Rovsing, the Dane who recommended Wancher’s bag, became professor of surgical techniques, including anesthesia, without facilitating the specialty’s development. It would perhaps have been better if his colleague, Fritz Levy, had been given the opportunity to take the lead. At a 1904 meeting, Levy stated:

“To perform a good anesthetic is an art which has to be taught just as everything else in life. It is also a gift which not all have been given. Thus this task cannot be handed over at random to anyone in the surgical staff. On the contrary it is necessary to secure an adequate number of well trained anesthetists” [19].

A Roth-Dräger's anesthesia machine came into use in Copenhagen in 1902–03. For the first time a Nordic anesthetist could administer chloroform in a controlled way and also give the patient "a surplus of oxygen".

Local Anesthetics

News of Karl Koller's demonstration of the local anesthetic effects of cocaine, in Vienna in 1884, traveled quickly to Scandinavia. In 1885, the Swedish laryngologist, K Malmsten, vividly described the application of this breakthrough. After relating how earlier trials with local application of morphine/chloroform had been unsuccessful, he stated that "*in 6 months all earlier scientific quarrels stopped when cocaine came into use*" [20]. The Dane, Ernest Schmiegelow, used it in 1886 for topical administration [21]. Shortly thereafter another Dane, Christian Paulsen, performed the first trials with infiltration of cocaine for local anesthesia

In Norway's Tromsø hospital, still the most northern university hospital in Europe, a young surgeon, Kristian Igelsrud, performed a spinal anesthetic shortly after August Bier's 1898 report. He also gave cocaine for superficial and infiltration anesthesia. These techniques gave the lone surgeon a perceived safer method than general anesthesia, safer because the surgeon could establish a stable level of anesthesia before attending to the surgery [22]. In major centres, the spinal anesthetic was often placed by a junior doctor with little experience in anesthesia, and when it was seen to work, nurses or technicians took over observation of the ongoing effect of the anesthetic. Contemporaneous similar reports were published by H Munch-Pedersen in Denmark [23] and by G Nyström in Sweden [24].

1900–1920

Surgeons in Control

By the early 1900s, many doctors in England and the US had specialized in anesthesia, but in Nordic countries, surgeons were responsible for anesthetic delivery and remained so for another four decades. Nurses provided general anesthesia under the surgeon's supervision. Such approaches became increasingly used in all Nordic countries. No scientific reports refer to general anesthesia in Scandinavia in this period. In the weekly journal *Hospitaltidende*, the co-editor, Aage Kiaer, stated in 1904: "*As well as I don't want to be operated by anyone, I don't want to be anesthetized by anybody*" [25]. His warning went unheeded. In 1916, the need to control the supply of ether and oxygen by an anesthetic machine was questioned (*the equipment would be too expensive!*) by a Danish professor of internal medicine.

Surgeons like Regional Anesthesia

Surgeons like Kristian Igelsrud in Norway, and Gunnar Nyström and his teacher KG Lennander in Sweden, brought regional anesthetic techniques to various hospitals. In 1904, Nyström, who later became professor of Surgery in Uppsala, published a comprehensive review of local anesthesia including the production of regional anesthesia by nerve blocks in the journal of the Swedish Society of Physicians [24]. In 1907, Lennander wrote a chapter about local and subarachnoid anesthesia in *Keen's Surgery* [26] in which he presented his results for spinal anesthetics, and described Cushing's method of anesthetizing the abdominal wall and the lower thoracic region with intercostal blocks, using cocaine.

Central Europe, rather than GB or the US, influenced anesthetic developments in Scandinavia during this period. A 1906 Swedish summary of a survey on spinal anesthesia, by the Austrian E Slajmer, recommended restricting the method to surgery below the umbilicus, using the thinnest needle possible, and applying pure alcohol for skin disinfection [27]. In 1909, Swedish surgeon G Bäärnhielm, reported on 100 spinal anesthetics with procaine [28]. Three years later Gustaf Petrén described his use of intravenous regional anesthesia with 0.5% procaine, as advocated by Bier. Procaine remained the standard local anesthetic until the introduction of lidocaine in the 1940s.

Much knowledge of this period comes from the research of the Dane, Preben Berthelsen. He describes a 1904 report of a trial with "Scopolamine/Morphine anesthesia for otologic surgery" [29], and a report on "Subcutaneous nutrition with dextrose and peptone."

Intermittent Positive Pressure Ventilation (IPPV)

In 1910, Holger Mollegaard, a young student working with Christian Bohr, constructed a ventilator providing continuous positive pressure [30]. A mixture of chloroform and air was used for ventilation in 17 operations involving the lung. The trial was stopped because the surgical technique was inadequate and severe postoperative infections ensued.

Swedish surgeon K Giertz used Sauerbruch's sustained negative pressure method, proving in dogs that IPPV was needed to guarantee carbon dioxide elimination. He unfortunately published his results only in Swedish [31]. Giertz' pupil Clarence Crafoord, used IPPV for thoracic surgery. In his thesis, "On pneumonectomies in Man", Crafoord describes anesthesia with cyclopropane, using tracheal intubation and mechanical IPPV [32]. The Swedish company AGA and Paul Frenckner (A Swedish ENT physician), had constructed the respirator (Spiropulsator). It was used in Sweden until the 1970s.

Except for Finland, Nordic countries were sheltered from the worst effects of World War I, suffering however from

isolation, leading to shortages of medical supplies, and to a lack of information. In Finland, the 1917 civil war did not make things better.

In 1916, Norwegian Nils Backer Groendahl, published the first Nordic anesthesia textbook for nurses entitled: *Anesthesia and Care of Surgical Patients* [33]. In this book he stresses the importance of skill and knowledge. By 1920, anesthetic practice had improved. Experienced nurses gave most of the anesthetics.

1920–45

Anesthetic Practice

The Swedish pioneer in neurosurgery, Herbert Olivecrona, observed that

‘usually the American neurosurgeons prefer ether anesthesia. This method is, however, very difficult and demands an anesthetist with long experience... For myself I have entirely changed to only use local anesthesia in brain surgery as long as the patient’s mental condition permits it’ [34].

This reflected the situation in all Nordic countries. Surgeons wanted to expand their practice but were constrained by a lack of experienced anesthetists. In part, this was a problem of their own making; they were “in charge” and unable/unwilling to relinquish this power.

In the 1930s, new ultra short acting barbiturates (in Scandinavia the German compound hexobarbital, Evipan was practically the only one) attracted interest, but their introduction in Sweden was marred by scientific quarrels about their use and dangers. New equipment like the McKesson apparatus increased interest in nitrous oxide anesthesia. These developments pointed to a need for specialists in anesthesia. Prominent surgeons like P Nylander in Finland, E Husfeldt in Denmark, J Holst and C Semb in Norway, and C Crafoord, J Strömbeck and G Söderlund in Sweden became convinced that anesthesia should be established as a medical specialty. Young surgeons were approached but their enthusiasm was limited for reasons previously discussed.

Wars usually bring improvements in surgical care. World War I advanced thoracic and neurosurgery, but did little to improve the performance of anesthesia. World War II varied in its effect on Nordic countries. Denmark was mostly spared. Norway was less fortunate, especially northern Norway where in late 1944, Russian troops fought the Germans, who burned everything as they retreated, leaving a desolate countryside. Medical development in both Denmark and Norway suffered from 5 years of isolation and restrictions. Nazi deportations of medical doctors (not only Jews) caused great hardship. JGBU’s father, a doctor, remembers the Germans taking a Dr. Bernstein while he was on ward rounds. He

never returned. The Allies occupied Iceland which was minimally affected by the war. In contrast, Finland fought two bitter wars against the Soviet Union, one in 1939, and the second in 1941–44. The Finns were obliged to pay a postwar indemnity to the Soviet Union, a huge financial burden for many years. Sweden remained neutral during the war, and thanks to Torsten Gordh’s pioneering work, anesthesiology began to develop as a specialty.

Nordic Pioneers: Denmark

A Danish pharmacologist, Knud Moeller, believed that most surgeons had little interest in anesthesia. He began a campaign to develop anesthesiology as a specialty. In 1936, while participating as a member of a doctoral committee involving a candidate defending a doctoral thesis about lumbar anesthesia, he raised public awareness that the quality of Danish anesthesia was inferior to that in other countries [35].

The first Danish anesthetist for a patient undergoing pneumonectomy (1939) was Ole Lippmann, the young director of Simonsen & Weel (a Danish manufacturer of medical instruments). He was not a physician but had learned how to administer nitrous oxide anesthesia during a 3 month stay in Toledo, Ohio while attached to the McKesson factory [35]. Lippmann introduced the technique to Ernst Trier Mørch, who later became Denmark’s first anesthesiologist [36].

The thoracic surgeon, Erik Husfeldt, had recruited Mørch to help with his operations. Between 1941 and 1949, Mørch acted as a freelance anesthetist in Copenhagen. In 1943, the Germans permitted him to have a 3 week sabbatical stay with Torsten Gordh in Stockholm, an experience that committed him to anesthesia. During the rest of the war he also contributed to the Danish resistance and took an active part in the smuggling of Jews to Sweden.

