodilian, it is difficult to provide specific guidelines for each species and situation (Table 19.1). It is important to consider the species, medical condition, enclosure, temperature, staffing, and ultimate goal of the immobilization when formulating a plan. In the next section are a few of the author's suggestions for anesthetizing crocodilians. However, these drugs and dosages have not been evaluated in all crocodilian species, and some variability in response is inevitable.

Adult Crocodilian

1. Medetomidine 70–100 µg/kg and ketamine 7–10 mg/kg IM or IV, intubate, then isoflurane at 2–3% at 1–2 L/min via an endotracheal tube (circle system) with forced ventilation at 3–4 breaths/min should be used. While isoflurane reaches steady state, the medetomidine can be reversed with atipamezole at five times the medetomidine dose.
2. Nile crocodile: gallamine 1–2 mg/kg IM (diazepam 0.25 mg/kg IM optional). This may be sufficient for noninvasive procedures such as translocation. For invasive or painful procedures (surgery), maintenance with isoflurane at 2–3% at 1–2 L/min via an

Table 19.1. Commonly used drugs in crocodilians

Drug	Dosage	Species	Remarks	Reference
Analgesia				
Morphine	0.8 mg/kg IM	<i>Crocodylus porosus</i>		Kanui and Hole (1992)
Meperidine	1–2 mg/kg IM	<i>C. porosus</i>		Kanui and Hole (1992)
Meloxicam	0.1–0.2 mg/kg IM or PO SID for 5–7 days	Most species		Whiteside and Black (2004); Wellehan (2006)
Tramadol	5 mg/kg PO q 5 days	Most species		Baker et al. (2011)
Ketoprofen	2 mg/kg IM q 24–48 h	Most species		Tuttle et al. (2006)
Butorphanol			May cause sedation but not analgesia	Sladky et al. (2007); Sladky et al. (2008); Fleming and Robertson (2006); Mosley (2011)
Anesthesia				
Ketamine	11–110 mg/kg IM	Most species	Variable response when used alone	Frye (1991); Jacobson (1984); Loveridge and Blake (1972); Millichamp (1988); Olsson and Phalen (2012a)
Medetomidine	500–750 µg/kg IM	<i>C. porosus</i> and <i>C. johnstoni</i>	Juvenile crocodilians >3 kg. <i>C. johnstoni</i> required higher dosage for immobilization.	
Medetomidine	130–170 µg/kg IM triceps	<i>C. porosus</i> 150–370 kg	Dosage inversely proportional to mass.	Olsson and Phalen (2012b)
Ketamine and medetomidine	10 mg/kg and 0.1 mg/kg IM	Most species	American alligator	Heaton-Jones et al. (2002); Smith et al. (1998a, 1998b, 1998c)
Ketamine and xylazine	7.5–10 mg/kg and 1–2 mg/kg IM	Most species		Idowu and Akinrinmade (1986)
Tiletamine/zolazepam	5–15 mg/kg IM	Most species		Jacobson (1984)
Propofol	3–10 mg/kg IV	Most species	Start at low end of dose for intubation	Divers (1996); Schumacher (1996)
Alfaxalone	3–5 mg/kg IV	Most species	Start at low end of dose for intubation	Franklin et al. (2009); Seebacher and Franklin (2004)
Diazepam	0.22–0.62 mg/kg IM	Most species	Poor IM absorption	Loveridge and Blake (1972)
Reversal agents				
Atipamezole	5 times the dose of medetomidine IM	Most species		Heaton-Jones et al. (2002); Smith et al. (1998a, 1998b, 1998c)
Yohimbine	0.1 mg/kg IM	Most species		Lang (1987)
Flumazenil	1:13 or 1:20 times the dose of benzodiazepine IV	Most species		Lang (1987)
Naltrexone	100 times the dose of opioid	Most species		G.J. Fleming, pers. comm., 2011
Neostigmine	0.03–0.06 mg/kg IM	<i>Crocodylus niloticus</i>		Jacobson (1984); Flammard et al. (1992); Fleming (1996)
Inhalant agents				
Isoflurane	1–5%	Most species	2–3% for maintenance	Bennet (1996); Schumacher (1996)
Sevoflurane	1–5%	Most species	Higher than isoflurane for maintenance	Bertelsen et al. (2005); Chittick et al. (2002); Rooney et al. (1999)
Halothane	1–5%	Most species	Not recommended due to hepatotoxicity and cardiotoxicity	
Paralytics				
Gallamine	1–2 mg/kg IM	<i>C. niloticus</i>	No analgesia	Fleming (1996); Frye (1991); Jacobson (1984); Lang (1987); Loveridge (1979)
Succinylcholine	0.33–5 mg/kg IM	Most species	No analgesia	Blake (1993); Jacobson (1984); Millichamp (1988); Spiegel et al. (1984)

endotracheal tube (circle system) with forced ventilation at 3–4 breaths/min should be used. The gallamine may be reversed with neostigmine methylsulphate at a dose of 0.03 to 0.06 mg/kg IM. Reversal with IV injection is discouraged, as the crocodilian may become alert within a few minutes.

3. Telazol 4–8 mg/kg IM (this will not be sufficient to reach surgical anesthesia; however, intubation should be possible). Maintenance with isoflurane at 2–3% at 1–2 L/min via an endotracheal tube (circle system) with forced ventilation at 3–4 breaths/min. Long recovery of 4–8 hours may be encountered with using Telazol, care should be taken not to immerse the crocodilian in deep water during this period.

Juvenile or Restrained Adult Crocodilian

1. Propofol 3–5 mg/kg IV (caudal/ventral tail vein). Animal will have to be properly restrained, or behaviorally conditioned to achieve IV access. Additional propofol may have to be titrated to effect. Maintenance with Isoflurane at 2 to 3% at 300–500 mL/kg/min via an endotracheal tube (nonbreathing system) with forced ventilation at 3–4 breaths/min.

20 Venomous Reptile Restraint and Handling

Frederick B. Antonio

INTRODUCTION

This chapter presents information and recommendations for the restraint of venomous reptiles in either a clinical environment or field conditions. For simplicity, a venomous reptile refers to venomous snakes. A section at the end of the chapter will review management of venomous lizards of the family Helodermatidae (Gila monsters and beaded lizards). Envenomation will be referred to as snakebite, although it is recognized heloderms can also inflict a serious bite.

It is intended that the employment of the techniques described in this chapter will greatly reduce the probability of snakebite. There is always some inherent risk, however, when handling and restraining venomous reptiles. The combination of planning, training, and gaining experience for the skills necessary for proper handling will significantly reduce the probability for error.

In recent years, captive venomous reptiles have increased in popularity in the private sector. They are the topics of numerous television series, and are portrayed as both exciting and dangerous, often by actors and commentators that inspire young viewers to engage in interactions with venomous species. Many private collectors, researchers, and zoo professionals have only a vague notion of the potential lethality of their charges. Their ignorance includes both the potential physiological effects of venoms and the behaviors that make venomous snakes difficult to restrain (Altimari 1998). Some states within the United States prohibit personal possession of venomous reptiles, while others lack any regulation. Florida annually issues over 500 venomous reptile permits for personal possession. Many private collections are “underground” and reptile clinicians should expect to examine virtually any

species of native or exotic venomous reptile. Safe handling of these animals requires veterinarians, researchers, and support staff be familiar with and use proper methods. The following sections present current procedures and techniques designed to limit unrestrained contact with venomous reptiles and thereby promote safety during examinations, clinical procedures, and field work.

General Characteristics

Snake venoms evolved primarily to aid in prey acquisition and secondarily for defense. More than 2700 snake species are currently recognized within about 18 families and 420 genera (Greene 1997). Of these, 250–500 species may induce serious physiologic effects in humans. These belong primarily to the families Elapidae (cobras, kraits, mambas, coral snakes, and sea snakes) and Viperidae (true vipers and pit vipers).

Almost every colubrid snake family has at least one species whose venom has the potential to produce either morbidity or mortality in humans. These include (Fry 2006a) Colubridae (*Dispholidus* and *Thelotornis*), Dipsadidae (*Hydrodynastes*, *Xenodon*, and *Waglerophis*), Atractaspidae (*Atractapis* and *Homoroselaps*), Homalopsidae (*Cerberus*, *Enydris*, and *Homalopsis*), Natricidae (*Macropisthodon* and *Rhabdophis*), Psammophiidae (*Malpolon*, *Psammophis*, and *Rhamphiophis*), and Pseudoxyrhophiidae (*Leioheterodon* and *Madagascarophis*). Of these, the most commonly imported are the boomslang, *Dispholidus typus*; African twigsnake, *Thelotornis capensis*; Blanding's treesnake, *Boiga blandingi*; road guarder, *Conopsis lineatus*; Japanese water snake, *Rhabdophis tigrinus*; and the false pitviper, *Xenodon* spp.

Evolution of reptilian venom systems (Fry et al. 2006b), demonstrates some extant “nonvenomous”

snake taxa and certain lizards of Varanidae (monitor lizards) and Iguania to have toxin-secreting oral glands. A thorough review of nonfront-fanged colubroid snakes (Weinstein et al. 2011) analyzes documented case reports of bites inflicted by approximately 100 species and discusses clinical management of medically significant species, most commonly referred to as “rear-fanged” snakes. Studies of this kind confirm toxic salivary secretions in extant reptiles, usually products of the Duvernoy’s gland, that present a continuum of toxicity from mild to severe. Their presence and effects in human victims requires further study to build clinical evidence as to their potential severity. Thus, it is prudent for the clinician to treat suspect or unusual species, especially opisthoglyphs, with the same precautions as they do with recognized venomous species.

Venom delivery systems originate from modified salivary glands. These vary from mucous-producing oral glands to well-developed encapsulated glands with separate compressor musculature to express venom through a duct to individual hollow fangs. There are four dental patterns in snakes (Greene 1997): aglyphous, undifferentiated maxillary teeth, present in primitive snakes and some colubrids; opisthoglyphous, enlarged teeth (may be grooved to facilitate induction of salivary secretions) located on the posterior ends of the maxillary bones, present in rear-fanged snakes; proteroglyphous, enlarged true hollow fangs located on the anterior end of the maxillary bones that have restricted movement, present in elapids; and solenoglyphous, elongated hollow fangs located on highly movable maxillary bones, fangs are folded back along the roof of the mouth when not in use, present in vipers and pitvipers. These four basic dental morphologies represent a progression in efficiency for venom induction when biting.

One impressive variation in fang structure with management implications is found in the elapid species referred to as spitting cobras. Eye injuries by spitting snakes (Chippaux 2006) include African species (*Naja nigricollis*, *Naja katiensis*, *Naja mossambica*, *Naja pallida*, *Naja crawshayi*, and *Hemachatus hemachatus*) and some populations of Asian cobras (*Naja sputatrix*). These species have a fang structure and discharge orifice to defensively eject venom aimed at the eyes of an intruder. Target accuracy and the distance of ejection are from 1 to 5 m (Russell 1980). Full face shields (Fig. 20.1) are recommended at all times when working these species. If venom comes in contact with an eye, wipe remaining venom away from the eyes and begin immediate copious irrigation with sterile saline solution (Boyer & Murphy 1999). A long-sleeved lab coat or protective garment is recommended to shield skin. Venom may also be expressed on the inside of a restraint tube. Expelled venom must be treated with extreme caution during both the procedure and the cleanup process. Dried venom on glass can be aerosolized during

Figure 20.1. Full face shields and protective garments are recommended when working with all species of spitting cobras. Red-spitting cobra, *Naja pallida*, Central Florida Zoo and Botanical Gardens.

cleaning and cause injury to eyes and mucous membranes.

SNAKE BEHAVIOR

Handling and restraint should be approached every time as a novel experience that may be significantly different from previous procedures. Planning the procedure with the total focus of all persons involved is required. Complacency or a casual approach, no matter how experienced the handler, can result in an unexpected and disastrous outcome.

Every species exhibits different behaviors when manipulated. Defensive behaviors vary with the individual temperament of each snake, and the handler must observe and read these behaviors to adjust their response and modify techniques if needed. Altimari (1998) describes the temperaments of many captive venomous snake species. Viperids tend to defensively coil and may strike out in any direction. Elapids are more dangerous to manipulate and may initially attempt to flee. However, they can turn and strike at any time, or strike first then look for an escape route. Striking distances are approximately two-thirds of the total body length. For some species, however, when traveling and lunging while striking, it is difficult to determine a safe working distance in an open environment. Always over estimate the strike range.

Snakebite

In the United States prior to 1950, exotic venomous snakes were primarily found in zoos. Increased interest in reptiles during the latter twentieth century has resulted in the United States as the major importer of reptiles, representing 80% of the world trade or approx-

imately 2,000,000 reptiles imported annually (Keyler 2006). The vast majority of snakebites occur in private collections comprising a large variety of genera and species (Seifert 2006a). Of these nearly half are elapid bites. The incidence of nonnative envenomations has increased significantly over the past decade. Statistics on snakebite in clinical situations are difficult to obtain as many are not reported to data surveillance systems. Toxic Exposure Surveillance System (TESS) data for 2002 showed the number of exotic snakebites in the United States to be 125 (Keyler 2006), and around 100 exotic bites reported to the American Association of Poison Control Centers annually (Lai et al. 2006).

In a survey of 40 academic institutions that used venomous reptiles in research projects (Ivanyi & Altmani 2004), 18 facilities reported 42 envenomations and 6 dry bites from 20 species. The majority of these bites (87.5%) were the result of inappropriate capture techniques and inadequate restraint methods, including free handling snakes, pinning, handling with gloves, and improper use of restraint tubes. Card and Roberts (1996) surveyed North American zoos to determine the incidence of venomous reptile bites received by staff. Out of 30 reptile collections that maintained venomous reptiles, 21 zoos reported a staff member bitten during a 25-year period, with a total of 31 incidents. Of these, 15 envenomations occurred during routine handling, 5 during physical restraint, and 1 during a veterinary procedure. In a survey of 32 venom extraction facilities worldwide (Powell et al. 2006), envenomation averaged one per facility every 2 years. Although records of envenomation in veterinary medicine are lacking, the potential is ever present when a client presents a venomous reptile for examination and treatment. In many cases, this is a novel experience for the practitioner who lacks behavioral knowledge of the species, handling expertise, and proper equipment.

Antivenom

Antivenom is the only product recommended for treatment of snakebite. The goal of this immunotherapy is to neutralize venom components with antibodies and prevent them from reaching their sites of action. All snakebites are medical emergencies requiring effective response protocols and knowledgeable case approach by the treating physicians once the victim arrives in the Emergency Room. Treatment of snakebite is outside the scope of this chapter, but it remains the responsibility of the veterinary clinician or researcher to either possess the appropriate antivenin or know the nearest local source for the species to be restrained.

The appropriate foreign antivenom for exotic snake species should be present when working with these species as it is not stocked in hospital pharmacies. Ideally, it should be provided by the client and accompany the snake during transport to the clinician. Antivenom for native species is usually stocked at local

hospitals for venomous species found in that region. It is recommended to contact local hospital pharmacies to periodically check on current inventories as antivenom can be difficult to obtain and supplies may be limited.

Treatment of envenomations is a challenge to physicians as most have never treated a snakebite victim. Case approach, the appropriate use of antivenom, and patient support have also been controversial. Locating and obtaining appropriate antivenom may be difficult, resulting in critical delays (Seifert 2006b). Species-specific antivenom should be sought unless there is evidence for cross-species efficacy. Most private collectors do not routinely maintain exotic antivenoms (Keyler 2006). Lack of sufficient appropriate antivenin can be a determining factor in choosing not to accept cases or engage in specific research projects that involves the handling of venomous snakes.

In the United States, foreign-manufactured antivenom can be imported by facilities or individuals under an Investigational New Drug license issued by the Food and Drug Administration, Department of Health and Human Services. These products may be species specific or polyvalent. Some antivenoms have shown cross-species neutralization (Minton 1999), but evidence must be available for cross-species efficacy before relying on this strategy. The appropriate antivenom should be provided by a responsible owner or researcher and travel with the snake to the clinic. If the owner does not have the appropriate antivenin, the nearest source should be located prior to arrival. For long-term studies, the acquisition and stocking of the appropriate antivenom is recommended.

An Online Antivenom Index (OAI), developed by the Association of Zoos and Aquariums (AZA) and the American Association of Poison Control Centers (AAPCC), lists specific antivenoms for treatment of exotic snakebite and their locations across the country. This antivenom inventory can be accessed by calling Poison Control (U.S. phone: 1-800-222-1222) to locate the nearest source for specific antivenom appropriate for the species. In most cases, the source is an AZA facility that logs their institutional inventory on the OAI site. Poison control centers have access to this information and should be consulted when locating a potential source of antivenom for projects or procedures involving venomous snakes.

An additional source for foreign antivenoms is the Miami-Dade Fire Rescue Antivenin Bank (formerly the Florida Antivenin Bank, Inc.) which stocks a significant inventory of antivenoms. Information on their holdings and procedures for requesting antivenom can be found on their website (<http://www.venomousreptiles.org>). A phone call can arrange an emergency response (Emergency Envenomation, phone 786-336-6600; nonemergency 786-331-4444) to arrange antivenom transport to the attending hospital.

This service can be a critical element in the treatment of snakebite when quantities of appropriate antivenom are lacking.

MANAGEMENT GUIDELINES

Strict protocols for handling venomous reptiles, routine husbandry, and staff training promote safety for staff and animals. Written protocols for snakebite response must be in place prior to receiving venomous reptiles. Snakebite protocols and case approach for attending physicians should be established with the local hospital and emergency room physicians to help insure swift and consistent treatment. A list of consulting physicians, that are experts in treating snakebite, should be readily available as a resource for local treating physicians, as few will be familiar with proper clinical management of snakebite.

The following venomous reptile handling protocols serves as a baseline for establishing best practices and may be expanded to incorporate unique aspects of facilities or research projects.

1. Venomous reptiles should not be handled by anyone except designated personnel.
2. Staff should be thoroughly trained, knowledgeable, and comfortable with handling procedures.
3. Always review techniques and procedures with staff. Set up the work space in advance and clear the area of unnecessary objects or obstacles. Have all appropriate tools readily available.
4. Never work venomous reptiles when in a hurry, mentally distracted, or on medication that may impair alertness, reflexes, or response time.
5. Two qualified personnel should always be present. Assistance is often needed and a second person is crucial should snakebite occur.
6. Cages should remain locked until they are ready to be opened. Always announce a cage is to be opened so the attention of support staff is immediately focused on the procedure.
7. All cages should be clearly marked "VENOMOUS." An additional label should state the name of the species (common and scientific name), the number of animals in the enclosure, type of antivenom to be administered, and the typical number of vials recommended for a moderate envenomation.
8. Never handle a reptile that appears dead directly with your hands. Always use a tong or snake hook to test for movement. The mouth of a dead specimen should be carefully taped closed to avoid unintentional contact with the fangs.

EQUIPMENT AND METHODS

Venomous reptiles can be managed safely by using the proper tools and techniques. Training and experience

plays a significant role in developing expertise. A working knowledge of snake behavior and their reaction to stimuli will aid in strategizing the best methods to use for a particular procedure. An organized and methodical approach to handling and restraint increases control and is assuring to support staff that may be unfamiliar with working venomous reptiles. Equipment and methods described here are proven techniques. Innovations can produce further modifications for specific procedures. Historic methods, such as pinning a snake behind the head for manual restraint (Fig. 20.2), are a dangerous manipulation and should be discouraged.

Snake Hooks

The manipulation of venomous snakes using snake hooks (Fig. 20.3), as opposed to tongs, lowers the potential of injury to the animal. Reptiles have a single

Figure 20.2. Pinning behind the head for manual restraint is not recommended. Snakes when struggling can move fangs independently while dislodging the mandible to succeed with envenomation. Eyelash viper, *Bothriechis schlegelii*, The Orienne Society.

Figure 20.3. Snake hooks (top to bottom): Wide-blade "python hook," extension hook, double-handled hook, various styles, and "L hook" or pinning hook.

occipital condyle supporting their skulls upon the cervical spine. Rough handling or improper restraint can cause spinal injury (Frye 1991) when the snake twists or thrashes. Vertebral morphology and the limitations of movement by vertebrae and axial musculature reviewed are by Gasc (1976). Using tongs for restraint can also induce the snake to bite itself. This can result in self-inflicted fang penetration and envenomation. Although the effects of self-envenomation are usually minimal due to immunity, mechanical damage due to fang penetration can have a serious outcome.

Choice of snake hook is dependent on the size and species. Hooks come in a variety of sizes and configurations and can be “homemade” or purchased from specialty suppliers (e.g., Midwest Tongs, Greenwood, MO, <http://www.tongs.com>). Two main design aspects need to be considered when choosing the appropriate hook. First, the length of the hook handle must be longer than the striking distance to the hand. In most species, this is usually two-thirds the length of the snake or more! The second is the terminal end of the hook, which supports the snake, should be of sufficient diameter to comfortably hold the weight of the snake. Large, heavy animals require the wider support surface found on larger diameter hooks. “Python hooks” have wide flattened surfaces of 3–6 cm for added comfort to the snake during lifting. This results in a more consistent manipulation of large vipers (genus *Agkistrodon*, *Bitis*, *Crotalus*, *Lachesis*, and *Vipera*). The main disadvantage of “python hooks” is they usually lack sufficient shaft length for large specimens. A hook with a terminal “L-shaped” end is not recommended. The snake will slide down the shaft if it is lifted higher than the handle of the hook. Hooks are relatively simple tools that can be made and tailored to problematic species or individuals.

Basic steps when using a hook:

1. Always set up all required equipment first (transfer or holding containers, and a clear work area) and review with personnel the procedure steps. It is desirable to have a second potential handler with a hook should assistance be required.
2. Always open bags, containers, and cages using proper safety methods.
3. The hook tip is initially inserted under the anterior portion of the snake and slid caudally to the midpoint or its approximate center of gravity, on the body side facing the handler.
4. Once the hook is at the desired location, lift the snake in one motion, just high enough for the head and tail to clear the surface. This will induce the snake to hold and balance. If it is still moving and not balanced, gently set the animal down and repeat the process.
5. Once balanced, lift and move the snake to the desired location. Prevent the head and tail from touching objects during transfer. This will often startle the snake and induce it to come off the hook.
6. Gently set the snake down and remove the hook. Be prepared to use the hook to keep the snake under control or to further manipulate it for the intended procedure.

Longer handled hooks for larger and more agile snakes may have a second grip located above the base grip of the hook. Using two hands on the hook, with the second (anterior) grip as a pivot point, aids in lifting heavier specimens while increasing dexterity and control of the specimen. Care must always be taken that the position of the second grip (hand closest to the snake) is outside the striking range of the snake.

Some snakes require “double-hooking” to distribute their weight at two points. This includes very large, massive specimens where support on a single surface will cause discomfort or injury. Snakes with medical problems (e.g., fused vertebrae, or a recent surgery) are also supported this way. Active snakes and arboreal prehensile-tailed species are also handled with greater control when double-hooked.

The use of two snake hooks requires more finesse than one.

1. Hold a hook in each hand and insert them under the middle portion of the snake, on the same side of the body that faces the handler.
2. Move the hooks away from each other to points dividing the snake’s length into thirds. While the hooks are being moved to these locations, each hook should be lifted slightly testing the snake’s tendency to balance.
3. Once the hooks are appropriate for balance, lift the snake and determine if it is stable. If so, transfer the in a smooth, deliberate movement.
4. When lifting, outward pressure (away from the snake’s midpoint) of the hooks will help keep tension on the snake and not draw the hooks together if the snake tries to progress forward.

This technique requires practice, but is not difficult. Each snake reacts differently to the double-hooking process. For specimens that benefit from double-hooking, this is an excellent technique and should be used routinely.

Tongs and Forceps

Various styles of snake tongs and forceps (Fig. 20.4) are available from reptile equipment dealers (e.g., Midwest Tongs). They should not be used as a primary method of restraint due to their potential to injure. Many snakes will thrash or bite the tongs when held tight enough for restraint. If tongs are used directly for restraint, the contacting surface of the tongs should be padded to create a firm but “soft” restraint. This style

Figure 20.4. Tongs and forceps (top to bottom): Midwest Tong®, Pilstrom Tong®, hemostatic forceps, endoscopic forceps, and tissue forceps.

of tong can be very useful when working in the field, primarily with small to medium-sized specimens. In captivity, tongs should only be used as a last resort or in an emergency. Their use is not an acceptable substitute for lack of training or skill with a snake hook (Altamari 1998).

Long-handled tongs are ideal when used for feeding, removing cage items, manipulating container lids, holding restraint tubes, and lifting holding bags. Tong length must always be longer than the maximum striking distance of the snake.

Elongated forceps (Fig. 20.4) are used for feeding small snakes, removing retained shed or ectoparasites, and assessing in judging the depth of anesthetized animals. Forceps length may range from 30 to 45 cm. They must be used cautiously when working in close proximity to the head, allowing for potential movement and strike ability.

Protective Gloves

Wearing protective gloves for handling venomous snakes (Fig. 20.5) has been used by a limited number of researchers. While this method does have its advocates, extreme caution must be used as it places the handler in close proximity to the snake. Defensive strikes may not only target the gloves, but also the handler's arms and body that are not protected. Some snakes appear not to recognize gloves as strike targets as they do bare fingers and hands. This gives the impression that the snake is tame and not prone to biting. That condition can change quickly and the snake should always be handled so that its strike range is limited to the padded/protective areas of the gloves. A popular brand, HexArmor® (HexArmor, Grand Rapids, MI, <http://www.hexarmor.com>) produces the Hercules™ R6E glove made with SuperFabric® that may offer sufficient protection for most small- to medium-sized

Figure 20.5. Puncture-resistant gloves can offer protection from snakebite of small- to medium-sized species. However, all handling precautions must be met as this method requires the handler to work in very close proximity to the snake. Tiger rattlesnake, *Crotalus tigris*, Glades Herp Farm.

species. The company does not offer any guarantees in regard to protection from snakebite. The condition of the gloves with prolonged use needs to be monitored as the integrity of the material may break down over time (R. Kesze, pers. comm., 2011.).

Shift Boxes

Most snakes will enter boxes where they can seek visual and tactile security. Shift boxes are placed either inside the enclosure or attached to the outside. Box size need only be large enough for the snake to lie comfortably in a resting coil. Many snakes prefer to wedge into a tight fitting space for physical and tactile security. Normally, the snake's head when residing in a shift box is pointed toward the opening (entrance hole), awaiting the passing of potential prey. They will commonly strike out at any movement in front of the opening. Training some elapids to enter shift boxes (Kipp et al. 2006) is achieved with classical conditioning techniques. This is a very useful management tool for long-term captive animals requiring routine handling.

Shift boxes are most appropriate for large, swift elapids. They can be designed to attach directly to the cage (Fig. 20.6). In snake collections requiring multiple enclosures, the openings in cages, shift boxes, and the points of attachment are standardized so boxes can be interchanged. Cages are also designed with a center divider that allows the handler to shift the snake from one side to the other to facilitate safe servicing. The divider slide space should be sufficiently narrow to prevent escape when the divider is removed.

Shift boxes within a cage (Fig. 20.7) should be solid with a bottom and locking door (Rossi 1995). They are easily fabricated from plywood and sealed with poly-

Figure 20.6. Shift box and interfacing cage for an arboreal snake. Not shown are transparent top and side panels of shift box. Used for Gold's tree cobra, *Pseudohaje goldii*, Central Florida Zoo and Botanical Gardens.

Figure 20.7. Shift box in cage. Shift box door can be slid close with a snake hook and locked. Black mamba, *Dendroaspis polylepis* (courtesy of Medtoxin Venom Laboratories).

urethane to facilitate cleaning. A horizontal sliding door is designed to be closed with a hook once the animal is enclosed. A locking pin or mechanism for the shift box door is secured prior to removing from the cage and when transporting the snake.

Many styles and designs for shift boxes that attach to the outside of enclosures have been used to facilitate safe cage servicing or to aid with restraint and immobilization for veterinary procedures. Historically in zoos and research facilities, boxes have been designed and fabricated "in house" to fit a specific enclosure for a designated species or individual. Shift boxes have primarily been used for shifting large elapids that are dangerous to work in an open environment using a

Figure 20.8. Shift box/squeeze box. Inner panel manually slides toward the entrance hole in the box for tube restraint or against transparent slotted end for injections (Dallas Zoo, courtesy of Habitat Systems Limited).

hook. However, any venomous species is a candidate for shifting to insure a safe and controlled procedure.

Shift boxes attached to enclosures need to incorporate the following design elements:

1. Appropriate comfortable size for the snake
2. Sturdy construction, able to endure dropping and long-term use
3. Secure method of attachment to the enclosure
4. Locking slide door that corresponds to the door on the cage
5. Large top opening access door (lockable)
6. Clear top and/or side section to view the snake
7. Adequate ventilation holes
8. Sealed surfaces to promote easy cleaning.

Variants on the above design combine a squeeze for restraint. An interior sliding wall (Fig. 20.8) is used to push the snake toward the opening and into the restraint tube. Care is taken to ensure restraint tube diameter matches the box opening so no gaps exist. Additionally, the tube and the box must be securely attached (usually manually braced) to prevent changes in restraint tube position. Once the snake enters the tube a safe distance, it is grabbed and restrained using a normal tube restraint grasp.

More advanced designs (Habitat Systems Limited, Des Moines, IA. <http://www.habitatsystemslltd.com>) combine features to aid in the husbandry and management of venomous snakes (Fig. 20.9). Optional elements include removable squeeze apparatus with a slotted end panel for injections, capped side ports with interchangeable openings of various diameters for tube restraint, enclosed top feeding chamber with sliding false floor (drops feed rodent into shift box without directly opening the box), and removable center dividers

Figure 20.9. Shift box/squeeze box. Features include removable squeeze apparatus, slotted end for injections, two capped side ports for tube restraint, and top capped feeding chamber with sliding false floor for protected feeding. Not shown is removable center divider to create “U-maze” to facilitate total entry of long snakes. Jacksonville Zoo and Gardens, black mamba exhibit, *Dendroaspis polylepis* (courtesy of Habitat Systems Limited).

to create a “U-maze” to facilitate total entry of long snakes. These features increase control while emphasizing safety.

Some boxes incorporate a built-in restraint shield or framed wire mesh panel that can be pushed down for temporary restraint. A common application of this design using a wire mesh top panel is for king cobras (*Ophiophagus hannah*) that frequently retain spectacles. This design is also helpful if treatment requires repeated intramuscular injections.

Shift box design is a function of intended use (Fig. 20.10). They can be used to accomplish tube restraint and anesthesia using the entrance hole of the box. Variations have been described (Bertram & Larsen 2004), but the basic design and function remains the same. When using shift boxes, the users must know how all doors operate (especially when removing the box and a second snake is in the cage!) along with corresponding locking and safety features. Some boxes are overdesigned, increasing the opportunity for an open or unsecured door. Doors and locks are always double checked visually and for movement prior to assessing if a snake is safely secured.

Unattended boxes that have been removed from the enclosure are placed in larger, secured, and labeled containers to alert staff to the presence of a venomous snake.

Restraint or “Squeeze” Box

These boxes are (Quinn & Jones 1974) used to restrain movement of a snake for examination, measurement, and radiography. They consist of a box and a clear shield to press the snake against the bottom of the box for temporary restraint (Fig. 20.11). Most have been made of wood, but acrylic boxes have the advantage of

Figure 20.10. Traditional shift box. This simple design enables the snake to shift out of cage eliminating direct contact. Snake can then be transferred for anesthesia or other procedures.

Figure 20.11. Traditional restraint box for clinical and field applications. Primarily used for injections and measuring. Western diamondback rattlesnake, *Crotalus atrox*.

being able to view the snake from all sides, including the ventrum (Krebs et al. 2006).

The size of the box is determined by the snake; it should enable the animal to lay coiled in a normal position. The open top of the box is fitted with 0.5 cm thick Plexiglas shield, with a center handle, that can be lowered to press the snake against a thick foam rubber or other soft material pad.

It is important the shield closely fits the sides of the box to prevent the snake from wedging its head through a gap. The shield is initially lowered using tongs, then secured by hand once safely in place. Holes are drilled into the shield to facilitate injections. Multiple holes

are drilled across the shield since the position of the snake is random. Shields made of diamond mesh expanded sheet metal have also been used (M. Whitney, pers. comm.), but care must be taken to avoid the snake striking and injuring oral areas.

Measurement is accomplished using a dry-erase ink marker to draw a mid-dorsal line equaling the length of the snake. A thin wire is superimposed over the drawn line, then straightened and measured. Map measurers have also been used to trace line lengths.

If a restraint box is to be used for a period of time, holes are drilled through the sides to permit the passage of aluminum rods to hold down the shield (Fowler 1978). If a restraint box is used for radiology, it must have a locking mechanism for the top acrylic shield. Snakes secured in such a fashion should not be left unattended and placed in a secured, labeled container.

Restraint Tubes

Manual restraint and immobilization of venomous snakes has been described using a wide variety of techniques for a variety of applications. For many procedures, manipulation of venomous snakes without chemical immobilization is desirable for initial examination, medication, and simple procedures, including removal of adhered shed, palpation, blood sampling, and sex determination.

Techniques that employ restraint tools as the primary method of restraint such as nooses, tongs, strap sticks, bucket restraint (Gillingham et al. 1983), noose tube restraint (King & Duvall 1984), strap boards (Ward & Harrell 1983), and manual restraint following pinning with a snake hook are to be avoided. While used with some success by professional snake handlers in the venom extraction industry, these methods increase the risk of snakebite for the occasional handler and can injure the snake. Safer methods using clear tubes and shift, restraint, and anesthesia boxes are preferred. These remote handling methods require more time and equipment, but greatly reduce direct contact with the snake. All procedures should optimize protected contact and effective control, thereby insuring handler safety.

The standard for safe handling of venomous snakes is Plexiglas tube restraint (Murphy 1971). This method minimizes risk to the handler and potential injury to the snake. Clear, hollow tubes are available in a variety of acrylic materials. They can be purchased as individual tubes, usually sold in 2-m lengths, of various diameters (McMaster-Carr, Atlanta, GA, <http://www.mcmaster.com>). Sets of restraint tubes are also available from some reptile supply companies. Thin-wall, flexible tubes crack easily and, therefore, less safe than thicker-walled tubes. Polycarbonate hollow rods and PETG (a copolyester material) with a minimum wall thickness of 0.25 cm are best. These products are more durable and do not break if dropped.

The basic steps for tube restraint are as follows:

1. Choose a tube with an inside diameter that will not allow the snake to turn around (inside diameter less than the length of the snake's head or slightly larger than the snake's girth at mid-body).
2. Using a hook, place the snake on a smooth surface. Small and medium-sized specimens are worked within a container. This is usually a trash can or other open-top container large enough to facilitate movement by the handler to manipulate the snake into the tube. Large and more sedentary snakes are worked on the floor or the ground in field conditions. There must be ample open space for handlers to maneuver safely around the snake. Containers are preferred since they limit the range of motion and position of the snake.
3. Use tongs that are longer than the snake's striking range to hold the tube. Grasp the tube in the middle with the tongs in one hand (usually the left hand for a right-handed person) and slowly lower the open end of the tube toward the snake in a manner that will not induce the snake to strike at the tube. Snakes that strike the open end of the tube may incur oral lesions, primarily associated with the mucous membranes that cover the fangs.
4. Using a hook that is longer than the snake's striking range and held above that point, gently touch or hook the animal to manipulate it into the tube (Fig. 20.12). This is a combined maneuver moving the tube and the snake in a fashion that will entice it to enter the tube.

This procedure requires patience! Never hurry and always stay in control of the process.

1. The first goal is to get the snake's head inside the opening of the tube. This should be done quickly to reduce the chance of the snake striking.

Figure 20.12. Tube restraint. Position of primary handler and snake in tube just prior to restraint. Florida cottonmouth, *Agkistrodon piscivorus*, Central Florida Zoo and Botanical Gardens.

2. Sometimes moving the snake backward with the snake hook will encourage it to move forward, entering the tube.
3. Once the snake starts to enter the tube, hold the tube motionless so as not to startle the snake.
4. More active snakes require the tube to be “worked down” the body following its undulating movements.
5. Once the snake has entered the tube, and is at least half way in (the tong grasp point on the tube if the tube is grasped in the middle) and still moving forward, lay the hook down (or hand it to an assistant), and with that hand quickly grasp the snake and the end of the tube in which the snake entered (Fig. 20.13). This secures the snake in the tube and prevents it from backing out. The other hand is used to grasp and support the animal.

Never over commit to the grab! If the snake begins to back out of the tube or quickly progresses to the end of the tube, abort the procedure and start over.

1. Once restrained, immediately visually check your grasp! Both the tube and the snake should be held firmly to keep the snake from progressing forward or backward.
2. Make sure there is not an opening between your fingers and the palm of the hand that could allow the snake to withdraw a body coil and withdraw from the tube.
3. With medium to large snakes, the assistant should immediately support and restrain the animal’s body once it has been successfully restrained. This permits the primary handler to focus their attention on securing the snake while supporting the tube with their other hand.

Figure 20.13. Tube restraint completed. With large specimens, the primary handler secures the snake and tube while the secondary handler supports and restrains the body. Florida cottonmouth, *Agkistrodon piscivorus conanti*, Central Florida Zoo and Botanical Gardens.

4. If a snake has a large girth at mid-body and a relatively small head, a smaller-diameter tube is inserted inside the open end of the tube and over the snake’s head to keep it from turning around.

Snakes that are anesthetized require a controlled release from the restraint tube in the following sequence:

1. The primary handler grasps the tube midway with the tongs while maintaining tube restraint with the other hand.
2. The snake and tube are placed in a container and angled vertically. The grip on the snake is released and the hand is withdrawn rapidly from the container (and snake’s striking range).
3. The primary handler and the assistant pick up hooks for further handling.
4. The container is secured and labeled appropriately.

The primary handler and the assistant always review the steps before and during the process to ensure an understanding of roles and expectations.

Many large-bodied pitvipers will attempt to progress up the tube when released. This should be avoided to prevent the snake becoming stuck in the tube. While still maintaining manual restraint, these snakes should be pulled down the tube to a safe point near the end prior to release. When released, many snakes will quickly withdraw from the tube and immediately strike back at the handler. Alternatively, some species (i.e., elapids) will attempt to flee. Handlers need to be prepared to use hooks to keep the snake under control.

Tube restraint can also be accomplished directly from a shift box, facilitated by a squeeze apparatus adapted to the box (Fig. 20.14). The diameter of the restraint tube must match the hole in the shift box.

Figure 20.14. Tube restraint directly from a shift box containing a squeeze apparatus. In addition to tube restraint, the body of this 14’ king cobra (*Ophiophagus hannah*) is also manually held in the shift box during examination to maintain control of the body (Central Florida Zoo and Botanical Gardens, photo credit Sarah Burke).

Tube restraint provides the handlers and clinicians a high degree of control during the examination. The snake is advanced to the end of the tube for cranial and oral examination. Various locations along the snake's body can also be examined. Care is taken to keep a significant portion of the anterior body in the tube. Restraint tubes are also used for administering oral medications and force-feeding (Radcliffe 1975). The major advantage of this technique is that the snake is restrained without grasping the head, and the animal is positioned in a relative straight line to facilitate examination, medication, tube-feeding, and anesthesia.

A variation of acrylic tube restraint (Mauldin & Engeman 1999) employs wire mesh cable holders as the restraint "tube". While this method can be used with some snakes, it is not recommended for venomous species since they will bite through openings in the mesh resulting in either envenomation of the handler or oral trauma to the snake.

Restraint Tube Modifications

Clear acrylic restraint tubes can be modified for the needs of the clinician. Tubes are cut to various lengths to facilitate safe handling (i.e., longer tubes for longer snakes). Tubes can be drilled to create access holes and elongate cut-outs are made for increased access for minor procedures. Appropriately sized PVC caps, rubber stoppers, or wooden corks are temporarily or permanently secured at one end to prevent the snake from progressing through the tube.

Care is taken when any opening is made along the length of the tube to prevent hands and fingers from crossing these openings. Many species are capable of biting and protruding a fang through these openings. Bite attempts on the inside of the tube will release venom that will run down the inside of the tube to the hand. Handlers should wear latex gloves to prevent venom contact with the skin that may lead to envenomation through microcuts. All tubes must be thoroughly washed and disinfected immediately after use.

Anesthesia Boxes

Full clinical examination and surgical procedures require chemical immobilization and anesthesia (See Chapter 20). This is essential when evaluating cranial features, such as the nostrils, infra-orbital pits, spectacle and eyes, oral cavity, glottis, and tongue. More general procedures, such as blood sampling, examination of the integument, removing adhered shed skin, removal of ectoparasites, cloacal examination and sampling, and palpation may be accomplished by tube restraint. Radiology may be performed on snakes in shift boxes, squeeze boxes (through a fixed acrylic shield) or through bags if the specimen is inactive. If an intended procedure presents a safety concern for personnel, full chemical immobilization is strongly recommended. Some snakes can be induced in restraint

Figure 20.15. Anesthesia box. A clear plastic storage box with fitted with an adapter to receive the corrugated breathing tube from the anesthesia machine. The transparent container facilitates viewing to judge level of induction. Rhinoceros viper, *Bitis nasicornis*, Central Florida Zoo and Botanical Gardens.

tubes with propofol administered into the ventral coccygeal vessels (Chapter 20).

A variety of containers for venomous snakes can be used as inhalant anesthesia boxes. Large clear plastic Rubbermaid® or Sterilite® storage boxes (Fig. 20.15) are available from retail stores. Snakes are placed directly into these boxes only if the lids can be secured to prevent escape. Transparent containers allow observation of the snake during anesthetic induction. A snake contained in a cloth snake bag may be placed inside an anesthesia box. However, judging anesthetic level will depend on evaluating declining movement in the bag. When testing the movement of a snake inside a bag, always use instruments (forceps and tongs) and never manually palpate the bag.

A snake contained in a shift box or ventilated restraint box can also be placed in an anesthesia box. The anesthesia box, fitted with an adapter for the breathing system, allows for infusion of the inhalant anesthetic in oxygen from the machine. A shift box may also be enclosed in a plastic bag for administration of inhalation anesthetic through the opening. However, induction is very difficult to evaluate when the snake is enclosed in two containers.

Guidelines to assess whether a snake is safely anesthetized include lack of response to tactile stimulation, inhibition of tongue flicking, and lack of ability to right itself when turned over on its dorsum. Snakes can hold their breath for 15–20 minutes and anesthetic induction can be prolonged. Once anesthetized, a restraint tube is placed over the head and anterior portion of the body as a secondary safety precaution and the snake is then carefully removed from the box. For continued

delivery of inhalant anesthetic, either a cover can be fitted over the open end of the restraint tube, a mask placed directly over the head if removed from a restraint tube, or direct endotracheal intubation, whereby a tube is inserted through the snake's glottis and into the trachea (Chapter 20).

Transport

Safe transport and receiving of venomous reptiles requires planning and setting up the appropriate equipment in advance. Securing the snake in a cloth bag and placing it in a ventilated locked box is recommended. The cloth bag should be of tight-woven, strong material that allows for good ventilation. Bags are examined for small holes that may be tested by the snake and enlarged, leading to escape. Bags are turned inside out so the seam is on the outside to avoid entanglement in loose threads. Only one animal should be contained in each bag to eliminate defensive striking and to facilitate removal. Bags should be long (deep) enough to be easily knotted at the open end and additionally secured with strong tape or plastic cable ties.

To place a snake in a bag, it is hung inside an empty container and secured in an open position using clips (clothes pins work well). Tongs are used by an assistant to hold the sides of the bag open. They are then used to close the bag after the snake is guided in by a hook. Commercially available "snake baggers," long-handled rods with an attached and removable bag, increase safety in the bagging process (Snake Bagger[®], Midwest Tongs). Never be too anxious to manually close the top of the bag. Most snakes tend to climb upward after being dropped into the bag. Always visually know where the snake is. Use tongs to close and secure the bag, or twist and pull the neck of the bag under the shaft of a secured snake hook prior to knotting.

When knotting, first transfer the bagged snake to a flat surface. Place the shaft of the snake hook across the twisted neck of the bag, pull to secure the snake in the far end of the bag, and tie the neck of the bag. For additional security, the bag is secured with strong tape or cable ties on either side of the knot. This must be done away from the portion holding the snake. Bags are labeled to identify the snake species with a noticeable "VENOMOUS" notation made on the label. Red labels with the "skull and crossbones" symbolizing poison are most effective. Tongs are used to clamp the bag just under the knot for lifting. Bags should always be carried above the knot and away from the handler's body. Bagged snakes are placed in a suitable container or box while waiting for procedures or transport. Transport boxes containing more than one bagged snake have solid dividers to eliminate the potential for snakes biting each other.

Transport boxes are locked, well ventilated, and kept away from temperature extremes. Boxes are kept out of the sun and transported in air-conditioned vehicles to avoid hyperthermia. Boxes are clearly labeled

"CAUTION: VENOMOUS SNAKES" and stored in locked rooms while awaiting transport.

The same level of caution used in bagging the snake must be used during removal from transport containers. Open the transport boxes using the level of caution as if the snake inside had escaped the containment bag. Keep fingers and hands away from openings (use tongs) and be prepared to hook a snake into a holding container. The bag is removed from the container using tongs. Snakes can bite through cloth bags, induced by limited visual capability or when the bag is touched. Bites through either bags or screened surfaces can result in significant envenomation. Under these circumstances, a snake's fangs can become momentarily hung up in the bag material, resulting in the expression of large quantities of venom.

Prior to untying the snake bag, place the bag on a flat surface and position the shaft of the snake hook across the neck of the bag below the knot, securing the snake in the end of the bag. All extremities are held safely away from this portion of the bag. Once untied, tongs are used to secure the open bag end. It is then picked up and lowered into a container. The snake is released by picking up the bottom end of the bag with the tongs. Bags with a hemline sewn across the bottom corners of the bag provide an area of material to grab without pinching the snake.

A field transport box (Birkhead et al. 2004) for carrying large numbers of venomous snakes combines both tube restraint and a modified transport container. In this design, 10 polyethylene restraint tubes, capped at both ends, are secured by spacers in a transport container. The advantage of this design is individual containment of each snake that is positioned for immediate manipulation or restraint.

The International Air Transport Association (IATA) publishes Live Animal Regulations that are adopted by most airline carriers. When shipping air freight, it is prudent to review these regulations in case airline employees question the design and features of the shipping crate and the methods by which the snakes are contained. IATA requirements (for snakes see Part 8, Container Requirement #44) are presented as examples to be adopted depending on the species and size of the snake. Specific suggestions in the IATA regulations include container rigidity, packing material, size and type of container, specification for snake bags, double-bagging snakes with a transparent mesh inner bag for inspection, wire-covered containers, and an abbreviated listing of venomous snakes and some colubrids that are considered venomous. It is the responsibility of the shipper to ensure materials and methods are appropriate for safe transport. It is rare that an airline employee will ask the shipper to open a container of venomous snakes for inspection. This is not the case for international shipments that are routinely inspected by wildlife customs agents charged with monitoring

species covered under the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES).

VENOMOUS LIZARD MANAGEMENT

Gila Monsters and Beaded Lizards (Helodermatidae)

Venomous lizards known to produce significant envenomation in humans are restricted to two species, the Gila monster (*Heloderma suspectum*) and the Mexican beaded lizard (*Heloderma horridum*). As studies continue on the evolution of reptilian venom systems (Fry et al. 2006b) additional “nonvenomous” lizard taxa will be recognized as having toxin-secreting oral glands. Currently, this is restricted to some species of monitor lizards (family Varanidae), especially the desert monitor (Ballard & Antonio 2001).

Helodermatids are large, stout-bodied lizards with large heads, powerful jaws, and short legs adapted to digging. They are easily recognized by their colorful, intricate skin patterns, and rounded tuberculate scales that give them a beaded appearance. Gila monsters average 36 cm as adults, while beaded lizards can reach 1 m in total length.

Helodermatids have evolved a “defensive venom” tailored to create significant pain to ward off predators. Bites are extremely painful and can have systemic effects, including a rapid drop in blood pressure that may result in hypotensive shock (Preston 1988). Unlike snakes, the venom glands of helodermatids are mandibular and appear as a rounded swelling located midway on the lower jaw. The large triangular-shaped head is the result of well-developed musculature associated with biting and maintaining a vice-like grip. When biting, helodermatids exhibit a pumping action of the jaw musculature while embedding the enlarged, grooved, venom-conducting teeth, located above the venom glands. Accounts of severe gripping bites result in the use of pliers, crow bars, severing of jaw musculature, and decapitation to disengage the lizard from the bitten extremity. Severity of envenomation is a function of the amount of time the lizard is allowed to bite. Envenomation is treated symptomatically as there is no antivenom for helodermatids.

Helodermatids are deceptive, normally exhibiting slow movements and a sluggish behavior, but are capable of swift lateral and upward movements of the head and upper body when attempting to bite. Of 21 venomous bites received by zoo workers over a 25-year period (Card & Roberts 1996), four were inflicted by helodermatids. The authors concluded that because helodermatids are generally considered relatively benign captives, this assumption misleads individuals to handle them carelessly. No matter how much their owner professes its tameness; all helodermatids should be handled with the same caution as for venomous snakes.

Manual restraint of helodermatids requires first pinning the head down on a flat surface with a snake hook or pinning bar prior to restraint (Fig. 20.16). Once secured, they are picked up with a firm grip at the base of the head and a forelimb held between the fingers to maintain control of the upper body. Once elevated, the second hand is used to support and hold the body (Fig. 20.17). Locking hemostats (40–60 cm) have also been used to successfully pin helodermatids (Poulin & Ivanyi 2003) by using the interlocking base portion (area between the finger eyelets) as the pinning bar.

Figure 20.16. Prerestraint position for helodermatids. Head should be immobilized prior to manual restraint. Gila monster, *Heloderma suspectum*, Central Florida Zoo and Botanical Gardens.

Figure 20.17. Helodermatids can be manually restrained by securing a firm grip at the base of the head with a forelimb held between the fingers to maintain control of the upper body. Once elevated, the second hand is used to support and hold the body. Gila monster, *Heloderma suspectum*, Central Florida Zoo and Botanical Gardens.

Helodermatids can be closely examined using manual restraint. Examination of the oral cavity using a hard rubber speculum has limited use since they will vigorously bite down on any object placed in its mouth.

Helodermatids can be anesthetized by administering an inhalant anesthetic into an induction chamber. Anesthetized helodermatids should again be pinned as described earlier before removal from the anesthetic chamber. One of the last reflexes to be lost is the defensive bite.

Squamates (Snakes and Lizards)

Mads F. Bertelsen

INTRODUCTION

Sedation and anesthesia are essential components of veterinary care of lizards and snakes. These techniques are employed to enable surgery and other painful or invasive procedures, to facilitate handling and to enhance the quality or safety of diagnostic procedures while minimizing stress and discomfort. Within the field of reptilian anesthesia, there has been a gradual and continuing evolution from hypothermia and manual restraint to balanced, well-controlled anesthesia. Several excellent reviews on reptile anesthesia are available (Bennett 1998; Heard 2001; Malley 1997; Schumacher & Yelen 2005), while controlled clinical studies are still comparably scarce. Generally speaking, squamates are rather tough, and life-threatening anesthetic complications are rare.

TAXONOMY AND BIOLOGY

The nomenclature within the class Reptilia is undergoing continuous change, and taxonomy remains controversial. Briefly, the order Squamata consists of more than 50 families and 7700 species of lizards and snakes. While members of the group range from the tropics to the near-arctic, and vary in size from a few centimeters to 8 m, the basic anatomical and physiological features as well as reactions to anesthetic drugs are surprisingly uniform.

ANATOMY AND PHYSIOLOGY

Reptiles are ectothermic vertebrates with relatively low metabolic rates. Their pulmonary and cardiac anatomy, as well as their control of respiration, differs from those of mammals. Despite 200 years of study, many aspects

of reptilian anatomy and, more notably, physiology remain poorly understood.

Cardiovascular System

All reptiles possess two atria divided by a complete atrial septum. Each opens into the ventricle by a separate atrio-ventricular ostium. The ventricle of noncrocodilian reptiles is incompletely divided by a horizontal septum-like muscular ridge. This ridge and an opposing thickening in the ventricular wall divide the ventricle into two subcompartments. The incomplete ventricular separation creates the potential for intracardiac mixing or shunting of blood. This may occur as a left-to-right (L-R) shunt or a right-to-left (R-L) shunt. A L-R shunt results in oxygenated pulmonary venous blood reentering pulmonary circulation, while a R-L shunt results in a fraction of deoxygenated systemic venous blood bypassing the lungs and returning into systemic circulation, resulting in alveolar to arterial gradients for respiratory gases. The reduction in arterial oxygen pressure in reptiles during R-L shunting is considerable and is well documented in turtles as well as lizards (Hicks & Comeau 1994; Hlastala et al. 1985; Hopkins et al. 1996; Wang & Hicks 1996).

The extent and direction of shunting is highly dependent on the degree of functional separation, determined by evolutionary adaptations. At one extreme, turtles, which have poorly developed ventricular separation and similar pulmonary and systemic arterial blood pressures, have large intracardiac shunts (Shelton & Burggren 1976; Wang & Hicks 1996; White et al. 1989). In contrast, varanid lizards have a very well-developed muscular ventricular septum, and a large difference between pulmonary and systemic pressures (similar to that seen in mammals) resulting in

only low grade shunting (Burggren & Johansen 1982; Heisler & Glass 1985; Heisler et al. 1983). In some species (e.g., varanids), the shunting patterns are essentially identical during apnea and ventilation (Heisler & Glass 1985). In other species, however, a clear relationship exists between cardiac shunting patterns and the stage of respiration. Breath holding is associated with decreased pulmonary perfusion, and large R-L intracardiac shunts, while periods of pulmonary ventilation are characterized by increased pulmonary blood flow leading to a reduction in the R-L shunt (Hicks & Krosniunas 1996). This is thought to stabilize oxygen content in the blood during respiratory pauses and to ration pulmonary oxygen by forcing periods of tissue hypoxia during diving.

Respiratory System

The squamate glottis is located at the base of the tongue, quite rostrally in the oral cavity. The glottis is closed during most of the respiratory cycle, opening only during inspiration and expiration. The trachea of the squamates has incomplete cartilaginous rings, while those of chelonians and crocodylians have complete tracheal rings (Davies 1981; Kardong 1972a, 1972b). Lizards and primitive snakes have two roughly symmetrical lungs, while in more advanced snakes, the left lung is reduced in size or absent. In general, gas exchange occurs in the cranial portion of the lung, while the caudal portion may be reduced to an air sac-like structure. The relative lung volume, as well as the compliance of the reptilian lung far exceeds that of mammals, but the surface available for gas exchange is smaller.

The basic pattern of respiration is an exhalation followed by an inspiration, followed by a nonventilatory period of varying length. Most reptiles exhibit an intermittent breathing pattern characterized by periods of apnea interrupted by brief ventilatory periods consisting of one to several breaths (Abe & Johansen 1987; Glass & Wood 1983; Templeton & Dawson 1963).

Reptiles, most notably freshwater turtles, are remarkably resistant to ambient hypoxia. While green iguanas can breath hold up to 4.5 hours (Moberly 1968), chelonians may survive complete environmental anoxia for hours or days at their normal body temperatures (Belkin 1963, 1968; Bickler 1992), and weeks to months at very low temperatures (Hicks & Farrell 2000; Ultsch & Jackson 1982). An increase in body temperature leads to increased metabolic oxygen consumption, and consequently to increased ventilation.

Implications for Inhalational Anesthesia

As described, the systemic arterial blood of reptiles may have gas tensions considerably different from the gas within the lung (Hicks & Comeau 1994; Wang & Hicks 1996). The main reasons for this gradient are functional intrapulmonary venous admixture, and R-L

intracardiac shunting. Of these two, ventilation/perfusion heterogeneity appears remarkably constant among species, whereas the degree of intracardiac shunting shows marked species differences (Powell & Hopkins 2004). For example, reported values for the pulmonary to arterial oxygen difference, when breathing 21% oxygen, range from only 13.6 mmHg in monitor lizards (Mitchell et al. 1981) to 60–70 mmHg in turtles (Burggren & Shelton 1979) and snakes (Seymour & Webster 1975). In comparison, the pulmonary to arterial difference created by a small physiological shunt in mammals and birds is minor. The consequence of R-L shunting may be that induction and recovery from inhalational anesthesia is slower and less predictable than in mammals and birds.

VASCULAR ACCESS SITES

The most reliable vascular access site is the ventral tail vessels, located immediately ventral to the coccygeal vertebrae. In snakes, these vessels are mostly approached from the ventral midline, but in many lizards, a lateral approach is often more convenient. The palatine veins may be accessed in larger anesthetized snakes. Indwelling catheters may be placed in the cephalic, femoral, abdominal, or ventral cervical vessels using cut-down techniques. Fluids and certain drugs may be administered by the intraosseus route. In lizards, intraosseus catheterization may be performed in the humerus, femur, or tibia following local analgesia of the cannulation site. Cardiac puncture for drug administration as well as for obtaining blood samples is an option in snakes, but although only minor damage to the myocardium following cardiac puncture has been documented in ball pythons (Isaza et al. 2004; McFadden et al. 2011), the procedure is likely stressful and this author sees the approach as a last resort.

PREANESTHETIC CONSIDERATIONS

Body weights vary markedly, and an accurate weight should be obtained prior to administering drugs to the reptilian patient. The hydration status of the subject should be assessed, and abnormalities corrected. Animals should be subjected to a physical examination prior to anesthesia, and if time, budget, and facilities allow, a blood sample for PCV, CBC, and plasma biochemistry profile, as well as ultrasonographic or radiographic imaging may aid in preanesthetic evaluation. Starving the animals prior to surgery is not generally indicated, but large quantities of feed in the stomach may theoretically impair pulmonary function. In infrequently feeding snakes, massive increases in oxygen consumption follow feeding (Overgaard et al. 1999), and heart as well as liver weight increases (Andersen et al. 2005; Secor & Diamond 1997). As these factors are all likely to increase the risk of anesthetic complica-

tions, elective procedures should be avoided in recently fed snakes. In a recent study, however, no effect on recovery times were found in garter snakes anesthetized 1, 2, 3, and 10 days post feeding (Preston et al. 2010).

MAINTAINING BODY TEMPERATURE

Induction time, anesthetic dose, and recovery time (Arena et al. 1988; Dohm & Brunson 1998; Green et al. 1981; Preston et al. 2010), as well as general metabolism, are all temperature dependent and maintaining the animal's body temperature within the preferred optimum zone (POZ) is crucial. This is achieved through the use of heating pads, circulating water blankets, water bottles, bean bags, and so on. For most temperate and tropical species, a body temperature of 25–35°C during induction, anesthesia, and recovery will be appropriate. In garter snakes anesthetized with methohexital, recovery time at 21°C was twice as long as at 31°C (Preston et al. 2010), and warming animals toward the high end of the POZ once the procedure is over may be attempted to obtain faster recoveries.

MONITORING PHYSIOLOGICAL FUNCTION

Most monitoring modalities used in domestic species may be applied to reptiles. Body temperature should be monitored with a cloacal thermometer or temperature probe able to measure low temperatures. Heart rate and rhythm may be monitored using ECG or Doppler flow detection units. Particularly, the latter offers simple audible monitoring. In snakes, the heart rate may usually be determined by visual inspection of the ventral scales approximately 25% of the snake's length from the head, while in many lizards, the heart rate may be visually observed in the jugular groove. The position of the heart in lizards varies between different species. For example, the heart in iguanids and agamids is located very close to the pectoral girdle, while in varanids and chameleons, it is located more caudally, almost to the middle of the coelomic cavity.

Blood pressure may be measured invasively only following cut-down procedures, limiting usefulness to research settings. Commercially available oscillometric devices applied to the tail of snakes or the femoral region of lizards unfortunately seem to have limited value, but may perhaps provide trend information (Chinnadurai et al. 2009, 2010)

Respiration may be assessed visually and in intubated animals main stream or side stream capnography provides useful information, although cardiac shunting and dilution as a consequence of excessive sampling rates of the devices used may give rise to erroneous readings (Hernandez-Divers et al. 2005). The use of pulse oximetry in reptiles remains controversial (Diethelm et al. 1998; Hernandez-Divers et al. 2005;

Mosley et al. 2004) as values obtained may not correlate with measured arterial oxygenation (Mosley et al. 2004). If monitored continuously, however, pulse oximetry may provide trends to assess oxygenation over time.

Arterial blood gas analysis can provide valuable information on oxygenation and acid-base status. Although cost-effective portable equipment is increasingly available, the difficulty of obtaining arterial blood samples reduces relevance in the clinical setting. Venous blood samples are readily available and may partly reflect arterial values. In anesthetized iguanas, for example, arterial and venous oxygen pressures may be almost identical, and carbon dioxide pressure only slightly different, which may suggest very low tissue metabolism and oxygen consumption during anesthesia (Mosley et al. 2004).

MONITORING DEPTH OF ANESTHESIA

The clinical signs associated with induction of general anesthesia in reptiles are fairly consistent. Generally, muscle relaxation in lizards starts at mid-body and moves forward, then backwards so that tail tone is lost last (Bonath 1977; Bonath & Zschege 1979). In varanids induced with inhalation anesthetics, the front limbs lose tone first, followed by the hind limbs and the neck approximately simultaneously. Then righting reflex is lost, and finally, the tail tone (Bertelsen et al. 2005b). The tongue retraction "reflex" in snakes and varanids persists beyond the loss of tail tone and righting reflex (Schumacher et al. 1997), and often is present at the surgical plane, as is the corneal reflex (Arena et al. 1988; Bertelsen & Sauer 2011). Loss of these reflexes may indicate excessive anesthetic depth. Animals retain the ability to react to painful stimuli even after the loss of righting reflex and tail tone, and the response to toe or tail pinching should be evaluated before deciding that surgical anesthesia has been achieved.

ENDOTRACHEAL INTUBATION

Due to the large oral cavities and rostral position of the glottis, lizards and snakes are easily intubated. The glottis is visualized at the bottom of the mouth, immediately caudal to the tongue (Fig. 21.1a,b). A noncuffed endotracheal tube of appropriate size is inserted and taped in place allowing positive pressure ventilation, either manually or using mechanical ventilators. Snakes and some lizards may be intubated awake, following the application of topical analgesics to the glottis. Endotracheal tubes are commercially available down to 1 mm ID, but for the smallest subjects, over-the-needle IV catheters (12–19 G) may be used.

A piece of rubber tubing, a folded gauze pad or a wooden mouth gags, depending on the size of the subject, may be used to prevent the animal from biting

Figure 21.1. (a) The oral cavity of a boa constrictor (*Boa constrictor*). Note the rostral location of the partly open glottis. (b). The oral cavity of a boa constrictor showing the endotracheal tube within the glottis after intubation.

on the tube. In small reptiles, taping the animal, the endotracheal tube, and the breathing system to the table, a board, or a tongue depressor may prevent tube displacement and injury.

VENTILATION

The combination of very low metabolic rates and extreme resilience to hypoxemia allow anesthetized reptiles to experience long periods of apnea without deleterious effects. However, until more is known about the exact requirements, mechanical ventilation is recommended during deep or prolonged anesthesia. Apart

from preventing hypoxemia, mechanical ventilation ensures delivery and removal of inhalational anesthetics' anesthetic agents.

Following endotracheal intubation, mechanical ventilation may be achieved by manually "bagging" the animal or by means of a ventilator of appropriate size. For many species, specialized laboratory animal or very small animal equipment is necessary to avoid overventilation, and even with this equipment it may be hard to achieve respiratory rates that are low enough. When artificially ventilating lizards and snakes, the larger tidal volume and lower minute ventilation compared with mammals should be taken into consideration, and if available, capnography should be used to monitor the level of ventilation. A minute ventilation of 50–75 mL/kg and a frequency of 0.5–4 breaths/minute will be adequate in most species.

INHALATION ANESTHESIA

Inhalational anesthesia is commonly used for induction and maintenance of reptile anesthesia (Read 2004). As in other species, the advantages of inhalational anesthetics include superior control of anesthetic depth, wide safety margins, excellent muscle relaxation, faster recovery, and "built-in" oxygen supplementation. As mentioned earlier, induction and recovery times in reptiles tend to be longer and more variable than in mammals and birds, due to breath holding, intracardiac shunting, and slow circulatory time.

Anesthetic Potency

Minimum alveolar concentration or minimum anesthetic concentration (MAC) is the standard measure of potency of inhalational anesthetic agents (Quasha et al. 1980). MAC is defined as the anesthetic concentration that prevents gross purposeful movement in 50% of an anesthetized population subjected to a supra-maximal noxious stimulus, traditionally a surgical incision. Apart from permitting comparison of anesthetic agent potency, the value allows standardization and comparison of various depths of anesthesia as multiples of MAC. Using MAC values also provides a way of assessing the synergism between two anesthetics. Other terms, essentially equivalent to MAC are sometimes reported in birds and reptiles (e.g., minimum anesthetic dose, effective dose 50, and minimum infundibular concentration). Generally, MAC for a given agent varies little across mammalian species (Quasha et al. 1980) and the limited number of reports available indicate that the same applies to reptiles, although evolutionary differences in cardiopulmonary performance may give rise to greater variability among reptiles (Bertelsen et al. 2005c).

As MAC only "accounts for" 50% of the population, vaporizer settings of 1.3 MAC are recommended to

achieve surgical anesthesia. As a likely consequence of R-L intracardiac shunting, the equilibrium between inhaled substances and body occurs more slowly in reptiles. Consequently, effective MAC decreases over time in iguanas (and probably other reptiles) (Barter et al. 2006; Brosnan et al. 2006), indicating inhaled gas levels should be decreased toward the end of lengthy procedures.

Equipment

Inhalant anesthetics are delivered by agent-specific vaporizers using oxygen or a mix of oxygen and nitrous oxide as the carrier gas. Standard anesthetic machines fitted with nonrebreathing (Bain's) or circle systems are used, and for smaller specimens, laboratory animal equipment has great potential. Commercially available small animal face masks, as well as masks home made from plastic bottles or syringe cases work well.

Due to low metabolic rates, oxygen consumption is low (<1 mL/kg/min, Perry 1989), and flowrates may be reduced considerably compared with mammalian settings. In practice, the flow rate is often determined by the performance of flow meters and vaporizers and rates of 250–1000 mL/min will be appropriate for most reptiles.

Induction

Unlike chelonians, where inductions may be prohibitively prolonged, mask induction is feasible in lizards and snakes (Fig. 21.2). Animals may also be induced in chambers or plastic bags filled from a vaporizer at maximal setting, or simply by adding a small volume of the concentrated agent on a piece of cotton wool (e.g., approximately 1 mL isoflurane/L chamber volume). With the latter approach, close attention should be

Figure 21.2. Mask induction of a monitor lizard with isoflurane. Note the use of a standard small animal face mask.

kept, as inductions may be quite rapid, and toxic levels could be reached if animals are left too long.

INHALATION ANESTHETICS

Early Inhalants

One of the first reports of anesthesia in reptiles is of John Tait describing the surgical removal of venom glands from rattlesnakes under chloroform anesthesia (Tait 1938). Later, prolonged induction and recovery periods were described in several snake species anesthetized with methoxyflurane (Burke & Wall 1970; Gandal 1966). There are no recent reports on the use of either agent, and the drugs have long been superseded by newer agents.

Ether anesthesia is associated with very long induction (40–60 minutes) and recovery periods in lizards and snakes (Bonath & Zschege 1979; Brazenor & Kaye 1953), and while still occasionally used in physiological research and venom production, the agent must be considered obsolete in a clinical setting. It is also flammable and potentially explosive and, therefore, a hazardous chemical to store and use.

Halothane

Halothane delivered at 3–6% results in moderate sedation to profound anesthesia in lizards and snakes. At halothane concentrations of 5.8% the mean induction time at 22–25°C has been reported to be 24 minutes in lizards ($n = 38$), and 35.3 minutes in snakes ($n = 12$) (Bonath 1977, 1979; Bonath & Zschege 1979). Shorter induction times (5–19 minutes) were reported using 5% halothane in a 3:1 nitrous oxide/oxygen mixture (Custer & Bush 1980). A transient initial excitement stage has been described in rattlesnakes at very high doses (Hackenbrock & Finster 1963).

In snakes, halothane significantly decreases respiration rate and tidal volume (Bonath 1977, 1979; Bonath & Zschege 1979; Custer & Bush 1980), leading to respiratory acidemia (Custer & Bush 1980), while heart rate decreases mildly or remains unchanged (Bonath 1977, 1979; Bonath & Zschege 1979; Custer & Bush 1980).

Recovery times following brief anesthetic events are relatively short (24–35 minutes), while recovery times from deeper anesthesia are reported to be much longer (Bonath 1977, 1979; Bonath & Zschege 1979).

No information exists on the potency of halothane in reptiles, and data on cardiopulmonary function during halothane anesthesia is limited to that described earlier. Halothane continues to be used in physiological research, but in the clinical setting has been replaced by isoflurane and sevoflurane.

Isoflurane

Isoflurane is used extensively in reptiles. In lizards, the time to initial relaxation and loss of righting reflex

breathing 5% is typically 4–9 minutes (Hernandez-Divers et al. 2005; Mauthe von Degerfeld 2004; Schildger et al. 1993; Spelman et al. 1996), while the time to complete relaxation is 13–20 minutes depending on the species (Bertelsen et al. 2005b; Mosley 2000). In snakes, induction times with mask induction tend to be slightly longer (Schildger et al. 1993), but direct intubation of the awake snake followed by mechanical ventilation with the drug leads to rapid induction. As mentioned, faster inductions may be achieved using higher inspired concentrations by adding isoflurane directly to the induction chamber.

Isoflurane causes a moderate (approximately 25%) reduction in heart rate (Hernandez-Divers et al. 2005; Maas & Brunson 2002) and a severe reduction in respiratory rate (Maas & Brunson 2002) compared with values in manually restrained animals. It should be considered, however, that values in manually restrained subjects are significantly higher than in undisturbed animals (Bertelsen et al. 2005b). During anesthesia, a dose-dependent reduction in systemic blood pressure is observed (Chinnadurai et al. 2010; Mosley et al. 2004). At low concentrations animals continue breathing (Spelman et al. 1996), but at levels adequate for surgical anesthesia mechanical ventilation is usually necessary.

The minimum alveolar concentration at 30–35°C has been reported to be $1.9 \pm 0.59\%$ in rat snakes (Maas & Brunson 2002), $1.8 \pm 0.3\%$ to $2.1 \pm 0.6\%$ in iguanas (Barter et al. 2006; Mosley et al. 2003a), and $1.54 \pm 0.17\%$ in monitors (Bertelsen et al. 2005c), indicating that vaporizer settings of 2–2.5% will be appropriate to maintain surgical anesthesia in most subjects. As a likely consequence of R-L intracardiac shunting at the beginning of anesthesia, MAC decreases over time in iguanas (Barter et al. 2006), indicating that inhaled gas levels should be decreased toward the end of lengthy procedures. The MAC decreases with decreasing body temperature (Dohm & Brunson 1998). In an attempt to determine the cardiac anesthetic index, seven iguanas were subjected to up to 9.2% isoflurane without any apparent signs of cardiac arrest, suggesting a very wide margin of safety (Mosley et al. 2003b).

Recovery time depends on the depth and duration of anesthesia, and is relatively short (2–12 minutes), following brief, shallow anesthetic events (Schildger et al. 1993; Spelman et al. 1996), intermediate (30–40 minutes) following light surgical anesthesia, and more prolonged (50–70 minutes) following deep anesthesia (Bertelsen et al. 2005b; Mosley 2000). In general, recovery times appear longer and more variable in snakes than in lizards.

Sevoflurane

Induction times using sevoflurane are slightly shorter than with isoflurane (Bertelsen et al. 2005b; Hernandez-Divers et al. 2005). In lizards induced with 8%, the time

to initial relaxation and loss of righting reflex is around 6 minutes (Hernandez-Divers et al. 2005) while the time to complete relaxation is approximately 11 minutes (Bertelsen et al. 2005b). As for isoflurane, direct intubation of the awake animal followed by mechanical ventilation with the drug leads to rapid induction. The addition of 66% nitrous oxide will speed up inductions slightly (Bertelsen et al. 2005b).

Sevoflurane induction has been subjectively judged as smoother and associated with less breath holding than with isoflurane (Hernandez-Divers et al. 2005), but the respiratory rate during induction appears to be similar or even marginally lower with sevoflurane (Bertelsen et al. 2005b). Sevoflurane causes a moderate reduction in heart rate (Hernandez-Divers et al. 2005; Maas & Brunson 2002) and a severe reduction in respiratory rate (Maas & Brunson 2002) compared with values in manually restrained animals. The hemodynamic effects of sevoflurane in iguanas are similar to those with isoflurane (Barter et al. 2006).

The minimum alveolar concentration at 30–35°C has been reported to be $2.42 \pm 0.57\%$ in rat snakes (Maas & Brunson 2002), $2.51 \pm 0.46\%$ in monitor lizards (Bertelsen et al. 2005a), and $3.1 \pm 1.0\%$ in iguanas (Barter et al. 2006), indicating that vaporizer settings of 3–3.5% will be appropriate to maintain surgical anesthesia in most subjects. In a study of monitor lizards, the coadministration of 66% nitrous oxide resulted in a 25% reduction in sevoflurane MAC (Bertelsen et al. 2005a), and similar reductions are likely to occur in other species and with other inhalants.

With the modern inhalant anesthetics, the length of the recovery period appears to be influenced more by the duration and depth of anesthesia (and the extent of intracardiac shunting) than by the agent used (Brosnan et al. 2006). After short time, relatively superficial anesthesia sevoflurane will result in faster recoveries than isoflurane (Hernandez-Divers et al. 2005), but following prolonged, deep anesthesia, that difference is marginal (Bertelsen et al. 2005b).

Desflurane

Desflurane is the least soluble of the volatile anesthetics, and thus theoretically has the fastest inductions and recoveries. However, it may cause airway irritability, requires specialized heated vaporizers, and is rarely used in veterinary practice. The minimum alveolar concentration at 34–35°C has been reported to be $8.9 \pm 2.1\%$ in iguanas, with hemodynamic effects being similar to those of isoflurane and sevoflurane (Barter et al. 2006).

Nitrous Oxide

Nitrous oxide (N_2O) may be used as a supplemental anesthetic (at 50–66% with oxygen) during induction with inhalational agents (Bennett et al. 1999; Custer & Bush 1980), resulting in marginally shorter induction

times (Bertelsen et al. 2005b). In monitor lizards, 66% N₂O delivered with sevoflurane reduced the sevoflurane requirement (MAC) with 25% (Bertelsen et al. 2005a). Assuming that a relationship of simple linear additivity between sevoflurane and nitrous oxide exists, the MAC for N₂O in varanids can be estimated to be 244%. Apart from reducing the concentration of the primary agent which may improve cardiopulmonary function, the use of N₂O likely provides improved analgesia over delivery in 100% oxygen.

Carbon Dioxide

Carbon dioxide (CO₂) is occasionally used for the immobilization of venomous snakes during venom extraction (Wang et al. 1993). Unconsciousness is thought to be mediated through central nervous system acidosis, and this procedure is not recommended in clinical practice. A mixture of 3–5% CO₂ in oxygen may be used during mechanical ventilation to achieve high oxygenation and delivery of inhalational agents while avoiding the respiratory acidemia seen during hyperventilation (T. Wang, pers. comm.), and the use of a 10% CO₂ mixture has been suggested to stimulate respiration during recovery (Malley 1997).

PARENTERAL ANESTHESIA

Numerous injectable anesthetics have been used in snakes and lizards with varying success. These include etorphine hydrochloride (Hinsch & Gandal 1969; Wallach & Hoessle 1970), pentobarbital sodium (Arena et al. 1988; Betz 1962; Karlstrom & Cook 1955), thiopental sodium (Karlstrom & Cook 1955), methohexital (Preston et al. 2010; Wang et al. 1977), MS-222 (Green & Precious 1978; Karlstrom & Cook 1955), urethane (Calderwood 1971), nicotine (Calderwood 1971), decamethonium iodide (Brazenor & Kaye 1953), tubocurarine chloride (Brazenor & Kaye 1953), and procaine hydrochloride (Livezey 1957). While still occasionally used in experimental settings, these agents must be considered obsolete in clinical practice.

Propofol

Provided vascular access can be gained, propofol is this author's agent of choice for anesthetic induction. Administered intravenously or intraosseously at dosages of 5–10 mg/kg, propofol will cause induction in 1–5 minutes (Anderson et al. 1999; Bennett et al. 1998; McFadden et al. 2011). Propofol administered perivascularly is ineffective, but unlike barbiturates does not cause tissue damage. Administration via the ventral tail vessels is generally feasible in patients larger than 250 g, although there are significant species differences.

In lizards and snakes, propofol causes a slight decrease in heart rate and a marked respiratory depression (Anderson et al. 1999; Bennett et al. 1998). The respiratory depression is dose dependent and appears

to be affected by the duration of administration; low doses given slowly cause less apnea than high doses administered as a bolus.

The duration of anesthesia depends on the dosage; 5 mg/kg results in 20–30 minutes of anesthesia, while longer recovery times are seen following 10 mg/kg dosage. Anesthesia may be maintained by inhalation or by continuous propofol infusion. An infusion rate of 0.5 mg/kg/min proved excessive in green iguanas (Bennett et al. 1998), and rates of 0.2–0.4 mg/kg/min are likely more appropriate.

For most species, a dose of 5–10 mg/kg given slowly is appropriate for short procedures or as induction for inhalational anesthesia.

Alfaxalone

The steroid anesthetic alfaxalone is highly insoluble in water and historically was formulated in combination with alphadalone and the solubilizing agent cremaphor. This drug found some use in reptiles (Calderwood & Jacobson 1979; Lawrence & Jackson 1983), but its use was discontinued as cremaphor was associated with allergic reactions in domestic animals. More recently, alfaxalone has been solubilized with 2-hydroxypropylbeta-cyclodextrin (Estes et al. 1990). When given IV, this formulation has much the same effects as propofol. In veiled chameleons, a surgical plane of anesthesia lasting for 5–10 minutes was achieved 2 minutes following 5 mg/kg IV (Knotec et al. 2011a). In green iguanas, 5 mg/kg IV resulted in about 15 minutes of anesthesia with minimal effect on heart rate and respiratory rate (Knotec et al. 2011b). Interestingly, unlike propofol, alfaxalone is effective when administered intramuscularly at higher dosages. In iguanas, 10 mg/kg provides light sedation, 20 mg/kg provides a level suitable for minor procedures or for endotracheal intubation and supplementation with inhalational anesthesia, and 30 mg/kg provides an anesthetic plane suitable for surgical procedures of limited duration (up to 40 minutes) (Bertelsen & Sauer 2011). In iguanas, there is an initial dose-dependent depression of respiration followed by a significant increase in frequency over time (Bertelsen & Sauer 2011). In accordance to principles of metabolic scaling, smaller individuals require higher dosages. In an unpublished study in leopard geckos, 30–40 mg/kg of alfaxalone IM was required for heavy sedation, and 50 mg/kg IM is likely required for a surgical level. Unfortunately, at these dosages the low concentration of the commercially available formulation requires clinically excessive IM injection volumes.

Ketamine

Ketamine hydrochloride has been used extensively in reptiles, primarily snakes, since its discovery in the late 1960s (Glenn et al. 1972; Schumacher et al. 1997).

The effective dosage depends on the body temperature (Arena et al. 1988); at lower body temperatures, lower doses are required, but longer induction and recovery times are observed (Arena et al. 1988; Green et al. 1981). Effects are highly species dependent (Arena et al. 1988; Cooper 1974; Hill & Macklessy 1997; Ogunranti 1987; Schildger et al. 1993), but large individual variation is also observed (Cooper 1974; Hill & Macklessy 1997).

Recommended dosages range from 12–44 mg/kg for sedation (Bennett 1998; Glenn et al. 1972; Schildger et al. 1993; Spelman et al. 1996) to 55–88 mg/kg for surgical anesthesia (Bennett 1998; Glenn et al. 1972; Schildger et al. 1993). Even higher dosages (100–220 mg/kg) are occasionally reported (Arena et al. 1988; Harding 1977). The time to peak effect following intramuscular injection is approximately 30 minutes (Cooper 1974; Custer & Bush 1980; Glenn et al. 1972; Green et al. 1981).

In snakes and lizards, moderate ketamine dosages are associated with increased heart rates (Arena et al. 1988; Schumacher et al. 1997), hypertension (Schumacher et al. 1997), and respiratory depression (Arena et al. 1988; Ogunranti 1987; Schumacher et al. 1997), the latter peaking at 30–60 minutes (Arena et al. 1988; Ogunranti 1987). At increasing dosages, the drug will induce apnea, bradycardia (Cooper 1974; Custer & Bush 1980; Glenn et al. 1972; Green et al. 1981), and eventually death.

The main problem with ketamine anesthesia in reptiles is the extended recovery periods. Reported recovery times range from 6–24 hours at 15 mg/kg (Hill & Macklessy 1997) to 2–3 days at 40–80 mg/kg (Custer & Bush 1980; Glenn et al. 1972; Green et al. 1981) and 6–7 days at 100–130 mg/kg (Glenn et al. 1972).

Ketamine may be combined with sedatives, such as benzodiazepines and alpha-2-agonists, for better muscle relaxation, a reduction in required dose, and shorter recovery times (Bennett 1998; Heard 2001; Malley 1997). Due to the variable effects, long recovery periods and the availability of alternative protocols, the author rarely uses the dissociative agents.

Zolazepam-Tiletamine

The potent cyclohexamine tiletamine combined with the benzodiazepine zolazepam has found some use in reptile anesthesia (Boever & Caputo 1982; Gray et al. 1974; Read 2004), but very little published information exists. The onset of effects is faster than with ketamine (Mauthe von Degerfeld 2004), while cardiopulmonary effects are likely similar to those produced by ketamine. In early studies, dosages of 30–40 mg/kg administered to iguanas resulted in surgical anesthesia lasting 8–16 hours, while variable effects were seen with doses of up to 88 mg/kg in snakes (Boever & Caputo 1982). In Komodo dragons, dosages of 5.5 mg/kg caused repetitive head and neck movements 10–25 minutes before resulting in sedation (Spelman et al. 1996). In iguanas,

10 mg/kg resulted in a brief period of excitement followed by good relaxation (Mauthe von Degerfeld 2004). Despite its long duration of action and variable effects, low doses (2–5 mg/kg) may be useful for sedation prior to handling or intubation, particularly of larger animals.

Sedatives

Sedative and tranquilizing drugs such as benzodiazepines and alpha 2-agonists may be used in squamates, but studies to document their effects are lacking. Because of the difficulty in accessing the vascular system and airways in chelonians, there has been much more focus on the use of these drugs in turtles and tortoises, and as results may likely be extrapolated to snakes and lizards.

OTHER TECHNIQUES

Hypothermia, once used as a means of immobilizing reptiles (Calderwood 1971; Kaplan 1969), is considered an unacceptable clinical practice, as is electroanesthesia (Northway 1968).

RECOVERY

As mentioned earlier, recovery times in reptiles are prolonged compared to birds and mammals. Body temperature critically affects speed and quality of recovery so animals should be kept warm. If mechanical ventilation was used, animals should gradually be weaned off ventilation. The easiest way to do so is by manually ventilating every 1–5 minutes using an Ambu-bag or similar to allow buildup of CO₂. Periods of apnea of 5–10 minutes are unlikely to cause deleterious effects. Since hyperoxia may downregulate respiration in reptiles (Glass & Johansen 1976), and possibly promote R-L shunting, recovery in room air (21% oxygen) as opposed to 100% oxygen may be used. However, while faster recoveries were experienced when ventilating iguanas with 21% oxygen following short-time isoflurane anesthesia (Diethelm & Mader 1999), no difference could be demonstrated following longer anesthetic events (Bertelsen et al. 2005b).

COMPLICATIONS

Complications are relatively rare using the protocols suggested, but respiratory depression or apnea and prolonged recoveries are among those most commonly encountered (Read 2004). These problems may be reduced by providing adequate mechanical ventilation and by maintaining body temperature within physiological limits.

ANALGESIA

Since the first edition of this book, more attention has been given to pain perception and modulation in

reptiles (Mosley 2011). Despite these efforts, reptilian analgesia is still an obscure subject, and solid recommendations are hard to give.