Immediately after the war, Mørch spent two years studying anesthesia in London and Oxford. Returning to Denmark, he taught anesthesia and established anesthesiology as a specialty there. He published the first Danish textbook on anesthesia in 1949. In 1949, he abruptly emigrated to the US, perhaps protesting against the government’s failure to create a department of anesthesiology at the Rigshospitalet (the National Hospital). In the US he led departments of anesthesia at major hospitals in Kansas City and Chicago [36].

Nordic Pioneers: Finland

After visiting Crafoord, Per Nylander, a Finnish surgeon, brought a ‘Spiropulsator’ back home. Another surgeon, Aare Järvinen, went to Sweden to study new anesthetic techniques. Nylander, and pharmacologist Armas Vartiainen, persuaded two resident surgeons, Eero Turpeinen and Lauri Aro, to become anesthetists. Before the war Turpeinen had studied the effects of anesthetic gases on animals, work for which he earned a PhD. Aro began work as an anesthesiologist after 1944.

In 1941, Turpeinen planned to travel to the US. The war delayed this until 1945, when he spent three months in the US and another three in the UK. On returning home he proposed the establishment of a position for an anesthetist at the Surgical Hospital in Helsinki. When this was rejected, he specialized in surgery, but in 1950 he was appointed as an anesthetist at Maria Hospital in Helsinki. After this, Turpeinen played a central role in the development of the specialty in Finland, and in founding both the Finnish and the Scandinavian Societies of Anesthesiologists.

Lauri Aro began surgical training in 1943 but, encouraged by Nylander, he converted to anesthesia. In 1948, he spent half a year in the UK, training at the Brompton Chest and Westminster Hospitals. Returning home he became a full time anesthesiologist with a special emphasis on anesthesia for thoracic surgery. He played a prominent role in the development of the specialty in Finland. In 1953, a new anesthetic position was created for him in Helsinki University Hospital [37].

Nordic Pioneers: Iceland

Three of the first four anesthesiologists in Iceland trained in the US, reflecting the close contact with the ‘occupants’ during World War II. Although Elias Eyvindsson studied anesthesia at the Mayo Clinic from 1948 to 1950, he became a surgeon after working for a few years at Landspítalinn (Iceland’s National Hospital). Torbjörg Magnúsdóttir became the real pioneer, returning home in 1952 after training in Copenhagen and Lund (Sweden). The other two anesthesiologists trained in the US, were Alma Torarinsson and Valtýr Bjarnason [38].

Nordic Pioneers: Norway

Otto Mollestad (1908–1973) became the first Norwegian anesthetist, having shown a special interest in anesthesia during his medical studies. He had become friends with the surgeon Semb, just before World War II. After the war, Semb, who had joined the Norwegian resistance in London, arranged a position for Mollestad as an assistant to Robert Macintosh in Oxford. In 1946, a position as an anesthesiologist was created for Mollestad in Rikshospitalet, in Oslo.

Another surgeon, Johan Holst, arranged a residency position for Ivar Lund (1911–1992), at the Massachusetts General Hospital, with Henry Beecher. Lund returned to fill the second position for anesthesia in Norway in 1947. By 1950, four Norwegian hospitals had salaried positions for anesthesiologists [39].

Nordic Pioneers: Sweden

In Sweden, Gustaf Söderlund, professor of surgery in Stockholm, and the British anesthesiologist, Michael Nosworthy, persuaded a 29 year-old surgeon, Torsten Gordh (1907–2010), to train with Ralph Waters’ at the University of Wis-

consin in 1938. The start of World War II shortened Gordh’s stay with Waters to 18 months, but before returning home, Gordh made a ‘grand tour’ through the US, meeting American pioneers including Virginia Apgar and Emery Rovenstine, contacts that later proved valuable to the development of Nordic anesthesiology. Just before the German invasion of Denmark and Norway (April 1940), Gordh journeyed home to Sweden, bringing with him a Foregger anesthesia machine, laryngoscopes, tracheal tubes and two Waters soda lime canisters [40].

Gordh immediately (1940) took up the first anesthetist position created in Sweden (and mainland Europe), a position at the Karolinska university hospital in Stockholm, and worked independently from the start. In contrast to the evolution of anesthesia in other Nordic countries, Sweden’s neutrality allowed Gordh to develop anesthesiology in (relative) peace, albeit with an enormous clinical workload. Not only did he direct anesthesia at the Karolinska, he also provided anesthesia for the neurosurgical department at the Seraphimer hospital, the original university hospital in the city centre.

His biggest problem was a shortage of medicines and instruments. Gordh had his Foregger machine, but further imports proved impossible. However, the Swedish company AGA, an enterprise founded at the end of the nineteenth century by the Nobel laureate Gustaf Dahlén, soon met the demand for anesthetic machines. AGA, manufacturer of the ingenious equipment for lighthouses and also the ‘Spiropulsator’, also provided oxygen, nitrous oxide and cyclopropane. Swedish manufacturers of surgical equipment started making laryngoscopes, and the pharmaceutical company Astra synthesized a new ultra short acting barbiturate (Narkotal). Other drugs and items remained scarce.

A remarkable pharmacological breakthrough occurred in Sweden during the early part of the war. The local anesthetic lidocaine, was synthesized and tested by two chemists, Löfgren and Lundqvist [41] Initially they had difficulty interesting the Swedish Pharmaceutical Industry in lidocaine. They even considered travelling to London for negotiations with the British pharmaceutical industry, but German air attacks made any flight too dangerous. In 1943, Astra acquired the rights to lidocaine. It became Astra’s first ‘golden’ product. Sweden continued to play a major role in local anesthetic development. Pharmacologist Bo af Ekenstam, introduced mepivacaine and bupivacaine in the 1960s. Ropivacaine was introduced in 1995. All three drugs were tested in Swedish hospitals [42] (Table 32.1).

Doctors and nurses in Sweden and other Nordic countries recognized Gordh’s great ability as a teacher, and came to train with him. Three additional anesthesia positions in Sweden were established in the 1940s, and given to doctors trained in GB or the US. In Stockholm, Olle Friberg was employed in 1943 at the Sabbatsberg’s hospital, where Crafoord had his cardiothoracic center. In 1945, Eric Nilsson

Table 32.1 Some Nordic contributions to anesthesiology

Country	Date	Contribution	Contributor/manufacturer
Denmark	1950s	Gas analysis	P Astrup; O Siggaard Anderson
	1955	Ruben valve; Ambu bag	H Ruben
Sweden	1940s	Gordh-Olovsson needle	T Olovsson; T Gordh
	1940s	Lidocaine	N Löfgren, B Lundqvist
	1957	Mepivacaine	Bo af Ekenstam
	1965	Bupivacaine	Bo af Ekenstam
	1996	Ropivacaine	Bo af Ekenstam
	1952	Engström ventilator	CG Engström
	1971	Servo ventilator	B Jonsson, L Nordstrom; Elema-Schönander
	1958	Implanted pacemakers	Å Senning, R Elmqvist; Elema-Schönander
	1948	<i>Inkjet ECG printers</i>	R Elmqvist; Mingograph-Elema-Schönander
Norway	1870	Jaw thrust	J Heiberg
	1901	First open CPR	K Igelsrud
	1961	Resuscitation simulators	B Lind; Asmund Laerdal Industries

was appointed in Lund, and is remembered for his contributions to intensive care. At the Bispebjergs Hospital in Copenhagen, Nilsson, together with the director Carl Clemmesen, adapted basic anesthesiological principles (open and clear airways, physiotherapy, frequent changes of body positions and careful positioning of the patient; and, if necessary, artificial ventilation and circulatory support) to treat patients with barbiturate intoxication, thereby decreasing the mortality rate from 20 to 1%. This ‘Scandinavian method’ continues as a cornerstone of the treatment of barbiturate intoxication and of intensive care [43].

In 1947, Olle Lundskog was appointed in Malmö, and in 1949, Karl-Gustav Dhuner received the first position for an anesthetist in Gothenburg—Sweden’s second largest city. Göran Haglund, the first pediatric anesthetist in Sweden and a pioneer in pediatric intensive care, was appointed in 1951. At Uppsala University, Martin Holmdahl, a PhD in physiology and trained in Great Britain, received an independent position in 1954. He developed a prominent research center and produced several academic scientists, including Ake Grenvik.

A Nordic Society

In 1949, Gordh, Mollestad, Turpeinen and Henning Poulsen (Denmark) met in Helsinki to form a Nordic Society (Nordisk Anaesthesiologisk Forening, NAF) and create a Nordic Anesthesia journal. In 1950, the first congress was held in Oslo and the first bylaws were approved. Subsequently, these congresses have been held every second year, the venue rotating between countries. The president of the current congress also

serves as society chairman. A general secretary guarantees continuity.

Acta Anaesthesiologica Scandinavica (AAS) first appeared in 1957. Eric Nilsson in Lund, became the first editor-in-chief, and Poulsen played a pivotal role, acting as a member of the first Editorial board and taking responsibility for publishing the journal. For the first 15 years, the journal was printed in his home town in Denmark—Aarhus [44]. He also became the NAF’s first Secretary General.

1945–60

An expanding surgical work load forced the few existing anesthesiologists to focus on clinical demands. Such pressures precluded research or teaching, and recruitment of doctors into anesthesia. Although the specialty had become indispensable, financial constraints limited the number of new anesthesiologist positions. Despite these problems, Nordic anesthesiology developed rapidly.

While almost all of the first generation of Nordic anesthetists went to GB or the US for training, domestic centers slowly developed specialty training. Initially, importation of British and Irish colleagues was needed to fill new positions, and some of these doctors stayed and became valuable contributors to the specialty, particularly outside regional centers.

The initial creation of only one anesthesia position per hospital, required anesthesiologists to recruit anesthetic nursing staff to get the work done. But the nurses had worked under the surgeon’s supervision, and both surgeons and nurses sometimes found it difficult to accept physician anesthesia-led departments. Eventually harmonious anesthetic departments were created with teams of nurses (with post-graduate specialty training) directed by anesthesiologists.

This team approach continues to the present. Although the number of doctors progressively increased, a shortage existed early in the history of the specialty, partly because anesthesiologists earned less than most other doctors (they received the same hospital salary but lacked the opportunity to gain income from private outpatients). Mollestad’s successor, Jacob Stovner summarized the situation: ‘*At the end of the working day we biked homewards in the exhausts from the surgeons’ limos!*’

Anesthesia from 1945–1960 paralleled that in the rest of the western world, a barbiturate induction and maintenance with nitrous oxide and ether. Cyclopropane was sometimes used for pediatric anesthetic induction. The introduction of muscle relaxants was enthusiastically accepted. Although Hunt and Traveau synthesized succinylcholine in Boston in 1906, the Swedes Thesleff, von Dardel, and Holmberg first tested it clinically in 1950 [45]. In the same year, the Swedish ENT surgeon Eric Carlens published experiences with the use of his invention, the double lumen tracheal-bronchial

tube for separation of the lungs [46], a prerequisite for pulmonary surgery.

A Gradual Expansion

Denmark is more densely populated than Finland, Iceland, Norway or Sweden, but all have metropolitan areas where a majority of the inhabitants live. In Iceland and Norway, the population is concentrated in coastal areas. These conditions led to differences in the development of anesthesiology. Hence separate descriptions are necessary for each country. We rely on the book *Scandinavian Anaesthesia during 150 years*. (Nordisk anesthesiologisk forening), to describe these differences.

Denmark [47]

In Denmark, development after Lippmann and Mørch was slow. Willy Dam (1914–1990) assumed the first position as an anesthetist, created in 1944 at Bisbebjergs Hospital in Copenhagen (within the department of surgery). In 1948, Erik Andersen was employed at Gentofte hospital, where he provided anesthesia services to three different surgical departments. He was later given the first independent anesthetic position.

Poulsen and Ole Secher started their careers after the end of World War II. Secher worked at the major state hospital—Rigshospitalet—where in 1953, he received an academic position as a lecturer. Poulsen initially worked in Copenhagen, soon moving to Aarhus where he created a university department. As noted, in 1949, he started the Danish Society for Anaesthesiologists and was a founder of the Nordic association.

Around 1950, the state recognized anesthesiology as an independent specialty and anesthesia development expanded throughout Denmark. The World Health Organization started a one-year international course in anesthesiology (the Anesthesiology Centre) in Copenhagen, with the initial faculty including Henry Beecher, Harry Churchill-Davidson, Stuart Cullen, Francis Foldes, Emmanuel Papper, John Severinghaus and Jackson Rees. The course was repeated 23 times in the ensuing two decades. In 1953, the first independent anesthetic departments were created under Secher and Henning Ruben (famous for the development of the Ruben valve and the self filling ventilating bag, Table 32.1).

In 1952, a lethal poliomyelitis epidemic in Copenhagen led to the development of Intensive Care Units (ICUs). The epidemic prompted professor HCA Lassen to form an expert group charged with finding a strategy for treatment of cases with severe respiratory insufficiency. The free-lancing anesthetist, Bjørn Ibsen, (who had earlier spent a year in Boston with Beecher) with physiologist Poul Astrup, convinced this group that the patients had to receive intermittent posi-

tive pressure ventilation (IPPV). Physiologist Poul Astrup helped guide the ventilation by pioneering a new method of blood:gas analysis. Volunteer doctors, nurses and students performed this radical treatment, manually squeezing reservoir bags attached to tracheotomy tubes. Mortality decreased from 87 to 37 per cent, a remarkable achievement. Ibsen established a permanent ICU in the city hospital (Kommunehospitalet), in April 1954. Two Danish anesthesiologists, Henrik Bendixen and Henning Pontoppidan, emigrated to the US in the 1950s, becoming pioneers of ICU medicine at the Massachusetts General Hospital.

Finland [48]

Immediately after World War II, severe shortages of medical equipment, and the absence of positions for anesthesiologists, hindered development of anesthesia. Some conservative surgeons claimed that “*ether anesthesia administered by a nurse was quite sufficient*” (a well-known point of view). The first positions were created in the county hospital in Lahti in 1950, for Sakkari Pelttari and Jorma Airaksinen. As mentioned before, the pioneers Turpeinen and Aro had to wait until 1950 and 1953 before obtaining positions. Turpeinen, Aro and their colleagues worked diligently to establish the specialty. Turpeinen was one of the 1949 founding fathers of the Nordic Society. In 1952, he and three colleagues founded a national society, promoting the spread of the specialty in Finland. The Society focused on the need for education and training of doctors in anesthesia, and the creation of independent departments and positions for specialists.

The WHO anesthesiology centre in Copenhagen provided an important educational resource, attended by 22 Finnish anesthetists between 1950 and 1967. Others gained training in the UK. A domestic training program began in 1957–1958, requiring three years of anesthesiology, and one year of surgery, internal medicine, otology or basic sciences. The Society proposed establishment of university departments in Helsinki and Turku (Åbo), a dream realized in 1969–1970.

During this period, the Finnish Society of Anesthesiologists successfully negotiated for new positions and salaries. However, recruitment remained difficult and several measures were taken to improve the situation. A three-month compulsory training course in anesthesia for all surgical residents was implemented, and at their own request medical students were approached by the Society regarding careers in anesthesiology at several meetings. How much these measures affected recruitment is unclear, but the number of specialist members in the Finnish Society of Anesthesiologists steadily increased to reach 300 in 1980.

Iceland [49]

Jon Sigurdson observed that

“In Iceland as in all neighboring countries the development from 1950 was gigantic... When the specialty anesthesiology

took its first steps it was not highly valued by other specialists. Less experienced colleagues, medical students, nurses and even unqualified staff members were entrusted to perform anaesthetics. Anyone could do it!"

After Magnúsdóttir, came Alma Torarínsson and Valtyr Barónason, both having studied in the US. Thereafter, most anaesthesiologists were educated in Nordic countries. The number of specialists increased from 11 in 1975 to 67 in 1999, for an Iceland population of 300,000 (i.e., by 1999 the same ratio as in the US). Several of these doctors pursued research in and outside Iceland.

Norway [50]

The first anaesthesiologists worked in Oslo; Mollestad at the central State hospital (Rikshospitalet), and Ivar Lund at Ullevål's hospital (the major city hospital). Both faced a lack of support and understanding of what anaesthesia could provide. Upon retirement, Mollestad noted that he started without a chair to sit on. The challenges were a general lack of doctors and low salaries for anaesthesiologists, but an advantage that half of the specialists in Norway were women. The Norwegian pioneers worked to establish a professorship, finally succeeding in 1973, when Jakob Stovner was appointed at Rikshospitalet.

Norway/Scandinavia Contributed to Cardiopulmonary Resuscitation (CPR)

In 1901, Igelsrud performed the world's first successful open CPR (i.e., where an incision is made in the chest to allow resuscitation by directly squeezing the heart in a rhythmic manner), at the Tromsø Amtsykehus (Hospital) where he was the only doctor. Igelsrud has not received proper acknowledgement for this crucial first step in CPR. The description of this first resuscitation was published in 1904 in *Therapia Gazette*, by an American doctor WW Keen from Philadelphia, who was visiting Igelsrud.

In the late 1950s, in cooperation with Peter Safar and Åsmund Lærdal of Laerdal Industries, Norwegian anaesthesiologists further contributed to the field of resuscitation. Bjørn Lind, at the hospital in Stavanger, pioneered the development of Resusci-Anne (Fig. 32.1). Laerdal's support facilitated the first meeting on the new management of cardiovascular collapse, "Symposium on Emergency Resuscitation-Rescue Breathing and Closed Chest Cardiac Massage" in Stavanger Norway from 21–25 August 1961 [51]. Since then Laerdal Industries have achieved international prominence, producing Resusci-Anne and her followers and also developing sophisticated equipment for simulators (Table 32.1).