In anoles, the administration of the μ -receptor opioid morphine (5 mg/kg IM) caused a latency of the tail-flick response (Mauk et al. 1981). Similarly, morphine (10–20 mg/kg) increased thermal withdrawal latency in red-eared sliders (Sladky et al. 2007) and bearded dragons (Sladky et al. 2008), but appears to be ineffective in corn snakes at dosages up to 40 mg/kg (Sladky et al. 2008). Morphine is associated with severe respiratory depression, but another μ -receptor opioid tramadol appears to have similar effects on thermal withdrawal latency (10–15 mg/kg PO, SC) in turtles with much less respiratory depression (Baker et al. 2011). Similarly, another μ -receptor opioid hydromorphone (0.5 mg/kg IM) increased thermal withdrawal time in sliders (Mans et al. 2012). In contrast, the predominant κ -receptor opioid butorphanol (20 mg/kg SC) was ineffective in bearded dragons and sliders, but effectively increased thermal withdrawal latency in corn snakes (Sladky et al. 2007, 2008). Accordingly in iguanas, butorphanol (1 mg/kg IM) failed to decrease the minimum anesthetic dose of isoflurane (Mosley et al. 2003a), and did not provide demonstrable analgesia in a heat pad test (Fleming & Robertson 2012). These differences are likely associated with species differences in expression of the different classes of opioid receptors (Sladky et al. 2009), making extrapolation to other species very difficult. In contrast, nonsteroidal anti-inflammatory drugs would be expected to behave much the same across species, and although the role of the cyclooxygenase system in reptiles has not been studied, clinical evidence supports the efficacy of nonsteroidal anti-inflammatory drugs (NSAIDs) in reptiles (Hernandez-Divers 2006), and they appear widely used (Read 2004). A pharmacokinetic trial of meloxicam in iguanas showed excellent bioavailability following PO administration, and suggested administration of

meloxicam at a dose of 0.2 mg/kg IV or PO results in plasma concentrations $>0.1 \mu\text{g/mL}$ for approximately 24 hours (Divers et al. 2010). Further, daily administration of high doses (1 or 5 mg/kg) for 12 days did not induce any histologic changes in gastric, hepatic, or renal tissues (Divers et al. 2010). Similarly, daily administration of meloxicam (0.2 mg/kg IM for 10 days) in iguanas failed to demonstrate any significant clinical, biochemical or hematological abnormalities (Trnkova et al. 2007). In an attempt to evaluate the effect of meloxicam (0.3 mg/kg IM) and butorphanol (5 mg/kg IM), the postoperative physiological stress response in ball pythons was evaluated, failing to demonstrate an effect of any drug (Olesen et al. 2008). However, even in the saline-treated control group, there was only minimal measurable physiological response to surgery, questioning the validity of the model.

Despite the lack of documentation, analgesics should be part of any anesthetic regimen that involves potentially painful procedures. Opioids and NSAIDs are the most relevant candidates for successful treatment, and suggested dosages of selected drugs are given in Table 21.1.

As in any species, preemptive analgesia offers intraoperative as well as postoperative analgesia, and likely will reduce the amount of anesthetic needed. Local analgesics (e.g., lidocaine) are commonly used in reptiles. In small subjects, diluting the drugs (e.g., 1:10 in sterile water) prior to administration will help to avoid overdosing.

SELECTED PROTOCOLS

For most snakes and lizards, the author recommends one of three approaches (Table 21.2): induction with propofol (5–10 mg/kg, IV) or alfaxalone (5 mg/kg, IV; 20–30 mg/kg, IM) followed by isoflurane or sevoflurane anesthesia for longer duration; mask or chamber induction with isoflurane or sevoflurane; or direct

Table 21.1. Selected anesthetic, sedative and analgesic drugs used in snakes and lizards

Generic Name	Dosage (mg/kg)	Reversal Agent	Reference
Propofol	5–10	None	Anderson et al. (1999); Bennett et al. (1998); McFadden et al. (2011)
Alfaxalone	5–10 IV 20–40 IM	None	Knotec et al. (2011a, 2011b) Bertelsen and Sauer (2011)
Midazolam	1–2	Flumazenil	
Medetomidine	0.05–0.15	Atipamezole	
Ketamine	10–40 ^a	None	Custer and Bush (1980); Glenn et al. (1972); Schumacher et al. (1997)
Zolazepam-Tiletamine	2–10	Flumazenil for zolazepam	Mauthe von Degerfeld (2004)
Meloxicam	0.1–0.3	None	Divers et al. (2010); Hernandez-Divers (2006)
Morphine ^b	10–15	Naltrexone, naloxone	Sladky et al. (2008)
Tramadol ^b	10–15	Naltrexone, naloxone	Baker et al. (2011)
Butorphanol ^c	0.5–2	Naltrexone, naloxone	Sladky et al. (2008)

^aDosages up to 220 mg/kg have been reported (Arena et al. 1988).

^bIn lizards.

^cIn snakes.

Table 21.2. Recommended anesthetic protocols for snakes and lizards

	Pre-Medication	Induction	Maintenance
Small snake	None	Propofol 5–10 mg/kg, IV Chamber induction with isoflurane or sevoflurane	Isoflurane or sevoflurane by endotracheal tube
Large snake	None or Alfaxalone 10 mg/kg, IM or Telazol 5–10 mg/kg, IM	Propofol 2–7 mg/kg, IV Direct intubation ^a followed by ventilation with isoflurane or sevoflurane Chamber-induction with isoflurane or sevoflurane	Isoflurane or sevoflurane by endotracheal tube
Venomous snake	None	Propofol 5–10 mg/kg, IV ^b Chamber-induction with isoflurane or sevoflurane	Isoflurane or sevoflurane by endotracheal tube
Small lizard	None	Propofol 5–10 mg/kg, IV Alfaxalone 20–40 mg/kg, IM Chamber-induction with isoflurane or sevoflurane	Isoflurane or sevoflurane by endotracheal tube
Large lizard	None or Telazol 5–10 mg/kg	Propofol 3–10 mg/kg, IV Mask with isoflurane or sevoflurane	Isoflurane or sevoflurane by endotracheal tube

Note: Please refer to chapter for details.

^aDesentization of the glottis with a drop or spray of local analgesic recommended.

^bIf properly restrained.

intubation and induction with isoflurane or sevoflurane. For large and aggressive specimens, injection with low doses of ketamine (e.g., 5 mg/kg, IM) or tiletamine/zolazepam (e.g., 3 mg/kg, IM), with or without medetomidine (e.g., 100 µg/kg, IM) or midazolam (e.g., 1 mg/kg, IM), may be used to allow safe handling. Dosages of commonly used drugs are presented in Table 21.1.

FIELD TECHNIQUES

For field work, when equipment must be kept to a minimum, the protocols using parenteral drugs are recommended. Depending on the size of the animal and the invasiveness of the procedure, intramuscular alfaxalone (10–40 mg/kg) or intravenous propofol (5–10 mg/kg) may be employed. Liquid isoflurane or sevoflurane administered directly into a small airtight container or plastic bag containing the animal is another straight forward means of induction even in the field, but care should be taken to ensure effective breathing of the animals once removed from the container.

22 Chelonia (Tortoises, Turtles, and Terrapins)

Alessio Vigani

INTRODUCTION

Within the class Reptilia, the order Chelonia includes almost 300 species of tortoises, turtles, and terrapins. They inhabit many different habitats, from tropical rain forests to deserts, from freshwater swamps to oceans. The wide variety of environments, dietary preferences, and activity levels explains the substantial differences in metabolic rate among chelonian species. They also differ significantly in body size, from the 0.1-kg adult Cape tortoise (*Homopus* spp.) to the 1000-kg adult leatherback sea turtle (*Dermochelys coriacea*) (Raphael 2003). Most tortoises are generally shy, harmless animals, but there are differences in temperament among chelonians. Many aquatic species are natural predators and often respond with aggression to potential threats. These species can be dangerous and require caution when handled.

Interventions in the field for research purposes and the management of patients in the hospital setting represent the main conditions where sedation and general anesthesia are needed. It follows that the choice of the anesthetic protocol will depend on the invasiveness of the procedure and on the environment where it will take place. Collection of diagnostic samples in the field generally only requires mild to moderate sedation and, ideally, wild animals should return to the wild without the risk of any residual anesthetic effect. For this purpose, sedative protocols that include short-acting and reversible agents are particularly suitable.

Invasive surgical procedures, instead, should be performed under general anesthesia in the controlled environment of a veterinary hospital. The facility should be equipped with specific anesthesia equipment and monitoring devices. Prior to anesthesia, the patient should be thoroughly evaluated and acclimatized,

homeostasis should be restored, and thermoregulation should be supported in order to optimize the response of the patient to the anesthetic. Appropriate analgesia should be provided to any patient that is to undergo a painful procedure. New information on the ability of reptiles, chelonians included, to feel pain underlines the responsibility of every veterinarian to properly prevent and manage pain in these species.

Furthermore, independently from the operative setting, prerequisites to the design of a safe anesthetic protocol are a good knowledge not only of the anatomy and physiology, but also of the species-specific differences in response to anesthetic drugs and dosages. Multiple studies have evaluated the efficacy of a variety of single or combined anesthetic and analgesic drugs in different species of chelonians. Interesting pharmacokinetics data on some drugs, as well as information on their respiratory and cardiovascular effects in chelonians, are now available.

The perfect anesthetic agent does not exist for any species, including the chelonian. There is no anesthetic drug devoid of side effects and even the most recently marketed agents produce dose-related toxicity. For this reason, the use of combinations of small doses of multiple drugs has become popular in anesthesia. This anesthetic technique is referred to as *balanced anesthesia* and has been shown to be superior to single-agent anesthesia in humans and many veterinary species (Kushiro et al. 2005; Sanders et al. 2008). The explanation of its success is the use of small doses summates the advantages, but not the disadvantages, of the individual components of the mixture. It follows the safety of the anesthetic protocol largely depends on the right choice of drugs, used at the adequate dose for the patient. Excellent previous reviews on chelonian anesthesia are present in the literature and represent

invaluable sources of information for the veterinarian. This chapter focuses on reviewing, to the best of the author's knowledge, the most current literature on anesthetic and analgesic techniques used in turtles, tortoises, and terrapins. The specific drugs, protocols, and dosages are reported with the sole goal to establish a database from which informed medical decisions can be independently made.

ANATOMY AND PHYSIOLOGY

Cardiovascular

The cardiovascular system is characterized by many morphological and functional peculiarities. The heart is three chambered and valentine shaped. It is located within the pericardial sac, at midline, above the cranial portion of the plastron, immediately cranial to the liver. The large right and left atria are distinct and open independently into an anatomically single but functionally divided ventricle. The right atrium receives deoxygenated blood from the systemic venous circulation via a preatrial muscular, thin-walled chamber called the *sinus venosum*. The latter represents the confluence site of blood from the left and right precaval veins, the postcaval vein, and the left hepatic vein.

The cardiac muscle constituting the *sinus venosum* acts also as the pacemaker of the heart. This electrical activity is detectable on the electrocardiogram by the presence of a "SV wave" preceding atrial depolarization.

The left atrium receives oxygenated blood from the pulmonary circulation via the left and right pulmonary veins. The ventricular muscle is internally organized in a series of ridges that divide the ventricle into three functional chambers: namely, *cavum pulmonale*, *cavum venosum*, and *cavum arteriosum*. Blood coming from the right atrium enters first the *cavum venosum* and then the *cavum pulmonale*, which has a direct pulmonary arterial output into the pulmonary trunk. Left atrial blood enters the *cavum arteriosum* and secondarily the *cavum venosum*, which opens into the systemic arterial systems via the left and right aortas (Farrell et al. 1998). It follows that the *cavum venosum* receives both deoxygenated (directly from right atrium) and oxygenated blood (indirectly from the left atrium), with the potential for mixing of the two.

The ventricular anatomy is such that in physiologic conditions of normal ventilation, there is a high degree of separation between the systemic and pulmonary circulations, with minimal mixing between venous and arterial blood. During ventilation, systemic ventricular output matches with the pulmonary ventricular output and intracardiac shunting is low. With the animal at rest, the nature of the physiological cardiac shunting in chelonian is bidirectional, with coexistence of right-to-left and a left-to-right components (Farrell et al. 1998).

The extraordinary adaptability of chelonians is fully displayed during apnea. The dive reflex induces

complex physiologic changes, including modulation of intracardiac shunting (Hicks & Malvin 1992). During breath holding, arterial tension of oxygen progressively decreases. This induces vasoconstriction of the pulmonary arterial vasculature and causes a substantial decrease in pulmonary blood flow (Crossley et al. 1998). During apnea in turtles, the increased pulmonary arterial pressure causes the systemic venous return to be preferentially directed into the systemic circulation (R-L shunt), bypassing the lungs. This mechanism produces an oxygen sparing effect in the lungs (Jackson 2000). Aquatic, and to a lesser extent terrestrial chelonians, have been shown to develop right to left intracardiac shunting in hypoxic conditions (Hicks et al. 1996). During ventilatory periods, the cardiovascular changes are the reciprocals of those occurring during apnea: the heart rate increases, the pulmonary vascular resistance falls, and pulmonary blood flow is maximized. Blood flow measurements indicate a net formation of a left-to-right shunt during ventilation, which increases hemoglobin oxygen saturation of pulmonary arterial blood (Shelton & Burggren 1976). Low rates of elimination of inhalant anesthetics, such as isoflurane or sevoflurane, can be expected whenever cardiac shunting exists.

Hypoxemia and the subsequent R-L shunt trigger a generalized hypometabolic state (Hicks & Wang 1999). This hypometabolic condition significantly decreases the hepatic function, with a potential detrimental effect on the clearance of drugs (Platzack & Hicks 2001). Therefore, it is important to provide ventilation and oxygenation during anesthesia to maintain a steady cardiovascular and metabolic state. Once cardiac shunting is present, it may be difficult to provide oxygen supplementation.

The direction (right to left vs. left to right) and size of shunting in chelonians are influenced by multiple factors that control cardiac function. These include both adrenergic and cholinergic innervation. Stimulation of the vagus in tortoises results in an increase in pulmonary arterial pressure and net formation of R-L shunt (Hicks & Comeau 1994). In contrast, epinephrine or the stimulation of the cardiac sympathetic nerves abolish R-L shunting and induce vasodilation of the pulmonary vasculature. In *Trachemys scripta*, it has been shown that the infusion of epinephrine increases the blood flow in the pulmonary circulation (left-to-right shunt) and eliminates the systemic venous admixture in the aortic arches (Hicks & Malvin 1992).

An additional important factor that modulates cardiac shunting is thermoregulation. Variation of body temperature from the physiologic optimal conditions has major effects on the circulatory system (Krosniunas & Hicks 2003). At normal body temperature, the intracardiac shunting is relatively stable, with a small right to left shunt. Interestingly, both heating and cooling result in the development of an increased R-L intracardiac shunt (Galli et al. 2004). The ability to

selectively shunt blood flow away from the pulmonary circulation is likely the cause of prolonged recoveries from inhalant anesthesia. Therefore, during anesthesia, the maintenance of steady physiologic thermal conditions is important to provide optimal gas exchange, including inhaled anesthetics.

The renal portal system (RPS) maintains sufficient blood flow to the renal tubules at times when a decreased effective circulating volume generates a low glomerular blood flow. The portal vein is a large vessel that enters the kidney and originates at the confluence of the *epigastric* and *external iliac* veins. It contains muscular valves capable of shunting blood from the caudal half of the body directly to the kidney. Hydration status seems to play a primary role in the activity of the RPS and affects the degree of shunting. Dehydration causes an increased diversion of blood. The blood in the RPS is exposed to the renal tubular surface and this may result in increased clearance of drugs normally excreted through the tubules into the urine. Angiographic studies have also shown that a large amount of venous blood from the hind limbs is directed to the liver (Holz et al. 1997b). Therefore, renal and hepatic levels of some drugs injected into the caudal limbs may be unpredictable. It has been demonstrated, however, that the injection site is unlikely to have any influence over the activity of most drugs and the caudal half of a chelonian is available for drug administration (Holz et al. 1997b). For example carbenicillin, a drug largely excreted by tubular secretion, was injected into the hind limbs of turtles. The systemic blood levels of the drug obtained were just slightly lower compared with the fore limb injection (Holz et al. 1997a). Whether the same scenario applies to drugs injected into the dorsal venous sinus of the chelonian tail remains unclear. In green iguanas (*Iguana iguana*), the venous flow from the tail was found to directly enter the kidney through the renal portal circulation (Benson & Forrest 1999). Until adequately investigated, it is advisable not to use the dorsal venous sinus for drug administration in dehydrated chelonians.

Respiratory System

Chelonians are obligate nasal breathers. Open mouth breathing indicates decreased airflow through the nasal cavities, possibly due to pathology. The external nares open into a keratinized vestibule divided symmetrically by a cartilaginous septum into right and left nasal chambers. The nasal chambers lay above the hard palate and extend aborally into the oropharynx through a ventral recess. Turbinates, sinuses, and soft palate are absent. The glottis is located at the base of the tongue, with species-specific differences in morphology. In aquatic species in particular, it is characterized by a strong muscular component needed to provide efficient sealing of the distal airways during immersion. The trachea is composed of complete rings, is relatively

short, and bifurcates in paired bronchi at the level of the mid-cervical region (McArthur et al. 2004). It is, therefore, easy to unilaterally intubate most chelonians.

The lungs are located dorsally in the coelomic cavity, and their dorsal surface is attached to the carapace. All chelonians have multichambered lungs with paired unbranched intrapulmonary bronchi reinforced by cartilage over their entire length. In sea turtles, the intrapulmonary bronchi are supported by cartilaginous rings, are broad cranially and taper caudally. In other chelonians, the bronchi are uniform in diameter for their entire length, and the supporting cartilage forms a network instead of separate rings. Each bronchus opens into 3–11 chambers from which multiple subcompartments, referred to as “niches”, originate. The chelonian analogues of mammalian alveoli are termed “faveoli,” “ediculae,” and “trabeculae,” and represent the parenchymal gas exchange units (Perry 1998).

The presence of the carapace impedes the costal component of ventilation; therefore, muscle induced movements of the viscera and limbs are responsible for alterations in intrapulmonary pressure. Chelonians do not possess a functional muscular diaphragm. A horizontal septum, or pseudodiaphragm, separate the lungs from other intracoelomic organs. In some chelonians, such as sea turtles, the horizontal septum is extensive and attaches the liver and stomach to the ventral surface of the lung. This attachment maximizes the transmission of the movement of the body wall and limb girdles through the visceral mass to the lungs. Limb movements stretch the septum downward, causing expansion of the lungs. The lung expansion generates a negative intrapulmonary pressure and facilitates the passive inflow of air during inspiration. The “muscle pump” mechanism is abolished by immobility; subsequently, ventilation is then profoundly depressed during anesthesia. Ventilatory artificial support by intermittent positive pressure ventilation (IPPV) is, therefore, always recommended in anesthetized chelonians. IPPV can be provided either manually or mechanically with a ventilator.

Chelonians are unable to cough and lack effective ciliary clearance of respiratory material. This explains why their ability at clearing secretions and foreign material from their lower respiratory tract is very poor. Consequently, inflammatory exudates tend to accumulate in dependent area of the lungs with severe effects on respiratory function and gas exchanges. The innate resilience of chelonians, however, allows them to withstand extreme physiologic perturbations, such as severe hypoxia or hypercapnia, and clinical signs of respiratory distress occur late in the course of the primary disease (McArthur et al. 2004).

Reptiles, compared with avian and mammalian species, have a relatively large lung volume in which is distributed a relatively small respiratory surface area. The multichambered lungs of chelonians, however,

represent the advantage of a more complex surface elaboration compared with the single-chambered lungs of other reptiles. Studies in *T. scripta* showed the septa that divide the pulmonary chambers provide a 40% larger surface area used for gas exchanges compared with the outer wall of the lungs. This yields effective gas exchange to cover metabolic requirements (Perry 1998).

Respiration is characterized by intermittent breathing patterns with ventilatory periods alternated with nonventilatory pauses. The respiratory cycle in terrestrial species consists of a passive inspiratory followed by an active expiratory phase. The latter is reversed in aquatic species. These peculiarities, along with the high compliance values of chelonian lungs, produce a significantly lower work of breathing compared with mammals. In regard to anesthesia, however, the chelonian highly compliant lungs are extremely easy to inflate and hence highly sensitive to barotrauma (Herman et al. 1997). It is recommended, therefore, that low peak inspiratory pressures be used during IPPV.

The need to maintain low the energy requirements of ventilation is also reflected by the adaptive mechanisms that chelonians operate in response to increased metabolic stress. Increasing tidal volume is ineffective and represents a major energy expense in chelonians. This explains why most tortoises and turtles during activity increase their minute ventilation by increasing the respiratory rate and not by increasing tidal volume. In regard to the driving mechanisms of ventilation, hypoxia and hypercarbia affect the length of respiratory cycles differently. Hypoxia induces bradypnea, while hypercapnia causes tachypnea. The explanations of these opposite effects are oxygen preservation and the elimination of carbon dioxide, respectively. Conversely, both the artificial induction of hyperoxia or hypocapnia, independently from one another, cause persistent cessation of spontaneous ventilation (Wang et al. 1998). Therefore, the maintenance of blood gas variables within physiologic range is critical during anesthesia to avoid long lasting alteration of ventilatory function.

Many chelonians can perceive a low oxygen environment and develop a cardiorespiratory response similar to the dive reflex described in mammals. They become apneic, bradycardic, and convert to anaerobic metabolism. These physiological changes, combined with cardiac shunting, facilitate diving and hibernation, but complicate the use of inhaled anesthetic agents. The alterations in respiratory circulation typical of the chelonian dive reflex can affect the uptake and excretion rates of inhalant anesthetics.

Pain and Nociception

Pain and nociception are often mistakenly considered synonymous. Pain is inherently subjective, and in animals is defined as an unpleasant sensory and emotional experience associated with actual or potential tissue damage. Pain represents the interpretation by the

cerebral cortex of a noxious stimulus, and consciousness, therefore, is a prerequisite to feel pain. Nociception instead, refers to the physiologic or neuroanatomical components necessary to sense and transmit the noxious stimuli to the brain (IASP 1994). Any organism that has developed these neuroanatomical structures is defined as sentient. In a sentient animal, therefore, nociception persists during unconsciousness and anesthesia unless analgesic interventions are provided (Giordano 2005).

Multiple studies in different reptile species have demonstrated the presence of the neuroanatomical apparatus for sentience and nociception (Liang & Terashima 1993; ten Donkelaar & de Boer-van Huizen 1987). It has been shown that environmental stimuli elicit impulse transmission from sensory receptors, through the spinal cord, to the animal's brain. Furthermore, the reptile cerebral structures are operationally sophisticated enough to convert the impulses into perceived sensations (Giordano 2005). The opioid receptor gene family is highly conserved across multiple vertebrate orders, and new information is now available on opioid receptors and their modulation in chelonians (Li et al. 1996; Reiner 1987). For example, μ and δ opioid receptors are located throughout the brain in aquatic turtles, with δ opioid receptors being more abundant than μ opioid receptors (Xia & Haddad 2001). With respect to endogenous opioid related neurotransmitters, proenkephalin and other neuropeptides (i.e., neuropeptide FF) are present in the brain of turtles with a distribution similar to that in mammals and birds (Munoz et al. 2008). New information is also now available on the role of the different opioid receptors in nociception and analgesia in chelonians (Sladky et al. 2009). For example, kappa (κ) opioid receptors are significantly less involved in nociception and pain compared with μ -opioid receptor. Kappa receptor agonists do not produce any detectable analgesic effect in turtles whereas agents with μ agonist activity significantly increase the nociceptive threshold (Wambugu et al. 2010).

In nonverbal species, suffering is expressed in the form of behavioral changes that are often not obvious to the observer (Holsti et al. 2008; Holton et al. 2001). Chelonians are not an exception. It follows, independently from the inability of these animals to show evident expressions of pain, that veterinarians should consider that chelonians are capable of suffering when a noxious stimulus is applied, and therefore they should be provided with appropriate analgesia.

PERIANESTHETIC CONSIDERATIONS AND PATIENT MANAGEMENT

Preanesthetic Assessment

A complete history provides crucial information regarding the patient's environment, husbandry, and diet,

and helps to determine duration and severity of clinical signs of the medical condition. The observation of the unstressed patient is important to determine the level of activity of the patient unbiased by any restraint.

Ideally, prior to anesthesia, the patient should be acclimatized to the new environment, and the room temperature and humidity should be set within the ideal range for the species. This obviously does not apply to emergency cases where immediate intervention is required. As with all ectotherms, chelonian body temperature is reliant on the environmental temperature. The preferred optimal temperature zone (POTZ) refers to the ideal environmental temperature range selected by a particular species. Each species has its own POTZ and it is only when the animal is in its POTZ that its physiology is functioning at its best. For most chelonians, data regarding optimal environmental temperature and humidity can be found in the literature. If the specific POTZ is uncertain, exposure to a room temperature range of 24–28°C during preanesthetic stabilization seems to be appropriate for most chelonian species (McArthur et al. 2004).

Body temperature should be measured prior to anesthesia. Oscillations in body temperature in ectothermic species are common, and it is important to identify and correct wide variations from the normal range. All chelonians have what is referred to as an “active temperature range” or “ATR.” This is the body temperature range where they are capable of normal, voluntary activity. Each species has a different ATR (McArthur et al. 2004). Critically ill patients are often hypothermic and the prompt restoration of normothermia is of critical importance to maximize the chance of patient stabilization. On the other hand, overheating should also be carefully avoided. Hypothermia and hyperthermia have significant effects on metabolic rate (drug clearance), acid base status, intracardiac shunting (respiratory gas exchanges and inhalant anesthetic uptake and clearance), and inhalant agent potency (decreased minimum alveolar concentration [MAC] during hypothermia). Therefore, attention to maintaining normothermia in the perianesthetic period is a priority for the anesthetist.

The preanesthetic physical examination consists of the assessment of systems and organs and should include a preliminary visual examination aimed to determine body condition, nutritional and hydration status, and presence of trauma. Body weight must be recorded in order to ensure accurate dosing of anesthetics.

A basic assessment of the cardiovascular system of the patient should be performed prior to anesthesia. Heart rate and pulse rate and strength can be evaluated noninvasively with a Doppler flow detector. Pencil and flat probes are selected based on the size of the animal and the location where the probe must be placed. For cardiac auscultation, a pencil probe can be placed lateral to the neck at the level of the thoracic inlet. For

pulse assessment, a flat probe can detect blood flow in vessels directly beneath the probe. Suitable arteries for pulse assessment are the carotid and femoral artery (McArthur 2007). Several formulas to determine the normal heart rate based on body weight in reptiles have been given by different authors. However, the absence of validation studies and the significant physiologic differences between species often make those equations clinically inadequate for predicting heart rate.

Baseline respiratory rate and depth are measured before induction. Identification of even mild signs of respiratory disease should be considered as an expression of potentially severe respiratory illness. Chronic respiratory disease is fairly common, and chelonians are able to withstand extensive injury to the respiratory system before showing signs of distress.

Ideally, when planning elective procedures, a venous blood sample should be collected prior to anesthesia for hematologic and plasma biochemical evaluation. Blood should be collected into lithium heparin tubes as EDTA causes lysis of reptilian erythrocytes. As a general rule, the sample size should not be larger than 1% of the body weight of the subject. Abnormalities in the laboratory variables of special interest for the anesthesiologist are represented by, but not limited to, the following: presence of anemia or hemoconcentration, hypoproteinemia, hypoglycemia, hyperuricemia, and electrolytes and acid-base imbalances. The presence of any of the earlier-mentioned abnormalities warrant further investigation to identify the underlying cause and properly treat prior to anesthesia.

The patient's hydration status should be assessed based on history, physical examination, and laboratory findings. At present, however, the evaluation of hydration status is still somewhat subjective. Indications of dehydration are sunken eyes, reduced skin turgor, and hematological and plasma biochemical alterations, such as hemoconcentration and hyperproteinemia (McArthur 2004). Ion pump activation and significant fluid reabsorption by the lower urinary tract and digestive tract complicate the use of many variables as indicators of hydration. In most reptiles, approximately 75% of body weight is water. In chelonians, the presence of the carapace reduces the value closer to that found in mammals, which is approximately 66%. However, in contrast to mammals, the total body water is equally distributed between the intra- and extracellular fluid compartments, and 30% of the extracellular fluid volume exists in the intravascular space (Smits & Kozubowski 1985). These differences should be considered to accurately plan and administer fluids to chelonians.

Differences in response to various inhaled and injectable sedatives and anesthetics have also been shown between chelonian species. The drugs and doses effective and safe in one species may not apply to other chelonians.

Handling of Dangerous Chelonians

Chelonians generally do not need significant restraint during examination, and most herbivorous animals can be handled with no real risk of danger to the personnel. However, aggressive and potentially dangerous species represent exceptions. Snapping turtles (*Chelydra* spp.), softshell turtles (*Trionyx* spp.), and marine chelonians may show unpredictable, aggressive reactions, and these large animals can inflict serious injuries with their beaks and claws. These species should be handled with extreme caution. Wearing heavy-duty gloves is recommended, but serious bite injuries can still occur despite their use. These animals can be examined more safely after they have bitten or locked on nontraumatic objects, such as a PVC pipe. When working with aggressive species, the help of an assistant is often necessary.

Smaller marine, snapping, and softshell turtles can be held with a hand on either side of the carapace, with the head directed away from the operator and other people (Fig. 22.1). Turtles of the genera *Chelydra* and *Trionyx* are able to extend their head up to the level of their hindlimbs. It is important to determine the “safe zone” around the animal. Medium-sized (10kg–40kg) marine and snapping turtles are better controlled with one hand around the nuchal scute (cranial carapace above the neck) and the other on the caudal carapace (Fig. 22.2). Very large individuals of these species are capable of incredible strength, and stretchers or canvas slings should be used during maneuvering procedures. Marine chelonians should never be picked up by their

flippers. This is due to the risk of causing luxations and fractures.

While necessary in some cases, chemical immobilization should be considered as a last resort in the simple physical examination procedure. Whenever sedation is used, an aquatic animal must not be reintroduced into water until it is fully recovered in order to avoid the risk of drowning.

Venipuncture and Intravenous Catheterization

Venipuncture and venous catheterization for phlebotomy and drug or fluids administration purposes are difficult. The diversity in morphology of turtles and tortoises precludes any single dependable venipuncture site for all species. Therefore, it is important to know the location of multiple potential sites and select the most appropriate for the individual species. Venipuncture sites previously described include the jugular veins, dorsal cervical sinus, subcarapacial (subvertebral) sinus, and the dorsal coccygeal vein (Lloyd & Morris 1999). Other peripheral venipuncture sites, where only small blood samples can be obtained, are the radio-humeral venous plexus and the femoral vein. These sites may be more yielding in larger animals.

It is recommended that blood collection be from the jugular veins when possible. Samples taken from the jugular site are least likely to be lymph diluted (Jacobson et al. 1992). On either side of the neck, external and internal jugular veins are present in many chelonian species. Either can be used for venipuncture. The external jugular vein is larger and located in a lateral

Figure 22.1. Appropriate physical restraint of a medium-size (15 kg) alligator snapping turtle (*Macrochelys temminckii*). Note the position of the hands on either side of the shell. The use of reinforced gloves provide additional protection from the claws.

Figure 22.2. Physical restraint of a large (30 kg) alligator snapping turtle (*Macrochelys temminckii*). The animal is controlled with one hand on the nuchal scute and the other on the caudal carapace. The head of the animal is directed away from the operator.

Figure 22.3. CT-scan 3D reconstruction of the neck of the Gopher tortoise (*Gopherus polyphemus*). The vascular structures are identified as follows: (a) carotid artery, (b) external jugular vein, (c) internal jugular vein, (d) occipital venous sinus. (e) Indicates a intravenous catheter placed in the left external jugular vein.

to dorsolateral position. It runs approximately in a line from the dorsal edge of the tympanic membrane parallel to the dorsal plane of the neck in the direction of the thoracic inlet (Fig. 22.3). Extension of the neck is needed to allow the jugular vein to be raised and seen. This is possible in many small chelonians, but in large individuals (>10 kg), or aggressive species such as snapping turtles, it is often impossible without adequate chemical restraint. Should the jugular site prove impractical, the subcarapacial sinus or the dorsal coccygeal vein may represent good alternatives, particularly for intravenous drug administration.

The subcarapacial venous sinus can be easily accessible in small chelonians (<10 kg) (Fig. 22.4). It is located under the carapace, on the dorsal midline, at the junction of the common intercostal and the caudal branch of the external jugular veins, just cranial to the eight cervical vertebra (Hernandez -Divers & Hernandez -Divers 2002). To the author's knowledge, the quality and reliability of diagnostic blood samples taken from this site has not been evaluated. It appears, however, to be a suitable site for intravenous injections.

The dorsal coccygeal vein is a safe and dependable venipuncture site in snapping turtles (Fig. 22.5). The dorsal coccygeal vein runs in the dorsal midline from the tip of the tail to the carapace. Blood samples from this site can be unpredictably lymphodiluted; therefore, when clear fluid is sampled, another attempt should be made at a different site. The vessel is occasionally more superficial than expected, and a needle that is inserted between the vertebrae too deep has the potential to enter the vertebral canal. Therefore, accurate disinfection of the skin of the tail is mandatory before attempting venipuncture.

Figure 22.4. Use of the subcarapacial venous sinus for blood withdrawal (a) in a Florida softshell turtle (*Apalone ferox*), and for intravenous injection of propofol (b) in a gopher tortoise (*Gopherus polyphemus*). The needle is inserted on the midline of the neck, at the junction between the skin and the carapacial nuchal scute. The needle is advanced caudally while maintaining gentle negative aspiration on the syringe until blood is flowing into the chamber.

In marine turtles, the dorsal cervical sinus is a reliable venipuncture site and it is popular with those working with these chelonians. It is useful both for blood withdrawal and intravenous injections. The paired sinuses are parallel to the midline and are located on either side, 0.5–1 cm away from the dorsal spinous processes of the proximal cervical vertebrae. They are found 0.5- to 3-cm deep depending upon the size of the animal.

Suitable anatomical locations for intravenous catheter placement are limited; the jugular veins are usually the only option. Jugular catheter placement can be performed with either a venous cut-down or percutaneously. Prior sedation is recommended and often necessary for a successful catheter placement. In general, over-the-needle, 22- to 24-gauge, 2- to 4-cm long IV catheters can be used for short-term placement. When

Figure 22.5. Venipuncture in a alligator snapping turtle (*Macrochelys temminckii*) using the dorsal approach to access the dorsal coccygeal vein. The main advantage of this venipuncture site is represented by its location in the “safe zone” around the animal. For safety, an assistant should be restraining the animal during the venipuncture procedure.

Figure 22.7. Placement of a long-term jugular catheter in an Aldabra tortoise (*Aldabrachelys gigantea*). In the anesthetized animal, the external jugular vein is identified by palpation of the dorsolateral aspect of either side of the neck. A hollow needle is advanced through the skin until blood is aspirated. The catheter is then inserted using the Seldinger technique: a blunt guidewire is passed through the needle (a), then the needle is removed. A dilating device may be passed over the guide wire to slightly enlarge the vessel. Finally, the central line itself is then passed over the guidewire, which is then removed. All the lumens of the line are aspirated and flushed. The catheter is finally secured with sutures to the skin (b).

Figure 22.6. Single-lumen jugular catheter placed in the external jugular vein of a green sea turtle (*Chelonia mydas*). The catheter was inserted using a over-the-wire technique. The winged proximal portion is secured to the skin with sutures.

long-term venous access is required, indwelling polyurethane or silicon central venous catheters should be used (Fig. 22.6). This author recommends the use of the standard Seldinger technique (over-the-wire) for percutaneous placement of long-term catheters (Fig. 22.7).

Fluid Therapy

When a fluid deficit is clearly identified or the hydration status of the patient is unknown, peri-anesthetic fluid therapy is indicated to replace the deficit in active circulating volume and restore tissue perfusion and

homeostasis. Hypotonic fluids, such as 5% dextrose in water (D5W), generally diffuse primarily in the intracellular space whereas isotonic crystalloids contain a sodium concentration similar to that of the extracellular space, making them the ideal solution for replacing extracellular volume deficits.

There is still debate on the best type of fluids to administer to reptiles given their blood is hypotonic compared with birds and mammals. There are several guidelines for fluid replacement in reptiles, but most of the standard crystalloids, such as lactated or acetated Ringer’s, and normal saline solutions can safely be

used. Two recipes of isotonic solution are “diluted saline” (9 parts 0.9% NaCl and 1 part sterile water) and “reptile Ringer’s” (2 parts 2.5% dextrose/0.45% saline with 1 part lactated Ringer’s). It is generally accepted a rate of 25 mL/kg every 24 hours is appropriate as a rehydrating rate. In chelonians, total fluids given at one time should not exceed 2–3% of total body weight (Norton 2005). Constant rate infusion is preferable over intermittent boluses. Fluids can be administered orally, intravenously, or intracoelomically. Oral rehydration is recommended for clinically stable, mildly to moderately dehydrated patients; whereas the intravenous route is preferred in severely dehydrated patients. Intracoelomic fluids should be avoided in patients with present or suspected respiratory disease, intracoelomic space-occupying lesion, obstipation, and egg retention (McArthur 2004).

Traumatized patients that have suffered severe hemorrhage should be promptly fluid resuscitated. In these cases, the intravenous route is considered ideal for fluid administration. In these patients, however, the low intravascular volume and vasoconstriction often limit intravenous access.

In the presence of life threatening hypovolemia, the intravenous administration of hypertonic solutions (i.e., 7.5% NaCl) and colloids (hydroxyethyl starches and dextrans) is indicated to provide selective intravascular volume expansion. The recommended doses of hypertonic solutions and colloids in mammals are 2–4 mL/kg and 5–10 mL/kg, respectively. The safety of such indications has not been proved in chelonians. Thus, the author recommends to start with lower initial volumes (1–2 mL/kg) and then re-assess the response of the patient.

ANALGESIA

A recent survey of the use of analgesics by reptile veterinarians indicated analgesia is withheld in more than 50% of the patients by more than 60% of the responders (Read 2004). This finding may be partially explained by our inability to detect pain in reptiles due to lack of definitive information on behaviors proven to be pathognomonic of pain. Ultimately, pain assessment is made even more difficult by the evidence that reptiles seem to voluntarily suppress pain-related behaviors when they are observed (Fleming & Robertson 2006). Sadly, for all these reasons, pain control in reptiles has been largely overlooked. The current knowledge and better understanding of pain perception in reptiles support the importance of providing appropriate analgesia whenever an invasive procedure is performed. An excellent review of the current literature on pain assessment and analgesia in reptiles has been recently published (Mosley 2011).

Among opioid analgesics, morphine has been shown to provide analgesia in chelonians whereas butorpha-

nol, even at dosages largely exceeding the mammalian therapeutic doses, did not have any effect on thermal threshold (Sladky et al. 2007). The analgesic action of morphine (1.5 mg/kg) in chelonians appears to have a time of onset of 2–8 hours postadministration and duration of more than 24 hours. Unfortunately this analgesic effect is coupled with a significant, long-lasting respiratory depression (Sladky et al. 2007). Meperidine, a synthetic μ pure agonist, induced significant decrease in the duration of limb retraction after formalin injection in Speke’s hinged tortoise (*Kinixys spekii*) at the dose of 20 mg/kg. This drug appears to provide a degree of analgesia equivalent to morphine (Wambugu et al. 2010). Pharmacokinetic data of buprenorphine in red-eared sliders (*Trachemys scripta elegans*) established the subcutaneous administration of 0.075–0.1 mg/kg every 24 hours is sufficient to maintain plasma drug concentrations considered analgesic for humans (Kummrow et al. 2008). The analgesic effect of buprenorphine in chelonians has not been evaluated. Tramadol, an atypical synthetic opioid, has been recently shown to provide long-lasting analgesia in chelonians with minimal respiratory depression. In red-eared sliders (*T.s. elegans*), the oral administration of 10–25 mg/kg increased thermal threshold for up to 96 hours (Baker et al. 2011). These dosages are much higher than those generally used in clinical practice (0.5–4 mg/kg).

Nonsteroidal anti-inflammatory agents (NSAIDs) are widely used in reptiles based on their proven potent analgesic activity in mammals. Interestingly, there is no proven scientific evidence of the analgesic activity of NSAIDs in chelonians or other reptiles. This could be due to our incapacity to effectively assess pain. To the author’s knowledge a limited number of studies evaluated pharmacokinetics (PK) and pharmacodynamics (PD) of NSAIDs in chelonians. In green iguanas (*Iguana iguana*) the oral administration of meloxicam at 0.2 mg/kg resulted in plasma concentrations considered analgesic for mammals (Divers et al. 2010). In loggerhead sea turtles (*Caretta caretta*), it was shown the clearance of meloxicam was significantly higher than reported for the iguana suggesting the need for more frequent dose intervals to maintain effective plasma concentrations (Soloperto et al. 2012). This may not, however, correlate with analgesia because the plasma concentration of NSAIDs does not directly correlate with clinical effect.

The safety of the use of NSAIDs in reptiles has been evaluated in studies involving repeated daily administrations. No significant biochemical abnormalities or histopathological lesions were seen (Hernandez-Divers et al. 2004). Despite this, it is still possible NSAIDs can cause severe side effects as reported in mammals. Normal hydration status and renal function should always be ensured prior to NSAID administration. Although the clinical use of NSADs in reptiles does not

appear to delay wound healing, it has been shown the administration of selective NSAIDs cyclooxygenase-2 inhibitors to geckos after tail amputation significantly retards the regenerative process (Sharma & Suresh 2008).

Local anesthesia represents an irreplaceable component of a multimodal anesthetic approach. Local anesthetics (LA) prevent the transmission of nerve impulses by interrupting the sodium influx into the neurons. In sensory nerve fibers, the signal from a noxious stimulus is then stopped at its origin and is prevented from reaching the central nervous system. LA agents vary in potency and duration of action. Lidocaine and bupivacaine represent the most commonly used agents in veterinary practice. Bupivacaine is more potent and longer acting compared with lidocaine, but the actual duration of action in reptiles is undetermined. In chelonians, the local injection of LA is useful for facilitating minor surgical interventions, but local anesthesia alone is not sufficient to provide analgesia for more invasive procedures. The infiltration around the surgical site (local block) represents the most diffuse use of LA in chelonians, but more advanced techniques have also been described (Hernandez-Divers et al. 2009).

Lidocaine (2%) injected intrathecally at an approximate dose of 1 mL per 25 kg in hybrid Galapagos tortoises (*Geochelone nigra*) was sufficient to perform phallectomy (Rivera et al. 2011). The technique provided adequate analgesia, without need of supplemental systemic analgesics. The ambulatory function returned to normal within 60 minutes after administration in all the animals in the study. The short analgesic effect limits the single administration use of LA to the perioperative period. To provide prolonged analgesia using LA, repeated administrations are required. For this purpose, the placement of long-term intrathecal catheters is possible in chelonians and, in this author's experience, has been effective (Fig. 22.8).

It is suggested to not go over the dosages of LA described for mammals until specific toxicological information in chelonians is available. The analgesic agents for which PK and PD data are currently available in chelonians are listed in Table 22.1.

ANESTHETIC INDUCTION AND MAINTENANCE

Generally, induction and maintenance of anesthesia are relatively simple, but at times they can be particularly challenging and frustrating to the anesthetist.

Mask induction with inhaled anesthetics can be used, but is associated with prolonged induction times. Aquatic species are well adapted to the episodic breathing pattern and able to stay apneic for very extensive periods of time, preventing the adequate delivery of inhaled anesthetic (Bienzle & Boyd 1992). Induction times may be reduced by inducing respiration by gently moving the forelimbs forwards and backwards.