In 2000, doctors at Tromsø Hospital were again in the news, saving a victim of severe accidental hypothermia (13.7°C), a world record [52]. While skiing, the victim fell head first through a hole in thick ice. Rushing water filled

Fig. 32.1 Resusci Anne's face was supposedly based on "the death mask of an unidentified young woman reputedly drowned in the Seine River around the late 1880s." (Courtesy of Phil Parker, Leamington Spa, UK)

her clothes, wedging her in place. But she managed to turn her face sufficiently to breathe air beneath the ice. After 40 min, she ceased to move. When the rescue team arrived they declared her clinically dead. But they started Basic CPR because she was so cold. Within 2 hours cardiopulmonary bypass was initiated, and she was slowly warmed. She made a remarkable recovery, returning to work as a physician. What would Igelsrud have said about this achievement?

Sweden [53]

From 1945 to 1960, hospitals outside the major cities recruited increasing numbers of anaesthetists. By 1960, almost all hospitals had anaesthetic departments. However, as stated before, usually only one doctor was initially appointed. The anaesthetist could not do all the cases and needed help from nurses who had previously performed anaesthesia. This reflected the typical development of doctor–nurse teams in operating wards in all Nordic countries.

Surgeons in the central hospital in Borås (a regional centre in Southwest Sweden), convinced the board of directors in 1951, that it was necessary to engage an anaesthesiologist. Eric Nilsson suggested Åke Bauer who accepted the offer

with three conditions. (1) He should finish his specialty training. (2) He should be allowed to travel to GB and Germany to visit the postoperative wards of some major military hospitals. (3) An ICU should be established in Borås. All proposals were accepted, and on 1 June 1952, a properly equipped ICU was opened. For a few months it was only open during the daytime, but from December 1952, it was open 24 hours a day, caring for both surgical and medical cases. Bauer created nursing routines and even ethical guidelines for intensive care. He is regarded as one of the world's pioneers in intensive care [54].

A few years earlier, using the van Slyke method for gas analysis, Carl-Gunnar Engström at the Stockholm Hospital for Infectious Diseases, found that the available external methods for artificial ventilation (e.g., iron lungs) did not adequately ventilate the lungs of patients with severe poliomyelitis. He had been working with Crafoord and the 'sipopulsator', and realized that the problem could be solved by IPPV via a tracheotomy. At first this was done manually, but soon Engström and the engineer Paul Herzog constructed the ventilator thereafter named for Engström. The ventilator soon came into use in Stockholm, and in the 1952 polio epidemic in Copenhagen [54, 55].

1960–1980

During this period, anesthetic developments in Nordic countries converged. All hospitals established departments as the specialty's importance to medical care became obvious. Domestic specialist training and the number of specialists increased, although the number of positions lagged. For example, the Swedish Society of Anesthesiologists in 1966 had around 180 members; in 1974, 400 members; and in 2011, 1400 members. 'Sub-specialization' arose early in pediatric, cardiothoracic and neurosurgical sectors, and in intensive care medicine.

ICUs were gradually established, mostly as the province of departments of anesthesiology. Separate units also arose in some departments of cardiothoracic and neurological surgery. In smaller hospitals, postanesthesia care units (PICUs) might care for trauma and septic cases, drug overdoses, and severe internal medical emergencies. Most of these smaller units evolved to include intensive care. Before the development of coronary care units, PICUs might care for medical patients with cardiac dysfunction. Demand for care in ICUs was greater in larger hospitals. The severity of illness was greater and the criteria for admission stricter. In these hospitals, doctors increasingly specialized in ICU medicine, leading to a new subspecialty.

After 1975, Nordic anesthesiology developed in line with the rest of the western world—with some stylistic differences. Kjell Eric Strömskog described these in the context of a

Specialty on Four Pillars—(1) Anesthesia, (2) Intensive Care Medicine, (3) Prehospital Emergency Care and Transportation and (4) Pain treatment [51].

Regarding anesthesia, the close cooperation between anesthesiologist and nurse anesthetists is a typical Scandinavian feature, without which early development would have been difficult. This cooperation has resulted in mature organizations with well-defined roles. Another feature is the small size of the private sector. The public sector runs most hospitals and is financed by taxation.

ICU Medicine. The early bonds created between anesthesia and ICU medicine remain close. Departments of anesthesiology run most ICUs, and the directors are anesthesiologists. Patients' primary care physicians and the director jointly decide treatment, but the director decides who is admitted.

Prehospital acute care and transportation. Scandinavian anesthetists have taken responsibility for prehospital acute care and interhospital transportation, particularly in Norway. Norway's long and jagged coastline hinders emergency access, and a good helicopter service is imperative. Anesthetists are responsible for the organization and medical protocols applied in this service. An anesthetist or ICU nurse usually accompanies the patient in the helicopter. Similarly, an anesthetic nurse is almost always in the crew of an ordinary ambulance service.

Another condition necessitating a special transportation organization is that patients in need of specialized care must often be transported to a tertiary hospital some 300 to 600 kilometers away. This has created a need for special expertise both in smaller and large hospitals. Some of the large centers have a special organization for these transports.

Treatment of pain. Nordic anesthesiologists have always participated in the development of pain treatment, beginning with consultations in terminal cases. Special pain units were formed in the 1970s, and the need for close cooperation with other specialties has resulted in the present multidisciplinary pain-clinics.

Nordic Organizations

Since its inauguration in 1951, congresses of the Nordisk Anestesiologisk Forening have been held every other year, alternating among the five countries. Before 1999, the president of the coming congress also acted as the chairman of the Society during the 2 year interval. However, the elected Secretary General in reality guaranteed the continuity of the administration. As the activities grew, the way of working with alternating presidents became inadequate. In 1997, the NAF General Assembly agreed on a change. Now a board and an executive president are elected for four years. The Society acts as an umbrella organization for the 5 national

societies. This organization became the Scandinavian Society for Anesthesiology and Intensive Care (SSAI). The SSAI has assumed responsibility for education, quality of care, and research in anesthesiology in the original five countries and in the three Baltic countries. The national Societies continue their work both as unions and as organizations for education and research [56].

From its first issue, the journal *Acta Anaesthesiologica Scandinavica* (AAS) was published in English, intending to have an international presence. The first editor-in-chief was Eric Nilsson from Lund, Sweden, with Ibsen and Poulsen as Co-editors. Initially, four issues totaling approximately 250 printed pages were published each year. The number of pages increased progressively and several supplements were published.

In 1972, Olof Norlander succeeded Nilsson as Editor-in-Chief. Viggo Dyrberg from Gentofte, Denmark and Jan Eklund joined the board. Munksgaards became the publisher, and the characteristic red cover appeared. Under the editorship of Norlander and his successors Eklund and Sven E Gisvold (Trondheim, Norway), AAS has become a truly international, peer reviewed journal, which in 2010, published ten issues containing approximately 1300 printed pages [57].

Conclusions

Outside influence prompted the initial development of anesthesia practices in Nordic countries. Subsequently, Nordic physicians have made key contributions to anesthesia, intensive care medicine, pain therapy, airway management, blood-gas analysis, ventilatory care, the development of PACUs and ICUs, resuscitation, and simulations (Resusc-Ann). They have played an important part in making anesthesia and perioperative care what it is today—safer.

Acknowledgments Substantial parts of this text originate from the book: 150 År med Nordisk Anestesiologi (Scandinavian Anesthesia during 150 years, SA 150 yrs) which was published by the Nordic Society of Anesthesiologists, (Stockholm 1999). The contributing authors who are frequently cited in this text were: Preben G. Berthelsen, Denmark, Lena Janhunen, Finland, Jon Sigurdson, Iceland, and Per H. Rosenberg, Finland for the Society. We thank them all for valuable insights.

Adolfo Héctor Venturini

Summary

Before the discovery of anesthesia, clergy and shamans used opium, herbal extracts, and alcohol to diminish surgical pain. Infection and mortality were great. By 1847, ether anesthesia was used in Peru, Uruguay, Brazil, Argentina, and Venezuela, and in 1848, in Chile. By 1850, chloroform displaced ether. Surgeons gave or directed anesthetic delivery by colleagues, nurses, medical students, orderlies, midwives, priests or sisters. Chloroform use continued until the late 1800s when reports of cardiac arrest and liver damage decreased its appeal. French surgeon Ombrédanne invented an ether inhaler in 1908 that became the preferred method of anesthetic delivery in the first half of the 1900s. Waters' 1930s experiences with cyclopropane prompted its use until fatalities from explosions occurred in Chile and Peru. Various barbiturates were given in the 1920s and 1930s, with thiopental becoming the preferred induction agent throughout Latin America. Curare was used by the early-mid 1940s in Brazil, Venezuela, Argentina, and Uruguay. Many Latin American countries took up anesthesia with the inexpensive combination of procaine and thiopental, after its description in Argentina in 1949. Halothane replaced ether in the 1960s.

Soon after Bier's demonstration in 1899, most Latin American countries adopted spinal blocks with cocaine. In 1910, Peruvian Odriozola described paracervical block. Epidural blocks were reported in most Latin American countries between 1915 and 1939.

In 1939, Chilean anesthesiologist Meneses designed the "*Chilean Midget*" portable anesthetic machine that the Foregger company manufactured. In 1951–1952, Brazilian anesthesiologist Takaoka developed the Takaoka Respirator, and subsequently the Takaoka Universal Vaporizer which delivered various volatile anesthetics.

In 1921, Argentine surgeon Arce founded a "*School of Anesthesia Specialists*" in Buenos Aires. Aspects of training in anesthesia were offered in 1934, expanding to the first Brazilian specialty school in 1941. In 1947, Marín founded the first "*School of Anesthesia*" for Columbian physicians. In 1948, the University La Plata, Argentina, created the first University Graduate Course in Anesthesiology. Residencies arose in the 1950s in Brazil, Colombia, and Uruguay, and in Peru and Bolivia in the 1960s. In 1967, the Postgraduate Course of Anesthesia in the University Hospital of Caracas became the first International Training Center of Anesthesiologists of the World Federation of Societies of Anaesthesiologists (WFSA). The Latin American Confederation of Societies of Anesthesiologists was founded in Lima, Peru in October 1962, and in October 1987 became a Regional Chapter of the WFSA. The South American Federation of Anesthesiology was established in Paysandú, Uruguay, in 1987.

The first Spanish language journal, "*Revista Argentina de Anestesia y Analgesia*" (today "*Revista Argentina de Anestesiología*"), began publication in Buenos Aires in 1939. Currently, anesthesia societies in Argentina, Bolivia, Brazil, Colombia, Chile, Ecuador, Peru, Uruguay, and Venezuela publish journals.

Introduction

Ether and chloroform were used in South America only a few months after their first administration by Morton in Boston, and Simpson in Edinburgh. South America has subsequently

been home to political and scientific events that influenced the history of anesthesia.

The Nineteenth Century

Pre-anesthesia Period

Before anesthesia came to South America, common surgical operations included exploration, draining and suturing of wounds, setting of fractures and dislocations, opening and

1419 Buenos Aires, Argentina
e-mail: aventurini@anestesiologo.org

draining of boils and abscesses, excision of external tumors, and amputation followed by cautery with a hot iron [1]—procedures that could be rapidly accomplished. Operations were performed in homes or hospitals. Infection, erysipelas, septicemia, tetanus and gas gangrene were common and mortality was great, even for simple operations. Chest and abdominal wounds were invariably fatal.

Various practitioners provided treatment [2]. Physicians and Surgeons were “*Latinos*” and “*Romancistas*”, classifications deriving from the Spanish. The Latin surgeon, equivalent to the current surgeon, was called a medical surgeon. Those setting fractures were “*ensalmadores*”, “*calculistas*” and “*algebristas*”, while “*flebótomos*” or “*sangradores*” (bleeders) performed bleeding, applied leeches and cupping glasses, and used tourniquets to stop bleeding. Midwives conducted home deliveries. Apothecaries prepared and dispensed medicines, and as in other parts of the world, members of religious communities, including Jesuits, Bethels, Dominicans and Franciscans provided medical care. Self-taught religious sisters and nuns living in hospitals, assisted in surgery. There were no schools of nursing.

Opium, Herbs, and Alcohol

As elsewhere in the world before the advent of anesthesia, the substances used to “alleviate” surgical pain [3] included opium, herbal extracts and alcohol. Pain killing confections (“*electuario*”) such as “henbane opiate” might offer anise, fennel, myrrh, henbane seeds, opium, cinnamon, saffron and chamomile flowers, with honey as a carrier. Alcohol, including wine, sugar-cane liquor, beer, gin and rum were also used. In Argentina’s Province of Mendoza “*analgesia was achieved through alcohol intoxication and opium, but these methods were not very effective to relieve pain during operations*” [4]. In Chile, according to Bulnes [5], “*the only anesthetic used, when mercy called for it, was alcohol*”, which was given “*in the form of rum, wine, beer or ale, until the patient was drunk*”. Jaime Pontón [6] wrote that in Colombia, it was common to use “*large doses of alcoholic beverages or preparations based on mandrake, Indian hemp and opium; the patient was strapped to a pallet or table and held by as many assistants as possible*”.

Surprise, Deceit, and Restraint

In the absence of analgesic substances, the methods applied might include surprise, deceit and restraint. All ancient societies applied restraint. Pontón [6] wrote that in 1844, José Quevedo performed the first caesarean section “*without anesthesia*”, in Medellín, Columbia. In 1838, in Montevideo, Uruguay, Spanish surgeon Cayetano Garviso [7] operated on a patient with an iliac artery aneurysm. He applied a peritoneal ligature to the left common iliac artery “*without anesthesia*”, in twelve minutes.

The First Administration of Anesthesia with Ether

The news of Morton’s demonstration of ether anesthesia on 16 October 1846 in Boston reached South America within months, and during 1847 and 1848, ether anesthesia was administered for surgery in several South American countries. The adoption of chloroform anesthesia decreased the use of ether (Table 33.1).

Peru

Higgins Guerra and Hernández de la Haza [8] wrote that Julián Bravo gave the first ether anesthetic on April 29, 1847, in Lima, adding that a headline in the local newspaper “*El Comercio*” announced: “*First test on etherization in this Capital City*”. However, Zaldívar Sobrado [9] wrote:

“In Peru, the first anesthesia with ether was applied in 1848 by the great surgeon Dr. J. Sandoval at Remy Apothecary on a young man who had fractures in the right humerus at the neck and its lower third. Anesthesia came from a bottle at the bottom of which there was a sponge soaked with sulfuric ether and two tubes, one of which was for gas inhalation. A few minutes later, while already intoxicated, the fractures were set and a plaster bandage applied”.

The author concluded that the patient awoke without pain.

Uruguay

In early April 1847, the Montevideo newspaper “*Comercio del Plata*” reported the discovery of ether anesthesia [10]. In late April, the surgeon Adolfo Brunel tested the effect of ether by inhaling it himself. On 2 May, in the “*Charity Hospital*” of Montevideo, Brunel amputated the lower right arm of a soldier, accidentally shot when handling a cannon, the soldier being under ether anesthesia. Patricio Ramos, an Argentine physician born in Buenos Aires, administered the ether using an animal bladder (loaded with an ounce of ether) attached to a long tube that ended with a nozzle inserted into the patient’s nose. The operation lasted four minutes, and the patient said he had felt little pain. During the ensuing months, Brunel as surgeon and Ramos as anesthetist, performed twelve operations with some untoward results, including restlessness, excessive saliva, coughing, and inadequate analgesia.

Brazil

In Rio de Janeiro on 20 May 1847, Roberto Lobo [11] and Domingo Marinho de Azevedo anesthetized Francisco Leme, a medical student. A description of this experiment was later published: “*As experiencias insensibilizantes do éter*”. On 16 July, Leslie Curtis and Borges Monteiro used ether for surgical anesthesia in the “*Court of Military Hospital*”, in Rio de Janeiro [12].

Table 33.1 First Administrations of Ether and Chloroform in Latin America

Date	Country	City	Anesthesia	Surgery	Anesthetist
11 Mar 1847	Cuba	La Habana	Ether	Hydrocele	V de Castro
29 Mar 1847	Mexico	Velacruz	Ether	Wound repair	E Barton
29 Apr 1847	Peru	Lima	Ether	Fractured humerus	J Sandoval Bravo
2 May 1847	Uruguay	Montevideo	Ether	Arm amputation	P Ramos
20 May 1847	Brazil	Rio de Janeiro	Ether	Experiment	RH Lobo
Aug 1847	Argentina	Buenos Aires	Ether	Strabismus	J Tewksbury
30 Nov 1847	Guatemala	Guatemala City	Ether	Finger amputation	J Luna
1847	Venezuela	Maracaibo	Ether	–	B Valbuena
Feb 1848	Uruguay	Montevideo	Chloroform	Phimosis	F Ferreira
Feb 1849	Cuba	La Habana	Chloroform	Breast tumor	N Gutierrez
July 1848	Argentina	Buenos Aires	Chloroform	Osteoclasia	J Mackenna
23 Oct 1848	Chile	Valparaiso	Chloroform	Arm amputation	F Villaneuva
1848	Brazil	Rio de Janeiro	Chloroform	Delivery	R de Bivar
1849	Columbia	Bogota	Chloroform	Breast tumor	A Reyes

1864	Paraguay	–	Chloroform	War injuries	–
1873	Ecuador	Quito	Chloroform	–	D Domec

“–” indicates absence of data

Argentina

Assisted by Teodoro Aubain (1814–1896), Jacob Tewksbury (1814–1877) operated on a male for correction of convergent strabismus, in Tewksbury’s house, in Buenos Aires, without anesthetic or surgical complications. A report was published in the “*British Packet and Argentine News*”, in Buenos Aires, on Saturday, 4 September 1847: “*A few days ago, we saw a correction of strabismus in a patient who was under the narcotic influence of ether vapor.*” In 1849, Tewksbury married Emilia Sutton, an Argentine, and returned with her to San Francisco, California, where he gained fame and wealth, thanks to the discovery of gold, but not ether [13].