Figure 22.8. Lateral radiographic views of the placement of an intrathecal catheter in a Galapagos tortoise (*Chelonoidis nigra*). A Tuohy needle is slowly advanced between the spinous processes of two consecutive coccygeal vertebrae and placed in the vertebral canal (a) into the intrathecal space (space between dura mater and leptomeninx). The catheter is threaded through the needle and advanced a few centimeters into the vertebral canal (b). The needle is then withdrawn over the catheter. The catheter is secured to the skin with sutures to prevent it becoming dislodged. The catheter can be used for repeated administrations of analgesics and local anesthetics. The small black arrows indicate the catheter placed into the intrathecal space.

Awake intubation and induction is more effective. The mouth is forcibly opened and the endotracheal tube inserted through the glottis. This allows controlled ventilation to deliver the inhaled anesthetic. Large tortoises, however, are unbelievably powerful animals and are impossible to forcibly intubate without sedation. Further, strong laryngeal sphincter muscles seal the glottis of aquatic species, making awake intubation difficult. Repeated attempts to force open the closed glottis are not recommended due to risk of causing severe tissue damage. Instead, gentle manipulation and patience in waiting for the animal to voluntarily open the glottis often facilitate the intubation. A short piece

Table 22.1. Analgesic agents with pharmacokinetic and pharmacodynamic data available in chelonian species

Drug	Dose (mg/kg)	Route	Analgesic Activity	Comments	Source
Buprenorphine	0.075–0.1	IV, IM	Not established	Elevated drug plasma concentrations up to 24 hours	Kummrow et al. (2008)
Butorphanol	2.8–28	IM, IV	None	No analgesic effect even at high doses; at high doses prolonged respiratory depression	Sladky et al. (2007)
Lidocaine	0.8	Intrathecal	Good	Duration of analgesia up to 60 minutes; temporary paraparesis can occur	Rivera et al. (2011)
Lidocaine	1	SQ (local infiltration)	Moderate	Used alone not sufficient analgesia for celioscopy	Hernandez-Divers et al. (2009)
Meloxicam	0.2	SQ	Not established	Anecdotal evidence of clinical efficacy	McArthur (2004)
Meperidine	20	IV, IM	Good	Analgesic efficacy similar to morphine	Wambugu et al. (2010)
Morphine	1.5	IV, IM	Good	Dose-dependent respiratory depression	Sladky et al. (2007)
Tramadol	5–10	PO	Good	Long-lasting analgesic effect up to 96 hours	Baker et al. (2011)
Tramadol	10–25	SQ	Good	Slower onset and shorter duration of analgesia compared with PO administration	Baker et al. (2011)

Figure 22.9. A piece of PVC pipe used as oral speculum facilitates intubation and protects the endotracheal tube. Both the mouth gag and the endotracheal tube are secured with tape to the head of the animal to prevent dislodgment.

of PVC pipe used as that mouth gag facilitates intubation and protects the endotracheal tube (Fig. 22.9).

Injectable sedative and anesthetic agents are commonly administered intramuscularly due to the difficulty of gaining intravenous access without previous sedation. Intramuscular administration of ketamine combined with benzodiazepines or α_2 -adrenergic agonists often produce adequate sedation and muscle relaxation. The pectoral muscles are a preferred site for intramuscular injections. Reported parenteral drug combinations and dosages are given in Table 22.2.

In some species, the presence of easily accessible veins and venous sinuses facilitate direct intravenous administration of anesthetics. In sea turtles, the cervical venous sinus is an easily accessible site for injection (Moon & Hernandez Foester 2001). It is often used for induction, but limited information is available on the rate of distribution of anesthetics using this route. If the desired effect is not achieved at the recommended dosage of a drug, it is recommended not to repeat the administration to avoid overdose (Wood et al. 1982).

The dorsal coccygeal vein is in this author's experience a safe and reliable site for IV injection in unsedated snapping turtles (*Chelydra* spp. and *Macrochelys temminckii*). The subcarapacial venous sinus is easily accessible for injections in small chelonians; however, extravasation of drug is likely when this access is used. The subcarapacial sinus runs close to the submeningeal space where the cervical vertebra join the carapace. Deaths in gopher tortoises (*Gopherus polyphemus*) have been associated with the inadvertent injection of propofol into this space while attempting subcarapacial injection (Quesada et al. 2010).

When the intravenous (IV) route is utilized, propofol titrated to effect is a good choice for induction of anesthesia. Used as a single agent, it requires doses between 4 and 8 mg/kg to produce anesthesia. Alternatively, the combination of ketamine (5 mg/kg) and medetomidine (0.05 mg/kg) given intravenously appears to be safe in many aquatic and terrestrial species. Alfaxalone/alfadolone at the dose of 24 mg/kg given intracoelomically was shown to produce surgical anesthesia in red ear sliders (Lawrence & Jackson 1983). A new formulation of alfaxalone (Alfaxan[®]) is now

Table 22.2. Selected sedative and anesthetic protocols used in chelonian species

Species	Protocol (Drug)	Dose (mg/kg)	Route	Onset (Minutes)	Reversal (Drug/Route)	Recovery (Minutes)	References
Aldabra tortoises <i>Albarrachelys gigantea</i>	Medetomidine + Ketamine + Morphine	0.03 3 0.4	IM	30–45	Atipamezole IM Naloxone IM	Up to 45	Vigani (2010)

Red-eared sliders <i>Trachemys scripta elegans</i>	Midazolam	1.5	IM	6	Not administered	40	Oppenheim and Moon (1995)
Side-neck turtle <i>Podocnemis expansa</i>	Xylazine + Propofol	1.5 5–10	IM IV	1–2	Not administered	156–198	Santos et al. (2008)
Snapping turtle <i>Chelydra serpentina</i>	Ketamine + Midazolam	20–40 2	IM	15	Not administered	210	Bienzle and Boyd (1992)
Softshell turtle <i>Pelodiscus sinensis</i>	Lidocaine	700 mg/L	Immersion	6	Not administered	5	Park et al. (2006)
Yellow-footed tortoises <i>Geochelone denticulata</i>	Medetomidine + Ketamine	0.1 5	IV	16	Atipamezole IV	Up to 30	Lock et al. (1998)

available. It can be administered intravenously or intramuscularly for short surgical procedures, at the same dosages described for the previous mixture. The low concentration (10 mg/mL), however, precludes intramuscular injection in any animal larger than a kilogram.

Softshell aquatic turtles appear to possess an amphibian-like modality of fluid absorption across nonenteral surfaces (e.g., skin and mucous membranes beside the enteral mucosa) (Bagatto et al. 1997). In spiny and Florida softshell turtles (*Apalone apinifera* and *Apalone ferox*), tricaine methanesulfonate (MS-222) has been tested as an immersion anesthetic. A concentration of g/L provided a quick onset of surgical anesthesia. All the animals in the study survived and the technique was considered safe by the authors (Bagatto et al. 1997). Lidocaine-hydrochloride diluted in bicarbonate-buffered water was also used as anesthetic in softshelled turtle (*Pelodiscus sinensis*). Immersion at 700 mg/L produced anesthesia within 6 minutes after exposure. Recovery time was short, after removal of the animal from the anesthetic solution (Park et al. 2006).

Succinylcholine and other neuromuscular blocking agents alone have been used in the past for immobilization of chelonians. This class of drugs does not have any anesthetic or analgesic properties and the patient is completely conscious while paralyzed. The depolarization before muscle relaxation associated with succinylcholine also causes pain, lactic acidemia, and hyperkalemia. For these reasons, the use of neuromuscular blocking agents alone for immobilization is considered unacceptable.

Endotracheal intubation is facilitated by the use of a tongue depressor to better expose the glottis. In aquatic turtles, there is abundant soft tissue at the base of tongue, which can make visualization of the glottis difficult (Fig. 22.10).

Gentle upwards pressure on the skin surface between the mandibular branches helps to expose the glottis. The size of endotracheal tube can be estimated either by external palpation of the trachea or by visualizing the glottal diameter during inspiration. The glottal opening is usually smaller than the tracheal diameter. Cuffed endotracheal tubes can be used, but overinflation of the cuff can potentially cause tracheal injury. The trachea is relatively short, particularly in sea turtles, and the selective intubation of a bronchus is possibly if a long endotracheal tube is inserted too far.

Immobility has a substantial negative impact on ventilation due to the important role of limb movement for lung expansion (Gatten 1974b; Taylor et al. 2010). The respiratory drive is also depressed by the direct effect of anesthetic agents on the respiratory centers. This predisposes the patient to hypoxemia and hypercapnia. Also, hypoventilation prevents the constant delivery of anesthetic when inhalation anesthesia is used. Manual or mechanical intermittent positive

pressure ventilation (IPPV) are, therefore, recommended for general anesthesia. Tidal volumes are highly variable and influenced by species and body position. Sea turtles have much higher tidal volumes compared with terrestrial tortoises (Lutcavage & Lutz 1996). The lung compliance is also much lower in dorsal recumbency compared with ventral recumbency (Lutcavage et al. 1989). Concerns exist to the possible detrimental effect of positive pressure ventilation on the cardiovascular system. However, examination of the effect of artificially manipulating lung volume on blood flows and heart rate in the freshwater turtle (*Trachemys scripta elegans*), showed increases in lung volume have no effect on pulmonary blood flow (Herman et al. 1997). It is difficult to assess effective artificial ventilation in the clinical setting. Current recommendations for IPPV are two to six breaths per minute using tidal volumes ranging from 15 to 20 mL/kg, with peak airway pressures less than 10 cm H₂O.

For pronged procedures, anesthesia can be maintained by use of supplemental doses of the drug combination

Figure 22.10. Glottal apparatus of an alligator snapping turtle (*Macrochelys temminckii*) during breath holding (a), and during inspiration (b). Note the perfect seal of the closed glottis. Waiting for the animal to voluntarily open the glottis facilitates the endotracheal intubation.

used for induction or more commonly by use of inhaled anesthetics. Gaining familiarity with multiple anesthetic agents and protocols in different species, allows prediction of the patient response and the duration of effect of each specific anesthetic agent or combination.

Important aspects of patient care during anesthesia include continuous patient monitoring, appropriate fluid therapy, maintenance of the species' preferred body temperature, appropriate analgesia, and lubrication of the eyes. In giant tortoises, the protection of the limbs and the phallus (frequently prolapsed in males during anesthesia) is also critical for avoiding severe crushing injuries caused by the weight of the anesthetized animal.

MONITORING

The extreme physiologic resilience of reptiles should never be considered an excuse to overlook constant assessment of an anesthetized patient. Information is now available on the application of several types of monitoring equipment in chelonian anesthesia (Bailey & Pablo 1998; Hernandez-Divers 2004; Mosley et al. 2004). The accuracy and reliability of much of this equipment, however, is only beginning to be determined and for the most part has not been validated. This underlines the importance of the role of the anesthesiologist in the constant direct assessment of anesthetic depth, cardiopulmonary function, body temperature, and other physiologic parameters.

Anesthetic Depth

The accurate assessment of anesthetic depth is challenging. Several authors have previously proposed guidelines for the assessment of the stage of anesthesia in chelonians (McArthur 2004). Stages 1 and 2 are associated with minimal muscle relaxation, persistence of head withdrawal reflex, and voluntary response to painful stimuli. These anesthetic stages are indicated for noninvasive or minimally invasive procedures.

Stage 3 (Surgical anesthetic stage) is characterized by immobility, absence of head withdrawal reflex, marked muscle relaxation occurring craniocaudally as anesthetic depth increases, and no voluntary muscle response to noxious stimulation. This is considered a suitable stage for performing invasive surgical or diagnostic procedures.

The deepest anesthetic stage (Stage 4) represents severe medullary depression due to anesthetic overdose. This stage is associated with life-threatening, severe cardiovascular depression and is clinically detected by the loss of all reflexes, including the vent and corneal reflexes.

In chelonians, hypoventilation and apnea are common during anesthesia even at lighter stages. Therefore, the assessment of respiration does not rep-

resent a good indicator of anesthetic depth, and ventilatory support should be provided to all anesthetized chelonians. Heart rate is influenced by multiple factors including temperature and oxygenation, making this an unreliable parameter for the assessment of anesthetic depth (Krosniunas & Hicks 2003; McArthur et al. 2004).

Cardiovascular Function

The main aim of cardiovascular monitoring is to assure adequate blood flow to the tissue. Monitored variables include heart rate and rhythm, pulse, and changes in intravascular volume caused by blood loss. It has been reported that baseline heart rate in reptiles, maintained within its preferred optimal temperature zone, can be estimated using the formula: $33.4 \times (Wt_{kg}^{-25})$ based on allometric scaling (Sedgwick 1991). However, insufficient data is available on the reliability of this calculation in chelonians. Further, given heart rate is highly affected by variations in body temperature, any kind of approximation is of limited significance and potentially misleading during anesthesia.

Direct auscultation of cardiac sounds is a simple method of basic assessment of heart rate and rhythm. In anesthetized patients, an esophageal stethoscope can be placed into the thoracic esophagus to the level of the heart for direct auscultation. Since it may cause reflux of gastric contents, the trachea should be intubated prior to its placement. The stethoscope tubing has to be slowly advanced until the maximal sound intensity is reached. It can be connected to a standard stethoscope headpiece for intermittent monitoring or to a portable amplified speaker for continuous assessment.

The electrocardiogram (ECG) detects the electrical activity of the heart. It should be noted the presence of normal electrical activity does not indicate normal cardiac function. Myocardial conduction can continue despite absence of myocardial contraction, which is referred to as pulseless electrical activity. Therefore, the monitoring of cardiovascular function should not rely solely on an ECG. The ECG can be used as a standard three-lead configuration, but the thick scaly skin limits its sensitivity in this configuration and requires the use of a hypodermic needle for effective lead attachment (Bailey & Pablo 1998). A base-apex ECG configuration represents a good alternative during anesthesia. Esophageal base-apex ECG lead configurations are commercially available in different sizes and are often combined on the same tubing with an esophageal stethoscope. For anesthetic monitoring, the ECG is usually viewed in lead II. The reptilian ECG tracing is comprised of three primary complexes: P wave, QRS complex, and T wave. An SV wave may precede the P wave and represents the depolarization of the sinus venosus (Fig. 22.11). As in mammalian species, the P wave and the QRS complex represent atrial depolarization

Figure 22.11. Electrocardiographic tracing of an anesthetized Galapagos tortoise (*Chelonoidis nigra*). On the tracing, the following waves are identified: (SV) sinus venosus depolarization, (P) atrial depolarization, (R) ventricular depolarization, and (T) ventricular repolarization. Note that systolic phase of the cardiac cycle is physiologically prolonged (R-T interval is approximately 1.6 seconds).

Figure 22.12. Cardiovascular monitoring of a juvenile alligator snapping turtle (*Macrochelys temminckii*) during anesthesia. A 8-Hz Doppler pencil probe is placed on the side of the neck with the detecting crystal directed toward the thoracic inlet. The ECG is used in a standard three limb lead configuration.

and ventricular depolarization, respectively. The T wave indicates ventricular repolarization. In chelonians, this repolarization phase is physiologically very prolonged (Holz & Holz 1995).

Due to the paucity of research, there is still limited understanding regarding ECG interpretation in chelonians and all reptiles in general (Kik & Mitchell 2005).

The use of an 8-Hz Doppler ultrasonic flow probe is a good alternative to direct auscultation to detect blood flow. It also allows the detection of pulse in major vessels. For these reasons, many authors promote the Doppler as the most useful and reliable cardiovascular monitoring device in reptiles (McArthur 2004; Schumacher 2007). Several types of probes are available, adult and pediatric flat probes and pencil probes. In chelonians, the pencil probe is most useful for the detection of cardiac blood flow. It is placed on either side of the neck on the ventral aspect of the thoracic inlet (Fig. 22.12). Flat probes can also be taped over the carotid

arteries (ventrolateral aspect of the neck), the coccygeal artery (base of the tail), and femoral arteries for continuous assessment of pulse rate and quality.

Pediatric probes are preferred over adult probes due to the higher sensitivity in detecting flow in small vessels.

Determination of peripheral pulse rate and rhythm can also be obtained with the use of a pulse oximeter. As discussed in the next section, pulse oximetry is more often used as a respiratory monitor. Unfortunately, the use of pulse oximetry in chelonians for detecting pulse is limited by placement sites for the probe. Reflectance probes placed in the oral cavity or the cloaca may be a better choice. Some pulse oximetry units are extremely sensitive, and the presence of a strong pulsatile signal does not necessarily correlate with adequate blood flow to the tissues. When the probe is correctly applied, less than 10% of normal blood flow is required for pulse oximeters to detect a pulse (Bailey & Pablo 1998).

During surgery hemorrhage is common and monitoring blood loss is always indicated to determine the need for intervention. In small patients (<1 kg), any detectable blood loss can produce a significant decrease in circulating blood volume and consequent deterioration of patient homeostasis.

Respiratory Function

The direct visualization of respiratory movements, such as thoracic excursions, can be difficult. The presence of respiratory movements does not indicate adequate ventilation. The use of respiratory monitoring, therefore, is essential.

Arterial blood gas analysis is the ideal method for assessment of respiratory gas exchange, directly measuring the degree of oxygenation (arterial oxygen concentration or PaO₂) and ventilation (arterial carbon dioxide concentration or PaCO₂). Unfortunately, the clinical applicability of blood gas analysis in chelonians is limited. Arterial blood sampling in chelonians is difficult and impractical. Additionally, multiple blood draws can represent a significant blood loss in very small patients. Reptiles tend to tolerate alterations in PaCO₂ and PaO₂ much more than mammals, and thus normal values for mammals may not be applicable (Hernandez-Divers 2004). In mammalian species, venous blood gas analysis can be used for assessing ventilation (venous CO₂ concentration approximates arterial concentration) but not oxygenation. However, the reliability of venous blood gas analysis in chelonians has not been demonstrated. For all of these reasons, the value of routine blood gas analysis in chelonians remains questionable. Other monitoring devices of respiratory function are capnometry and pulse oximetry.

Capnometry measures carbon dioxide concentration in expired gases (PetCO₂). In mammalian species, capnometry is a noninvasive monitoring tool for

assessing ventilation due to the good correlation between the end tidal concentration of CO₂ and arterial CO₂ concentration. In chelonians this correlation is not consistent due to cardiac shunting. The absolute values of PetCO₂, therefore, may not be a reliable indicator of arterial CO₂ due to the unpredictable gradient between end-tidal and arterial carbon dioxide (Hernandez-Divers 2004). Capnometry is best used over time to assess trends and to identify potential anesthetic complications. For this purpose, devices with graphing capability (capnograph) that display a continuous waveform (capnogram) are more useful than standard capnometers. Any large, sudden decrease in PetCO₂ requires further investigation. These drops are commonly associated with obstruction or kinking of the endotracheal tube, but can also be indicative of an abrupt decrease in cardiac output.

Mainstream and sidestream capnometry devices are commercially available. Mainstream analyzers use a detecting window inserted into the anesthetic circuit. A sensor mounted on the detecting window measures PetCO₂. Sidestream analyzers continuously aspirate gas from the anesthetic circuit, and the sensor for the analysis is located away from the ventilator circuit. There are some concerns when capnometry is used in small species. Large detecting window (mainstream) or sampling chamber (sidestream) attached to the endotracheal tube add significant mechanical dead space. Pediatric connectors can reduce this added dead space. The sensor of mainstream devices may add an excessive amount of weight on the endotracheal tube, causing possible kinking. Sidestream devices require the continuous removal of gas from the circuit (100–200 mL per minute), and in very small animals, this sampling rate can be similar to or higher than the tidal volume of the patient. Relatively new veterinary designed sidestream capnometers, such as the Capnovet-10 (Vetronic Services, Devon, UK) use smaller sampling volumes and are suitable for use in patients weighing less than 100 g (Stanford 2004).

Pulse oximetry is used to noninvasively measure the oxygen saturation of arterial hemoglobin (SpO₂). A plethysmograph (to detect pulsatile blood flow) and a combined spectrophotometer (to measure changes in light absorbance) constitute the functional components of a pulse oximeter. Although pulse oximetry is one of the most commonly used anesthetic monitoring devices in reptiles, its technical limitations and high susceptibility to measurement errors and artifacts should be considered. Pulse oximetry has been designed for use in mammals, meaning it detects typical mammalian pulse, and is calibrated using the mammalian oxygen hemoglobin dissociation curve. In reptiles, the characteristics of these variables are markedly different when compared with mammals (Frische et al. 2001). In green iguanas, it was shown the absorbencies for oxyhemoglobin (660 nm) and deoxyhemoglobin (990 nm)

were in agreement with mammalian references, indicating that pulse oximetry could be reliable in certain reptile species (Diethelm et al. 1998). Unfortunately, the transmittance probes used in mammals do not provide consistent readings when applied to the skin of reptiles. Reflectance probes are more easily placed inside the esophagus or the cloaca to maximize the chance of reading. In the green iguana, a reflectance pulse oximeter probe placed in the esophagus and was inaccurate (Mosley et al. 2004). As for capnography, pulse oximetry is best used to look at the trends in measurements, rather than at the absolute saturation values.

Body Temperature

As in all ectothermic animals, normal thermoregulation in chelonians results from the direct interaction between the animal and the external environment. A series of behavioral patterns and modulations of the cardiovascular system tightly regulate the amount of heat derived from the environment (Galli et al. 2004). During anesthesia, all of these mechanisms are blunted or even abolished and hypothermia is a common occurrence. The direct effect on the cardiovascular system is a progressive decrease in cardiac output and an increase in intracardiac shunting (Krosniunas & Hicks 2003). The anesthetist, therefore, is responsible for appropriately monitoring and modulating body temperature in anesthetized chelonians. The aim is to minimize variations from the species' preferred body temperature range allowing better patient homeostasis (Gatten 1974a). Intraoperatively, this goal is accomplished by appropriately insulating and actively warming the patient (Fig. 22.13).

Figure 22.13. Active warming the patient with a forced warm air blower (Bair Hugger[®], Arizant Healthcare Inc., Eden Prairie, MN). The maintenance of the patient's temperature within the preferred body temperature range is an important aspect of patient care in chelonians. Unpredictable disarrangement of the chelonian's homeostasis can occur in response to sudden changes in body temperature.

Patient temperature can be continuously monitored using cloacal or esophageal probes. The patient should not be in direct contact with cold surfaces and should be covered with plastic drapes during prolonged surgical procedures to decrease the dispersion of internal heat. Warm water bottles, circulating warm water blankets, and forced warm air blowers, in ascending order of efficiency, also represent suitable tools for actively increasing and maintaining normothermia. When active warming is provided, attention should be paid not to overheat the patient. Increasing the temperature above the ATR increases oxygen consumption and the animal breathing room air (e.g., during the recovery period) may be unable to meet the increased oxygen demand. It should be noted body temperatures above 38°C are lethal for most chelonian species.

As mentioned in a previous section, the preferred body temperature or ATR in chelonians is species dependent. For example, many freshwater turtles will tolerate temperatures between 20 and 25°C, whereas sea turtles and land tortoises are better adapted to temperatures between 25 and 30°C (George 1996; McArthur et al. 2004).

Suboptimal temperatures are associated with decreased metabolic rate and consequent unpredictably prolonged clearance of anesthetic agents. When body temperature declines, recovery times are commonly prolonged while inhaled anesthetic requirements are reduced.

Blood Glucose

Monitoring blood glucose in juvenile patients and debilitated patients or during prolonged anesthesia is recommended to detect hypoglycemic episodes. However, the occurrence of hypoglycemia in anesthetized chelonians has not been documented and the need for repeated glucose checks is debatable.

RECOMMENDED SEDATIVES AND ANESTHETIC AGENTS

Injectable Drugs

Combinations of parenteral drugs belonging to different classes permit a reduction the required dosages of each agent, therefore reducing their potential side effects. It has been shown multiple drug combinations provide better sedation, muscle relaxation, and shorter induction and recovery times compared to the use of single agents. The administration of specific antagonists for some classes of sedatives makes it possible to modulate the duration of their effect.

α_2 -Adrenergic Agonists α_2 -adrenergic agonists are extensively used sedatives in chelonian anesthesia (Holz & Holz 1994; Lock et al. 1998; Sleeman & Gaynor 2000). The rapid onset of action, the potent sedation, and the possibility to reverse their sedative effect with

specific antagonists are the major advantages of α_2 -agonists compared with other sedatives. α_2 agonists are also characterized by a mild analgesic activity (Greer et al. 2001b). α_2 -adrenergic agonists are part of many anesthetic protocols owing to their synergistic effect with other agents, such as ketamine (Chittick et al. 2002; Greer et al. 2001b). Xylazine when combined with ketamine produced moderate sedation in freshwater turtles (*Trachemys*) (Holz & Holz 1994). Xylazine (1.5 mg/kg), administered intramuscularly, followed by intravenous induction with propofol (5 mg/kg), also produced moderate sedation for 2.5 hours in Amazonian turtles (*Podocnemis expansa*) (Santos et al. 2008). In loggerhead sea turtles (*Caretta caretta*), medetomidine (0.05 mg/kg) combined with ketamine (5 mg/kg) was shown to produce rapid induction (Chittick et al. 2002). Wild leatherback sea turtles (*Dermochelys coriacea*) were effectively immobilized for measurement of physiologic variables with a combination of medetomidine (0.03–0.08 mg/kg) and ketamine (3–8 mg/kg) (Harms et al. 2007). In Galapagos tortoises (*Ge. nigra*), medetomidine (0.1 mg/kg) and ketamine (10 mg/kg) given intravenously as a combination produced a surgical plane of anesthesia sufficient to perform celioscopy for about 45 minutes (Knafo et al. 2011). In adult Aldabra tortoises (*Aldabrachelys gigantea*), intramuscular medetomidine (0.02–0.03 mg/kg), ketamine (2–3 mg/kg), and midazolam (0.1 mg/kg), have been used by the author as an induction and maintenance anesthetic protocol for both diagnostic and minor surgical procedures.

Pronounced cardiopulmonary side effects, however, are common after administration of α_2 -adrenergic agonists in chelonians and appear to be similar to those seen in mammals (Dennis & Heard 2002). The effect of α_2 -adrenergic agonists on the cardiovascular system appears to be dose-unrelated. Bradycardia and hypoxemia were described in desert tortoises (*Gopherus agassizii*) sedated with medetomidine (0.15 mg/kg) (Sleeman & Gaynor 2000). Medetomidine (0.1 mg/kg) produced good sedation, but also moderate bradycardia in leopard tortoises (*Geochelone pardalis*) and yellow foot tortoises (*Geochelone denticulata*) (Lock et al. 1998). Similar effects were seen in Aldabra tortoises (*Aldabrachelys gigantea*) at the dose of 0.025–0.08 mg/kg (Lock et al. 1998). In gopher tortoises, the combination of medetomidine (0.1 mg/kg) and ketamine (5 mg/kg) produced moderate hypertension, hypercapnia, and hypoxemia (Dennis & Heard 2002). For these reasons, the use of supplemental oxygen is highly recommended when α_2 -adrenergic agonists are used.

Severe cardiovascular changes can be also caused by the intravenous administration of reversal agents. The antagonist atipamezole (0.5 mg/kg) given IV was demonstrated to produce severe hypotension and even undetectable carotid pulse in gopher tortoises (*Gopherus polyphemus*) (Dennis & Heard 2002). Based on these

findings, it is recommended to utilize the intramuscular route for injection of the reversal agent of α_2 -agonist.

The stereoisomer dexmedetomidine is now commonly used in veterinary anesthesia. Its potency in mammals appears to be twice as high as that of medetomidine (Kuusela et al. 2001). There are no published studies on the sedative effect of dexmedetomidine in chelonians. Medetomidine is still commercially available as a compounded preparation at high concentrations (10–20–40 mg/mL). In large chelonians (>100 kg), these concentrated solutions are a good choice for intramuscular administration to significantly reduce the volume of injection.

Ketamine Ketamine is a dissociative anesthetic commonly utilized in many reported anesthetic protocols for chelonians. Ketamine has a large margin of safety due to its supportive cardiovascular effects and its lower respiratory depression when compared with other induction agents, such as barbiturates and propofol. Used alone, ketamine requires very high dosages to produce general anesthesia in chelonians (30–50 mg/kg), does not produce adequate muscle relaxation, and is associated with prolonged induction and recovery times of up to 24 hours (Holz & Holz 1994). The combination of ketamine with other sedatives produces a synergistic effect at reducing the doses of the single agents. Benzodiazepines and α_2 -adrenergic agonists improve the anesthetic profile of ketamine, producing better muscle relaxation and making it possible to obtain a plane of anesthesia more suitable for surgical interventions (Chittick et al. 2002). Benzodiazepines are primarily added to produce muscle relaxation (Bienzle & Boyd 1992). Alpha₂-adrenergic agonists are often used to significantly decrease the ketamine dose and to achieve deeper anesthetic planes (Greer et al. 2001a; Harms et al. 2007; Lock et al. 1998). Medetomidine and xylazine, added to ketamine, are a very common induction protocol for both aquatic and terrestrial species. Several dosing regimens have been reported in different chelonians, showing significant interspecies variability in dose and sedative effect (see Table 22.2). Ketamine also has intrinsic analgesic properties, due to its antagonist effect on N-methyl-D-aspartate (NMDA) receptors. The presence of this type of receptor has been demonstrated in chelonians (Bickler et al. 2000). The analgesic effect of ketamine is mild and short-lived for treatment of surgical pain and superior analgesia is provided by the use of a multimodal approach. The addition of more potent systemic analgesics, such as opioids, and the use of LA are recommended for management of acute surgical pain.

Propofol Propofol is a fast-acting hypnotic agent formulated for intravenous injection only. Several reports

describe the safety of propofol as induction agent in several chelonian species (McArthur 2007; Smith et al. 2000; Ziolo & Bertelsen 2009) (see Table 22.2). Propofol produces induction of general anesthesia within 1–2 minutes after injection (Santos et al. 2008). The duration of effect is usually 30–45 minutes at the typical dosages of 2–10 mg/kg. Large species appear to require lower doses compared with small chelonians (McArthur 2004). In a study in loggerhead sea turtles (*Caretta caretta*), propofol (5 mg/kg) produced an adequate plane of anesthesia for laparoscopic sex determination. The duration of effect lasted 30 minutes (MacLean et al. 2008). Prolonged apnea following induction with propofol is a common complication in chelonians and prompt intubation and manual ventilation are therefore required. Dose-dependent hypotension can be severe following rapid administration. Slow injection over 1 minute allows the anesthetist to titrate the administration to the desired effect, minimizing the cardiovascular depression. Propofol does not have any analgesic activity and it should always be combined with analgesics when performing surgical procedures. Propofol given as a constant rate infusion (0.2–0.4 mg/kg/min) or as incremental boluses (0.5–1 mg/kg) is suitable for maintenance of anesthesia in mammals, but the safety and the appropriate rates of infusion in reptiles have not been determined. The fast induction and recovery time and the possibility to modulate the effect by adjusting the dose, make propofol the author's anesthetic of choice whenever the intravenous route is accessible.

Midazolam

Midazolam is a benzodiazepine with similar potency to diazepam. Compared with diazepam, the more hydro-soluble molecule of midazolam produces more constant absorption and better bioavailability after intramuscular injection. Midazolam used alone, even at dosages 10 times higher than the therapeutic doses for mammals, was repeatedly shown not to produce significant sedation in some chelonian species (Harvey-Clark 1993). In sliders, 1.5 mg/kg IM provided moderate sedation with minimal cardiovascular and respiratory changes (Oppenheim & Moon 1995). In snapping turtles (*Chelydra serpentina*), the combination of midazolam and ketamine appeared to produce better sedation and muscle relaxation compared to use of single agents (Bienzle & Boyd 1992). General anesthesia, however, could not be achieved even at high dosages. The recommended dosages for chelonians range between 0.1 and 1 mg/kg. When midazolam is used in chelonian anesthesia, it is suggested to combine it with other agents, such as ketamine or propofol, to produce adequate anesthetic depth (Holz & Holz 1994; Wood et al. 1982). The sedative effect of midazolam can be reversed by the specific antagonist flumazenil (0.01–0.04 mg/kg).

Alfaxalone Alfaxalone is a neurosteroid that exerts its anesthetic effect by binding to GABA-receptors. It was originally introduced in the 1970s as a mixture with alfadolone for induction of anesthesia. The trade name of the compound in the veterinary market was Saffan[®]. This formulation was later withdrawn from the market because of the occurrence of lethal anaphylactoid reactions in small animals. These adverse effects were induced by the presence in the compound of Cremophor EL[®], as a solubilizing agent.

Recently alfaxalone, as a new water-soluble formulation, has been reintroduced on the veterinary market under the brand name of Alfaxan[®]. Water solubility of this preparation is due to the binding of the alfaxalone molecule to a cyclodextrine molecule. This mixture does not cause histamine release unlike the old formulation.

Unlike propofol, alfaxalone can also be administered via the intramuscular route, providing a possible alternative of anesthetic induction when vascular access is not available. It should be noted, however, that the use of the intramuscular route requires higher dosages compared with the intravenous route. In chelonians, alfaxalone given IM produced anesthesia at the dosage of 10–20 mg/kg (Lawrence & Jackson 1983). Alfaxan is available at the concentration of 10 mg/mL and its use in large chelonians (>10 kg), therefore, may be limited by the very large volume of drug which then must be injected intramuscularly.

Neuromuscular Blocking Agents The use of nondepolarizing neuromuscular blocking agents (NNMBAs) has been recently described to facilitate endotracheal intubation in chelonians (Kaufman et al. 2003). Nondepolarizing neuromuscular blockers have a much safer toxicological profile compared with depolarizing agents such as succinylcholine. NNMBAs do not have any anesthetic or analgesic activity, therefore, they should never be utilized alone for immobilization. They must be considered only as complementary to a balanced anesthetic technique. Rocuronium is a NNMBA with rapid onset and intermediate duration of action. Rocuronium (0.2 mg/kg IM) has been shown to permit endotracheal intubation in Gulf Coast box turtles (*Terrapene carolina major*) and in Amazon turtles (*Podocnemis expansa*) within 15 minutes after administration (Kaufman et al. 2003; Scarpa Bosso et al. 2009). The effects of NNMBAs can be antagonized with neostigmine. In the studies mentioned earlier, recovery time (time to walking) from rocuronium occurred within 30 minutes after administration of neostigmine (0.04–0.07 mg/kg IM). Glycopyrrolate (0.01 mg/kg) can be coadministered with neostigmine to prevent its potential parasympathetic effects.

Inhaled Anesthetics

Currently, the inhalants isoflurane and sevoflurane are favored for maintenance of anesthesia in reptiles (Shaw

et al. 1992). High concentrations of inhaled anesthetics and awake endotracheal intubation are required when these agents are used for induction. The potency of inhaled anesthetics is conventionally expressed as the < MAC. The values of MAC for isoflurane and sevoflurane in green iguanas (*Iguana iguana*) were 1.8% and 3.1%, respectively (Barter et al. 2006). Specific values of MAC for chelonian species have not been determined yet, but clinical evidence suggests the inspired concentrations required for surgical anesthesia are similar to the ones reported for other reptiles. Sevoflurane, by virtue of its low solubility in blood, is associated with faster anesthetic induction and recovery times when compared with isoflurane in mammals. Similar findings were shown in reptiles. In green iguanas (*Iguana iguana*), recovery time was significantly longer in animals anesthetized with isoflurane (35 ± 27 minutes) when compared with sevoflurane (7 ± 4 minutes) (Hernandez-Divers et al. 2005). Recovery times after 2 hours of anesthesia with 2% isoflurane averaged 4 hours in Kemp's ridley sea turtles, whereas prolonged anesthesia in desert tortoises, induced and maintained with sevoflurane, was associated with recovery times averaging 30 minutes (Moon & Stabenau 1996; Rooney et al. 1999). However, the high intracardiac shunting typical of aquatic chelonians may have contributed to these significant differences.

Interestingly, it has been shown in green iguanas that the MAC of inhalants tends to decrease over time, most likely reflecting limitations to anesthetic uptake and distribution. The progressive decrease in anesthetic requirements could also suggest that for any given end-tidal anesthetic concentration, the plane of anesthesia may deepen over time during prolonged procedures (Brosnan et al. 2006). For this reason, it is important to constantly monitor the depth of anesthesia and to titrate the concentration of inhalant to decrease the risk of overdose.

Chelonians can voluntarily breath-hold and successful use of inhaled anesthetics requires controlled ventilation for adequate drug uptake and elimination. Pure oxygen is the carrier gas usually utilized with inhalants. However, experimental evidence suggests hyperoxia depresses ventilation in both terrestrial and aquatic chelonians (Glass et al. 1978). Hypoxia, however, appears to be a common anesthetic complication in chelonians supporting the use of high inspired oxygen concentrations. Consequently, the ideal carrier gas mixture that would provide adequate oxygenation and maintain appropriate ventilation is still undetermined.

Inhalants do not provide any analgesic effect; therefore, appropriate addition of analgesics is required for any surgical procedure. Intraoperative pain management and use of balanced anesthetic techniques will also decrease the requirements of inhalant and hence side effects. For example, the cardiovascular depression

associated with inhalant anesthesia in reptiles, as in mammals, has been shown to be dose dependent (Mosley et al. 2004). For this reason, the multimodal approach to chelonian anesthesia using injectable and inhaled agents has gained the favor of many investigators (Chittick et al. 2002; McArthur 2004; Moon & Hernandez Foester 2001; Shaw et al. 1992) (see Table 22.2).

RECOVERY

Recovery time from anesthesia appears to be prolonged in chelonians when compared with mammals exposed to the same anesthetic agent. This difference may be due to the lower efficiency of the metabolic pathways of reptiles (McArthur et al. 2004). Additionally, temperature significantly affects the metabolic rate and the cardiovascular physiology of chelonians (Krosniunas & Hicks 2003). Both represent critical factors affecting a timely and successful recovery from anesthesia. For instance, hypothermia is associated with a decrease in metabolic function, which could delay the clearance of many injectable agents. Additionally, the amplification of intracardiac shunting, occurring when body temperature is below the ATR, can decrease the elimination of inhaled anesthetics through the lungs. Warming the patient above the preferred temperature for the species is also discouraged owing to the risk of increased oxygen demand (Galli et al. 2004). Consequently, the maintenance of body temperature within the ATR is recommended. Respiratory depression also persists during the recovery period. Noticeably, chelonians can occasionally take spontaneous breaths in the early postoperative period, but these should not be misinterpreted as signs of complete recovery from anesthesia. It is recommended to maintain the patient intubated until consistent spontaneous ventilation and voluntary movements are present.

There is evidence that catecholamines modulate cardiac shunting in chelonians (Overgaard et al. 2002). Particularly in *Trachemys*, epinephrine was shown to increase pulmonary blood flow by directly reversing the presence of right to left shunting. Ongoing studies at the University of Florida are investigating the efficacy and safety of the administration of epinephrine in reducing recovery time after inhalant anesthesia in chelonians.

Section III

Bird Anesthesia

23 Avian Anatomy and Physiology

Ashley M. Zehnder, Michelle G. Hawkins, and Peter J. Pascoe

INTRODUCTION

When considering anesthetic procedures for avian patients, it is critical to be aware of their unique respiratory and circulatory physiology. By appreciating the ways in which birds differ from mammals, clinicians can approach anesthetic procedures with more confidence and can hopefully improve outcomes for their patients.

RESPIRATORY SYSTEM

The avian respiratory system is different from mammals in that it has separate ventilatory and gas exchange compartments, making it highly efficient compared with other vertebrates (James et al. 1976).

Ventilatory Compartment

This compartment includes the major airways, an air sac system, and the thoracic skeleton with its associated muscles. When the beak is closed, the choanal slit located on the dorsal palate of the oral cavity covers the glottis. This allows air flowing through the nares to be directed into the trachea. The epiglottis is absent from the upper respiratory tract. In most species, the glottis is easily visualized at the base of the tongue, which makes endotracheal intubation straightforward.

All bird species have complete tracheal rings making the trachea less susceptible to collapse. However, this can still occur during handling of smaller species. The presence of complete tracheal rings may also make birds more susceptible to the formation of tracheal membranes secondary to damage of the tracheal mucosa. This is discussed more thoroughly in the following chapter on cagebird anesthesia. There are a handful of species with notable anatomical variations

of the upper respiratory tract. Male ruddy ducks and both sexes of emus have a tracheal sac-like diverticulum that can be confused for a ruptured trachea. (King 1989) In emus, this diverticulum arises as a slit-like opening through incomplete tracheal rings from the ventral surface of the caudal one-fourth of the extra-thoracic trachea. The caudal end may extend almost to the sternum (King 1989). This sac allows for the booming call of the emu. In the ruddy duck, a pear-shaped sac opens from the dorsal tracheal wall just caudal to the larynx and extends between the esophagus and trachea (King 1989). This sac is only found in males and may be involved in the bill-drumming display. In both species, positive pressure ventilation will inflate the sac and some anesthetic gas may be sequestered, potentially affecting anesthetic depth. A bandage can be wrapped around the neck over this area to prevent inflation of the sac. A bullous enlargement of the trachea is found in some species of Anseriformes (King 1989). A median septum is present in the trachea of some penguins and petrels. This septum divides the trachea from the bronchial bifurcation cranially for variable distances depending upon the species. For example, the median septum of the rockhopper penguin is only 5 mm in length (King 1989), but still may allow for unilateral endobronchial intubation. The median septum of the jackass penguin extends to within 1 cm of the larynx allowing both unilateral endobronchial intubation and the potential for trauma during intubation (Zeek 1951). However, endotracheal tubes can be modified to allow bilateral intubation in species with median septa.

There is significant variation in tracheal length between species, which has important implications for anatomical dead space. The typical bird trachea is reported to be 2.7 times longer than that of a similarly

sized mammal, but because it is approximately 1.3 times wider, the net effect is resistance to air flow is similar to mammals (King 1989). Tracheal dead space volume is approximately four times that of comparably sized mammals (King 1989). In some species (e.g., some swans, cranes, spoonbills, and curassows), convoluted loops and coils further increase dead space. Healthy, conscious birds compensate for this larger dead space with a larger tidal volume and lower respiratory frequency than mammals. This results in minute ventilation rates that are about 1.5–1.9 times those of mammals (Frappell et al. 2001; Powell & Whittow 2000). Anesthetic drugs will, however, depress ventilation and a greater percentage of minute ventilation becomes dead space ventilation (Ludders 1998; Ludders & Matthews 1996).

In most caged birds, there are four paired air sacs that extend throughout the coelomic cavity (cervical, cranial thoracic, caudal thoracic and abdominal) and one unpaired interclavicular air sac (Duncker 1971, 1972; Jaensch et al. 2002; McLelland 1989). There may also be diverticula that pneumatize the cervical vertebrae, some thoracic vertebrae, vertebral ribs, sternum, humerus, pelvis, and femur (Duncker 1971, 1972, 1974; Jaensch et al. 2002; James et al. 1976; McLelland 1989). The air sacs are poorly vascularized and function primarily as mechanical bellows providing airflow to the lungs during ventilation (Duncker 1971, 1974; Magnussen et al. 1976; Scheid 1979). Due to the lack of a muscular diaphragm, differing pressures do not occur between the thoracic and abdominal cavities (Duncker 1971, 1974; McLelland 1989; Scheid & Piiper 1989). Inspiration and expiration occur through movement of the sternum by contraction of the cervical, thoracic, and abdominal muscles (Duncker 1971; Scheid & Piiper 1987). Since both inspiration and expiration are active movements that require muscle activity, anything that depresses muscle function or impairs thoracic movement will decrease ventilation. The degree of muscle relaxation caused by anesthetic drugs depends upon the anesthetic(s) used, depth of anesthesia, and physical condition (Ludders 2001).

Restriction of movement of the sternum and thoracic muscles due to overexuberant physical restraint, and dorsal and ventral recumbency are reported to lead to hypoventilation (Curro 1998; Forbes 1999; Heard 1997; Jaensch et al. 2002; King & Payne 1964; Pettifer et al. 2002). It has been hypothesized that dorsally recumbent patients have their air sacs and lung openings (ostia) compressed by the internal organs, which may be exacerbated by increasing anesthetic duration (King & Payne 1962, 1964). This hypothesis has led to recommendations to avoid dorsal recumbency in anesthetized birds when possible. Until recently, the only studies of this effect have been in the domestic chicken. The chicken has a very well-developed pectoral musculature that may compress the thorax during respiration

in dorsal recumbency more so than lighter-bodied birds. Chickens and other domestic poultry also usually have large amounts of intracoelomic fat that reduces air sac volume. Additionally, chickens have a somewhat different gas exchange anatomy that may affect ventilation in dorsal recumbency. It was shown in a recent evaluation of air sac and lung volume in red-tailed hawks that even birds with significant coelomic fat did not demonstrate a reduction in lung volume, only air sac volume when in dorsal recumbency (Malka et al. 2009). In a recent study evaluating effects of positioning on spontaneous ventilation in red-tailed hawks during isoflurane anesthesia, no significant differences were found in minute ventilation, heart or respiratory rates, or arterial blood pressures when birds were placed in either dorsal or lateral recumbency. The PaO₂ was significantly higher in dorsal recumbency (Hawkins et al. 2013). Any adverse effect of positioning appears to be negated by assisted ventilation.

Gas Exchange

The parabronchial lungs are the primary tissues for gas exchange (Barnas et al. 1991; Duncker 1971, 1972; Scheid & Piiper 1970). The paired lungs are firmly attached to the ribs and vertebral column dorsally and extend from the thoracic inlet caudally to the level of the adrenals and the cranial division of the kidneys (Duncker 1971, 1972). Avian lungs are relatively smaller compared with mammalian and the parabronchi are nonexpandable. There are two types of parabronchial tissue and the ratio of these tissues varies with species. The paleopulmonic parabronchial tissue is found in all birds and comprises the majority of the lung volume in most species (Duncker 1971, 1972; McLelland 1989) (Duncker 1971, 1972; McLelland 1989). In this tissue, airflow is unidirectional throughout the respiratory cycle. Penguins and emu have only paleopulmonic parabronchi. The neopulmonic parabronchial tissue is also found in most species. However, it is only well developed in domestic poultry and songbirds, accounting for approximately 20–25% of total lung volume (Duncker 1972; Fedde 1980). Air flow through the neopulmonic parabronchi is bidirectional (Duncker 1971, 1972; McLelland 1989). Two complete cycles of inspiration and expiration are necessary to exchange the inhaled gas completely (Scheid & Piiper 1970, 1989). Most air from the first inspiration is directed to the caudal air sacs. That gas flows from the caudal air sacs into the lungs on the first expiration through a unique system of aerodynamic valving (Banzett et al. 1987; Powell & Scheid 1989). Air from the lungs moves into the cranial air sacs with the second inspiration and is moved out through the trachea into the environment on the second expiration. This two-breath cycle allows a continuous flow of air to the gas exchange surfaces, whereas the less efficient mammalian breathing cycle allows gas exchange to occur only at the end of inspira-

tion. Due to this unique system of air flow, a bird with an upper respiratory obstruction can still be ventilated effectively if an air sac is cannulated through the body wall (Korbel et al. 1993, 1996; Korbel 1998; Mitchell et al. 1999; Piiper et al. 1970; Rode et al. 1990; Whittow & Ossorio 1970; Wijnberg et al. 1991). Additional information on air sac cannulation is provided in Chapter 24.

Gas exchange is extremely efficient and a cross-current model is used to describe the blood and gas association (Duncker 1972; Maina et al. 2010; Makanya et al. 2011; McLelland 1989; Powell & Whittow 2000; Scheid 1979; Scheid & Piiper 1970, 1987). As the gas flow through the majority of parabronchi (i.e., the paleopulmonic parabronchi) is unidirectional, the cross-current anatomy of the pulmonary vasculature allows for the continuous exchange of gases throughout the length of the parabronchi. This results in a more efficient oxygen and carbon dioxide exchange than in the mammalian alveolus (Gleeson & Molony 1989; King & Payne 1964; Powell & Whittow 2000). In addition, birds have a larger relative gas exchange surface area, longer capillary blood transit times, and thinner blood-gas barrier than mammals of comparable weights, resulting in greater gas exchange efficiency (Gleeson & Molony 1989; McLelland 1989; Maina et al. 2010; Powell & Scheid 1989; Powell & Whittow 2000). More recently, it has been described that pulmonary capillaries in avian lungs are much less susceptible to pressure changes than mammalian lungs, primarily due to epithelial bridges within avian pulmonary capillaries. This makes them less susceptible to collapse or expansion due to changes in blood pressure (Watson et al. 2008).

Allometric analyses have been used to predict the effect of body size on respiratory variables associated with gas exchange efficiency between mammals and birds (Frappell et al. 1992, 2001; Maloney & Dawson 1994). A study using 50 avian species found general agreement with the older allometric equations with some minor differences in coefficients. The variables determined in this study agree with anatomic data and clinical observations, suggesting that irrespective of body size, birds tend to breathe slower and deeper, have lower minute ventilation, and have a greater demand for oxygen when compared with mammals, making the avian respiratory system more highly efficient in terms of oxygen extraction (Table 23.1).

In mammals, the functional residual capacity (FRC) acts to buffer changes in oxygen partial pressures during the respiratory cycle. In the past, it has been suggested that there is little FRC in avian lungs and, therefore, birds have little mechanism for blunting the effects of apnea on PaO₂ and PaCO₂ (McLelland 1989). However, there is a significant reservoir of gas in the air sacs and unidirectional flow of gases through the avian lung may minimize the potential for significant

Table 23.1. Comparison of allometric equations for respiratory variables in birds and mammals

Variable	Birds	Mammals
Oxygen consumption (VO ₂)	16.3M ^{0.68}	12.9M ^{0.73}
Minute ventilation (VE)	385M ^{0.72}	518M ^{0.74}
Tidal volume (VT)	22.9M ^{1.08}	10.8M ^{1.01}
Breaths per minute (f)	17M ^{-0.34}	49.1M ^{0.26}

M, body mass.

Figure 23.1. Change in oxygen tension during 8 minutes of apnea in six chickens anesthetized with isoflurane. In one treatment, the chickens were connected to an anesthetic circuit containing oxygen (100% O₂), and in the second, they were disconnected from the circuit at the onset of apnea (Disconnect).

fluctuations in blood gas tensions during short periods of apnea. For example, in chickens, 8 minutes of apnea after breathing 100% oxygen resulted in oxygen blood gas tensions that decreased at a similar rate to that seen in mammals (P.J. Pascoe, unpubl. obs.) (Fig. 23.1). Having a high concentration gradient (>95% O₂) and small distances to traverse allows for diffusion of oxygen through the lungs as the oxygen is being removed by the blood, accounting for this delayed onset of hypoxia. In a bird breathing room air, there is a very small diffusion gradient and, because oxygen consumption is higher in birds than mammals, any periods of apnea, however brief, must be treated immediately. Normal blood gas values for selected species are presented in Table 23.2. It should be noted that these values are obtained in awake birds on room air. Over a range of 19 species, PaO₂, PaCO₂, and pH were noted to average (SD) 91.6 (8.5), 31.4 (4.2), and 7.50 (0.03), respectively (Powell & Whittow 2000). From these data, it is clear that birds tend to have PaCO₂ tensions that are lower than many mammals.

Avian ventilation is controlled by both central and peripheral mechanisms. Respiration rates are lower, in some cases one-third of the mammalian rate, for a comparably sized animal (Powell & Whittow 2000; Scheid & Piiper 1989). The anatomical location of the central ventilatory controls appears to be in the pons

Table 23.2. Published blood gas values for selected species of birds

Species	PaO ₂ (Torr)	PaCO ₂ (Torr)	PH	Reference
Pigeon	95	34	7.50	Bouverot (1978)
Female domestic fowl	87	29.2	7.52	Piiper et al. (1970)
Pekin duck	93.1–100	33.8–36.3	7.46–7.47	Bouverot et al. (1989)
Red-tailed hawk	108	27	7.49	Kollias and McLeish (1978)

Note: All values were obtained in awake, resting birds breathing room air.

and medulla oblongata, as in mammals, with facilitation and inhibition most likely coming from higher regions of the brain (Powell & Whittow 2000). Peripheral extrapulmonary chemoreceptors, specifically the carotid bodies, respond to changes in PO₂ and PCO₂ in the same manner as those observed in mammals (Scheid & Piiper 1989). The chemical drive on respiratory frequency and ventilatory duration also appears to depend on vagal afferent feedback from intrapulmonary receptors, as well as extrapulmonary chemoreceptors, mechanoreceptors, and thermoreceptors (Crank et al. 1980; Powell & Whittow 2000; Scheid & Piiper 1989; Scheid et al. 1978). Birds have a unique group of peripheral receptors, the intrapulmonary chemoreceptors (IPC). They are present in the lung and are exquisitely sensitive CO₂ receptors (Banzett & Burger 1977; Burger et al. 1974; Crank et al. 1980; McLelland 1989; Powell & Scheid 1989; Scheid & Piiper 1989; Scheid et al. 1978). The rate of action potential generation by IPCs is inversely proportional to PCO₂, as they are inhibited by increases in PCO₂. However, it is unclear whether low lung PCO₂ or high pH is the immediate stimulus for signal transduction in the IPCs (Bebout & Hempleman 1999). Compared with mammals, respiratory function in birds may be more sensitive to the effects of inhalant anesthetics because of their effect on the avian IPCs, depressing their ability to adjust ventilation in response to changes in PCO₂ (Ludders 2001). Studies have shown inhalants depress the responsiveness of a number of peripheral control mechanisms that can directly or indirectly affect ventilation (Bagshaw & Cox 1986; Molony 1974; Pizarro et al. 1990).

CARDIOVASCULAR SYSTEM

The cardiovascular system also exhibits significant adaptations to the high metabolic demands necessary for flight. The heart is four-chambered. Compared with mammals, birds have a proportionally larger heart, higher stroke volumes, cardiac output, and resting mean arterial pressures (Grubb 1983; Smith et al. 2000). Heart rates vary significantly among species, with resting rates ranging from 150 to 1000bpm. Such high frequencies make obtaining accurate heart rates difficult, and very few commercially available monitors are able to count greater than 250bpm.

The distribution of the Purkinje fibers within the ventricular myocardium allows for the fibers to com-

pletely penetrate the endocardium and through to the epicardium, facilitating synchronous beating at rapid heart rates (Keene & Flammer 1991). This pattern of fiber distribution is responsible for the QRS morphology of the avian ECG (Smith et al. 2000). The ventricles and atria receive a higher density of both sympathetic and parasympathetic nerve fibers compared with mammals (Smith et al. 2000). Endogenous catecholamines are released during stress and pain. They can have a significant impact during anesthesia because some inhalant anesthetics sensitize the myocardium to catecholamine-induced arrhythmias (Aguilar et al. 1995; Greenlees et al. 1990; Joyner et al. 2008; Ludders & Matthews 1996). Clinical observations suggest manipulation of fractured bones, especially the pectoral girdle, causes significant bradycardia and arrhythmias in some patients. However, it is unknown whether this is a vagotonic or baroreceptor effect. Hypercapnia, hypoxemia, and some anesthetics can depress cardiovascular function.

There is an increasing awareness of the need to monitor blood pressure in avian patients during anesthesia as techniques for monitoring improve. However, when direct blood pressure measurements are compared across a variety of species in different orders, there is significant variability (Table 23.3). This can make it difficult to determine what values are normal for a particular species. There appears to be a trend for Galliformes and pigeons to have lower pressures than Psittaciformes, which also appear to average lower than raptorial species, but this is based on a low number of species. Blood pressure is the result of cardiac output and peripheral vascular resistance. Both of these are affected by a number of factors, including autoregulatory control, humoral, hormonal, and neural influences (Smith et al. 2000). Very short-term adjustments are mainly the result of reflex responses within the small arteries and arterioles. Tissue production of metabolic products, including CO₂, pH, and others, may cause a functional hyperemia in local tissues (Smith et al. 2000). Circulating hormones, such as epinephrine, norepinephrine, and angiotensin II, also have significant effects on peripheral vascular resistance (Smith et al. 2000). There has not been sufficient research into the differences in the multitude of factors between species to know which is responsible for the differences in resting blood pressures noted clinically. This means that monitoring trends for a particular patient under

Table 23.3. Published direct blood pressure (DBP) ranges in avian species

Species	SAP ± SD	MAP ± SD	DAP ± SD	Experimental methods	Reference
Pigeon	93 ± 10	82 ± 14	72 ± 13	Isoflurane, SV	Touzot-Jourde et al. (2005)
	88 ± 11	75 ± 10	60 ± 11	Isoflurane, MV	Touzot-Jourde et al. (2005)

Crested caracara	226 ± 18	201 ± 19	180 ± 18	Sevoflurane anesthesia Spontaneous ventilation	Escobar et al. (2009)

^aValues reported are mean ± standard error.

^bThese studies utilized the same study population of animals, although the individual animals may vary. CRI, constant rate infusion; MV, manual or controlled ventilation; SV, spontaneous ventilation.

anesthesia is more important than the actual blood pressure value. More information on techniques for measuring blood pressure under anesthesia is provided in Chapter 24.

The renal portal system consists of an arrangement of smooth muscles forming a valve within the external iliac vein at its junction with the efferent renal vein (King & McLelland 1984). This valve is controlled by both adrenergic and cholinergic stimulation. Epinephrine causes the valve to relax, allowing venous blood to be directed to the systemic circulation. Acetylcholine causes the valve to contract, allowing venous blood from the legs to perfuse the renal tubules (Akester 1967; Akester & Mann 1969; Burrows et al. 1983; Johnson 1979; Palmore & Ackerman 1985). The clinical significance of this valve is controversial. The renal portal system may play an important role in conditions where consistent blood levels of a drug, such as an antimicrobial, are required (Ludders & Matthews 1996). There have been few studies to examine the effects of the renal portal system on anesthetics. There was no difference in onset, duration, or recovery between injection of xylazine/tiletamine/zolazepam in ostriches into

the thigh or muscles at the base of the wings (Carvalho et al. 2006). In great-horned owls, butorphanol injected into the medial metatarsal vein has a significantly smaller area under the curve than the same dose injected into the jugular vein, suggestive of increased excretion through the renal portal system (Riggs et al. 2008). Until additional studies have been performed, the authors recommend nephrotoxic drugs or drugs exhibiting high renal excretion be administered into the cranial half of the body.

THERMOREGULATION

Heat is lost via radiation, evaporation, convection, and conduction. The normal body temperatures of most caged birds range from 39 to 43°C (Dawson & Whittow 2000). Since many birds are small and have a high body-to-surface area ratio they radiate heat rapidly. Once anesthetized, the bird is immobile and relaxed so it will generate less heat from muscle contraction. It is also subject to evaporative loss from the respiratory tract (dry anesthetic gases), skin surfaces (surgical preparations solutions), and open-body cavities, conduction

of heat via surface contact, and convection of warm gases from around the bird (Wessel et al. 1966). Anesthesia redistributes blood flow and depresses thermoregulatory response, further promoting heat loss. The core body temperature of pigeons with no external heat support dropped $\geq 8^{\circ}\text{C}$ in ≤ 30 minutes of inhalant anesthesia (Harrison et al. 1985). Hypothermia has a number of adverse physiologic effects. It results in bradypnea, and decreased minute ventilation and tidal volume (Moon & Ilkiw 1993). Hypothermia decreases anesthetic requirement and metabolism and will prolong recovery (Ludders & Matthews 1996). Therefore, monitoring of core body temperature and providing thermal support are mandatory to reduce anesthetic morbidity and mortality in the anesthetized and recovering patient.

24 Cagebirds

Michelle G. Hawkins, Ashley M. Zehnder, and Peter J. Pascoe

INTRODUCTION

The anesthesia of caged (and other species) of birds is unique not only from the aspect of anatomy and physiology, but also due to unique requirements for anesthetic equipment, monitoring, and species-specific pharmacology. It is critical to understand the limitations of currently available technologies when dealing with small patients to plan safe anesthetic procedures.

PREANESTHETIC EVALUATION

The medical history and husbandry of the pet bird is essential for preanesthetic evaluation. History regarding diet, appetite, previous diseases, and drug therapy should always be collected. Examination of the bird's cage and its contents is useful to assess heavy metal exposure and the bird's droppings. The quantity and quality of the droppings will help determine whether the bird has been eating. Changes in color or consistency of the droppings suggest abnormalities in the gastrointestinal, hepatic, or urinary systems (Doneley et al. 2006).

Allowing time for acclimation to new surroundings will reduce stress and unmask clinical disease. A complete physical examination, including respiratory, cardiac, renal, and hepatic function, should always be performed and baseline values recorded for comparison during anesthesia. The bird should first be examined closely in its cage, paying particular attention to respiratory rate and effort. The resting respiratory rate is recorded prior to physical restraint for comparison with rates under anesthesia. The quality of respiration is evaluated by auscultating the air sacs ventrally and the lungs dorsally for evidence of harsh airway sounds or

evidence of wheezing. The trachea is also auscultated and gently palpated for any abnormalities. The heart is auscultated carefully for murmurs and a baseline heart rate recorded for comparison during anesthesia. Pulse quality is assessed at either the median ulnar or medial metatarsal arteries, evaluating it for symmetry and strength. The body weight is recorded for calculating accurate fluid and medication dosages.

Accurate assessment of renal and hepatic function is difficult during the physical examination. Urine and urates in the droppings are evaluated for quantity and color. Red-tinged urine could be due to hematuria, but may be due to dietary colorings. Green or yellow urate discoloration may be biliverdinuria and a sign of hepatic dysfunction (Doneley et al. 2006). Coelomic palpation is performed to assess for organomegaly that may mechanically compress the air sacs and lungs.

Hydration status is evaluated, recorded, and dehydration corrected, if possible, prior to anesthesia. Compensatory mechanisms are blunted under anesthesia, exacerbating underlying hypotension and poor peripheral perfusion. Hydration assessment includes examination of the moistness of the cloacal and ocular mucous membranes and the elasticity of the skin at the eyelids and over the keel. Sunken eyes and cool extremities also indicate dehydration. The refill time after digital compression of the median ulnar vein should be immediate; venous refill times of >1 second have been suggested to correlate with >7% dehydration (Steinohrt 1999). The PCV will often be increased during dehydration. In pigeons, water deprived for 72 hours, the plasma urea nitrogen increased 6.5–15.3×, but the uric acid only showed a 1.4–2× increase (Lumeij 1987). Clinically, however, it appears uric acid does go up with moderate-to-severe dehydration, and will resolve with rehydration.

Ideally, a complete blood count and biochemical profile are performed prior to anesthesia. If one hematocrit tube of blood can be collected, a packed cell volume (PCV), whole blood smear for estimated white blood cell count and differential, blood glucose, and several other biochemistry tests can be obtained. There are several new tabletop biochemical analysis systems that require only a very small volume of blood to provide a complete biochemistry profile. Any anemias are characterized as either acute or chronic and regenerative or nonregenerative. Acute anemias are corrected prior to anesthesia as birds may not be able to compensate for lowered levels of oxygen delivery. Transfusion is indicated as in mammals if the PCV is <15–20% and the total solids are <3–3.5 g/dL. However, pet birds often have PCV \geq 40% so if the blood loss is acute, the authors may perform a transfusion at a higher PCV. Also, avian total protein values are much lower than those in mammals (2–3 g/dL). There is a poor correlation between total solids measured by refractometer and protein values measured with the biuret method, making the former an inaccurate criterion for avian transfusion (Lumeij & de Bruijne 1985). The type of surgery to be performed and potential for blood loss are assessed so a fluid plan can be prepared. PCV may decrease 3–5% during anesthesia due to vascular hemodynamic changes associated with certain anesthetic drugs. Hypoglycemia (<200 mg/dL) is supplemented before anesthesia and glucose concentration monitored. Calcium gluconate is commonly administered in African gray parrots (50–100 mg/kg IM; diluted with saline 1:1) prior to induction to prevent hypocalcemia, a common problem in these species.

The gastrointestinal system has a very rapid transit time compared with most mammals. It is, therefore, important to carefully consider the nutritional plane of the patient. Prolonged anorexia will lead to a negative energy balance requiring nutritional support in the preanesthetic period. Other indications for additional nutritional support include reduced to absent fecal production and significant reduction in body weight. Nutritional requirements differ between species and classes. To calculate nutritional requirements for the critically ill patient, the basal metabolic rate (BMR) is first calculated: $BMR \text{ (kcal/day)} = K (BW_{\text{kg}})^{0.75}$; $K = 78$ in nonpasserines; $K = 129$ in passerines. While these two K-factors provide a basic means of estimating avian BMR, many additional factors have been calculated for specific species. The authors refer the reader to appropriate avian nutritional texts for additional detail (Klasing 1998). The maintenance energy requirements (MER) are adjustments to the BMR based upon hypermetabolism associated with any disease processes. The most common adjustments are $1.2\text{--}1.5 \times$ BMR (range $0.5\text{--}2.0 \times$) (McDonald 2006). The chosen diet depends upon the patient's nutritional needs. Foods can be blended to a liquid, or commercially

available enteral products are used based upon the patient's protein, carbohydrate, and fat requirements. Total parenteral nutrition or partial enteral nutrition is not commonly utilized due to catheter-related complications, poor patient tolerance, and lack of appropriate formulations.

PREANESTHETIC SUPPORTIVE CARE

Fluid Support

Daily maintenance fluid rates are approximately 40–60 mL/kg/day. This range is based upon studies where drinking is the main route of water intake. Birds weighing \geq 100 g drink approximately 5–8% of body mass/day. This increases at progressively smaller body masses to drinking rates as high as 50% for birds weighing 10–20 g (Bartholomew & Cade 1963; Skadhauge 1981; Zeigler et al. 1972). Estimation of fluid replacement is based upon body weight and dehydration percentage: Estimated dehydration (%) \times body weight (gm) = fluid deficit (mL). One-fourth to one-half the deficit is given in the first 6–12 hours, then the remainder over the following 24 hours (Abou-Madi & Kollias 1992).

Oral (PO) fluids are only useful for mild dehydration and are contraindicated in head trauma, GI stasis, lateral recumbency, or seizing. Subcutaneous (SC) fluids are commonly used for maintenance and mild-to-moderate dehydration. However, large volumes may not be absorbed due to the paucity of blood vessels in the subcutis and peripheral vasoconstriction. Volumes of up to 10–15 mL/kg/site can be injected into the inguinal folds, axilla, or dorsum. Overdistension of the SC site can result in compromise of the blood supply and decreased fluid absorption. Before each injection, the administration site is inspected for previous delays in absorption. Only isotonic or nonirritating fluids should be given SC. Dextrose solutions \geq 2.5% are not given SC as equilibration between the SC fluids and the extracellular fluid will exacerbate preexisting electrolyte imbalances (Abou-Madi & Kollias 1992; Steinohrt 1999).

Fasting

Preanesthetic fasting duration is determined by species, size, and clinical status, with a goal of reducing regurgitation yet minimizing hypoglycemia (Harrison 1991). Fasting times between 2 and 4 hours have been recommended in medium-sized psittacines, whereas birds \leq 100–200 g may not be fasted due to high metabolic rates and easily depleted glycogen stores. However, in broiler chickens and adult Japanese quail fasted 12 and 48 hours, respectively, blood glucose remained within clinically acceptable ranges (Lamosova et al. 2004; van der Wal et al. 1999). No studies have been performed evaluating the effect of fasting on psittacines. Scheduling procedures as early in the day as possible reduces fasting times. In species with high metabolic rates, clear

fluids high in carbohydrates may be provided to maximize calories while minimizing crop and stomach contents prior to anesthesia. The crop contents may be gently aspirated if anesthesia cannot be delayed.

EQUIPMENT

Endotracheal Intubation

The main advantages of tracheal intubation are that it provides a patent airway, reduces dead space, and allows easy application of positive pressure ventilation. The disadvantages are that it can be associated with trauma to the airway, it can significantly increase airway resistance and the tube can become occluded due to mechanical forces or because of secretions. These factors need to be carefully considered when deciding to intubate a patient. The increase in airway resistance is of greatest importance in very small patients since the resistance varies with the fourth power of the radius. For example, decreasing the radius from 5 to 3 mm would increase the resistance sevenfold, whereas a decrease from 3 to 1 mm would increase resistance >80 times. Since an increased resistance would require the patient to work harder to breathe, this effect can be minimized by providing positive pressure ventilation.

Despite the above cautions, the authors recommend that for any procedure that requires greater than 10 minutes of anesthesia, intubation should be performed. Many types of endotracheal tubes have been used in birds. Cole, noncuffed and cuffed tubes have all been used successfully in caged birds (Fig. 24.1). Cole tubes have a narrow tip that is static in diameter for a short distance then increases in diameter. The distal end is advanced into the trachea until the larger diameter abuts against the glottis, creating a seal. However, these tubes tend to plug with secretions easily.

Overinflation of the cuff on an endotracheal tube can cause tracheal mucosal epithelial trauma due to lack of expansion of the tracheal rings or, alternatively, the tracheal rings may rupture with severe overinflation. Inflammation of the tracheal epithelium may lead to fibrotic narrowing of the tracheal lumen with complete transtracheal membranes (Fig. 24.2). Cuffed tubes without the cuff inflated also have the potential to cause tracheal mucosal damage and inflammation due to the irregularity of the plastic surface of the cuff on the tracheal epithelium. Because this inflammatory process requires time, clinical signs of dyspnea associated with this type of tracheal trauma may not become evident for up to several weeks post intubation. There have been a small number of case reports and one multi-institutional review documenting tracheal stenosis or tracheal membrane formation in psittacines post intubation, as well as other species (blue-billed curasow) (de Matos et al. 2006; Evans et al. 2009; Jankowski et al. 2010; Sykes et al. 2013). These cases have been

managed with tracheal anastomosis with one bird having no respiratory signs for 2-year post resection (Jankowski et al. 2010). Various factors including ventilation techniques and endotracheal tube disinfection protocols have been suspected to contribute to this phenomenon, and these are factors that are associated with tracheal stenosis in humans (Wain 2009), but no definitive correlation with protocols or procedures has been identified to date.

Although noncuffed tubes are most commonly used, there are several disadvantages to their use. They do not provide a sealed airway, allowing escape of anesthetic

Figure 24.1. Various endotracheal tube types are used in avian clinical practice. Cole, noncuffed, and cuffed tubes have all been used successfully in caged birds (a). Catheters can be modified and used as ET tubes for very small patients (b). Intubation is straightforward as visualization of the glottis is not difficult in most caged birds (c).

Figure 24.2. Transtracheal membrane occluding approximately 75% of the tracheal lumen in a double yellow-headed Amazon parrot. Note the significant vascularization of the membrane. These membranes have been reported most commonly in birds up to several weeks after intubation with both cuffed and non-cuffed endotracheal tubes. Various factors such as over-inflation of the cuff, ventilation techniques and endotracheal tube disinfection protocols have been evaluated but no definitive correlations have been identified to date.

gases. This increases the amount of anesthetic gas required and environmental contamination. Also, airway protection from aspiration of secretions or gastrointestinal contents is reduced. This makes it imperative that the oral cavity be clean prior to intubation and monitored throughout the procedure. Elevation of the head and neck may reduce regurgitation of gastrointestinal contents from the crop, proventriculus or ventriculus into the oral cavity. Cuffed tubes have been used in larger avian patients. The cuff is carefully inflated with just enough air to prevent leakage when 10–15 cm H₂O pressure is applied (Curro 1998; Ludders & Matthews 1996).

The patient size determines the endotracheal tube size used. The smallest commercial noncuffed tubes have an internal diameter (ID) of 1 mm. However, tubes <2 mm ID are often highly flexible and kink easily. The smallest-diameter cuffed tube is 2.5 mm ID. Very small birds may be intubated with teflon IV, red rubber, or urinary catheters. Care is taken to ensure that no sharp edges are present at the end. This is achieved by using a small piece of silicone tubing over the end of the catheter. Ends of catheters can be cut and adapted for use as endotracheal tubes if they are gently filed with an emery board to remove rough edges.

As stated previously, endotracheal tubes with small internal diameters impose significant resistance to gas flow, especially if mucus accumulates. During inhalant anesthesia, copious thick mucus production can occur due to the drying effects of the inspired cold, dry gases.

In the authors' experience, humidification of the gases reduces mucus plug formation. Commercially available endotracheal tube humidifiers are available (Humivent Mini Agibeck Product, Hudson RCI, Temecula, CA). Disadvantages of their use include increased dead space and filter plugging with secretions. The use of an endotracheal tube with a Murphy eye, which has both side and end openings, decreases the likelihood of mucus occlusion.

Endotracheal tube obstruction is detected by monitoring the ventilatory pattern. As the airway occludes the expiratory phase duration becomes prolonged (Ludders & Matthews 1996). An anticholinergic (atropine and glycopyrrolate) reduces mucus production and mucus plug formation. However, it also increases mucus viscosity, making it harder to clear secretions from the tube. Some clinicians recommend that the endotracheal tube be removed and replaced after every hour of anesthesia for long procedures.

Extension of the neck, gentle traction on the tongue and pressure under the mandibular beak will push the glottis forward to aid in endotracheal tube placement. Psittacines have a thick, fleshy tongue that makes glottal visualization slightly more difficult. Some birds have very brisk glottal closure reflexes. Intubation in these patients can be facilitated by applying a very small amount of lidocaine to the larynx and waiting 60 seconds. If possible, the tube is secured to the mandibular beak to allow for monitoring the oral cavity during anesthesia. Any portion of the tube extending from the circuit to the glottis is dead space; cutting the tube as close as possible to its entry into the oral cavity will minimize this mechanical dead space.

Inhalant anesthetics can also be administered through a cannula inserted into an air sac for induction and maintenance in birds as small as zebra finches (Fig. 24.3) (Korbel R 1998; Korbel et al. 1993; Mitchell et al. 1999; Nilson et al. 2005; Piiper et al. 1970; Rode et al. 1990; Whittow & Ossorio 1970; Wijnberg et al. 1991). Air sac cannulation provides an airway when upper respiratory tract obstruction is present (e.g., syringeal foreign bodies or granulomas). It is also used for procedures involving the upper airway or cranium (Jaensch et al. 2001; Nilson et al. 2005; Piiper et al. 1970). It is also placed for acute life-threatening obstruction and can be left in place to provide longer-term respiratory support, but not generally for more than 3–5 days without replacing tubes, as inflammatory tissue and cells will accumulate on the tube tip (Korbel et al. 1996; Mitchell et al. 1999).

Materials used for air sac cannulas include sterile endotracheal tubes, large-gauge IV catheters (16–18 gauge), red rubber feeding tubes, and silastic tubing. If the bird is to breathe through the cannula, the tube diameter should be at least equal to the patient's tracheal diameter and short enough to minimize dead space and prevent coelomic soft tissue contusion.

Figure 24.3. Placement of an air sac cannula. Strict asepsis should be observed when placing the cannula. Feathers over the site for cannulation should be gently plucked, contour feathers taped away from the cannula site and the area should be surgically prepared. The landmarks for air sac cannula placement are caudal to last rib, ventral to the vertebrae and, in most cases, cranial to hindlimb. The proper site for cannula insertion is marked with * (a). Once the cannula has been surgically placed, it is secured in place with suture (b). A piece of sterile gauze can be used as a filter to minimize contamination of the cannula with particulate matter (c).

Air sac catheters are usually placed in the left caudal thoracic or abdominal air sac to prevent trauma to the larger right liver lobe. However, catheter placement into the clavicular air sacs has also been reported (Rode et al. 1990; Rosskopf & Woerpel 1989). In sulfur-crested cockatoos (*Cacatua galerita*) caudal thoracic air sac intubation provided stable isoflurane anesthesia without significant respiratory functional changes. Even though caudal thoracic air sac PCO_2 decreased to 12.7 ± 7.9 mm Hg, spontaneous respiration was still present (Jaensch et al. 2001). Clavicular air sac catheterization was also evaluated, but was not successful at either maintaining anesthesia or providing ventilation. In a separate study, clavicular air sac PO_2 and PCO_2 were significantly lower than in the cranial thoracic air sacs suggesting, at least in sulfur-crested cockatoos, ventilation of this air sac is less than the cranial and caudal thoracic air sacs (Jaensch et al. 2002).

Air sac cannula placement is a relatively simple surgical procedure (Fig. 24.3). For placement into the left caudal thoracic or abdominal air sac, the landmarks are the last rib, the cranial aspect of the femur and the flexor cruris medialis muscles. Following removal of overlying feathers and aseptic preparation of the skin, a skin incision is made over the desired site. The underlying muscle and air sac membrane are bluntly dissected with a hemostat. The tip of the sterile catheter is grasped with the hemostat and passed into the air sac. The muscle and skin are closed securing the catheter in place. In an emergency, gas flow and ventilation are provided through an IV catheter placed at the same site and connected to an oxygen source. Care is taken not to advance the catheter needle too far and to limit oxygen flow to prevent hypocapnia. In apneic 1- to 1.7-kg chickens, a flow of 500 mL/min reduced PCO_2 to ≤ 20 mm Hg (Pascoe, unpubl. obs., 1992) so with a small catheter and flow through ventilation the O_2 flow should probably be < 250 mL/kg. Oxygen and anesthetic gases from the cannulated site exit the trachea unless intubated with an occluded endotracheal tube. It is possible to scavenge waste gases by placing a mask or tube over the bird's head and connecting it to an active anesthetic scavenging system.

The most common adverse effects reported with air sac cannulation are apnea, subcutaneous emphysema, plugging of the tube, and bacterial contamination with associated coelomitis (Jaensch et al. 2001; Mitchell et al. 1999). Ensure meticulous cleaning/inspection of the tube to prevent plugging. Cleaning is performed with a sterile cotton tip applicator or Dacron swab. A filter can be designed from small weave gauze (i.e., from the inside of a Hepa-filtered mask) and placed over the end of tube to prevent particulate matter from entering. Although most birds tolerate air sac cannulas, an Elizabethan collar may be required for some. Following cannula removal, the body wall is closed to prevent subcutaneous emphysema.

Breathing Systems

Many nonbreathing systems (e.g., Ayre's T-piece, Mapleson systems, Magill, Jackson-Rees, Norman elbow, and Bain) have and can be used for avian anesthesia. These systems require a relatively high fresh gas flow rate to remove carbon dioxide. These higher flow rates have the added benefit of providing rapid equilibration in inhalant concentration with changes in vaporizer setting. Nonbreathing systems were traditionally viewed as ideal for small patients because of lower airflow resistance and reduced dead space. Circle systems were believed to have higher airflow resistance because they contain one way valves and soda lime canisters. However, the primary source of resistance is most likely the endotracheal tube. Studies in infants ≤ 10 kg (Rasch et al. 1988) and cats (Suter et al. 1989) have shown that resistance was insignificant compared with that produced by the endotracheal tube alone. Circle systems are heavier and bulkier, which predisposes to accidental extubation and difficulty working around the head. For this reason, a nonbreathing system, such as the Bain breathing system, is recommended in small birds due to its lightweight design.

Specific flow rates for avian patients have not been defined. As in mammals, 2–3 \times minute ventilation appears appropriate when using the T-piece or Norman elbow, but in the Bain circuit, a lower flow rate of 150–200 mL/kg/min is effective (Ludders & Matthews 1996; Paul-Murphy & Fialkowski 2001). The removal of waste gases from the circuit occurs during the pause between expiration and inspiration. If the respiratory rate is high (shorter pause and therefore more mixing of inspired and expired gases), a higher flow rate is used (e.g., RR >40 increase the flow rate to 300 mL/kg/min).

Ventilators

Both injectable and inhalant anesthetics cause dose-dependent respiratory depression. Sick or debilitated birds may not be able to accommodate these physiologic changes, requiring intermittent positive pressure ventilation (IPPV). In mammals, IPPV is associated with reduced cardiac output and hypotension (Steffey & Howland 1977, 1980). In cranes anesthetized with isoflurane, spontaneous ventilation was associated with elevations in PaCO₂, hypotension and acidemia compared with controlled ventilation (Ludders et al. 1989a). Similarly, there was a significantly reduced PaCO₂-PETCO₂ gradient and no significant difference in mean arterial blood pressure in Hispaniolan parrots (*Amazona ventralis*) ventilated using IPPV compared with birds breathing spontaneously (Pettifer et al. 2002). It is possible that reduced cardiovascular performance associated with IPPV may not be a concern in birds. However, it is still recommended that cardiovascular variables be monitored closely during IPPV.

Ventilators must cope with the range of tidal volumes in the species of interest. In very small birds, this may be ≤ 1 mL, while in a large ostrich, it might be ≥ 2 L. Modern ventilators are usually pneumatic, but control mechanisms may be either pneumatic or electric. If electronically controlled, an auxiliary power source is required if the bird is moved or power fails. The three variables controlled by a ventilator are tidal volume, rate of tidal volume delivery, and respiratory frequency. The method of control varies between ventilators. In volume-limited ventilators, tidal volume is set on the machine with the expectation that it will deliver the volume regardless of moderate changes in resistance. Even if the circuit is disconnected, the ventilator continues to cycle with no alteration in tidal volume or timing. Some ventilators allow the upper limit for inspired pressure to be set with an alarm. In pressure-limited ventilators, the end-inspiratory pressure is set. The ventilator will push gas into the bird until it reaches the set pressure, when the inspiratory phase will terminate and the ventilator allows for passive exhalation. A disconnect or large hole in an air sac is indicated by prolonged inspiration because the preset pressure is not reached. A third method is to set inspiratory time and achieve different tidal volumes by altering inspiratory flow rate. This is a form of volume-limited ventilation. The respiratory rate and tidal volume are determined by the gas flow rate. Hence, it is necessary to set a faster flow rate for a larger tidal volume. On some ventilators this is set by altering the knob labeled "I : E ratio." This is the inspiratory versus expiratory time and the setting will depend on the number of breaths per minute. If you want inspiration to take 1.5 seconds, the I : E ratio would need to be 1 : 3 for 10 breaths per minute (6 seconds per breath, 1.5 seconds for inspiration : 4.5 seconds for expiration) or 1 : 1 for 20 breaths per minute (3 seconds per breath : 1.5 seconds each for inspiration and expiration). The number of breaths per minute is mostly set by altering a timing device that begins a new inspiration after a set period of time.

When ventilating birds, it is essential to have a ventilator that can deliver small tidal volumes slowly to give an acceptable inspiratory time. During anesthesia, the ventilator should initiate the breath, not the bird, to control the PCO₂. In assisted ventilation mode, the bird initiates the breath when its PCO₂ reaches the point set by the central controllers of ventilation in the brain. Since the latter are depressed by anesthetics, assisted ventilation is not likely to decrease PCO₂.

The authors recommend initial inspiratory pressures of 8–10 cm H₂O and rates of 6–10 breaths per minute. Thoracic excursions are assessed as soon as the ventilator is started. The tidal volume is adjusted to achieve an appropriate thoracoabdominal expansion. The minute volume is lower than mammals (Frappell et al. 2001) and inspiratory times can be longer. At six breaths

per minute, the I : E ratio could be set to 1 : 2 to 1 : 3 (inspiration occurring over 3.3 to 2.5 seconds). During coelomic surgery, when the air sacs have been opened, anesthetic will be pushed by the ventilator into the air being breathed by the surgeons. It is important to avoid or minimize personnel exposure to inhaled agents. In some cases, injectable anesthetics are used if the concerns about using inhalant anesthetics are great.

During positive pressure ventilation, it is possible the direction of gas flow within the lung is reversed. However, the crosscurrent exchange system is not dependent upon direction of flow and does not significantly affect gas exchange (Ludders & Matthews 1996; Piiper et al. 1970). If a mechanical ventilator is not available, hand ventilation delivered from the reservoir bag provides assisted ventilation.

THERMAL SUPPORT

Body temperature is monitored continuously throughout anesthesia. Prevention of heat loss is essential in the anesthetized patient and supplemental heat sources are used regardless of procedure length. Electronic thermometers and temperature probes provide accurate readings. Cloacal temperatures have been correlated with thoracic esophageal readings, suggesting core temperature may be indirectly monitored (Phalen et al. 1996). However, as cloacal musculature relaxes, peripheral temperature readings are lowered. Esophageal temperature probes provide consistent readings when placed at the level of the heart in the thoracic esophagus. Care is taken to ensure the crop is not damaged during placement and the probe does not back out resulting in incorrect temperature readings.

Since most heat is lost via radiation, the most effective technique to prevent heat loss is to minimize the temperature gradient between the bird and the room. Options include increased room temperature, insulating the patient with clear, plastic drapes, and wrapping nonsurgical fields. The surgical time and the amount of time that the body cavities are open are minimized, as are feather plucking and alcohol use for skin preparation. Latex gloves, empty fluid bags, or plastic bottles can be filled with water, warmed in a hot water bath or microwave and placed next to the bird. Water bottles are always wrapped in a towel to prevent burns. Circu-

lating warm water blankets insignificantly diminish rate of heat loss in birds (Phalen et al. 1996; Rembert et al. 2001). Radiant heat lamps are effective at maintaining core body temperature, but the optimal distance between the heat source and the patient differs with patient size, heat lamp strength, and the heat setting (Phalen et al. 1996; Rembert et al. 2001). Forced air warmers (Bair® Hugger) are more effective at minimizing hypothermia during anesthesia than other methods (Borms et al. 1994; Machon et al. 1999; Rembert et al. 2001). They are particularly effective when set up to have warm air rising around the patient either by wrapping the patient in the blanket or by using a perforated table. The patient's eyes are well lubricated to prevent corneal ulceration due to drying from the warm air.