Venezuela

Francis Ramírez [14] reported that “*according to the information obtained from the Revista Venezolana de Anestesiología, some historians argue that Dr. Blas Valbuena witnessed*” the anesthesia procedure performed by Morton on 16 October 1846, “*and that he took to Maracaibo a round glass instrument with two holes, similar to that used by Morton*”, where he put a male patient to sleep with ether in 1847. No mention is made of the day or month.

Chile

While visiting the “*Hospital San Juan*” of Santiago, Chile on 13 April 1848, the historian Arnold Greene [15] wrote that “*Ether is now used here to perform operations*”.

Colombia

There is no precise record of the first time anesthesia with ether was used in Colombia., Referring to the early years of the second half of the nineteenth century, Herrera Pontón

wrote that “*ether and chloroform had probably arrived in Bogotá by that time*” [6].

The First Administrations of Anesthesia with Chloroform

In November 1847, Edinburgh obstetrician and surgeon, James Young Simpson used chloroform to ease the pain of childbirth. As in Great Britain, chloroform soon competed for acceptance with ether, initially tending to displace ether because of the faster and smoother induction found with chloroform. There was also the belief (without proof) that in abdominal operations it might cause greater muscle relaxation. Chloroform thus became widely used. However concerns arose regarding cardiac arrest associated with chloroform (white syncope) especially during induction, and chloroform ultimately fell into disuse.

Uruguay

“*Comercio del Plata*” [16] of Montevideo reported Simpson’s successful use of chloroform. The French pharmacist Francisco Thiballier in Montevideo then distilled ethyl alcohol over calcium chloride to obtain chloroform. On 11 February 1848, in the “*Charity Hospital*” of Montevideo, Fermín Ferreira applied a sponge soaked with this chloroform to Jose Silva, and then operated to correct his phimosis. On 17 February, using chloroform for anesthesia, Bartolomé Odiccini operated on two soldiers. Subsequently, Brunel, with the same anesthetic, repaired a strangulated hernia in a 52 year old patient, and reported no complications.

It seems likely that the substance prepared by Thiballier was, in fact, chloroform, but this is not certain. In 1853, pharmacy student Mario Isola, at a meeting in the Society of Medicine of Montevideo, introduced chloroform prepared according to the standards set by “*Codex Medicamentorum Gallicus*”, edition 1851.

Argentina

In 1848, John Mackenna in the “*British Medical Dispensary*” (from 1853 called the *British Hospital of Buenos Aires*) operated on a female patient for osteoclasia of the femur anesthetized with chloroform. On Saturday, 8 July 1848 the “*British Packet and Argentine News*” [17] in Buenos Aires, reported the event without referring to the day or the month of the surgical procedure.

Chile

In Valparaiso, in October 1848, Francisco Javier Villanueva administered chloroform for an upper limb amputation. The 23 October issue of “*El Mercurio*” [18] of Valparaiso, reported:

“*Brilliant success of chloroform...A 90 year old woman had been taken to the hospital with a shattered arm caused by a fall. Dr. Villanueva decided to make the amputation of the arm with the aid of chloroform, which took effect without the patient feeling any pain; today, 15 days later, she is almost fully recovered.*”

Brazil

Chloroform was used on a recently delivered mother by Rodrigo de Bivar [11] in Rio de Janeiro in 1848. There is no reference as to the day or month.

Colombia

In 1849, Antonio Reyes successfully resected a breast tumor with the patient anesthetized with chloroform [19]. In Bogotá, in 1864, chloroform was used to perform the first resection of an ovary, while in Medellín, it was first used in 1880.

Venezuela

Eliseo Acosta [14] used chloroform in Caracas in 1848, and Guillermo Michelena subsequently enhanced its popularity. In 1856, Carlos du Villards bought the first apparatus for administration of chloroform (an accurate description of the apparatus is not available).

Paraguay

Chloroform was used during the War of the Triple Alliance (1864–1870, Argentina, Brazil and Uruguay against Paraguay). Sanabria Ortiz wrote that “*Anesthesia, that had already begun to be used during the War of the Triple Alliance, was popularized*”. Apparently, chloroform came late to Paraguay.

Ecuador

Ettine Gayraud and Dominique Domec wrote in 1873 about “*the professionalism of surgical procedures in Quito since the early usage of chloroform anesthesia. In those years, alcohol (liquor) and exotic weeds were used for surgery*” [20]. Domec, an anesthesiologist from “*San Eloy Hospital*” of Montpellier, appointed as Professor of Anatomy and Anesthesia, introduced chloroform in 1873, at the “*Hospital San Juan de Dios*” in Quito, applying it with a handkerchief or dressing.

Ether or Chloroform?

In South America, chloroform was initially used more than ether because induction was faster and quieter, without salivation or coughing. It was easier to use in obese patients. There was the perception that greater relaxation was obtained during abdominal surgery and that patients awoke more rapidly. In the late nineteenth century, its use decreased because of reports of liver damage.

In 1848, Brunel (see above) said: “*Judging by the first times I used chloroform, it seems to have more advantages than ether; with the new chemical preparation, the patient does not cough, does not have muscle contractions and the effect is both more secure and faster*”.

Argentine surgeon and historian Oscar Vaccarezza [15], commented on the thesis by Leopoldo Montes de Oca “*Notes on surgical clinic in Buenos Aires in 1852, 1853, 1854*”, writing that Montes de Oca “*widely used chloroform anesthesia, which by then had displaced ether in the rest of the world and here in Buenos Aires*”. In Argentina, during the second half of the nineteenth century, eight doctoral theses were presented at the School of Medicine of Buenos Aires, all concerning chloroform administration: L Montes de Oca (1854), J Clara (1857), R Gutiérrez (1868), W Taylor (1880), E de Elía (1881), CR Seguí (1888), E Pittaluga (1888), and DI Rapela (1897). And Ricardo Gutierrez’ thesis “*Elimination of childbearing pain by means of chloroform*”, indicates that he was one of the first Argentine anesthetists (“*cloroformista*”) to treat pain in obstetric patients.

In Colombia, during the last quarter of the nineteenth century, according to Herrera Pontón [6], “*ether and chloroform were widely used, but it seems that the latter was the anesthetic product on the rise*”. Doctoral theses at the University of Colombia indicate that chloroform “*was mostly used*”. In 1891, Teodoro Castrillón suggested that the lower partial pressures of oxygen in the highlands of Bogotá contraindicated the use of chloroform and recommended that oxygen be added to devices used to vaporize chloroform. José Joaquín Azula’s 1895 thesis entitled “*General anesthesia*” is exclusively dedicated to chloroform. He argued that anesthesia procedures should be performed by physicians.

During the Pacific War (1879–1884), when Chile fought Bolivia and Peru, Huete Lira [21] wrote that chloroform “was simpler to use than ether, and it was not explosive, which was very important when operations were performed under the light of candles or gas lamps”.

In Brazil from 1896, ether acquired a greater popularity thanks to Daniel d’Almeida, a pioneer of Brazilian anesthesia who wrote “*Do éter como anestésico em cirurgia*”. Nevertheless, the Rio de Janeiro surgeon, Álvaro Ramos separated conjoint twins, Maria and Rosalina in 1899. The “narcotizers” Fajardo and Pereira (Maria) and Couto and Leal (Rosalina) used chloroform [22].

In Venezuela, chloroform was most popular until the early twentieth century.

Who Administered Ether and Chloroform?

Initially, surgeons administered anesthesia, but soon the task was delegated to internal medicine physicians, medical students, nurses, orderlies, midwives, priests and sisters, and, according to Herrera Pontón, hospital porters [19]. The surgeon directed the “*cloroformista*”, “*cloroformizador*” or “*eterizador*”, the people who administered chloroform or ether.

Administration Technique: The First Inhalers

The first South American anesthetists dropped ether or chloroform onto dressings, tissues, sponges and towels applied to the nose and mouth of the patient. In Buenos Aires [15], in 1852, anesthetists used a paper bag stuffed with fabric or lint (the precursors of gauze) obtained by fraying old sheets. The lips and nasal mucous membranes were smeared with substances such as cerate (white wax and olive oil) or sweet almond oil to protect them.

A Scottish physician, John Alston, performed the first ovarian resection in Argentina in 1870, administering chloroform with Snow’s Apparatus [15]. In 1877, Ignacio Pirovano, the most prestigious Argentine surgeon of the nineteenth century, also resected an ovary with the patient anesthetized with chloroform given via a Junker’s Inhaler [15]. Physicians praised the method because it produced “*the surgical anesthetic effect quickly without generating a period of excitement*”.