Further reductions in heat loss are achieved by warming fluids and reducing respiratory cooling. In pigeons anesthetized for 90 minutes, there was no significant difference in heat loss between either a circle system with mechanical ventilator producing heated air, a nonbreathing system with mechanical ventilator producing nonheated air and a Bain nonbreathing circuit (Boedeker et al. 2005). This is in contrast to humans, cats, and rabbits in which heated, humidified anesthetic gases reduce or prevent the development of hypothermia (Haskins & Patz 1980; Newton 1975; Shanks 1974; Tausk et al. 1976). In intubated anesthetized ring-necked doves (*Streptopelia risoria*) without thermal support, hypothermia was not lessened by humidification and heating of inspired gases (Phalen et al. 1996). However, in anesthetized pigeons maintained on a facemask, heated inspired gas did minimize hypothermia (Jenkins 1988).

EMERGENCIES

Emergencies during anesthesia should be planned for and anticipated. Many can be averted by careful monitoring of respiratory and heart rates, and body temperature. Emergency equipment (i.e., endotracheal tubes, oxygen, IV catheters and materials for securing them, ventilatory support, and emergency drugs) should always be close by and prepared for use. It is recommended that emergency drug dosages be calculated and that 1–2 doses be predrawn before induction (Table 24.1).

Table 24.1. Avian emergency drug doses

Drug	Dosage	Route	Comments
Atropine	0.01–0.02 mg/kg	SC, IM, IV	Most species/Preanesthetic
	0.04–0.1 mg/kg	SC, IM, IV, IO, IT	Bradycardia
Glycopyrrolate	0.5 mg/kg	IM, IV, IO, IT	CPR
	0.01–0.02 mg/kg	IM, IV	Slower onset than atropine
Epinephrine (1 : 1000)	0.04 mg/kg	IV	Most species/preanesthetic
	0.05–0.5 mg/kg	IM, IV, IO, IT	Ratites CPR, bradycardia

Respiratory depression and arrest are treated by turning off the anesthetic and controlling ventilation. Cardiac arrest is usually a result of myocardial hypoxemia and inotropic and chronotropic anesthetic drug effects. Although treatment is often unrewarding, administration of epinephrine IV, intratracheal or by intracardiac injection, is recommended. Cardiac massage is nearly impossible due to the heart's anatomical location dorsal to the large bony sternum, but should be attempted. Severe bradycardia is treated with atropine, assuming it is due to increased parasympathetic tone. In very small birds, it is possible to see spontaneous ventricular defibrillation as the mass of the heart is small enough that it cannot maintain a fibrillatory pattern.

ANESTHESIA

Restraint

Correct restraint is essential to minimize patient stress and time required for anesthetic induction. Stressed birds may die from physical restraint, and this risk is magnified in sick or debilitated patients. Appropriate means of physical restraint must be assessed for each patient and appropriate stabilization and supportive care prepared prior to handling. Paper towels, wash cloths, hand towels, large bath towels, or blankets may be used based on the patient size. Hooding calms some species (e.g., raptors and ratites), but care must be taken to ensure adequate air flow. Leather gloves will not protect handlers from the crushing bite of a large parrot. Nets are used to capture birds in larger enclosures or escapees. They should be sized appropriately for the patient to minimize iatrogenic trauma. Once netted, the bird is gently removed to avoid trauma to the wings, legs, or toes. Ear protection for the handler (e.g., cotton balls or ear plugs) can be used when handling large psittacines (e.g., cockatoos and macaws). Face shields or goggles are used when handling birds likely to inflict ocular damage with the tip of their beaks (e.g., Ciconiiformes).

It is preferable for caged birds to be captured from within their travel cage or hospital enclosure to reduce the chance for injury and reduce stress induced by escape attempts in a room. All perches, toys, and food and water dishes are removed to facilitate capture and minimize trauma and ambient noise should be reduced. If a patient must be captured from a larger area, this should ideally be done in a small area that is free of windows and doors leading to the outdoors. Alternately, windows can be covered to minimize self-induced trauma if an escape occurs and doors are locked. Some methods to aid capture from a room include placing the bird on the floor or turning off lights, as this will often reduce the excitement level of the patient. Regardless of the physical restraint technique employed, care should be taken not to compromise thoracic cage movement or the ability of the

anesthetist to monitor the patient. Movement with the bird in hand should be quiet and calm to reduce fright and stress. The capture is performed expeditiously to minimize stress. If a bird should escape and needs to be recaptured or is unduly excited, delay anesthesia until the bird has calmed down.

Once the bird is in hand, a towel is initially placed over the dorsum, then gently wrapped around the wings to restrict flapping and prevent damage to the wings and feathers. Once adequately restrained by the handler, birds are removed from the towel if possible to prevent hyperthermia that can occur subsequent to prolonged restraint. Small birds (e.g., passerines) are restrained with the head between thumb and forefinger, and the body within the palm. Alternatively, in smaller psittacines, the head is restrained using a "three point" technique, with thumb and middle finger supporting the mandible and the index finger on top of the head. Bruising of the face is possible in large macaws and only the minimum pressure necessary to restrict movement is applied. Gentle extension of the bird's neck further limits head movement. Large parrots are strong and will inflict severe wounds if the head and beak are not immediately controlled. Some prefer to encircle the birds neck with their fingers for restraint. A third technique places the thumb under the intermandibular space while the other fingers are placed over the top of the head. This is the author's choice for maintaining full control of the head during restraint. The other hand is placed on the dorsum to secure the wings and legs.

Preoxygenation

Preoxygenation is performed whenever possible and when hypoxemia may occur (i.e., upper respiratory obstruction, cardiac, pulmonary, or air sac disease). It replaces nitrogen in the respiratory system and can produce an oxygen reservoir 4–5× normal in the air sacs. The benefits are achieved in ≤1 minute of high inspired oxygen concentration in the healthy bird, but may take ≥5 minutes in a bird with compromised respiratory function. Preoxygenation is accomplished with an oxygen cage or an induction chamber in the unrestrained bird, or a facemask in the physically restrained bird. Levels rise slower in an unprimed oxygen cage or induction chamber than a tight-fitting facemask with minimal deadspace. If the bird is allowed to breathe room air, the parabronchial oxygen levels can fall precipitously if the bird becomes apneic.

Mask or Chamber Induction

Inhalant anesthesia induction is often performed with either a mask or induction chamber. Commercially available veterinary inhalant masks can be used for many species. However, differences in beak anatomy and location of nares require unique masks to be formed from syringe cases, plastic soda bottles, or other materi-

Figure 24.4. Sites for intravenous (IV) catheters include the ulnar (basilic) vein (a), medial metatarsal vein (b) or jugular vein. Small bore over-the-needle catheters (24 gauge or smaller) are most often necessary for avian patients.

als. The mask is as small as possible and the entire head of the patient is placed inside the mask. To minimize waste gas release, a seal is developed using a disposable latex glove placed over the mask with a central hole cut for the bird's neck. Although some have suggested that this seal can be used for positive pressure ventilation, it is not recommended by these authors. In addition to increased waste gas release, this technique will introduce gas into the gastrointestinal tract. Facemask induction in some birds (i.e., waterfowl) is associated with apnea and bradycardia that may last for 3–5 minutes (Ludders & Matthews 1996). This response may even occur from placing a facemask snugly onto the face and beak without inhalant anesthetic. This response is a stress response that appears to be mediated by stimulation of trigeminal nerve receptors in the beak and nares of diving ducks (Butler 1988; Jones et al. 1988; Woakes 1988). Premedication with a benzodiazepine may avert this response. If this response occurs, discontinue inhalation anesthesia, remove the mask, and provide 100% oxygen until bradycardia resolves.

Commercially available induction chambers sized for mice up to small dogs can be utilized for birds as small as hummingbirds. Advantages of these chambers are reduced waste gas and shorter induction times. In stressed birds, the chamber is covered with a towel to darken the chamber. Alternatively, an animal carrier or the front of a hospital cage is sealed with a plastic bag and inhalant anesthetic administered for induction of large or stressed patients. Disadvantages of induction chambers include the inability to auscult the patient, gas pollution when the chamber is opened, and trauma due to flapping during the excitement phase of anes-

thesia. The latter is reduced by padding the induction chamber and minimizing chamber size to reduce movement. Gas flow rates are adjusted to chamber size to provide an optimum rate of rise of the anesthetic concentration. This might be as low as 0.5L/min for a 1L up to 15L/min for a 60-L chamber. The efficiency of the respiratory system makes high inhalant induction concentrations unnecessary. For example, isoflurane vaporizer settings rarely need exceed 3%. The bird is promptly removed after the righting reflex is lost. The final phase of the induction is accomplished using a mask to facilitate monitoring.

Vascular Support

During anesthesia or emergencies, intravenous (IV) or intraosseous (IO) fluids are used to provide replacement fluids. Sites for IV catheters include the basilic (ulnar), medial metatarsal, or jugular veins (Fig. 24.4). Small-bore over-the-needle catheters (≤ 24 gauge) are used. If blood is to be repetitively collected from the catheter, it should be placed in either the jugular (small patients) or a large peripheral vessel. The increased fragility of avian blood vessels, the lack of soft tissue support and patient temperament make catheter maintenance difficult. The catheter site is gently plucked and aseptically prepared. Catheters are secured with a bandage tape butterfly and sutured with an everting mattress pattern. The catheter site is bandaged for additional security. Complications of long-term, indwelling catheterization include infection and possibly fatal hemorrhage. Jugular catheters require 24-hour monitoring because fatal hemorrhage can occur if the bird pulls or chews on the catheter and damages the vessel.

Intraosseous catheterization is used in smaller patients or during cardiovascular collapse (Aguilar et al. 1993; Lamberski & Daniel 1992; Ritchie et al. 1990; Valverde et al. 1993). IO catheter maintenance is easier to achieve due to stability in the medullary cavity. Products that can be utilized include 18- to 24-gauge, 2- to 5-cm spinal needles, or 18- to 25-gauge 2-cm hypodermic needles. The length of the catheter should be long enough to extend 1/3 to 1/2 the length of the medullary cavity. A wire stylet may be necessary with hypodermic needles to reduce the potential for a bone core. Most commonly used sites include the distal ulna and proximal tibiotarsus. Pneumatic bones (i.e., the humerus and femur) are avoided. Feathers are gently plucked and the site surgically prepared. Wearing gloves, the sterile IO catheter is positioned at the center of the cnemial crest of the tibiotarsus or slightly ventral to the dorsal condyle of the distal ulna and parallel to the bone. The bone is held firmly with one hand while the other applies firm pressure combined with slight rotation (Fig. 24.5). Once the cortex is penetrated, the catheter should advance easily with little resistance. If there is further resistance, the opposite cortex has most likely been penetrated. The cannula is flushed with heparinized saline and should flow easily. Fluids will be seen flowing through the basilic vein when the cannula is correctly placed in the distal ulna. The insertion site is covered with antibiotic ointment and the cannula secured with a bandage tape butterfly at the exit point in the skin and sutured. A bandage can be placed over the cannula site for additional security to prevent trauma or damage to the catheter. Although IO catheters are reported to remain patent for 72 hours without flushing (Ritchie et al. 1990), it is recommended that the catheter be gently flushed with heparinized saline twice daily.

Complications associated with IO catheterization include penetration of both cortices, failure to properly enter the medullary cavity, and extravasation of fluids with associated pain. Extravasation has been observed even with proper catheter placement after 1–2 days of use (Steinohrt 1999). Intraosseous catheterization is contraindicated in septic patients and those with metabolic bone disease. Osteomyelitis may occur due to duration or placement of the IO catheter (Steinohrt 1999). Administration of alkaline or hypertonic solutions may also contribute to osteomyelitis and will cause pain and transient microscopic changes in the bone marrow (Lamberski & Daniel 1992; Ritchie et al. 1990). These solutions are, therefore, diluted prior to administration and the catheter is flushed with heparinized saline after any drug injection.

Crystalloid fluids (e.g., 0.9% NaCl [Baxter, Deerfield, IL], lactated Ringer's [Abbott Laboratories, North Chicago, IL], Normosol-R [CEVA Laboratories, Overland Park, KS], and Plasmalyte-A [Baxter]) are commonly used for IV volume support, maintenance, and

rehydration. Fluids are warmed to body temperature (38–39°C) to prevent hypothermia.

Fluid rates of 10 mL/kg/h are recommended for healthy anesthetized patients. This rate is based on studies in human patients. While this is a starting point, it is recognized that rates in very small patients may need to be considerably higher, but caution should be exercised to not fluid overload small patients. Each patient is assessed individually for their fluid needs. Fluid boluses of 10–20 mL/kg over 5–7 minutes are well tolerated (Abou-Madi & Kollias 1992). For severe hemorrhage, whole blood transfusion (volume for volume) should be provided. If this is not available, it has been recommended to provide crystalloid fluids at 3× the volume of blood loss. However, this recommendation is based on mammals where the interstitial space is 2× the vascular volume. In birds, the interstitial space is 4× plasma volume (Skadhauge 1981). Replacement fluid volumes may need to be greater than 3× blood loss. Dextrose solutions are added to fluids for treatment of hypoglycemia. Parenteral dextrose use is minimized to prevent compartmental shifts in electrolytes and water leading to hypovolemia (Abou-Madi & Kollias 1992).

Hypertonic fluids (e.g., 7.5% NaCl) are used to expand intravascular volume during resuscitation following acute severe hemorrhage. Hypertonic saline has been evaluated in birds primarily for studying renal sodium excretion and the role of osmotic thirst in the control of normal drinking. In several studies, plasma osmolality increased after bolus infusion (Leary et al. 1998; Yeomans & Savory 1988). The major benefit of hypertonic saline is intravascular volume expansion at one-fourth the volume of isotonic solutions. The mammalian dosage (4 mL/kg) given over 10 minutes is used in birds. However, due to osmotic diuresis and rapid redistribution of sodium cations, the intravascular effect is transient (<30 minutes) and additional fluid therapy with a crystalloid or colloid must be used. Hypertonic fluids are contraindicated in dehydration, hypernatremia, and head trauma with intracranial hemorrhage. The sustained use of hypertonic saline is not recommended because hypernatremia and hyperchloremic acidemia, increased bleeding, and exacerbation of underlying cardiac and pulmonary disease due to fluid overload may occur.

Small patient size and species diversity often preclude the use of natural colloids, such as homologous or heterologous plasma. The indications for the use of synthetic colloids (e.g., hetastarch 6%, Hextend and hemoglobin-based oxygen carriers) are the same as hypertonic saline although the benefits last longer. All are cleared through the kidneys so they are used with caution in patients with cardiac or renal impairment. They do not provide albumin, thrombocytes, or coagulation factors. Potential adverse effects include anaphylactoid reactions and blood coagulation abnormalities.

Figure 24.5. Intraosseous (IO) catheter placement in the distal ulna of a bird. Strict asepsis should be observed when placing the catheter. Feathers over the site should be gently plucked and the site should be surgically prepared (a). Wearing sterile gloves, the sterile catheter is positioned slightly ventral to the dorsal condyle of the distal ulna and parallel to the bone (b). The bone is held firmly with one hand while the other applies firm pressure combined with slight rotation (c). The cannula should be flushed with heparinized saline and should flow easily (d). The insertion site should be covered with an antibiotic ointment and the cannula should be secured with a bandage tape butterfly at the exit point in the skin and suture (d). A bandage can be placed over the cannula site for additional security and to prevent possible trauma or damage to the catheter (e).

In critically ill raptors, boluses of hetastarch (10–15 mL/kg 6%, q 8 h) for four or more treatments were well tolerated (Stone & Redig 1994). Alternatively, dosages ≤ 20 mL/kg/d are suggested.

Reported circulating blood volume % based on body weight varies considerably (Campbell et al. 1994): 5% in ring-necked pheasants (Campbell et al. 1994), $7.5 \pm 1.5\%$ in quail (Takei & Hatakeyma 1987), 16.3–20.3% in the racing pigeon (Campbell et al. 1994), $10.6 \pm 2.9\%$ in the galah (Jaensch & Raidal 1998), and $5.4 \pm 10.5\%$ and $13.1 \pm 2.3\%$ in two strains of chickens (Makinde et al. 1986). Hemorrhage is better tolerated than in mammals. However, when severe ($>30\%$ blood volume) or the PCV $<20\%$, whole blood transfusion is indicated. Heterologous blood cells (e.g., from pigeon, chicken) transfused into parrots last only 12 hours, causing a significant metabolic drain on the recipient as the body utilizes energy to destroy the foreign cells (Finnegan et al. 1997; Sandmeier et al. 1994). The half-life of homologous and autologous blood transfusions were 8.5 and 9.9 days in conures (*Aratinga* spp.), (Degernes & Crosier 1999), 12.5 and 12.2 days in cockatiels (*Nymphicus hollandicus*), (Degernes et al. 1999), and 7.1 and 26.8 days in pigeons, respectively (Sandmeier et al. 1994). In pigeons, PCV and total solids were elevated for ≥ 102 hours following homologous transfusion. (Finnegan et al. 1997)

The storage of whole blood or blood products has been little studied to date (Morrisey et al. 1997), and transfusions with fresh whole blood are recommended. The anticoagulants citrate phosphate dextrose adenine (CPDA-1) and acid citrate dextrose (ACD) are used most commonly at a ratio of 1 : 9 whole blood : anticoagulant. If given rapidly, the citrate can decrease ionized calcium and decrease myocardial contractility. It may be necessary to give calcium gluconate or chloride to the patient to reverse this effect. Donors are screened for infectious diseases. A major/minor crossmatch is performed prior to transfusion. Sixty-six percent of major crossmatches performed between different species were positive for agglutination or hemolysis, whereas between the same species, they were all negative (Stauber et al. 1996). Mammalian protocols are presently followed for blood collection and administration. Pediatric blood filters have been evaluated for their ability to cause hemolysis in chicken blood and an 18- μ M filter did not cause hemolysis compared with nonfiltered control (Jankowski & Nevarez 2010).

There is little published information available on the safety and efficacy of hemoglobin-based oxygen carriers (HBOC). Evaluation of the effects of fluid resuscitation in an acute blood loss (60% blood volume) model in ducks (*Anas platyrhynchos*) showed decreased mortality in birds receiving HBOC combined with crystalloid fluids. The comparison groups received hetastarch combined with crystalloid fluids and crystalloid fluids alone (Lichtenberger et al. 2003). HBOC has a

Figure 24.6. In order to provide accurate infusion rates for small avian patients, fluid infusion pumps and syringe pumps are most commonly required.

short half-life in mammals (30–40 hours). Adverse effects in mammals include discolored mucous membranes, sclera, and urine, affecting patient monitoring (Antinoff 2003; Lichtenberger 2004). Rapid bolus infusion (5-mL/kg HBOC and 10-mL/kg crystalloid fluids over 1 minute) has been given in patients with acute blood loss without any adverse effects (Lichtenberger et al. 2001, 2002, 2003).

Standard micro-drip fluid sets used in small animal veterinary practice (60 drops/mL) will not allow appropriate infusion rates in very small patients. Instead, fluid infusion and syringe pumps are used for accurate fluid administration (Fig. 24.6).

PREANESTHETICS

Parasympatholytics

Several authors question the necessity of routine medication with parasympatholytics (Table 24.2). Atropine and glycopyrrolate reduce mucus production and plug formation, but increase viscosity (Ludders & Matthews 1996). Additionally, some practitioners avoid using anticholinergics in birds because they increase heart rate, cardiac work, and myocardial oxygen demand. Therefore, the use of these agents should be weighed against their potential side effects.

Sedatives and Tranquilizers

Sedatives and tranquilizers are used to decrease anxiety and fear during induction. However, most tranquilizers lack analgesia. Additionally, most require injection and the handling and restraint may be as much as required for anesthetic induction. The merits of premedication must be weighed against this additional stress.

Table 24.2. Injectable premedication/emergency, sedative, tranquilizer, and anesthetic drugs used in cagebirds

Drug	Dosage (mg/kg)	Route	Indication(s)	Comments	References
<i>Benzodiazepines</i>					
Diazepam	0.2–2.0	IM, IV	Most species. Premedication, sedation, anticonvulsant, appetite stimulant	IM administration may cause severe muscle irritation and absorption may be delayed 0.25–0.5 mg/kg has been used as an appetite stimulant and to improve acceptance to novel captive diets for raptors and wild passerines Reversal with flumazenil	Abou-Madi (2001); Samour (2000); Clyde & Paul-Murphy (1999); Rupiper & Ehrenberg (1994); Suarez (1993); Massey (2003)
	2.5–4.0 7.3–8.0	PO IN	Most species/sedation Canaries	Dose divided into each nares and given slowly. Dorsal recumbency for approx. 35 minutes.	Ritchie et al. (1994) Vesal and Eskandari (2006); Vesal and Zare (2006)
<i>Midazolam</i>					
				In larger macaws, the author's have noted regurgitation after doses of >0.3–0.5 mg/kg IM. Water soluble; does not cause muscle irritation with IM use.	
	0.1–2.0	IM, IV	Most species/ premedication, sedation, appetite stimulant	Reversal with flumazenil IM onset 5–15 minutes. Higher dosages may cause profound sedation.	Abou-Madi (2001); Day and Roge (1996)
	2.0–6.0	IM	Quail, sedation	High dosages give greatest sedation without cardiopulmonary effects, but adequate sedation also found with lower dosages, just shorter duration of sedation.	Day and Roge (1996)
	2.0 2.0	IM IN	Canada geese/sedation Hispaniolan Amazon parrots	For 15–20 minutes Mild-to-moderate sedation in 3 minutes; reduced vocalizations, struggling and defensive behaviors for 15 minutes; reversed with IN flumazenil	Valverde et al. (1990) Mans et al. (2010)
	7.3–8.0	IN	Canaries, ring-necked parakeets.	Dose divided into each nares and given slowly. Dorsal recumbency for approximately 17 minutes. Flumazenil reduced time to recovery.	Vesal and Eskandari (2006); Vesal and Zare (2006)
<i>Flumazenil</i>					
	0.02–0.10	IM, IV	Most species.	Benzodiazepine reversal agent.	Abou-Madi (2001); Day and Roge (1996); Machin and Caulkett (1998)
	0.05 0.13–0.15	IN IN	Mallard ducks Canaries, ring-necked parakeets.	Dose divided evenly between nares and given slowly.	Machin and Caulkett (1998b) Vesal and Eskandari (2006)

(Continued)

Table 24.2. (Continued)

Drug	Dosage (mg/kg)	Route	Indication(s)	Comments	References
<i>α-2 Adrenergic agonists</i> Detomidine	0.3	IM	Rock partridges	Marked sedation/significant decrease in HR, RR, decrease in cloacal temperature, prolonged recoveries (260 ± 18 minutes)	Uzun et al. (2006)
	12	IN	Ring-necked parakeets	Dose divided into each nare and given slowly; sedation <3 minutes but did not allow dorsal recumbency or manipulation; reversal with atipamezole significantly reduced time to recovery	Vesal and Eskandari (2006)
	12–15	IN	Canaries	Dose divided into each nare and given slowly; higher dose prolonged sedation but could not place in dorsal recumbency; prolonged duration of effect (258 ± 2 minutes) but completely reversed with yohimbine IN	Vesal and Zare (2006)
Dexmedetomidine				Use half the recommended dose of medetomidine. Reversal with same dose of atipamezole	
	0.025	IM	Common buzzards	Adequate restraint to prevent reaction to handling, but did not allow for intubation. Completely reversed with atipamezole. Mean times to loss of righting reflex = 3.5 ± 1 minutes in common buzzards. No arrhythmias noted on ECG. No excitement or major adverse effects observed in either group.	Santangelo et al. (2009)
	0.075	IM	Common kestrels	Adequate restraint to prevent reaction to handling, but did not allow for intubation. Completely reversed with atipamezole. Mean times to loss of righting reflex = 7 ± 1.2 minutes in common kestrels.	Santangelo et al. (2009)
Medetomidine	0.2–2	IM	Pigeon, yellow-crowned Amazon	0.08–2 mg/kg IM associated with inadequate sedation. Profound respiratory depression may occur. Much higher dosages appear to be required in some avian spp. when compared with mammals.	Pollock et al. (2001); Sandmeier (2000)
	0.25–0.35	PO	Chickens	Sedation	James et al. (1999)
Xylazine	1.0–10.0	IM, IV	Most species, combination with ketamine for anesthesia.	Not recommended by itself for tranquilization and seldom used in pet birds due to adverse effects—excitement, convulsions, bradycardia, arrhythmias, bradypnea, hypoxemia, hypercarbia, and death when used alone; most useful in raptiles	Clyde and Paul-Murphy (1999); Carpenter (2000); Huckabee (2000); Ludders et al. (1989a); Samour (2000)
				Adequate sedation often with <4 mg/kg, in smaller psittacines dosages up to 10 mg/kg may be required.	

α_2 Adrenergic antagonists
Atipamezole

α_2 -adrenergic antagonist; 1 : 1 volume reversal of dexmedetomidine/medetomidine is general rule; although the same effects would be expected as with medetomidine, there are no data available on the efficacy of atipamezole reversal of dexmedetomidine in birds

0.25–0.5	IM	Psittacines, pigeons, raptors, geese	Righting reflex regained 2–10 minutes after administration	Machin and Caulkett (1998a); Samour (2000); Pollock et al. (2001); Santangelo et al. (2009) James et al. (1999)
1.3–1.6	IV	Chickens		Machin and Caulkett (1998a)
0.18–0.28	IV	Mallard ducks		Vesal and Eskandari (2006)
6.0	IN	Ring-necked parakeets	Dose divided evenly between nares and given slowly, significantly reduced recumbency time after detomidine administration	

Yohimbine

0.1–0.2	IV	Psittacines, raptors, waterfowl, ratites	Reversal for xylazine.	Carpenter (2000); Heard (1997); Jensen et al. (1992); Keffen (1993); Raath et al. (1992); Samour (2000) Teare (1987)
1.0	IV	Most species including psittacines, guinea fowl		

0.1–0.2	IM, IV	Raptors		Huckabee (2000)
0.11–0.275	IM	Budgerigars		Heaton and Brauth (1992)
0.1–1.0	IM	Most species		Abou-Madi (2001)

Dissociative anesthetics

Ketamine

Usually combined with an alpha-2 adrenergic or with a benzodiazepine to improve relaxation, depth of anesthesia.
Not recommended as a sole anesthetic agent due to reports of poor muscle relaxation, myoclonic contractions, opisthotonus and violent recoveries
Smaller sp require a higher dose, large birds tend to recover more slowly.

20–50	SC, IM, IV	Psittacines, pigeons, ratites, poultry, waterfowl. Restraint 30–60 minutes		Beynon et al. (1996); Fowler (1995); Heard (1988); Jensen et al. (1992); Lawton (1996); Samour (2000)
50	IO	Pigeons	Provided effective analgesia	Kamiloglu et al. (2008)
5–30	PO	In bait, for ducks		Forbes (1991)
50–100	PO	In bait for raptors		Samour (2000)

Prolonged recoveries with moderate-to-severe excitatory CNS signs may occur in these species with an infusion Recovery times (15.4 ± 15.2 minutes) were prolonged when compared with isoflurane; 6/10 birds had agitated recoveries. Light anesthetic plane in 8/10 birds Smooth inductions, minimal excitation on recovery	Mostachio et al. (2008) Ajadi et al. (2009) Hawkins et al. (2003) Langlois et al. (2003) Schumacher et al. (1997) Machin and Caulkett (1998b, 1999) Muller et al. (2011)

Notes: These are suggested dosages based upon published information and the author's clinical experience. Species and individual variation in response to a given drug can be uncertain so the dosage should be adjusted depending upon the clinical response of the animal.

Benzodiazepines Diazepam may cause excitement, tachycardia, and tachypnea in birds if given IV. Uptake of diazepam from IM or SC injection is erratic. Midazolam (0.2–2.0 mg/kg IM) has been used as a sole sedative for minor, nonpainful procedures (i.e., radiographs) (Valverde et al. 1990). Low doses are most often used for preanesthetic sedation. In pigeons, midazolam (14–16 mg/kg IM) induced profound sedation and reduced isoflurane MAC by approximately $\frac{1}{3}$ (Smith & Muir 1992; Smith et al. 1993). In quail, midazolam (2–6 mg/kg IM) produced chemical restraint and 40–60 minutes of sedation at the higher doses (Day & Roge 1996). In ring-necked parakeets (*Psittacus krameri*), midazolam administered intranasally alone or in combination with ketamine produced sedation that allowed dorsal recumbency and adequate sedation for minor procedures (Vesal & Eskandari 2006). Intranasal administration of midazolam (0.5 mg/kg) has been used by clinicians to facilitate beak trimming and sample collection in macaws (D. Heard, pers. comm. May 28, 2012). Sedation duration is significantly reduced after flumazenil administration. The authors recommend titrating the dose to avoid the reversal of the beneficial anxiolysis, sedation, and muscle relaxation.

Midazolam IM did not produce major alterations in cardiopulmonary function in Canada geese (Valverde et al. 1990), quail (Day & Roge 1996), and racing pigeons (Smith & Muir 1992; Smith et al. 1993). Midazolam/ketamine IV produced anesthesia with full recovery in 23 minutes in ducks (Machin & Caulkett 1998b). Two authors (MGH/AMZ) have observed midazolam (0.25–1.0 mg/kg IM) associated regurgitation in larger macaws and cockatoos. Some animals did not stop until after flumazenil administration. Benzodiazepines should either be avoided in these species, or a lower midazolam dose be used and the patient closely monitored for regurgitation.

Alpha-2 Adrenergic Agonists Xylazine and medetomidine are most commonly reported alpha-2 adrenergic agonists in birds. However, as the use of dexmedetomidine supplants that of medetomidine, more information on the use of this newer agent will be available. Since 2007, dexmedetomidine has been approved for veterinary use in the United States. This drug is the dextro-enantiomer of medetomidine and has twice the potency of the racemic mixture, medetomidine, since levomedetomidine has no action at alpha-2 receptors. To aid dosing for practitioners, dexmedetomidine (0.5 mg/mL) is supplied at half the concentration of medetomidine (1.0 mg/mL), and dosing charts are available for dogs and cats. One study has examined the use of dexmedetomidine in two raptor species at a dose of approximately 25 μ g/kg for common buzzards (*Buteo buteo*) and 75 μ g/kg for common kestrels (*Falcon tinnunculus*) (Santangelo et al. 2009). The authors noted loss of righting in both species within approximately 8

minutes and sedation was sufficient to allow handling. In the study mentioned earlier, atipamezole was used for reversal at a total dose of 250 μ g and provided rapid reversal of sedation. It should be noted atropine was administered in conjunction with dexmedetomidine in this study, which has been reported to cause increases in mean arterial blood pressure, heart rate, and the occurrence of cardiac arrhythmias in dogs and is not recommended for coadministration with dexmedetomidine (Congdon et al. 2011).

The major advantage of these agents is they can be reversed with atipamezole, yohimbine, or tolazoline. Alpha-2 adrenergic agonists can have profound cardiopulmonary effects, including respiratory depression, second-degree heart block, bradyarrhythmias, and increased sensitivity to catecholamine-induced cardiac arrhythmias (Altman 1980; Paul-Murphy & Fialkowski 2001; Ludders & Matthews 1996; Machin & Caulkett 1998b; Maiti et al. 2006; Varner et al. 2004). When used alone at high doses, xylazine is associated with respiratory depression, excitement, and seizure activity (Machin & Caulkett 1998b; Paul-Murphy & Fialkowski 2001; Ludders & Matthews 1996; Varner et al. 2004) and is not recommended for sedation. In Pekin ducks, xylazine produced significant respiratory depression, resulting in hypoxemia and hypercapnia and behavioral changes (i.e., moving, paddling, and picking at their enclosures) that lasted ≤ 45 minutes (Ludders et al. 1989b). In mallard ducks, xylazine/ketamine/midazolam IV resulted in cyanotic membranes and apnea in three; two died and the surviving animal was reversed with atipamezole (Machin & Caulkett 1998a). Xylazine (10 mg/kg) in rock partridges produced profound sedation only 2–5 minutes post administration and marked hypoventilation, but did not produce a significant decrease in heart rate (Uzun et al. 2006). In roosters undergoing typhlectomy, xylazine (3 mg/kg) induced a loss of righting response in 3–4 minutes. When diazepam (4 mg/kg) and ketamine (25 mg/kg) were given subsequently, significant decreases in heart rate, respiratory rate and cloacal temperature were observed. A lack of response to painful stimulus was maintained for approximately 1 hour (Mostachio et al. 2008). Xylazine was also evaluated in guinea fowl in combination with ketamine. The addition of midazolam to the combination appeared to improve the duration and quality of analgesic effect (Ajadi et al. 2009).

Much higher dosages of medetomidine appear to be required compared with mammals. In pigeons and yellow-crowned Amazon parrots, medetomidine (2 mg/kg IM) alone did not induce reliable sedation (Sandmeier 2000). Similarly, in pigeons, medetomidine (0.2 mg/kg) alone produced only moderate sedation, but significant bradycardia and bradypnea (Pollock et al. 2001). Also in pigeons, a medetomidine (0.2 mg/kg), butorphanol, ketamine combination produced profound sedation. However, significant bradycardia,

bradypnea, and hypothermia were observed (Atalan et al. 2002). Arrhythmias in 3/8 pigeons resolved after atipamezole reversal.

In mallard ducks, medetomidine/midazolam/ketamine provided anesthesia and analgesia for 30 minutes duration when given IV, but not IM (Machin & Caulkett 1998a). Also in ducks, medetomidine/midazolam/ketamine IV produced respiratory depression, apnea, and acidemia; 1 of 12 died and 3 required assisted ventilation (Machin & Caulkett 1998a). Very high medetomidine dosages (≤ 10 mg/kg) in mallard ducks did not increase sedation over 0.2 mg/kg (Machin & Caulkett 1998a). One clinician reported seizures in canvasback ducks with medetomidine IV (N. Caulkett, pers. comm. May 28, 2012).

Since medetomidine appears to require combination with other injectable drugs for reliable effect, the advantages of rapid and smooth reversal with atipamezole are negated. Although the mammalian dosage of atipamezole ($5\times$ the medetomidine dose) has been shown to exhibit excellent reversal in some birds (Machin & Caulkett 1998b), a lower ratio ($2.5\times$) also produces effective reversal (Machin & Caulkett 1998b; Sandmeier 2000). Based upon the many adverse effects and disadvantages reported for this class of drugs in birds, it is recommended they be used with great caution. It should also be noted that doses provided in this chapter for medetomidine can be used at half the value if using dexmedetomidine.

INJECTABLE ANESTHETICS

There are several situations in which injectable anesthetics are preferable to inhalants (Table 24.3). Surgeries involving the beak, mouth, glottis, or trachea are complicated by the presence of an endotracheal tube. Surgery within the coelomic cavity, respiratory system, or pneumatic bones exposes personnel to high levels of inhalant anesthetics. It is also more difficult to maintain a consistent plane of anesthesia using injectable agents. Injectable anesthetics are more commonly used in the field due to the ease of transport compared with inhalant anesthetic delivery equipment.

Many injectable drugs are highly variable in their effects between species and individuals (Machin & Caulkett 1998b; Samour et al. 1984). Some of these effects may include poor induction, inadequate muscle relaxation, cardiopulmonary depression, and prolonged or violent recoveries (Langlois et al. 2003; Ludders & Matthews 1996; Samour et al. 1984). Different delivery routes also affect efficacy and dosage. For example, in mallard ducks, IM administration of many anesthetics is not effective, suggesting poor drug uptake from the pectoral musculature. Also, no effect was identified when evaluating many drugs given intranasally to mallard ducks (Machin & Caulkett 1998b). Elimination of injectable anesthetics depends upon

drug distribution, and hepatic and/or renal biotransformation and excretion (Paul-Murphy & Fialkowski 2001). Due to the potential for side effects, patients must be weighed accurately and monitored closely.

Dissociative Anesthetics

Ketamine alone is not recommended due to poor muscle relaxation, myoclonic contractions, opisthotonus, and violent recoveries. It is usually combined with an alpha-2 adrenergic agonist or benzodiazepine to improve relaxation and anesthetic depth (Muir 1988). Ketamine may produce convulsions, excitation, and salivation in vultures, but these signs are rarely observed in other species (Muir 1988; Salerno & van Tienhoven 1976). Ketamine/alpha-2 adrenergic and ketamine/benzodiazepine combinations are used for short procedures (i.e., physical examination and minimally painful diagnostics) or induction as part of balanced anesthesia (Borzio 1973; Boever & Wright 1975; Kollias & McLeish 1978; Machin & Caulkett 1998b; McGrath et al. 1984; Raffe et al. 1993; Redig & Duke 1976; Vesal & Eskandari 2006).

Intramuscular (IM) administration of ketamine induces immobilization within 5–10 minutes and lasts for 5–20 minutes, with recovery in 40–100 minutes. These times are dependent upon size, dose given, body temperature, and health status (Paul-Murphy & Fialkowski 2001). In mallard ducks, midazolam/ketamine IV produced anesthesia with recovery in 23 minutes (Machin & Caulkett 1998b). In chickens, ketamine (120 mg/kg IM) produced no significant change in respiratory rate, but did induce bradycardia (Salerno & van Tienhoven 1976). As noted earlier, ketamine (15 mg/kg IM) in combination with xylazine (2.5 mg/kg IM) produced lateral recumbency in 3 minutes that lasted approximately 56 minutes in guinea fowl. The duration of recumbency was significantly longer (91 minutes) with the addition of midazolam (0.3 mg/kg IM) (Ajadi et al. 2009). In red-tailed hawks (*Buteo jamaicensis*), ketamine (30 mg/kg IM) produced no significant effect, compared with awake birds, in arterial blood gas, or acid-base values, but did produce mild hyperventilation (Kollias & McLeish 1978). The effects of IO versus IM administration of ketamine were compared in domestic pigeons and both the onset of anesthesia and recovery times were found to be shorter with IO administration. Heart rate decreased significantly in both groups (Kamiloglu et al. 2008).

Propofol

In pigeons (Fitzgerald & Cooper 1990) and chickens (Lukasik et al. 1997), propofol had a very narrow margin of safety and respiratory depression. However, at much lower dosages in turkeys (Schumacher et al. 1997) and mallard ducks (Machin & Caulkett 1998b), propofol is effective and safe if cardiopulmonary function is monitored and ventilatory support provided. Further research

Table 24.3. Analgesic drug dosages commonly used in birds

Drug	Dosage (mg/kg)	Route	Frequency	Species	Comments	References
OPIOID and OPIOID-like medications						
Butorphanol	0.5	IM, IV	Single	Red-tailed hawks; great horned owls	Very short $T_{1/2}$ by both IM and IV administration (approximately 1–2 hours). Shorter when given in m. metatarsal v. compared with m. ulnar v.	Riggs et al. (2008)
	2.0	IV	Single	Domestic chickens	Remained above minimum effective concentration for analgesia in mammals for approximately 2 hours.	Singh et al. (2011)
	1.0–5.0	IM	Single	Hispaniolan Amazon parrots; African gray parrots	Withdrawal thresholds to electrical stimuli reduced after 2 mg/kg IM for 2 hours	Guzman et al. (2011); Paul-Murphy et al. (1999); Sladky et al. (2006)
	20–50 $\mu\text{g}/\text{kg}/\text{min}$	IV	CRI		MAC reduction in psittacines with 3-mg/kg loading dose	
Buprenorphine	0.01	IM	Single	African gray parrots	May not achieve plasma concentrations at this dose; no change in withdrawal response to noxious stimuli	Paul-Murphy et al. (1999, 2004)
	0.25–0.50	IM	Single	Domestic pigeons	Decreased withdrawal from noxious stimulus for 2 hours (0.25 mg/kg) and 5 hours (0.5 mg/kg)	Gaggermeier et al. (2003)
Fentanyl	0.02–0.2	SC	Single	Cockatoos	Affected withdrawal threshold in some birds, hyperactivity noted	Hoppes et al. (2003)
	0.2–0.5 $\mu\text{g}/\text{kg}/\text{min}$	IV	CRI	Red-tailed hawks	Reduced isoflurane MAC 31–55% in a dose-related manner, without significant effects on HR, blood pressure, PaCO_2 , or PaO_2	Pavez et al. (2011)
Nalbuphine	12.5	IM	Single		Excellent IM bioavailability; 12.5 mg/kg produced 3 hours analgesia; higher doses did not increase analgesic time	Keller et al. (2011); Sanchez-Migallon Guzman et al. (2011, 2013a)
Tramadol	7.5	PO	Single	Peafowl	Maintained human therapeutic concentrations for 12–24 hours (M1 metabolite)	Black et al. (2010)
	15.0	PO	q12h	Red-tailed hawks	Based on 11 mg/kg single dose	Souza et al. (2011)
	5.0	PO	q12h	American bald eagles	PO bioavailability high, based on 11-mg/kg single dose	Souza et al. (2009)
	30	PO	Single	Hispaniolan Amazon parrots	Reduced thermal withdrawal response for approximately 6 hours	Sanchez-Migallon Guzman (2012)

(Continued)

Table 24.3. (Continued)

Drug	Dosage (mg/kg)	Route	Frequency	Species	Comments	References
NSAIDs						
Carprofen	1.0	IM	Single	Chickens	Use caution in <i>Gyps</i> vultures Improved locomotion of lame birds 1 hour post treatment	Cuthbert et al. (2007) McGeowen et al. (1999)
	30.0	IM	Single	Chickens	Painful behaviors (arthritis) reduced for 1 hour	Hocking et al. (2005)
	3.0	IM	Q12h	Hispaniolan Amazon parrots	Arthritis pain partially reduced for <12 hours	Paul-Murphy et al. (2009b)
Ketoprofen					Avoid in Gyps vultures; mortalities associated with clinical doses	Naidoo et al. (2010)
	2.0	IV, IM, PO	Single	Quail	Low IM, PO bioavailability	Graham et al. (2005)
	12	IM	Single	Chickens	Painful behavior reduced for 1 hour	Hocking et al. (2005)
	5.0	IM	Single	Mallard ducks	12-hour activity noted	Machin et al. (2001)
	0.1–0.5	IV	Single	Chickens, ostrich, ducks, turkeys, pigeons	Half-life in chickens and pigeons was three times as long as for ostrich, ducks and turkeys	Baert and De Backer (2003)
Meloxicam	2.0	IM, then PO	q 12 h	Pigeons	Provided analgesia postosteotomy for 9 days	Desmarchelier et al. (2012)
	1.0	IM	q 12 h	Hispaniolan amazon parrots	Improved weight bearing on arthritic limbs	Cole et al. (2009)
Piroxicam	2.0	IM, PO	Single	Cape Griffon vultures	Short $T_{1/2}$, less than 45 minutes	Naidoo et al. (2008)
	0.5–0.8	PO	q 12 h	Whooping cranes	Used for acute myopathy and chronic arthritis	J. Paul-Murphy, pers. comm. May 28, 2012
Sodium salicylate	100–200	IM	Single	Chickens	Arthritis painful behaviors partially reduced for 1hr	Hocking et al. (2005)
	25	IV	Single	Chickens, ostrich, ducks, turkeys, pigeons	Rapid clearance except long $T_{1/2}$ in pigeons	Baert & De Backer (2003)
Local anesthetics						
Bupivacaine	2–8	Peri-neural		Mallard ducks	Variable effectiveness for brachial plexus nerve block	Brenner et al. (2010)
Lidocaine	1–3	Local		Most species	Incision site infusion	Toxic effects have been documented in birds at doses of 2.7–3.3 mg/kg
Ropivacaine	7.5	Peri-neural		Chickens	Successful brachial plexus block in 15 minutes, approximately 110 minutes of anesthesia	Cardozo et al. (2009)

Notes: These are suggested dosages based upon published information and the author's clinical experience. Species and individual variation in response to a given drug can be uncertain so the dosage should be adjusted depending upon the clinical response of the animal.

has confirmed it produces a rapid and smooth anesthetic induction. However, respiratory depression and significant apnea are common (Hawkins et al. 2003; Langan et al. 2000; Langlois et al. 2003; Machin & Caulkett 2000). In mute swans, propofol provided as a CRI was compared with multiple boluses for short procedures. The overall dose provided by boluses was lower, but the anesthesia was less predictable and the birds were prone to sudden awakening. On recovery, about 50% of the birds in both groups demonstrated a few minutes of excitement. Notably, these birds were maintained on room air, but did not experience a significant change in SpO₂ (Muller et al. 2011). However, ventilatory support is recommended for any bird anesthetized with propofol, regardless of whether bolus or constant rate infusion (CRI) techniques are utilized. Prolonged recovery, with or without moderate-to-severe CNS excitatory signs, has been reported, particularly after the use of a CRI (Hawkins et al. 2003; Langan et al. 2000; Langlois et al. 2003). However, one study evaluating its use in the field showed smoother recoveries than with isoflurane anesthesia (Machin & Caulkett 2000). The need for ventilatory support and the potential for excitatory and/or prolonged recoveries limit its use as a sole anesthetic. However, it has been proposed balanced anesthesia may produce propofol-sparing effects that may reduce these disadvantages (Langlois et al. 2003). The authors suggest a calculated propofol dose be given in 1/4 increments each administered over 30–60 seconds. This will allow more accurate dosing and minimize apnea and hypotension.