Sites of Anesthesia and Surgical Procedures

As mentioned above, surgery might be performed in hospitals or patients’ homes. In Montevideo [23], surgery was also performed in local inns, where a guest room, bare of furniture, became an operating room. The table used for lunch

and dinner became the operating table. The patient recovered in his usual bedroom. After Lister’s work was publicized in 1867, the “operating” room was sprayed with carbolic acid.

Nitrous Oxide

The high cost of storing and transporting nitrous oxide restricted its use in Latin America during the nineteenth century. It did attract interest because of its non-pungency, nonflammability, rapid action, and absence of circulatory depressant effects. However, the use of pure nitrous oxide by inexperienced anesthetists sometimes led to hypoxia and cardiac arrest. Co-administration of oxygen would circumvent this problem, but added to the storage and transportation costs. Most use in the nineteenth century was as brief administrations in dental operatories. Ecuador, Argentina, Colombia and Chile did use it in the nineteenth century, while other Latin American countries introduced it in the twentieth century. Its use became popular in the 1950s when it was locally manufactured.

Ecuador

In 1870, Alejandro Shibley, a Swedish national, used “*the nitrous oxide anesthetic, as advised by its discoverer*” [24], in Quito. The identity of the “discoverer” is unclear, but the author of the reference (Oswaldo Pinto) studied under Rovenstine in 1960–2.

Argentina

The dental surgeon, Louis Ernest [15], introduced nitrous oxide on 16 June 1871 in Buenos Aires, performing practical demonstrations of dental extractions before prestigious physicians. Ernest volunteered to take “*laughing gas*” (*sic*) administered by his colleague, Winkelman, a surgeon in the War of Paraguay. On 18 May 1874, the “*Buenos Aires Medical Surgical Journal*” called attention to deaths from the use of 100% “*laughing gas*” in dental extractions.

In 1905, Nicasio Etchepareborda spoke on “*Short general anesthesia*” at the School of Medicine of Buenos Aires, saying that nitrous oxide “*is the safest of all anesthetics*” according to statistics published in the US and England, and that accidents occurred in Argentina because the gas was “*handled by incompetent hands*”. He also suggested the addition of “*small amounts of oxygen*.”

Colombia

Lázaro Restrepo [6] used nitrous oxide in 1885, in the city of Antioquia.

Chile

According to Aureliano Oyarzún [18], some American dentists used “*nitrous oxide or laughing gas*” in Chile before 1890.

Uruguay

Nitrous oxide use began in the early twentieth century, although only in rare cases. Pedro Cantonet, José Bado and Manuel Herrera performed the first documented anesthesia procedures with it in 1926.

Paraguay

In Paraguay, nitrous oxide use was sporadic in the early twentieth century.

Venezuela

Beltrán Hurtado [14] delivered nitrous oxide in 1917 at the “Hospital Vargas” de Caracas.

Peru

In 1918, Novoa presented his doctoral thesis “*The N₂O narcosis*”. The author wrote that Graña administered most of the anesthetics, using an apparatus that delivered nitrous oxide, oxygen and ether. He said that nitrous oxide use should be reserved for short operations.

Brazil

Using Desmarest’s device, Leonido Ribeiro introduced nitrous oxide anesthesia in Rio de Janeiro in 1926, and then in Sao Paulo. In 1930, Pedro Netto of Sao Paulo presented his doctoral thesis “*Anestesia Geral pelo Protóxido de Azoto*”, the thesis becoming the first paper on anesthesia to be awarded a prize in Brazil.

August Bier was a Rural Physician in Argentina

The German physician August Bier (1861–1949) pioneered spinal analgesia in surgical procedures. After graduating in 1896, he served for a short time as a doctor in the rural city of Lincoln [15] in Buenos Aires province, 320 km from the city of Buenos Aires. He returned to Germany, where his further career is well known. Bier’s best quote is: “Medical scientists are nice people, but you should not let them treat you!”

Twentieth Century

Spinal Blocks

The first spinal anesthetics were performed in the late nineteenth century, in Brazil and Uruguay, but only in the twentieth century was this method fine-tuned and accepted worldwide. August Bier performed the first spinal anesthetic, anesthetizing his graduate student on 16 Aug 1898, in Kiel, Germany, injecting 3 ml of 0.5% cocaine. Bier should have received the first “spinal”, but after introducing the needle,

and while spinal fluid gushed forth, the graduate student found that the syringe containing cocaine didn’t fit the hub of the needle. Bier got a spinal headache, and the graduate student got the spinal anesthetic. Spinal anesthesia quickly spread throughout South America. Favoring its application were its low cost and the flexibility it permitted the surgeon who could (sequentially) give the anesthetic and perform the surgery. Spinal anesthesia also did not impose some of the dangers of general anesthesia, such as hypoxia and hepatotoxicity.

Brazil

Paes Lemes performed spinal anesthesia in the “*Santa Casa de Misericórdia*” of Rio de Janeiro in 1898 (no reference as to day or month). Starting in 1901, Daniel de Almeida [11] promoted the “*spinal*” in Brazil.

Uruguay

In 1899, Alfredo Navarro [25] used spinal anesthesia in the “*Hospital Maciel*” with 0.5% cocaine for amputation of a gangrenous leg. In 1921, Alberto Roldán [26] published a paper in the “*Annals of the School of Medicine*” on “*spinal anesthesia*”, using procaine in 165 patients at the “*Hospital Galán y Rocha*” of the town of Paysandú.

Venezuela

On 17 July 1900, Pablo Ortiz [14] used spinal anesthesia with cocaine, at the “*Hospital Vargas*” of Caracas. In that hospital on 18 August 1908, a medical student, Eudoro González, used stovaine for spinal anesthesia.

Argentina

In 1900, José Sabatini, in the “*Hospital Rawson*” in Buenos Aires, graduated from the School of Medicine of Buenos Aires. His thesis was: “*Analgesia with spinal injection of cocaine*” [15]. In another doctoral thesis, “*Cocaine injections in the lumbar arachnoid*”, Bartolomé Podestá [15] wrote that he had performed 195 spinal anesthetics under the surgery service of Aguilar, in “*Hospital San Roque*” of Buenos Aires, without complications. In 1905, surgeons Heinrich Braun (1862–1934) in Germany and José Arce [15] (1881–1968) in “*Hospital Alvear*” in Buenos Aires (where he was Chief of Surgery) used procaine for spinal anesthesia.

In the 1920s, Arce, as Director of the Institute of Surgery Clinic of the “*Hospital Clínicas*” in Buenos Aires, devoted his efforts to improving anesthesia in Argentina. In 1921, he founded a school for anesthesia specialists, and established a course “*Anesthesia for all practical physicians*” where he taught spinal anesthesia techniques and the use of Ombrédanne’s apparatus. In a 1931 paper presented at the Fourth National Congress of Medicine held in Buenos Aires, Arce and Braulio Pérez wrote: “*We believe that over 80% of operations can be performed with local or spinal*

anesthesia and in this way, the patient will benefit, because we avoid the serious poisoning threat that general anesthesia represents”.

Ecuador

Barzallo Sacoto [27] claimed that spinal anesthesia was introduced in 1901 in the city of Quito. However Moran Pinto [24] said that “in 1903 in Guayaquil, Dr. Miguel Achig Alcívar applied the first spinal anesthesia procedure”.

Peru

In 1902, at the “Hospital Dos de Mayo”, Barton gave a spinal anesthetic with cocaine for the resection of a testicle [8]. In the same year, two doctoral theses were presented: E Muñoz graduated with “Spinal anesthesia with cocaine at birth”, and V Diez Canseco with “Spinal surgery”, both physicians injecting 3 ml of 0.5% cocaine.

Colombia

In 1905, Lisandro Leyva at “Hospital San José” in Bogotá, performed the first spinal anesthetic [6] in Colombia. In 1913, Juan Montoya y Flores presented a paper at the Second National Medical Congress, on spinal anesthesia with cocaine and stovaine.

Chile

Vargas Salcedo [18] performed the first spinal anesthetic in 1905, according to a paper he presented in October 1923, at the “Chilean Medical Society”.

Headaches Due to Dura Mater Puncture

In 1963, Edgar Aguirre de Caracas [28] reported headache relief after a *dura mater* puncture, obtained by placing a “blood patch” in the epidural space. In 1967, José Usubiaga, Lilia Usubiaga and Jaime Wikinski [29] of Buenos Aires, addressed the same complication, by administering 60 ml of saline solution.

Paracervical Block

In 1910, the Peruvian doctor, E Febres Odriozola [30] presented the first description of the paracervical block, specifying the indications and contraindications that are still recognized today.

Ombrédanne’s Apparatus

The French surgeon, Louis Ombrédanne (1871–1956) created a hand-held inhaler for the administration of ether in

1908: “Un appareil pour l’anesthésie par l’éther” [31]. It was subsequently widely used in Europe, especially in France and Germany, and in Latin America, when ether started to prevail over chloroform. Ombrédanne’s inhaler found minimal acceptance in English-speaking countries, but was the most popular “anesthesia machine” in the first half of the twentieth century in many hospitals in Latin America, largely because of its safety and simplicity.