Inhalant Anesthetics

Inhalant anesthetics offer rapid induction and recovery, the ability to rapidly change anesthetic depth, and their use does not require an accurate body weight. Very little of the agent is metabolized, reducing the impact on hepatic and renal function, and recovery is independent of either. Disadvantages include pollution of the work environment and the expense of the anesthetic and associated equipment.

The minimum anesthetic concentration (MAC) necessary to prevent purposeful movement in response to a noxious stimulus in 50% of the patients is used as a measure of inhalant anesthetic potency. MAC for many species is very similar; most birds require approximately the same concentration of inhaled anesthetic for an equivalent amount of stimulation as mammals.

Halothane Halothane sensitizes the myocardium to catecholamine-induced arrhythmias in birds as it does in mammals (Naganobu et al. 2001). These arrhythmias occur especially during induction and recovery when catecholamine release is high. Halothane depresses the responsiveness of the avian IPC to CO₂. Thus, halothane anesthetized birds may have a depressed ability to adjust ventilation in response to changes in PCO₂

(Pizarro et al. 1990). Hypercapnia, ECG abnormalities, and hypothermia were more marked in galahs (*Eolophus roseicapillus*) anesthetized with halothane than with isoflurane (Wijnberg et al. 1991). Ducks anesthetized with halothane had a higher tendency for hypoventilation than did chickens, but heart rates were maintained in the ducks. This suggests some mechanism other than the dive response may be involved in this hypoventilation (Ludders 1992).

Isoflurane Isoflurane causes less cardiovascular depression than halothane (Jaensch et al. 1999; Ludders 1992; Ludders et al. 1990; Miller 2005). In mammals, it produces peripheral vasodilation and negative inotropic effects, possibly explaining the dose-dependent hypotension it induces in birds (Goelz et al. 1990; Greenlees et al. 1990; Ludders et al. 1989a; Ludders et al. 1990). When isoflurane was compared with sevoflurane and desflurane in red-tailed hawks, isoflurane caused a lower respiratory rate than desflurane. However, EtCO₂ did not change and the difference in respiratory rate is unlikely to be clinically significant (Granone et al. 2012). The MAC is 1.32% in chickens, 1.30% in Peking ducks, 1.34% in sandhill cranes, but only 1.07% in thick-billed parrots, demonstrating some significant species-specific variation (Ludders et al. 1989a; Ludders et al. 1990; Mercado et al. 2008). The isoflurane concentration required to produce apnea in ducks was 1.65× MAC and in cranes 2× MAC (Ludders et al. 1989a; Ludders et al. 1990). These values are less than those in dogs, cats, and horses (Miller 2005). If surgical anesthesia is achieved in 95% of patients at 1.3× MAC, isoflurane anesthesia has a low safety margin for apnea.

In addition to cardiopulmonary depression, inhalant anesthetics may cause cardiac arrhythmias. Cardiac arrhythmias have been noted in 35–75% of bald eagles (*Haliaeetus leucocephalus*) anesthetized with isoflurane (Aguilar et al. 1995; Joyner et al. 2008). In both of those studies, second-degree heart block was the most prevalent arrhythmia. In one study, they occurred during induction and recovery in 80% of the cases (Aguilar et al. 1995). Catecholamine release was suspected to be the cause. Cardiac arrhythmias are also commonly detected in other species (Aguilar et al. 1995; Goelz et al. 1990; Korbelt et al. 1996), but in the authors' experience arrhythmias are most common in raptors. Cardiac stability is a perceived advantage of isoflurane anesthesia in birds compared with halothane. However, where an electrical fibrillation model was used to investigate myocardial irritant effects of isoflurane and halothane, the former had a lower threshold for electrical fibrillation than halothane (Greenlees et al. 1990). Clinically, arrhythmias appear to be uncommon, but do occasionally occur and warrant vigilant monitoring.

Sevoflurane Sevoflurane has better solubility than isoflurane or halothane. Low solubility allows for faster

induction and recovery, as well as more rapid changes in anesthetic depth (Miller 2005; Thurmon et al. 1996). In pigeons, induction and recovery times were more rapid than with isoflurane (Korbel R 1998). This trend was also noted in bald eagles, with faster recovery times compared with isoflurane. A similar number of arrhythmias were noted with each agent (Joyner et al. 2008). In red-tailed hawks, only the time to visual tracking was faster with sevoflurane (and desflurane) compared with isoflurane. Induction time and time to extubation did not vary significantly. All recoveries were noted to be excellent or good (Granone et al. 2012). Sevoflurane administered at 3.5% provided adequate anesthetic plane in crested caracaras (*Caracara plancus*), with significant decreases in respiration rate (RR), arterial blood pressure (BP), cloacal temperature, and blood pH (Escobar et al. 2009). Time to induction and time to recovery were not recorded. Additionally, in several psittacine species, recovery times (time to extubation, sternal, and standing) were not significantly different between the two agents, but the birds subjectively appeared less ataxic (Quandt & Greenacre 1999). The time to intubation was longer with sevoflurane (≥ 4.4 minutes) than isoflurane. However, this was attributed to administration of sevoflurane below the suspected MAC in birds. In Hispaniolan parrots, the time to intubation (38 ± 2 seconds) was rapid with sevoflurane, which was attributed to the higher concentration used during induction. The time to extubation was also rapid (2.3 ± 0.4 minutes) (Klaphake et al. 2006).

In chickens, the MAC of sevoflurane was found to be $2.21\% \pm 0.32\%$, which is within the mammalian range (Naganobu et al. 2000). At this concentration, heart rate did not change significantly and cardiac arrhythmias were not observed up to $2 \times$ MAC (Naganobu et al. 2000). In another study in chickens, hypotension was observed during both spontaneous and controlled ventilation; dose-dependent hypotension was observed only during controlled ventilation (Naganobu et al. 2003). Tachycardia occurred during spontaneous ventilation while the heart rate remained unchanged during controlled ventilation. However, in Hispaniolan parrots, bradycardia was observed after 25 minutes using controlled ventilation (Klaphake et al. 2006). Increases in PaCO_2 (≤ 86 mm Hg) occurred with increased sevoflurane concentration during spontaneous ventilation. Hypercapnia-induced increases in sympathetic tone were suggested to account for the maintenance of the arterial blood pressures and heart rate in the spontaneously ventilated birds (Naganobu et al. 2003). In both chickens and Hispaniolan parrots, a significant bradypnea was observed (Klaphake et al. 2006; Naganobu et al. 2003).

Sevoflurane has a less irritating smell than other inhalants. In human pediatric patients, it is routinely used for mask induction to prevent struggling due to

smell. While the agent cost is much higher than isoflurane, many practitioners use sevoflurane for induction then switch to the more cost-effective isoflurane for maintenance.

LOCAL ANESTHESIA

There are few studies evaluating local anesthetics in birds. In chickens, successful brachial plexus nerve blocks using lidocaine 2% or levobupivacaine were observed for 30–60 minutes in the majority of birds evaluated (D/Otaviano de Castro Vilan et al. 2006). Another investigator compared local blocks using lidocaine and bupivacaine in chickens and noted a longer duration of sensory blockade in the chickens treated with bupivacaine, but this difference was not statistically significant due a large amount of variation (Figueiredo et al. 2008). Brachial plexus blocks using ropivacaine (7.5 mg/kg) provided sensory and motor blockade for approximately 2 hours (Cardozo et al. 2009). However, attempts to perform brachial plexus block in mallard ducks with lidocaine and bupivacaine resulted in no consistent alteration in compound nerve action potentials (CNAP) or sensory nerve conduction velocities (SNCV), suggesting ineffective nerve blockade (Brenner et al. 2010).

Birds may be more sensitive to the toxic effects of local anesthetics than mammals. Toxic effects have been documented in birds at overall lower total doses of lidocaine (2.7–3.3 mg/kg) than in dogs (Hocking et al. 1997). Toxic effects are similar to those reported in mammals and seizures and cardiac arrest have been reported with higher dosages in birds (Ludders 1994). Other adverse effects include depression, drowsiness, muscle tremors, vomiting, hypotension, and arrhythmias, as well as CNS signs, such as ataxia and nystagmus.

Appropriate lidocaine dosing is difficult in the small avian patient, but toxicity can be prevented by using appropriate concentrations and volumes. This often requires the commercial lidocaine solution (2%; 20 mg/mL) be diluted 1 : 10, and total dosages not exceeding 2.5 mg/kg (Hocking et al. 1997; Ludders 1994). It is unknown whether this dilution allows either appropriate tissue drug levels for analgesia or the expected duration of analgesia to occur (Farley et al. 1994).

Bupivacaine is used conservatively due to concerns that its toxic effects may take longer to resolve. In mammals, the maximum recommended dosage of bupivacaine is 2 mg/kg. In mallard ducks (*Anas platyrhynchos*), bupivacaine (2 mg/kg SC) was shorter acting than in mammals (Machin 2001), and showed a faster absorption versus elimination rate. In addition, sequestration and redistribution suggested by increases in plasma concentrations at 6 and 12 hours, may make toxicity delayed. A 1 : 1 mixture of bupivacaine and dimethyl sulfoxide (DMSO) applied to amputated

chicken beaks immediately after amputation improved feed intake (Glatz et al. 1992). Intraarticular bupivacaine (3 mg in 0.3-mL saline), was effective for treating arthritic pain in 1.5 kg chickens (Hocking et al. 1997).

EMLA is an acronym for “eutectic mixture of local anesthetic” and is a mixture of 2.5% lidocaine and 2.5% prilocaine for topical use. The depth of penetration of EMLA cream is dependent upon contact time with the skin. In humans, toxicity from EMLA cream is associated with improper administration (i.e., application to large surface areas, prolonged contact time, and application to damaged skin or mucous membranes). Common side effects in humans include skin blanching and local erythema. Less common side effects include methemoglobinemia or neurologic signs, generally when EMLA is applied to a large surface area for a prolonged time. Optimal use in humans requires application and occlusion for 1 hour prior. However, shorter times appear to be effective. There have been no studies evaluating shorter contact times in animals with thin skin as in birds. The maximum dosage must be calculated prior to administration to prevent toxicity. Systemic uptake may be increased after feather plucking due to skin damage and exposed feather follicles.

MONITORING

Due to the rapid rate at which birds may decompensate under anesthesia, monitoring is the most important aspect of avian anesthesia. Additionally, many monitors are not built for the small size and rapid heart rate of avian patients and may be more unreliable than in dogs and cats. This means having one person dedicated to consistent, hands-on monitoring and ensuring the anesthetist has a clear view of the patient are critically important.

Cardiovascular

Heart rate is widely variable between individuals and species. Knowledge of expected species values is important, but trends in rate during anesthesia are of more significance. Sudden bradycardia is an indication to decrease anesthetic depth and provide supportive care, such as fluid boluses

Heart rate and rhythm are monitored by an external or an esophageal stethoscope, ECG, or peripheral pulse rate. Peripheral pulse rates are determined at the brachial, medial metatarsal artery, or the carotid artery by direct palpation or with a Doppler ultrasonic probe. The Doppler probe is placed against the palatine artery on the dorsal palate of some species (Fig. 24.7).

ECG limb leads are placed close to the body. Due to the delicate nature of avian skin, the alligator clips are attached to needles or stainless steel suture passed through the skin, rather than directly attaching to the

skin. Heart rate and presence of an ECG trace are insensitive indicators of anesthetic depth.

Blood pressure may be subjectively assessed by palpating the pulse at the median ulnar or medial metatarsal artery. Changes in pulse pressure and velocity are also reflected in sound volume changes when using a Doppler ultrasonic probe. Direct arterial pressure monitoring can also be performed. The most common sites include the brachial and carotid arteries (Fig. 24.8). The catheters are usually placed percutaneously, but a cut-down procedure is sometimes required to confirm arterial location. Significant arteriospasm may occur in some species. In this author’s experience, cutaneous application of a small amount of EMLA 30 minutes prior to percutaneous arterial catheterization reduces arteriospasm. Alternatively, diluted 2.5% lidocaine is applied directly over the artery during a cut-down procedure. Occasionally, a profound bradycardia is associated with catheterization of a brachial artery.

Indirect blood pressure (iBP) monitoring is performed using a Doppler ultrasonic probe to detect arterial flow, a pressure cuff for occlusion, and a sphygmomanometer to measure pressure (Fig. 24.9). Recently, there have been several publications investigating the accuracy and precision of iBP monitoring in multiple avian species. In Hispaniolan Amazon parrots, iBP measurements obtained with a size 1 neonatal cuff (30–40% of limb diameter) did not provide adequate correlation with direct arterial measurements (Acierno et al. 2008). In red-tailed hawks, iBP measurements were found to more closely approximate MAP measurements over a range of blood pressures, and values obtained with a cuff 40–50% of the limb diameter did not differ significantly between wing or leg placement (Zehnder et al. 2009). A study evaluating the precision of multiple iBP measurements in awake psittacines found significant variability between repeated measurements when iBP cuffs were applied multiple times to the same limb (Johnston et al. 2011). Oscillometric devices have demonstrated high failure rates and unreliable measurements in avian patients and are not recommended for iBP monitoring (Acierno et al. 2008; Zehnder et al. 2009). From the studies that have been done, it seems that an appropriately sized cuff and sphygmomanometer can be used to evaluate trends in iBP during an anesthetic episode, but that repeated sampling that involves different cuff placements (as in different hospital visits) may be unreliable.

Respiratory

Respiratory rate and character should be closely monitored throughout anesthesia as this may be the first indication of problems and is a good sign for early intervention. Ventilation is assessed by observing the frequency and range of sternal motion and reservoir bag movement. Substituting balloons for regular reservoir bags will facilitate visualization of movement in

Figure 24.7. Peripheral pulse rates can be determined in many birds at the brachial artery (a), the medial metatarsal artery, or the carotid artery (b) either by direct pressure assessment or with a Doppler ultrasonic probe. Heart rate can also be detected by placement of the Doppler ultrasonic probe over the palatine artery (c) on the dorsal palate of some species of raptors and waterfowl.

Figure 24.8. Arterial catheterization of the brachial artery in a bird. The brachial (a) and carotid arteries are the most common sites for arterial catheterization in birds. Percutaneous placement is utilized most commonly, but sometimes a surgical cut-down procedure is required to confirm the location of the artery (b).

Figure 24.9. Indirect blood pressure monitoring can be performed using a Doppler ultrasonic probe to detect the arterial flow, a pressure cuff to occlude arterial blood flow and a sphygmomanometer to measure pressures.

patients with small tidal volumes. However, assessment of adequacy of ventilation by these methods in birds is inaccurate. A sudden change in respiratory pattern involving increased respiratory effort may indicate obstruction of the endotracheal tube, a particular concern in very small patients. Normal ventilation is associated with little to no respiratory tract noise. Whistling, wheezing, or harsh sounds may also indicate obstruction. Many birds (e.g., ducks) will normally have an expiratory syringeal noise during IPPV. Apnea ≥ 10 –20 seconds is an indication to decrease anesthetic depth and provide assisted ventilation. The time between respiratory and cardiac arrests may be ≤ 1 –2 minutes. Respiratory monitors that detect gas flow increase mechanical dead space.

End-tidal carbon dioxide (PETCO₂) monitoring is used to determine ventilatory efficacy. Ideally, the sampling port is located inside the endotracheal tube, but it should not increase airway resistance. Side-stream capnographs draw samples at a rate of 50–200 mL/min. This rate is usually fixed, but some allow alteration. In small birds, even this low flow may exceed minute ventilation so care should be taken to account for this removal of gas by the monitor.

There is relatively good correlation between PETCO₂ and PaCO₂, with PETCO₂ slightly exceeding PaCO₂ (Edling et al. 2001; Hawkins et al. 2003; Pettifer et al. 2002). In a study evaluating the accuracy of PETCO₂ in multiple raptor species, the authors found that side-stream PETCO₂ overestimated PaCO₂ at low levels with the reverse trend at higher levels (Desmarchelier et al. 2007). This can occur in the avian parabronchus, but is impossible in alveolar gas exchange (Powell &

Figure 24.10. Avian capnogram.

Whittow 2000). Carbon dioxide diffusion occurs across the length of the parabronchus, with a higher diffusion rate at the inspiratory, and a lower rate at the expiratory, end. Since arterialized blood returning to the heart is a mix of capillary blood draining the entire length of the parabronchus, PaCO₂ can be less than PETCO₂ in ideal cross current exchange. The capnogram provides important information regarding trends in PETCO₂ (Fig. 24.10).

Pulse oximetry has not been validated in birds. The absorption characteristics of oxygenated and deoxygenated avian and human hemoglobin are different resulting in underestimation of hemoglobin saturation (Schmitt et al. 1998). In pigeons, hemoglobin saturation trends were consistent, but values did not correlate with those derived from blood gas analyses and calculation (Schmitt et al. 1998). However, these monitors are often used to provide a pulse rate and some monitors have been adapted to count pulses up to 400bpm.

Anesthetic Depth

The cere, beak, head, cloaca, and digits are used to assess response to pain. Surgical incisions and needle pricks evoke less response under anesthesia than for mammals. Withdrawal reflexes include toe pinch, stimulation of the interdigital tissue, pinching the scaly areas of the skin, cloacal pinch and feather plucking. Slight corneal and palpebral reflexes are maintained at a surgical plane; their absence may indicate excessively deep anesthesia. In raptors anesthetized with propofol contour feather plucking did not initiate a response in any bird at any time period during the CRI (Hawkins et al. 2003). Rather, toe clamping was a better guide to anesthetic depth.

Glucose

Blood glucose is monitored when possible, particularly during prolonged procedures. In auklets, the values determined by four handheld human glucose monitors were comparable with Chemstrip BG. However, values

for all systems were 33% less than those determined by a reference chemistry laboratory (Lieske et al. 2002). Blood storage in heparin was preferable to ethylenediaminetetraacetic acid (EDTA). Stored blood glucose values were stable for 4 hours.

Recovery

Recovery complications are usually associated with long anesthetic procedures (≥ 0.5 –1.0 hours). This emphasizes the importance of minimizing anesthetic time. The vaporizer is turned off at the end of the procedure and circle breathing systems flushed with oxygen. This flushing is unnecessary with a nonbreathing system. The patient remains connected to the breathing system and oxygen as long as possible. Signs of recovery include muscle fasciculations, then wing and leg movement. Once beak tone returns, the bird is extubated to prevent severing the endotracheal tube. Once extubated, an anesthetic face mask with or without the rubber diaphragm is placed over the bird's head to continue oxygen supplementation. Most are placed loosely in a towel and held upright to minimize self trauma and regurgitation. Respiration is monitored during towel restraint to ensure adequate sternal movement. Once recovered, the bird is placed in a warm, well-oxygenated environment for continued recovery. A quiet dark environment minimizes stress and movement.

ANALGESIA

Pain Recognition

Pain recognition is critical for providing timely analgesic selection. It requires consideration of age, sex, and species differences, as well as individual behavior and environmental factors. Birds either hide painful or exhibit different behaviors outside their home cage. Pain assessment must also account for different types and sources of pain (i.e., acute, chronic, visceral, and somatic). In lieu of species-specific pain scores, the use of a generic pain scale of 1–10 to evaluate a bird's pain and the response to treatment may be useful. A study evaluating pain in pigeons following orthopedic surgery used a detailed numeric rating scale plus a simple 1–10 pain scale and there was significant correlation between both methods (J. Paul-Murphy, pers. comm., March 20, 2013). Developing objective means to quantitate pain will aid clinicians in choosing analgesic therapies for their patients.

The observer must be familiar with normal and abnormal behavior to assess pain. Social species exhibit pain behaviors dependent upon the group social dynamics (Clyde & Paul-Murphy 1999). Predatory species exhibit abnormal behaviors more readily than prey species. Painful behaviors attract unwanted attention from predators, requiring masking to survive. The clinician is viewed as a potential predator.

Many clinical signs are associated with pain including change in temperament (either aggressive or passive), restlessness, reduced mobility or reluctance to stand or perch, lethargy, hunched appearance, sleep deprivation, tachypnea, and lameness. Reduced food consumption may occur, and bodyweight should be monitored. Animals with abdominal pain can exhibit tensing with a “tucked up” or “hunched” appearance. Birds may either avoid a painful body area or bite/chew it. Decreased or overgrooming (feather-picking) may occur at a painful site. Vocalization and writhing occur rarely during acute or severe pain. Owners often describe reduced vocalization in birds with traumatic injuries.

Few physiologic variables are consistent indicators of pain. In chickens during feather plucking, heart rates and respiratory rates were variable, but increased blood pressure was a reliable indicator (Gentle & Tilston 1999). Catecholamines are well-recognized humoral indicators of stress, but vary between individuals and species because of differences in adrenal content (Harvey et al. 1984). Corticosterone significantly increases in birds following pain, but it also increases with handling (Heatley et al. 2000). The use of noxious stimuli (primarily thermal) as well as induced pain models (Paul-Murphy et al. 2009a) will allow researchers to more objectively evaluate the use of analgesics in birds.

A set of universal questions are used to determine if a patient is in pain:

1. Would the lesion or procedure be painful to any species?
2. Is the lesion or procedure damaging to tissues in any species?
3. Does the patient display any abnormal behavioral responses?

If the answer to any of these questions is yes, then the veterinarian must assume that the patient is in pain and an analgesic plan should be developed.

Opioids

Most opioid analgesics are used parenterally because of their overall poor oral bioavailability associated with the first pass effect. Analgesia is species and intraspecies variable at equipotent dosages. In pigeons, regional distribution of μ , κ , and δ receptors in the forebrain and midbrain were similar to mammals (Reiner et al. 1989). However, the κ and δ receptors were more prominent in the pigeon forebrain and midbrain than μ , and 76% were κ (Mansour et al. 1988). However, in 1-day-old chicks, receptor distribution was markedly different, suggesting either age or species effect (Csillag et al. 1990). Birds may not possess distinct μ and κ -receptors or the receptors have similar functions. This would explain why chickens are unable to discriminate μ and

κ agonists and the isoflurane-sparing effects of μ and κ agonists appear similar to mammals. (Concannon et al. 1995)

Morphine at high dosages (200mg/kg) produced analgesia in chicks (Schneider 1961). In another study, it produced a similar, but variable level of analgesia at dosages approximating those recommended in other species (Hughes 1990, 1990b). Variable morphine response has been detected between chicken breeds (Fan et al. 1981). Analgesic effects were observed in one breed, but two others exhibited hyperalgesia at the same dosage (Hughes 1990b). In a domestic fowl arthritis model, intraarticular injection of morphine (1–3 mg) showed no significant antinociception. However, it is unclear whether synovial fluid pH differences may have affected drug activity (Gentle et al. 1999).

Hydromorphone is primarily a μ -agonist, which is not frequently used in birds; however, it has been evaluated at doses of 0.1, 0.3, and 0.6 mg/kg in American kestrels (*Falco sparverius*) and was found to increase the foot withdrawal threshold to a thermal stimulus at all doses evaluated (Guzman et al. 2013). Fentanyl is a short-acting opioid that is uncommonly used in avian patients. One study in white cockatoos demonstrated no reduction in withdrawal thresholds following 0.02 mg/kg SC. A dose of 0.2 mg/kg did produce analgesia, but also hyperactivity (Hoppe et al. 2003). Fentanyl administered as an IV CRI in red-tailed hawks (*Buteo jamaicensis*) to target plasma concentrations of 8–32 ng/mL reduced the MAC of isoflurane 31–55% in a dose-related manner, without statistically significant effects on heart rate, blood pressure, or PaO₂. (Pavez et al. 2011)

In Hispaniolan parrots anesthetized with sevoflurane, preoperative butorphanol administration did not show significant anesthetic (including time to intubation and extubation) or cardiopulmonary effects. This suggests it is useful as part of a preemptive analgesic protocol with minimal adverse cardiopulmonary effects (Klaphake et al. 2006). Pharmacokinetic and pharmacodynamic data suggest 2–4 hours dosing intervals are appropriate in mammals. Butorphanol (1 mg/kg) produced an isoflurane-sparing effect in cockatoos and African gray parrots, but less in blue-fronted Amazons (Curro 1994; Curro et al. 1994; Paul-Murphy et al. 1999). In African gray parrots, butorphanol (1–2 mg/kg) showed an increased withdrawal threshold in response to electrical stimuli (Paul-Murphy et al. 1999). In red-tailed hawks and great-horned owls, butorphanol (0.5 mg/kg IV) had a half-life of 0.93 (0.94 IM) and 1.78 hours (1.84 IM), respectively (Riggs et al. 2008). In Hispaniolan parrots administered butorphanol (5 mg/kg SC), serum concentrations were undetectable at 2 and 12 hours (Sladky et al. 2006). More recently, the IV, IM, and PO pharmacokinetics of butorphanol were evaluated in Hispaniolan Amazon parrots (Guzman et al. 2011). Oral administration had very limited bio-

availability and is not recommended. The $t_{1/2}$ of IM and IV administration was very similar at 0.51 and 0.49 hours, respectively. The authors of that study recommend dosing every 2–3 hours (Guzman et al. 2011). Pharmacokinetics of butorphanol (2 mg/kg IV) in chickens demonstrated an elimination half-life of 69 minutes (Singh et al. 2011). In comparison with mammals, these studies indicate very frequent (impractical) butorphanol dosing is required to attain analgesic drug levels, and that the dosing seems to be very species-specific. In Hispaniolan parrots, a long-acting liposome-encapsulated, butorphanol tartrate formulation was safe and effective for up to 5 days following SC administration (Sladky et al. 2006). Dosing of 15 mg/kg with this formulation restored weight-bearing in an induced arthritis model of pain in Hispaniolan Amazon parrots and green-cheeked conures (Paul-Murphy et al. 2009a, 2009b). Unfortunately, this formulation is not commercially available.

There are few published reports of the use of buprenorphine. In a domestic fowl, arthritis model buprenorphine (0.05–1.0 mg) administered intraarticularly found no significant antinociception (Gentle et al. 1999). Early anecdotal reports suggesting buprenorphine (0.01–0.05 mg/kg IM) is effective in birds (Jenkins 1993; Schaeffer 1994) is contradicted by more recent studies. In African gray parrots, a high dose (0.1 mg/kg IM) achieved plasma concentrations in the human analgesic range for 2 hours (Paul-Murphy et al. 2004), and it affected withdrawal response to an electrical stimulus (Paul-Murphy et al. 1999).

Nalbuphine hydrochloride (HCl) is a semi-synthetic opioid that has recently been investigated for its use in psittacines. It is primarily a κ -receptor agonist and is a partial antagonist at the μ -receptor, similar to butorphanol. It is used in the treatment of moderate to severe pain in humans and has a relatively lower incidence of respiratory depression that does not appear to be dose dependent. Nalbuphine HCl was rapidly cleared after both IM and IV dosing of 12.5 mg/kg to Hispaniolan Amazon parrots and had excellent bioavailability following IM administration, with little sedation and no adverse effects (Keller et al. 2011). This dosage increased thermal foot withdrawal threshold values in this species for up to 3 hours while higher dosages (25 and 50 mg/kg IM) did not significantly increase thermal foot withdrawal threshold values (Sanchez-Migallon Guzman et al. 2011). A longer-lasting experimental formulation (*Nalbuphine decanoate*) was administered at 33.7 mg/kg IM to Hispaniolan Amazon parrots and thermal withdrawal threshold values were increased for up to 12 hours, four times longer than the standard formula (Sanchez-Migallon Guzman et al. 2013b). Additionally, this formulation resulted in prolonged plasma concentrations after IM administration in the Hispaniolan Amazon parrots, compared with nalbuphine HCl, maintaining plasma concentrations that may be

antinociceptive for 24 hours when administered at 37.5 mg/kg (Sanchez-Migallon Guzman et al. 2013c). Unfortunately, as with the liposome-encapsulated butorphanol, nalbuphine decanoate is not currently commercially available. Based upon the receptor activity of this drug, and its reportedly few side effects, nalbuphine warrants further investigation as an analgesic for avian patients.

There have been limited investigations of tramadol, a centrally acting μ -agonist with some weak κ and δ activity, in birds. One of its 26 metabolites, O-desmethyltramadol (M1) is a more potent μ agonist than the parent compound (1/30th—M1 vs. 1/6000th—tramadol as potent as morphine). Tramadol also inhibits the reuptake of norepinephrine and serotonin so it has further analgesic actions via the descending inhibitory pathways. In red-tailed hawks treated with 11 mg/kg PO, analgesic thresholds for humans were maintained for approximately 4 hours with a $T_{1/2}$ of 1.3 (± 0.6) hours (Souza et al. 2011). Based on the pharmacokinetic profile, the recommended dose is 15 mg/kg PO q 12 h, although the analgesic threshold for birds is not known. The same authors investigated tramadol given IV or PO in bald eagles (Souza et al. 2009). Oral bioavailability was found to be high (97.9%) and authors recommended a dose of 5 mg/kg PO q 24 h. In Hispaniolan Amazon parrots, doses of 10 or 20 mg/kg orally did not result in significant antinociception to thermal stimuli, and human analgesic thresholds were only reached after dosing with 30 mg/kg orally or 5 mg/kg IV (Sanchez-Migallon Guzman et al. 2012). Transient bradycardia was noted after IV administration. In adult peafowl gavaged with 7.5 mg/kg, levels of tramadol remained over the human analgesic threshold for approximately 1 hour in 2/6 birds. However, the levels of M1 metabolite remained above the human therapeutic threshold for 12 hours in 5/6 birds and >24 hours in 3/6 birds. (Black et al. 2010). This underscores the importance of assaying for pharmacologically active metabolites in these studies.

Nonsteroidal Anti-Inflammatory Drugs (NSAIDs)

Ketoprofen is most commonly used parenterally because of limited oral pharmacokinetic data and difficulty in accurately dosing in small species. In Japanese quail (*Coturnix japonica*), ketoprofen (2 mg/kg PO, IM, IV) showed very low oral (24%) and IM (54%) bioavailability and the shortest half-life reported for any species (Graham et al. 2005). Additional studies are needed to determine whether drug formulation or interspecies physiologic differences account for these differences. In mallard ducks, ketoprofen (5 mg/kg IM) decreased blood thromboxane B_2 levels for approximately 12 hours (Machin et al. 2001).

Carprofen given SC improved the locomotion of lame domestic fowl significantly in a dose-dependent

manner (McGeowen et al. 1999) and lame birds self-selected food containing carprofen (Danbury et al. 2000). Carprofen administered at 3 mg/kg IM q 12 h was insufficient to restore weight-bearing in induced arthritis in Hispaniolan parrots (Paul-Murphy et al. 2009b). The author (MGH) has used this NSAID (1–4 mg/kg PO, SC and IM q 12–24 h) short-term (<7 days) in many species. In pigeons, doses of 2, 5, and 10 mg/kg given IM once daily over 7 days resulted in significant increases in ALT, AST, and a mild decrease in total protein (primarily globulin) (Zollinger et al. 2011). Additionally, small intestinal vascular congestion was noted grossly and hepatic necrosis, renal congestion, and myoregeneration of the pectoral muscles were noted histologically, and the effects were significantly associated with dosing (Zollinger et al. 2011). While not significant, hepatic lipidosis was also noted and the frequency increased with dose. The authors speculate this may be secondary to decreased food consumption noted in pigeons within the highest dosing group (Zollinger et al. 2011). Additional research is needed to determine the appropriate dosing and frequency of dose-limiting side effects in birds.

Meloxicam, like carprofen, is a selective COX-2 antagonist. In ring-necked parakeets, oral meloxicam bioavailability approached 100% (Wilson et al. 2004). A significant variation in meloxicam half-life has been reported in birds. In ostriches, meloxicam IV had a very short half-life (0.5 hours) compared with ducks, turkeys, pigeons, and chickens (Baert & De Backer 2002, 2003). Dosing of meloxicam at 1.0 mg/kg IM q 12 h was found to return weight-bearing in an induced arthritis model in Hispaniolan Amazon parrots (Cole et al. 2009). In pigeons, a dose of 2 mg/kg q 12 h for 9 days was found to improve weight-bearing postosteotomy with no evidence of toxicity on hematologic or histopathologic assessment (Desmarchelier et al. 2012).

Celecoxib (10 mg/kg PO q 24 h) has been used in birds with clinical proventricular dilatation disease (PDD) (Dahlhausen et al. 2002). Treatment durations of 6–12 weeks are recommended. Clinical improvement is observed within the first 7–14 days with gradual resolution of clinical signs over the course of therapy. Premature treatment cessation may result in recrudescence of clinical signs. However, in some birds clinical improvement resumed with additional medical therapy.

Recently, massive mortalities in three vulture species on the Asian subcontinent lead to banning of the NSAID diclofenac (DF) on the Indian subcontinent. Common findings of diffuse visceral gout and proximal convoluted tubular damage indicated that the site of toxicity was the kidneys or the renal supportive vascular system (Meteyer et al. 2005; Naidoo & Swan 2009; Oaks et al. 2004; Swan et al. 2006). The association of DF with vulture mortalities led to several investigations to establish the mechanism of toxicity for DF and other NSAIDs in several avian species. The effect of DF on

inhibition of renal prostaglandins and subsequent closure of the renal portal valves was proposed to cause severe renal ischemia and nephrotoxicity (Meteyer et al. 2005). Recent studies, however, determined vulture susceptibility to DF results from a combination of an increased reactive oxygen species (chemically reactive molecules containing oxygen, such as oxygen ions and peroxide), interference with uric acid transport, and the duration of exposure (Naidoo & Swan 2009). Both DF and meloxicam were found to be toxic to renal tubular epithelial cells following 12 hours of cell culture exposure, due to an increase in production of reactive oxygen species, although in cultures incubated with either drug for only 2 hours, meloxicam showed no toxicity in contrast to DF (Naidoo & Swan 2009). DF also decreased the transport of uric acid, by interfering with the *p*-aminohippuric acid channel. Additionally, the half-life of DF in vultures (14 hours) is much longer than chickens (2 hours) thus exposing vultures to toxic effects of DF for prolonged time periods.

Balanced or Multi-Modal Analgesia

Combinations of drugs acting at different points in the nociceptive system are more effective and less toxic than either drug given alone. For example, opioids act centrally to limit nociceptive input, whereas NSAIDs act peripherally to decrease inflammation, limiting nociceptive information that enters the CNS. Synergy has been demonstrated in laboratory animals (Malmberg & Yaksh 1993) and is being tested in the clinical environment.

25 Penguins

Kate Bodley and Todd L. Schmitt

INTRODUCTION

The order Sphenisciformes (the penguins) consists of 18 species representing six genera. All occur in the Southern Hemisphere and are dependent upon nutrient-rich, cool to coldwater currents for their food sources. Most species are found in the northern cool temperate region of the Southern Ocean, up to latitude 30°S (Shirihai 2007). Several species are found in coastal and nearby waters of South Africa, South America, Australia, and New Zealand, and the most northerly species, the Galapagos penguin, occurs close to the equator. Two species live and breed on the Antarctic continent: the emperor penguin and the Adélie penguin (Table 25.1).

ANATOMY AND PHYSIOLOGY

Penguins are flightless birds that possess highly specialized anatomical and physiological features suitable for their pelagic lifestyle. Most penguin species spend >50% of their lives at sea. Many species make frequent, rapid, and prolonged dives while foraging. Emperor penguins may dive to depths greater than 500m and remain submerged for more than 20 minutes (Meir & Ponganis 2009). Many species are exposed to extremely low environmental temperatures while on land, during their breeding and molting periods. The Magellanic penguin and the Galapagos penguin, however, must tolerate high environmental temperatures while on land, and then forage in cool ocean currents.

Penguins demonstrate remarkable development of various anatomical and physiological adaptations that allow them to forage and breed in such extreme environments. These adaptations are of potential significance during procedures involving restraint and anesthesia.

Penguins may be at greater risk of developing hyperthermia during restraint procedures than other avian species. Penguin feathers are not laid down in pterylae, rather they are densely packed over the entire skin surface. The lance-shaped contour feathers are very stiff and short, and have an attached downy afterfeather that provides insulation. Feathers are flattened during swimming, but feather shafts may be held erect while on land, providing a thick, air-filled, windproof coat (Dawson et al. 1999). During the premolting period, when most species gain significant body mass, a subcutaneous fat layer provides further insulation.

One thermoregulatory adaptation is the humeral arterial plexus, a vascular counter-current heat exchanger that limits heat loss through the flipper. Evidence for development of this structure arose in the fossil record during the late Cenozoic era, 49 million years ago, and it is believed to be a key adaptive feature that allowed penguins to successfully forage in cool and cold environments (Thomas et al. 2011). In addition, a postorbital *rete mirabile* reduces heat loss from the head, and multiple-vein arteriovenous associations in the legs facilitate countercurrent heat exchange and assist heat retention (Frost et al. 1975). Penguins may be relatively overinsulated while on land, particularly when they live in warm terrestrial environments. The feet and flippers will function to dissipate excess heat at high temperatures, via a general increase in blood flow to these structures and the bypassing of the countercurrent heat exchange systems. When African penguins are heat stressed, blood is shunted through a large marginal vein located in the axilla, which allows the axilla to be used as an efficient heat dissipator (Frost et al. 1975). Heat loss is also facilitated by panting and postural changes.

Table 25.1. Species of penguins

Genus	Species	Common Name	Habitat
Pygoscelidae	<i>Pygoscelis adeliae</i>	Adelie penguin	Circumpolar Antarctica
	<i>Pygoscelis antarctica</i>	Chinstrap penguin	Circumpolar Antarctica
	<i>Pygoscelis papua</i>	Gentoo penguin	Antarctica and sub-Antarctic islands
Aptenodytidae	<i>Aptenodytes forsteri</i>	Emperor penguin	Circumpolar Antarctica
	<i>Aptenodytes patagonicus</i>	King penguin	Antarctica and sub-Antarctic islands
Eudyptidae	<i>Eudyptes moseleyi</i>	Northern rockhopper penguin	Sub-Antarctic and south temperate islands
	<i>Eudyptes chrysocome</i>	Southern rockhopper penguin	Sub-Antarctic and south temperate islands
	<i>Eudyptes chrysolophius</i>	Macaroni penguin	Antarctica and sub-Antarctic islands
	<i>Eudyptes pachyrhynchus</i>	Fiordland penguin	New Zealand
	<i>Eudyptes schleggeli</i>	Royal penguin	Sub-Antarctic islands
	<i>Eudyptes robustus</i>	Snares Island penguin	New Zealand
	<i>Eudyptes sclateri</i>	Erect-crested penguin	New Zealand
Megadyptidae	<i>Megadyptes antipodes</i>	Yellow-eyed penguin	New Zealand
Spheniscidae	<i>Spheniscus demersus</i>	African penguin	South Africa and Namibia
	<i>Spheniscus humboldti</i>	Humboldt penguin	Peru and Chile
	<i>Spheniscus magellanicus</i>	Magellanic penguin	Chile and Argentina, Falkland Islands
	<i>Spheniscus mendiculus</i>	Galapagos penguin	Galapagos Islands
Eudyptulidae	<i>Eudyptula minor</i>	Little penguin	Australia and New Zealand

Little penguins are restricted to a relatively narrow range of distribution in the temperate zone around Australia and New Zealand. They come ashore at night to nest in burrows, where they are not subjected to considerable heat loads, and mean sea temperatures are $>10^{\circ}\text{C}$ within their range (Stahel & Nichol 1982). Studies have demonstrated that this species differs from other birds in that it lacks a typical panting response. Little penguins are therefore less able to withstand heat stress than other species, and have limited ability to maintain body temperature in water $<5^{\circ}\text{C}$ (Stahel & Nichol 1988).

The upper respiratory tract contains several anatomical features of potential significance during anesthesia. The cricoid cartilage has a median ventral crest (the crista ventralis), which projects dorsally into the laryngeal lumen (McLelland 1989a). It forms an incomplete septum, and may reduce the diameter of the endotracheal tube used during anesthesia. A median septum that divides part of the trachea into right and left channels has also been observed in some penguin species. Its physiological significance is not known. The septum extends cranially from the bronchial bifurcation, and each tracheal tube is completely encircled by a cartilaginous ring. In African penguins, the septum terminates only a few centimeters short of the larynx; however, in rockhopper penguins, it is only 5-mm long (McLelland 1989a). In general, the septum is long in the Aptenodytes, short in the Eudyptes, and of intermediate length in the Pygosceles. Its length is variable within the Spheniscus. It is therefore possible to insert an endotracheal tube such that it enters only one side of the tracheobronchial tree.

The network of secondary bronchi and paleopulmonic parabronchi in penguins permits unidirectional airflow only, and neopulmonic anastomoses are poorly

developed (McLelland 1989b). They have a well-developed cervical air sac, which reaches from anterior to the clavicle to the level of the lung hilus. The abdominal air sac, in contrast, is very poorly developed and the skeleton is poorly pneumatized (McLelland 1989b).

Several penguin species have been found to have physiological adaptations that facilitate diving. Emperor penguins use a range of strategies to manage body oxygen stores while submerged, for example, hyperventilation and tachycardia during the pre-dive period improves ventilation–perfusion matching during the dive, and arteriovenous shunts allow isolation of skeletal muscle from the circulation during a dive (Meir & Ponganis 2009; Ponganis et al. 2003). Additionally, wild diving emperor penguins demonstrate true diving bradycardia to maximize respiratory oxygen uptake and prolong the dive (Meir et al. 2008). In emperor penguins, the myoglobin concentration in the pectoral muscle is among the highest measured in any vertebrate (Ponganis et al. 2010). Emperor, Adélie, gentoo, and chinstrap penguins are known to possess hemoglobin with enhanced oxygen affinity compared with other birds. This increases their available oxygen when blood oxygen partial pressure is low during a dive (Meir & Ponganis 2009).

Most penguin species undergo periods of fasting during breeding, and all penguins will fast during their molt. Prolonged periods of fasting involve marked decreases in body mass. During the breeding fast, body mass loss averages 36–40% in macaroni penguins; during the molting fast, this species has total body mass loss of 45–50% (Williams 1995). During the molt, there is increased energy requirement for heat production and for the breakdown of stored proteins to provide amino acids for synthesis of feathers. This

results in an increase in metabolic rate. Recent studies have demonstrated that there is a tradeoff between molting and the immune response in house sparrows (Moreno-Rueda 2010). The duration of the two fasting periods (the breeding fast and the molting fast) is greatest in the two largest penguin species: the emperor penguin and the King penguin (Williams 1995). Mazarro et al. (2007) determined that behavior and appetite of captive African penguins remained constant during seven handling events (weighing and blood collection under manual restraint) during molting; however, a molt-related anemia was detected. Heat loss in molting little penguins is about 1.6 times higher than in nonmolting birds (Williams 1995).

CAPTURE AND PHYSICAL RESTRAINT

Most penguin species may be captured by hand. Smaller species may be easily captured by hand from the burrow (Wallace et al. 1995) or while standing on land. Larger species may be caught by hand (Thil & Groscolas 2002a) or an appropriately sized hoop net may be used (Keymer et al. 2001). A metal rod, bent and covered with rubber at one end to form a hook, has been used to grasp the tarsometatarsus of free-ranging rockhopper penguins and draw them toward handlers, who would then restrain the birds (Karesh et al. 1999). A remote injection device has been used to administer intramuscular ketamine to free-ranging Humboldt penguins (Luna-Jorquera et al. 1996).

Penguins are relatively robust and can tolerate periods of restraint for noninvasive procedures; however, procedures must be planned so that they are performed quickly and efficiently, in order to reduce the risk of development of hyperthermia. Most penguins in captive environments will require placement in a carrier or crate for transport to the examination site. Penguins weighing less than 7 kg can be placed easily in a large, plastic dog kennel. For polar penguins, flat ice blocks are placed in the bottom of the kennel to aid with temperature regulation. Polar penguins larger than 7 kg require specially built wood or plastic transport crates that can accommodate flat ice blocks that are covered with a towel. Transport crates that have two folding doors opposite one another will provide adequate exposure to the penguin for restraint. The transport vehicle and receiving examination room must be air-conditioned, to prevent extreme temperature fluctuations and subsequent overheating.

The beak is large and sharp, so restraining the head is very important. Many institutions housing King penguins include safety glasses as standard personal protection equipment during handling.

Penguins are best approached from behind, so that the base of the head is grasped quickly and firmly. Penguin wings are powerful and may inflict injury during handling. The wings should not be grasped as

Figure 25.1. Restraint technique for a penguin less than 5 kg (little penguin). The animal is grasped behind the head and then held around the body caudal to the wings.

the initial point of restraint, as they may suffer significant injury (e.g., humeral fracture or joint injury). The wings should be held firmly against the body to avoid excessive flapping. If wing movement must then be controlled, a second handler may be required.

Penguins less than 5 kg body mass may be quickly restrained by hand. The rear of the head is grasped firmly at the base and then the limbs/body may be restrained. Very small penguins are grasped behind the head and then held around the body caudal to the wings (Fig. 25.1).

Most often, the larger penguin species can be guided into a smaller enclosure and loaded into a carrier for transport prior to a procedure. Larger penguins may be tucked under the handler's elbow, facing caudally. The handler kneels, facing the bird, and pulls it toward them, tucking its head under the elbow and against the body. The bird's head will sit under the handler's hip, the bird lies along the thigh, and the elbow secures the head. The handler then holds the feet secure. This level of restraint is suitable for minor procedures such as nail clipping (Fig. 25.2).

Restraint for induction of anesthesia generally requires more controlled restraint of the head and neck. The penguin is approached from behind. The handler wraps their arms around the body of the bird and presses the wings tightly against the body. The body of the penguin may be tucked between the knees, such that the handler has both hands free to position the head and neck (Fig. 25.3).

Procedures that require the bird to be immobile (e.g., venipuncture and anesthetic induction using a facemask) will generally require two or more handlers. Safe restraint of penguins larger than 10 kg generally requires two handlers. One handler controls the body, and the other controls the head by firmly grasping the back of the head and top or bottom of the bill base

Figure 25.2. Restraint technique for a large penguin (King penguin) (courtesy of Village Roadshow Theme Parks).

Figure 25.3. Restraint technique for a large penguin (King penguin) (courtesy of Village Roadshow Theme Parks).

(refer to Fig. 25.4). Penguins may be hooded to reduce stress during restraint procedures (Thil & Groscolas 2002a).

VASCULAR ACCESS

The medial metatarsal vein is easily accessible in penguins, but may be small, and the wound site is easily contaminated by fecal pathogens from unsanitary conditions in a rookery. It is located just above the medial

Figure 25.4. Blood can be collected from the external jugular vein (King penguin) (courtesy of SeaWorld San Diego).

claw (Redrobe 2000) and is the least preferable venipuncture site. In smaller species, the brachial or jugular veins may be more useful for collection of diagnostic blood samples.

The cutaneous ulnar or basilic vein is not discernable in the wing of penguins; however, the brachial vein can be raised via pressure in the axilla, and lies parallel to the distal 1/3 of the humerus (Samour et al. 1983). It is readily accessible in the anesthetized penguin. In the conscious patient, the brachial vein is more difficult to access and may be difficult to occlude following venipuncture.

The jugular vein may be palpated along the right and left side of the neck. It is most easily accessible when the neck is extended and curved slightly away from the operator (Fowler & Fowler 2001; Redrobe 2000). Pressure is applied just anterior to the thoracic inlet, and the vein may be palpated ventral to the cervical muscles and dorsal to the trachea. A straight needle of size 22- to 19-gauge may be used for venipuncture for penguins <7 and >10kg, respectively. Butterfly needles or scalp catheters, 25–21 gauge, may also be used but require more dexterity for successful blood draw. Samour et al. (1983) commented that penguins became stressed when the jugular vein was punctured, and considered the brachial vein a preferable venipuncture site in conscious birds. The jugular vein is readily occluded following venipuncture to prevent hematoma formation.

Specially designed penguin restraint devices have been used to facilitate venipuncture without anesthesia. Keymer et al. (2001) described a device made to

hold free-ranging penguins on the Falkland Islands, including Magellanic penguins, rockhopper penguins, and gentoo penguins. Birds were held in a plastic tube, with a slit in the side that enabled exposure of the flipper and access to the brachial vein.

In the captive setting, training of aviculturists to restrain penguins for jugular venipuncture is paramount. For penguins <7kg, most birds require the primary handler to restrain the body and the secondary handler to restrain the head. The primary handler can either kneel on the ground or sit on a chair or stool with the penguin (facing away from them) pinned/restrained using their knees. The secondary person gently and firmly grasps the top of the bill and back of head to extend the bird's head right or left over the primary restrainer's leg to allow venous access. Penguins larger than 10kg require the primary handler to approach the bird from behind and wrap their arms, and sometimes legs, around the penguin. The secondary handler can restrain the bill and back of head firmly, and gently direct it over the primary handler's shoulder, allowing jugular venous access. Sometimes, a third person is required to maintain restraint of the penguin by aiding the primary handler (Fig. 25.4).

Intravenous catheters have been successfully maintained in the brachial vein and the medial metatarsal vein in several penguin species (Bradford et al. 2008; Wallace & Walsh 2005). Intraosseous fluid administration is difficult due to the dense, poorly pneumatized bones. Breitweiser (1994) described a technique for repeated administration of large volumes of intracelomic fluids to gentoo and rockhopper penguins that was well tolerated by conscious birds. The needle was placed just caudal to the keel and slightly left of the midline, and warmed fluids were administered into the celomic cavity, between the body wall and the distal end of the proventriculus. Subcutaneous fluids, whether indicated for maintenance or treatment of deficits, are administered using a 19- or 20-gauge needle with a standard fluid administration set. The skin behind the nape of the neck or dorsal scapular region is tented and the needle is inserted into the subcutaneous tissue space. Fluid volumes of 250–300 mL per site can be administered for penguins <7kg. Fluid boluses 500 mL–1 L can be safely and efficiently administered in king and emperor penguins. Most penguins need only to be restrained briefly for placement of the needle and then can be allowed to roam in a confined space as the fluids are delivered.

ENDOTRACHEAL INTUBATION

The technique for endotracheal intubation is as for other birds. The presence of the crista ventralis may necessitate selection of an endotracheal tube with a smaller external diameter. The median septum of the trachea may result in unilateral intubation and/or tra-

cheal mucosal trauma. Some authors prefer to maintain penguins using a facemask because of the presence of the septum (Cranfield 2003). The point of separation of the two channels is generally distant enough from the glottis to allow insertion of a Cole endotracheal tube (Stoskopf & Kennedy-Stoskopf 1986).

Endotracheal tubes with the appropriate diameter should be selected. In the author's experience (KB), little penguins require endotracheal tube sizes 2.5–3.5 mm. The largest penguin species, emperor penguins, have been intubated using 9.0-mm endotracheal tubes (Kooyman et al. 1992). Inflation of the endotracheal tube cuff has not been shown to be harmful to the tracheal mucosa in the authors' experience, and may be required to prevent possible exposure to refluxed gastric fluid. Care must be taken not to over-inflate the cuff and cause subsequent tracheal membrane damage.

Laryngeal masks (LMA) have also been used to deliver anesthetic gases in penguins. Use of LMA is believed to reduce risk of postintubation trauma to the crista ventralis and tracheal mucosa (J. Sykes, pers. comm., Wildlife Conservation Society, Bronx, NY, August 2012). As laryngeal masks are designed for human pediatric patients, the airway should be repetitively evaluated during a procedure to ensure correct placement and patency.

PREANESTHETIC CONSIDERATIONS

In the zoological setting, it is preferable to obtain a complete history, physical examination, and blood analysis of the penguin to formulate a safe and efficient anesthetic protocol. Clinical history of the patient is reviewed to prepare for additional testing, monitoring, and/or avoid unnecessary anesthetic complications. Physical examination should include evaluation of: weight, body condition, hydration, nutritional status, and systematic evaluation of body organs. Apart from true emergencies, most anesthetic procedures should be conducted on stable patients. The clinical history and examination may identify physiological risks (ie. respiratory disease) or therapeutic needs of the patient prior to anesthesia. A preanesthetic blood analysis should include a cell blood count (CBC), hematocrit, total protein, albumin, globulins, glucose, uric acid, creatinine, aspartate aminotransferase (AST), calcium, phosphorous, and electrolytes (sodium, chloride, and potassium). Significant clinical pathology abnormalities should be corrected prior to anesthesia. Elective procedures should be postponed until the underlying condition is treated to alleviate risk of complications. Hydration status should be corrected prior to anesthesia, and the patient should be held in an environment where the temperature is appropriate for the species (e.g., using air-conditioning). The desired temperature range for polar to temperate species is approximately 5–18°C, respectively.

Capture and immobilization of wild penguins should be carried out in areas where there is no opportunity for escape into water. Where possible, fasting for a minimum of 8 hours is recommended, to empty the stomach prior to anesthesia.

Thil and Groscolas (2002a, 2002b) repeatedly anesthetized King penguins with tiletamine-zolazepam during their breeding (nonmolting) fast, and did not detect significant differences between induction time, duration of immobilization, and measured parameters (including heart rate [HR], cloacal temperature, and respiratory rate) during anesthesia carried out at different stages of the fast. However, anesthetic procedures conducted during periods of physiological stress, particularly molting, may carry greater risk of compromise for the patient. Vleck et al. (2000) determined that Adélie penguins that had fasted up to 40 days during courtship and early incubation showed no increase in corticosterone or heterophil : lymphocyte ratio with length of fasting, but in birds that had fasted more than 50 days, corticosterone levels increased. Such periods will be less nutritionally and environmentally stressful in penguins maintained under controlled conditions in captivity than in free-ranging birds. Breeding fasting and molting, however, will still occur in captivity and should be taken into consideration.

Penguin chicks are brooded by their parents, as they are unable to maintain constant body temperature. Adélie penguins are poikilothermic from hatching to approximately 9 days old (Williams 1995). Nonincubating adult birds (particularly during the period immediately prior to the molt) will have a thick subcutaneous fat layer. In King penguins, intramuscular administration of drugs requires injection to at least 2 cm depth (Thil & Groscolas 2002a, 2002b).

Positioning in dorsal recumbency adversely impacts respiratory function. Thil and Groscolas (2002a, 2002b) observed King penguins in dorsal recumbency developed tracheal obstruction due to accumulation of salivary secretions, and the birds lifted their heads to facilitate swallowing. They found penguins immobilized and placed in ventral recumbency had a reduced incidence of apnea and "head lifting" compared with those in dorsal recumbency. In addition, duration of immobilization was significantly prolonged in dorsally immobilized penguins. Penguins maintained with inhalant anesthesia can be manually or mechanically ventilated to compensate for the effects of dorsal recumbency.

INDUCTION AND MAINTENANCE PROTOCOLS

Inhalation anesthesia, using isoflurane or sevoflurane, is most frequently used for induction and maintenance in penguins. Anesthetic induction may be achieved by administration of 0.5–4% isoflurane and 3–8% sevoflu-

rane via facemask. Maintenance of isoflurane is commonly 2.5–3%, whereas sevoflurane is 3–4.5%, depending on species and whether assisted ventilation is used.

Apnea and bradycardia can develop during mask induction, and have been ascribed to the cardiorespiratory "dive response." These changes, however, may be elicited as part of the defensive response to stress (Jones et al. 1988). This stress response may be ameliorated by the use of premedicants, such as benzodiazepines (Ludders & Matthews 2007). Intubation may be attempted when there is reduced jaw tone, reduced menace or palpebral reflex, and recumbency. It is not uncommon for penguins to continue "swimming" with wings beating during the initial phase of anesthesia; this excitement phase will abate as anesthetic depth increases. Wing beating may persist if the penguin is hypoventilating. Assisted ventilation, two to three breaths per minute, may be necessary to obtain a smoother induction of anesthesia (Wallace & Walsh 2005).

Use of sevoflurane for anesthetic induction, +/- maintenance has been reported in a number of penguin species (Bradford et al. 2008; Ponganis et al. 2001; Wallace & Walsh 2005). Sevoflurane has the potential for more rapid induction and recovery, due to its lower solubility than isoflurane. Its less pungent odor may reduce stress experienced during a facemask induction.

Midazolam 1.5 mg/kg, given intramuscularly, has been used to sedate little penguins, yellow-eyed penguins, and Fjordland penguins for noninvasive procedures, such as radiology (J. Ward, pers. comm., New Zealand Wildlife Health Center, Massey University, April 2011). Peak sedative effect generally occurred in 5–10 minutes, and duration of action was approximately 1–3 hours. Premedication with midazolam (using the same dose rate) also facilitated smoother and more rapid anesthetic inductions using isoflurane in oxygen via facemask. Gradually increasing isoflurane concentration from 0.5% has been used as a means of avoiding breath-holding during mask induction of little penguins (J. Ward, pers. comm.).

Tiletamine and zolazepam (5 mg/kg IM) produced safe immobilization of free-ranging adult King penguins (Thil & Groscolas 2002a, 2002b). Induction time (time to sternal recumbency) averaged 4 minutes, and duration of immobilization was approximately 1 hour (mean = 69.3 ± 2.2 minutes). Transitory apnea (maximum duration 1.5 minutes) was noted in 30% of bird anaesthetized. The level of anesthesia was sufficient for noninvasive procedures. Preliminary trials suggested a higher dose rate (10 mg/kg IM) is suitable for immobilization for surgical adipose tissue biopsies (Thil & Groscolas 2002b). Five- to seven-month-old fasting chicks were immobilized for 80 minutes after receiving a 4 mg/kg dosage.

Administration of ketamine (2.0–7.5 mg/kg IM) resulted in sedation of free-ranging Humboldt penguins (Luna-Jorquera et al. 1996). Ketamine (5 mg/kg

IM) facilitated handling for attachment of data loggers, but did not result in anesthesia. Birds recovered after 40–45 minutes. Higher dosages (7.5 mg/kg) resulted in salivation, muscular rigidity, reduced consciousness, and more prolonged recovery. Higher ketamine dosages (5–10 mg/kg IM), administered to nesting African penguins, resulted in prolonged anesthetic recovery (Wilson & Wilson 1989).

MONITORING

The mean deep body temperature in little penguins in their thermoneutral zone in air was $38.4 \pm 0.8^\circ\text{C}$ (Stahel & Nichol 1982). Core temperature in male emperor penguins incubating eggs must be maintained at $37.6\text{--}38.5^\circ\text{C}$ during the Antarctic winter, via metabolic heat production and huddling behavior (Williams 1995). Deep body temperature measured in free-ranging emperor penguins during nocturnal rest (i.e., when birds were not diving) ranged from 36.0 to 38.7°C (Ponganis et al. 2001).

Esophageal probes may provide a more accurate measure of core temperature during anesthesia: the temperature taken 5 cm inside the cloaca represented core temperature in little penguins, whereas cloacal temperatures taken 3 cm from the vent were considerably lower (Stahel & Nichol 1982).

Mild hypothermia has been observed in King penguins undergoing prolonged anesthesia (duration approximately 75 minutes) using tiletamine-zolazepam in the field. This was addressed by placing the birds on insulative covers during the procedures (Thil & Groscolas 2002a, 2002b). Prolonged inhalant anesthetic procedures can cause hypothermia due to inhalation of dry cold oxygen; therefore, constant temperature monitoring is required. The presence of the highly insulative feathers will limit the effectiveness of contact heating methods.

In general, hyperthermia is considered a more likely adverse effect than hypothermia during restraint and anesthesia of penguins, due to the presence of an insulative subcutaneous fat layer and densely packed feathers. The anatomical adaptations that allow rapid cooling when penguins are exposed to high environmental temperatures may be utilized during anesthesia. In the field, application of snow to the underside of flippers and the feet has been used to cool penguins at risk of hyperthermia. In the captive setting, frozen ice blocks are initially placed on the feet and under the flippers to lower risk of hyperthermia (Fig. 25.5).

Respiratory rate and character should be constantly monitored during anesthesia, by observation of thoracic movements, and by those of the rebreathing bag during gaseous anesthesia. Pulmonary auscultation is best achieved over the dorsum.

The HR of a medium-sized penguin should be between 85 and 120 bpm (Stoskopf & Kennedy-Stoskopf

Figure 25.5. Inhalant anesthesia in a king penguin. Note the positioning of the animal on ice to minimize hyperthermia (courtesy of SeaWorld San Diego).

1986). Sinus arrhythmia is not a common feature during cardiac auscultation (Stoskopf & Beall 1980). The HR of adult King penguins anesthetized using tiletamine-zolazepam was 99–115 bpm (Thil & Groscolas 2002b). HR and rhythm should be monitored throughout anesthesia, either by external auscultation near the ventral pectoral girdle or by using an esophageal stethoscope. HR during anesthesia may also be monitored using a Doppler probe placed over the brachial artery. A standardized technique for lead placement and electrocardiographic monitoring of HR and rhythm has been reported (Stoskopf & Kennedy-Stoskopf 1986). Heart rhythm must be monitored so that abnormal rhythms, such as AV block, tachycardia, or bradycardia will be noted and corrected (by administering appropriate treatment or by ending the procedure). Pulse oximetry will allow continuous assessment of trends in pulse rate and oxygenation in stationary birds; however, the oxygen saturation values in birds do not correlate well with arterial saturation derived from blood gas analyses (Schmitt et al. 1998). At the same oxygen saturation, the high absorption ratio in birds compared with humans results in a low saturation value on the human calibration curve used by pulse oximeters. It is notable that the oxygen-hemoglobin dissociation curve determined in gentoo, chinstrap, Adélie, and emperor penguins is significantly left-shifted when compared with most other birds. In these penguin species, the partial pressure of oxygen at which hemoglobin is 50% saturated (P_{50}) lies within the mammalian range rather than the avian (Meir & Ponganis 2009).

RECOVERY

Gaseous anesthetic agents generally result in a more rapid recovery from anesthesia than injectable agents. A rapid anesthetic recovery is preferable, particularly in free-ranging penguins, as prolonged interruption of normal behaviors may result in negative effects, such as disturbance of breeding and nest abandonment.

Signs of recovery include “swimming” or flapping of the flippers, leg, and head movement. Recovering penguins should be supported upright to prevent regurgitation or trauma to the flippers. Mild gastric reflux is not uncommon and should be managed by close observation and gently swabbing of the oropharynx with gauze to prevent aspiration of fluid. The endotracheal tube can be removed when the penguin displays a cough reflex and appears to swallow. Once extubated, penguins should not be allowed access to water until they have completely recovered from the effects of anesthetic agents. Free-ranging penguins can be housed inside portable temporary enclosures, situated close to the colony, until they have completely recovered. They must be protected from extremes of temperature and closely monitored while they are still demonstrating effects from anesthetic agents.

FIELD ANESTHESIA

Field anesthesia techniques should be chosen carefully. The environmental conditions and the physiological status and behavioral features of the species concerned must be evaluated. Planning immobilization procedures must include consideration of the potential detrimental impacts that the intervention produces. Living in an extreme environment is energetically costly, and stressful interventions may compromise survivorship and/or reproductive success.

Use of injectable agents will facilitate remote delivery of immobilizing drugs, potentially reducing stress induced by capture and manipulation. When remote delivery techniques are used, anesthetic drug delivery is less precise and adjustments in dose rate are not possible. The use of inhalational anesthetic agents to induce and maintain anesthesia allows the operator greater control over anesthetic depth and duration than the use of injectable agents for this purpose. Precision vaporizers must be housed in insulated containers when environmental temperatures are low, as they function efficiently only within a limited temperature range (Gales et al. 2005). Therefore, the apparatus used to deliver gaseous anesthetic agents may prove cumbersome and difficult to deploy under the environmental conditions encountered in sub-Antarctic and Antarctic habitats. Use of injectable anesthetic agents may be logistically preferable in such circumstances.

POSTANESTHETIC CHALLENGES

There have been no studies investigating the pharmacokinetic basis of analgesic drug doses in penguin species. Empirical use of butorphanol (1 mg/kg IM) has been reported for postsurgical analgesia (Bradford et al. 2008). In the author's experience (TS), tramadol (2–4 mg/kg, SID to BID, PO) has provided postoperative analgesia for medium and large penguins.

Use of the non-steroidal anti-inflammatory drug (NSAID), ibuprofen (3–5 mg/kg SID-BID), has been reported (Wallace & Walsh 2005). The author (KB) has used orally administered meloxicam (0.1–0.2 mg/kg SID-BID) in little penguins, and behavioral observations suggested an anti-inflammatory/analgesic effect. However, dosage and administration of NSAIDs should be carefully considered prior to their use. A clinical study by Baert and De Backer (2003) compared the plasma clearance rates of three NSAIDs in five bird species. Between species, the difference in protein binding alone was so great that the authors recommended the pharmacokinetics of each NSAID should be independently assessed for each target avian species. Adverse effects (such as renal tubular necrosis, visceral gout, and mortality) may occur following NSAID use.

26 Ratites

Jessica Siegal-Willott

INTRODUCTION

Ratites belong to the avian orders Struthioniformes (ostriches), Casuariformes (emus and cassowaries), Rheiformes (rheas), and Apterygiformes (kiwis) (Smith 2003). Depending on the classification system, Tinamiformes (tinamous) may also be included.

Taxonomy and Biology

Ostriches (*Struthio camelus*) are the largest living birds (Table 26.1). There are several recognized subspecies confined to Africa and portions of the Middle East. Ostriches are sexually dimorphic; males are generally larger and have distinctive black feathers and wing plumes.

The common (*Rhea americana*) and Darwin's or lesser (*Rhea pterocnemia*) rhea are endemic to the grasslands of South America. The emu (*Dromaius novaehollandiae*) is confined to Australia. Emus are second in size to the ostrich, with the females slightly larger than males. There are three cassowary species, the double-wattled (*Casuarius casuarius*), single wattled (*Casuarius unappendiculatus*), and the Dwarf cassowary (*Casuarius bennetti*), all native to the Australasian rainforests. The three species of kiwi are confined to New Zealand; the great spotted (*Apteryx haastii*), the little spotted (*Apteryx owenii*), and the brown (*Apteryx australis*). Tinamous are small flighted ground-dwelling birds from the forests of South America. There are 47 recognized species, and they are either classified as, or are considered the closest avian relatives to the ratites described above.

Anatomy and Physiology

The term "ratite" refers to the flat raft-like sternum lacking a keel bone for attachment of the large flight

muscles. All have elongated necks and relatively long, muscular legs, but little pectoral muscle development. All possess elongated toenails for aggression or defense, and are strong and rapid runners. Ostrich toenails are blunted, whereas those of other ratites are sharp. Rheas can abruptly change direction when running, and both rheas and cassowaries are powerful swimmers.

As with other birds, ratites lack a diaphragm. They possess much reduced air sacs compared with flighted birds. Respiration requires movement of the sternum down and forward, with the ribs expanding outwards. This is inhibited when weight, such as from a person straddling the bird, is applied from above. Death of birds thus restrained has been attributed to hypoxemia. Only the femur is pneumatized in ostriches and emus (Fowler 1996).

The normal respiratory rate of an adult ostrich is 6–12 breaths/min (bpm), but may increase up to 40–60 bpm during periods of hyperthermia. Normal body temperature (38–40°C) is maintained during thermal stress using evaporative cooling from the trachea, air sacs, and pharynx (Fowler 1996). The ratite glottis is simple with a large opening, an adaptation proposed to facilitate inhalation of air during strenuous exercise (Fig. 26.1). The trachea is composed of complete cartilaginous rings.

Ratites possess a renal-portal system, similar to other birds. Although theoretically it might enhance excretion of renally eliminated drugs, in ostriches administered xylazine/tiletamine/zolazepam, there was no significant difference between injection in the thigh or muscles at the base of the wings in onset, duration, or recovery (Carvalho et al. 2006). The physiologic role of the renal-portal system is poorly understood; care is used when potentially nephrotoxic drugs or those primarily eliminated by the kidneys (i.e., ketamine) are

Table 26.1. Reported weight and height ranges for ratites and tinamous

Species	Height	Weight
Ostrich	2.1–3.0 m	≤160 kg ^b
Emu	1.5–1.9 m	30–55 kg ^a
Cassowaries		
Double wattled	1.3–1.7 m	♂ 29–34 kg
Single wattled	1.5–1.8 m	♀ ≤58 kg
Dwarf	1.0–1.1 m	NR
Rheas		17.6–25 kg
Greater	1.2–1.7 m	20–25 kg ^b
Darwin's	1.0–1.1 m	10–25 kg ^b
Kiwis	0.35–0.55 m	0.67–4 kg ^a
Tinamous	NR	0.04–2.3 kg ^a

^aFemales larger than males.

^bMales larger than females.

NR, not reported.

**Figure 26.1.** The glottis of most ratites, as in this rhea, is large and readily visible at the base of the tongue.

administered into the thigh musculature or medial metatarsal vein.

The ostrich is the largest living bird, with some males weighing as much as 160 kg (Table 26.1). Both male and female emus possess a ventral midline tracheal sac, approximately 10–15 cm cranial to the thoracic inlet.

The kiwi nares are located close to the beak tip; this location is thought to facilitate scent location of food among forest leaf litter. The kiwi egg is the largest proportionately of any living bird. Prior to oviposition, it occupies a large proportion of the coelomic cavity with a consequent reduction in air sac space. Further com-

promise to respiration due to pulmonary compression will occur if the animal is turned on her back. Kiwis also have lower body temperature (36.6–40.3°C) and metabolic rate than most other birds (Smith 2003).

PHYSICAL RESTRAINT

Young ratites (chicks and small juveniles) weighing ≤6 kg are manually restrained by supporting under the body and allowing the legs to hang or be folded. Birds weighing 6–15 kg are restrained with a hand around the abdomen, leaving the legs free. Care is taken during catching or handling to prevent damage to the legs. Chicks can also be wrapped in a towel for restraint or travel.

Juveniles and adult ratites require experienced handlers for restraint. These birds are large and strong, and possess large claws on the toes often used for defense. Emus and cassowaries in particular have large nails on the medial digit. Male ostriches are especially dangerous during the breeding season. Ratites jump, kick, and slash in a forward direction, and thus are approached from behind or the side to minimize risk of injury to the handler. Emus can also kick sideways, and rheas can kick in any direction. Gloves and protective clothing are often useful in preventing trauma from the distal limbs during restraint. Assuming a flat (prone) position on the ground will prevent trauma from kicking if escape from the bird is not possible.

Physical restraint of adult ratites by experienced handlers involves straddling the bird, with its legs in front of the holder. The wings should be grasped at the level of the humerus; the bird may also be restrained by a hand over the breast plate. Emus should not be restrained at the humerus, as the wings are reduced in size and may fracture. Emus accustomed to handling, and gently restrained from behind, may allow collection of blood or injection of anesthetics into the right jugular vein. The bird will, however, respond violently if the upper neck or head is grabbed.

Alternatively, in ostriches, the head may be grasped and quickly lowered below the level of the body. This prevents the ratite from kicking above its head level, minimizing the risks to the handler. This method of restraint is often used to place a hood, and possibly injection of medications.

Padded chutes, boards, alleyways, and stanchions are useful in the movement, separation, and isolation of individual animals for restraint and anesthetic procedures. Dim lighting (emus, rheas, cassowaries, and ostriches) and/or hooding (ostriches only) to decrease visual stimuli are useful for restraint. Hoods should cover the eyes without occluding the nostrils, and extend ~1/3 of the distance down the neck (Cornick-Seahorn 1996) (Fig. 26.2). Hooks are not recommended for catching or restraint as they may result in lacerations of the neck and/or trachea, and possibly death of

Figure 26.2. A hood reduces excitement and struggling in ostriches; it is not recommended in other ratites.

the bird if not used appropriately (Raines 1998). However, in some situations, this is the only way to catch the head for hood placement. Proper construction and application of hooks are described by Fowler (1995).

Emus present special challenges. Their skin is thin and easily lacerated. The head and long neck are vulnerable to injury because of the lack of significant muscle or soft tissue covering. The trachea is also easily collapsed. These birds are readily stressed, with subsequent respiratory or circulatory collapse, exertional rhabdomyolysis (Chapter 13), self-trauma, and hyperthermia (Chapter 5). Lastly, emus are capable of jumping high distances (≤ 2 m), and will attempt escape. Juvenile emus are more tractable, requiring only an experienced handler. One hand is placed between the legs and on to the sternum, leaving the other hand free to immobilize the head and neck (Mouser 1996).

Cassowaries are aggressive, requiring sedation or anesthesia for most handling procedures; hooding or covering the eyes is not adequate for safe restraint. During the very short period of sexual receptivity, captive females may be approached and allow examination and blood collection.

If possible, physical restraint occurs in secure areas, with solid, nonslip surfaces, free of large, deepwater sources, obstacles that may injure the bird or handler (hooks, nails, ledges, holes, wire, machinery, etc.), and at a suitable ambient temperature. Capture enclosures are designed to minimize risks to the patient and handlers, with easily accessible exit routes. Padded equine recovery stalls, with lights that can be dimmed, are excellent areas for restraint, induction, and recovery. Heavy foam pads, when used as shields, protect han-

Figure 26.3. Wooden shields are used to protect handlers when approaching partially anesthetized ratites.

dlers and are used to compress birds in a confined space for IM or IV injections. These pads are cleaned and disinfected between uses. Wooden shields are also useful to protect handlers when approaching lightly anesthetized animals (Fig. 26.3).

VASCULAR ACCESS

Intravenous injections and phlebotomy are performed using either the right jugular (14–22 g), brachial, or medial metatarsal vein. The medial metatarsal vein is not accessible in the awake adult. In emus, the basilic vein is small (although still able to be catheterized) as a result of vestigial wing development (Fig. 26.4). The wings are also prone to fracture during manual restraint (Cornick-Seahorn 1996).

Intravenous fluids are administered to anesthetized ratites at 5–10 mL/kg/h. Fluids commonly used include lactated Ringer's solution, Ringer's solution, and 0.9% sodium chloride. Fluid supplementation with dextrose may be warranted in young and/or debilitated birds. If IV access is not possible, intraosseous (IO) catheters may be placed in juvenile birds. The ulna and tibiotarsus are commonly used for IO access (Chapter 23).

ENDOTRACHEAL INTUBATION

Noncuffed endotracheal (ET) tubes are used to prevent pressure necrosis of the tracheal mucosa, although some authors prefer cuffed tubes to minimize the risk of aspiration, and ensure effective mechanical ventilation. The glottis is large and easily visualized for

Figure 26.4. The wings of emus and most ratites are small and can be fractured if used to restrain an animal. The basilic vein on the medial surface of the wing can be used for blood collection in sedated or anesthetized animals, and for catheterization for fluid administration under anesthesia.

insertion of the ET tube (Fig. 26.1). Light bandaging around the neck of emus prevents air from distending the subcutaneous air sac during positive pressure ventilation.

The head and neck are positioned to prevent kinking of the ET tube, and to minimize risk of regurgitation and aspiration. Tube internal diameter varies with bird size, ranging from 4 to 18 mm. Intubation and positive pressure ventilation are recommended for all prolonged (≥ 10 minutes) or surgical procedures. Ventilatory support aims to achieve a tidal volume of 10–20 mL/kg, respiratory rate of 6–12 breaths per minute, and a peak inspiratory pressure of 10- to 15-cm water (Cornick-Seahorn 1996; Fowler 1996).

ANALGESIA

Use of analgesics is based on experience in other avian species (see also Chapter 7). Limited work has been done to establish dosage ranges in ratites. Fentanyl and butorphanol have been used as adjuncts to general anesthesia for pain control (Cornick-Seahorn 1996).

CHEMICAL RESTRAINT AND ANESTHESIA

Drugs used for chemical restraint in ratites are summarized in Table 26.2. Intramuscular administration is routine; the cranial and caudal thigh muscles and lum-

bosacral area (in nonobese birds) are used, since the pectoral muscles are not developed (Fig. 26.5). Injections into larger, more proximal thigh musculature may be more effective than those at more distal locations (Cushing & McClean 2010). The role of the renal-portal system in drug elimination following administration into caudal musculature has not been fully elucidated. Intravenous drug administration offers the most rapid method of immobilization; in intractable animals, IM sedation may be required prior to IV access.

Fasting times vary based on age and size of the bird, with little to no fasting in those < 6 months old to prevent hypoglycemia. Adult ratites are fasted for 12–24 hours prior to induction (Cornick-Seahorn 1996; Lin et al. 1997).

Chemical immobilization is conducted in safe, secure areas with escape routes available for all personnel involved. Successful chemical immobilization varies with age and species, as well as experience level of the handlers and anesthetist(s).

Premedications

Anticholinergics are not commonly used, as they increase the viscosity of respiratory secretions, potentially leading to airway obstruction (Gilsleider 1998). Bradycardia is not commonly encountered during ratite anesthesia. In ostriches, anticholinergic therapy is indicated if heart rate falls below 30–35 bpm (Cornick & Jensen 1992). However, anticholinergic therapy is not consistently effective in treating bradycardia (Cornick & Jensen 1992). Many instances of bradycardia are likely due to hypertension and therefore refractory to anticholinergics.

Tranquilization and sedation have been achieved using acepromazine, azaperone, diazepam, midazolam, xylazine, detomidine, ketamine, and medetomidine, allowing for blood collection, minor procedures, and facilitation of induction of anesthesia (Table 26.2). These medications are usually administered IM; oral diazepam has been used successfully to sedate ostriches and cassowaries (Fowler 1995; N. Kapustin, pers. comm.).

Xylazine is commonly used, either alone or in combination with ketamine. Caution is warranted when using this alpha-2 agonist, as it has significant cardio-respiratory depressant effect. Onset of action is usually within 10 minutes, and may provide up to 30 minutes of sedation (Gilsleider 1998). High doses of xylazine IM allowed for IV ketamine induction 20 minutes later in adult ostriches (Al-Sobayil et al. 2009). Low dose medetomidine allowed for safe approach and limited handling in adult captive and free-ranging cassowaries, and was fully reversed with atipamezole administration (Westcott & Reid 2002). Higher doses produced heavy sedation adequate for full examination (Westcott & Reid 2002). Juvenile (< 1 year) cassowaries were heavily

Figure 26.5. Intramuscular injections are administered into the upper thigh. This is done with either remote or hand injection.

sedated using medetomidine/ketamine combination; degree of sedation was somewhat variable, and supplemental M/K was occasionally necessary for some procedures (S.B. Citino, pers. comm., 2006). Intramuscular medetomidine, followed by medetomidine/midazolam IM, in these same cassowaries produced mild sedation adequate for crate loading (S.B. Citino, pers. comm., 2006).

Acepromazine is useful for muscle relaxation, but is contraindicated in debilitated animals, and is not a preferred method of tranquilization. Safer drugs for healthy and ill birds include diazepam and midazolam. Azaperone is useful for transport of animals, as it provides little muscle relaxation, but adequate tranquilization for up to 24 hours (Cornick-Seahorn 1996; Gilsleider 1998).

Immobilization

Opioid Combinations Carfentanil and etorphine have been used with limited and variable success. Carfentanil produces rapid recumbency, but has been associated with excitatory activity (frenzied running, circling, and walking backwards) (Cornick & Jensen 1992; S.B. Citino, pers. comm., 2006). In severe cases, this excitatory phase results in exertional rhabdomyolysis or trauma. Etorphine has been used in combination with acepromazine, acepromazine and xylazine, ketamine, and with medetomidine. In each case, satisfactory muscle relaxation and sedation were achieved, and use of medetomidine allowed for complete immobilization. In ostriches, etorphine combined with medetomidine produced recumbency in <10 minutes in most cases (Ostrowski & Ancrenaz 1995). Risks with these combinations include regurgitation, aspiration, myopathy, and death (Cornick-Seahorn 1996).

In juvenile ostriches (<1 year), etorphine/acepromazine had no or variable effect, from mild sedation to profound immobilization. Etorphine/ketamine

showed similar, but more reliable immobilization and recovery when administered to adult ostriches (Stoskopf et al. 1982). Some of the variability may have been due to dart failure. Manual restraint was used to assist the adults into sternal recumbency following adequate tranquilization. In contrast, lower dosages of etorphine/acepromazine administered via blow dart produced moderate sedation for 10–20 minutes in juvenile birds, with some ataxia and excitement during the initial immobilization (Samour et al. 1990). In adult ostriches, higher dosages of etorphine/acepromazine, in combination with xylazine, improved sedation and allowed manual restraint for diagnostic procedures. Initial effects were similar to those noted earlier (Samour et al. 1990). Ostriches appear resistant to high etorphine dosages (Samour et al. 1990; Stoskopf et al. 1982). Given the unpredictable effects of etorphine/acepromazine combinations, alternative immobilizing and induction agents should be considered first.

In adult cassowaries, etorphine (≤ 10 mg) did not produce immobilization (Stoskopf et al. 1982). However, a combination of etorphine/ketamine produced immobilization within 25 minutes in most birds, but was associated with long, rough recoveries (Stoskopf et al. 1982). A similar etorphine/ketamine combination (6/400 mg) was used to successfully induce a cassowary for surgical removal of a mass (Ensley et al. 1984). This combination produced recumbency within 5 minutes; however, supplemental ketamine was necessary for safe handling and administration of general anesthesia (Table 26.2). Adult cassowaries have been immobilized with a carfentanil/midazolam/ketamine combination. Animals were recumbent within 10 minutes, and occasionally exhibited an excitatory phase. Supplemental ketamine was given in some instances to allow for safe transport (S.B. Citino, pers. comm., 2006).

In adult emus, thiafentanil/medetomidine administration via Pseudart produced recumbency within 10 minutes in most cases; supplemental ketamine was necessary in three cases. Risks with this combination included respiratory acidosis and bradypnea, treated with IV atipamezole and supplemental orotracheal oxygen administration. Recovery following reversal and midazolam administration was rapid and smooth (Cushing & McClean 2010).

Other Combinations In ostrich chicks undergoing four different anesthetic combinations, only metomidate/azaperone IM produced satisfactory anesthesia and analgesia with relatively few side effects (Van Heerden & Kefren 1991). In the same chicks, tiletamine/zolazepam, metomidate, and metomidate/azaperone IM produced successful immobilization; an adult ostrich given a similar dose of tiletamine/zolazepam exhibited violent kicking and self-trauma, and insufficient immobilization (Van Heerden & Kefren 1991). The immobilization times were dosage dependent and

most combinations did not fully eliminate voluntary movements. Medetomidine alone (0.1 mg/kg) did not produce immobilization (Van Heerden & Kefren 1991). In contrast, juvenile ostriches (9–11 months old) were successfully immobilized with a medetomidine/ketamine (0.08 mg/kg; 2 mg/kg) combination, although recumbency was not achieved in all cases (Langan et al. 2000). Tiletamine/zolazepam in combination with diazepam has also been used to immobilize a juvenile emu (Tully et al. 1996b), and ketamine alone has been used to immobilize an adult rhea, though quality of immobilization was not reported (Smith et al. 2005).

Induction