Ether was administered in increasing concentrations from Ombrédanne’s inhaler by moving a pointer that went from zero to eight. The device precluded spillage of liquid ether onto the patient’s face. A source of oxygen could be placed under the mask of the device. Practitioners, medical students, nurses and nuns used Ombrédanne’s inhaler.

Uruguay

In 1910, Enrique Pouey brought an Ombrédanne’s inhaler from Paris. The use of this apparatus greatly expanded the popularity of ether.

Argentina

Argentine surgeon, Pedro Chutro [32], introduced Ombrédanne’s inhaler in 1911. Until the mid 1950s, hospital interns in municipal hospitals in Buenos Aires were charged with its use in emergency operations. The intern who arrived late to the Emergency Service of “Hospital Juan A. Fernández” was punished by having to use Ombrédanne’s apparatus (author’s personal experience). The seat reserved for the anesthesiologist had a small drawer underneath that contained Heister’s mouth opener, a metal airway, Lucas Championnière’s tongue forceps and a Schimmelbusch mask.

Venezuela

Ombrédanne’s apparatus arrived in 1912, according to F Ramírez [14], and ether “displaced the use of chloroform almost completely”.

Chile

In October 1912, Zegers presented a paper on the use of Ombrédanne’s apparatus at the “Chilean Medical Society” [18]. The apparatus continued to be a mainstay of anesthetic practice in Chile for the next 50 years. In 1925, González Ginouvés [33] said: Ombrédanne’s apparatus was “the responsibility of an intern who, upon arrival, received nervous brief instructions from another intern who was finishing his shift. In infra-umbilical conditions, spinal anesthesia is preferred”. In 1927, Ombrédanne himself, visited the Pediatric Surgery Department at “Hospital Infantil Manuel Arriarán” in Santiago de Chile [34]. In 1960, the “Plan of Anesthesiology Education” at the School of Medicine, University of Chile, by Raúl Jeria, included a “hands-on learning approach” using Ombrédanne’s apparatus [35].

Peru

In 1914, L de la Puente described the first ether anesthesia using Ombrédanne's apparatus, administered by the intern R Ugaz [8].

Ecuador

Ombrédanne's inhaler was used after 1917, together with Ricard's apparatus [24].

Colombia

In the "*Hospital Municipal*" of the town of Manizales "*in the beginning, anesthetics were administered by an emergency nurse, or some young ladies, or a surgeon using ether with Ombrédanne's apparatus*". In 1932, Juan Marín, an important Columbian anesthetist of the time, gave ether anesthesia using Ombrédanne's apparatus [6].

Bolivia

According to Crespo Villegas [36] of the Medical Institute in the city of Sucre "*in Bolivia, there is no information on its (Ombrédanne's apparatus) use*".

Cyclopropane

After its first clinical administration in 1930, and the publication of Ralph Waters' experiences in 1934, cyclopropane use became widespread in South America—until explosions claimed several lives. Manufacture and use of cyclopropane then ceased.

Paraguay

In 1928, Roberto Olmedo, an orthopedic surgeon, returned from the US. Using a Foregger anesthetic machine, he was the first to give cyclopropane.

Venezuela

In the 1930s, Roberto Baptista [14] gave cyclopropane using a Foregger anesthetic machine.

Argentina

The first to use cyclopropane in Buenos Aires, was Roberto Elder [36], in 1935.

Brazil

Álvaro de Aquino Salles used cyclopropane in 1936, and in 1940 presented his paper "*Anestesia gaseosa em ginecología y obstetricia*".

Uruguay

In 1936, Eduardo Palma [37] administered cyclopropane to obstetric patients.

Colombia

Herrera Pontón wrote that cyclopropane was first used in 1938 by Juan Martínez, in the "*Clínica de Marly*" in Bogota [6].

Chile: Lethal Explosions with Cyclopropane

In April 1945, an assistant was transferring oxygen from a large cylinder at high pressure to a small cylinder of cyclopropane [38]. An explosion resulted, killing the assistant.

On 6 May 1963, in Santiago "*Hospital de Niños Manuel Arriarán*", a cyclopropane cylinder exploded, causing, in turn, the explosion of another cylinder on an adjacent anesthesia machine [39]. A fire ensued. Four doctors (two anesthesiologists and two surgeons) and two patients, both children, died. Two other physicians were seriously injured, and 12 assistants suffered injuries of various severity, two requiring amputation of the leg. The use of cyclopropane was then banned throughout the country.

Peru: Lethal Explosions with Cyclopropane

A uterine curettage was scheduled in July 1971, at a clinic in Lima [40, 41]. A portable lamp with a loose electric cable was switched on while near a leaking cylinder of cyclopropane. The resulting explosion killed an anesthesia resident and a nurse assistant.

Epidural Blocks

Peru

To produce obstetrical analgesia in 1915, F Ferreyra [42] used caudal epidural blocks (via the sacral hiatus), injecting 3 ml of 0.3% procaine. Patients were sedated with morphine and scopolamine subcutaneously.

Chile

In March 1920, Basilio Muñoz [18] published a paper on "*epidural anesthesia*".

Brazil

In 1926, Francisco Linz wrote on "*lumbar-sacrum epidural anesthesia*" as did Enio Mondatori in 1938. In 1940, Pedro Netto and Nicolau Manzini, published "*Contribution to the study of epidural anesthesia*" in "*Revista Argentina de Anestesiología*".

Venezuela

At the Medical Congress of Venezuela held in 1926, in Maracay, A Van Tienhoven [14] of Caracas, presented cases of caudal epidural anesthesia.

Argentina and the "Hanging drop sign of Gutiérrez"

Alberto Gutiérrez (1892–1945), Professor and Chief of surgery at the "*Spanish. Hospital*" in Buenos Aires, founded the

magazine “*Revista Argentina de Anestesia y Analgesia*” in 1939. In 1933, while performing an epidural needle insertion using the “loss of resistance” method (sign of Dogliotti), he found considerable resistance when reaching the ligamentum flavum (yellow ligament). On detaching the syringe, he noted a drop of anesthetic solution (1% procaine) hanging from the needle hub. He decided not to reattach the syringe, but slowly advanced the needle. Moments later, the drop disappeared into the needle, and he decided to inject 5 ml of procaine, repeating four boluses sparingly, and thus achieved successful analgesia. That year, Gutiérrez announced the finding in the Buenos Aires publications “*El Día Médico*” [43] and “*Revista de Cirugía*” [44]. Gutiérrez’ technique has gained international acceptance.

Ecuador

Barzallo Sacoto [27] wrote that he performed the first epidural in 1937, but Moran Pintos [23] claims it was 1938, and that it was performed by Elias Andas.

Uruguay

With Alonso and Pérez Fontana, Eduardo Palma [24] spoke on “*Segmental epidural anesthesia*” at the 22 November 1939 meeting of the Society of Surgery. After visiting Alberto Gutiérrez, Palma used 1% procaine.

Invention of Apparatus and Instruments

In 1934, José Delorme (Buenos Aires, 1903–1986), an important pioneer, a member of the National Academy of Medicine, and an advocate of anesthesiology in Argentina, created a machine for the delivery of anesthesia, particularly ethyl chloride, ether and chloroform. Delorme was a founding member and first president of the Argentine Association of Anesthesiology in 1945 [45, 46].

In 1939, Argentines Juan Miranda and Roberto Goyenechea, both anesthesiologists from the Institute of Surgery Clinic of the “*Hospital de Clínicas*” of Buenos Aires, devised a portable anesthesia machine called ADELIC (Institute of Surgery Apparatus). It worked with the “to and fro” system created by Ralph Waters, and could administer ether and cyclopropane. This device was taken to Montevideo by the Uruguayan, Ignacio Villar [47].

In 1939, the Foregger company in New York built a portable anesthesia apparatus, designed by the Chilean anesthesiologist Ernesto Meneses. The unit was called the “Chilean Midget” [48]. It was equipped with four cylinders (two oxygen, one cyclopropane, and one nitrous oxide), a flowmeter for each of the gases, and a vaporizer for ether. Meneses was a founding member of the Chilean Society of Anesthesiology, and President from 1957–1958.

In 1943, E de Souza [49] from Rio de Janeiro, Brazil, invented an apparatus comprising a balloon indicator, to confirm the correct location of an epidural needle. Robert Macintosh described this device in 1950, and introduced it into the anesthesia market.

In 1949, Argentine anesthesiologist and inventor Osmán Yanzón [50] created a device called “*Resucitador de Yanzón*” for newborns with respiratory problems. The device delivered oxygen during resuscitation and enabled aspiration of secretions. Yanzón was a founder, in 1945, of the Argentine Association of Anesthesiology.

In 1951–1952, Brazilian anesthesiologist and manufacturer Kentaro Takaoka developed a portable ventilator (Takaoka Respirator) for controlled artificial ventilation, cycling with a fixed delivered pressure [51]. In 1955, he conducted the first clinical trials. Subsequently, Takaoka designed and manufactured a small vaporizer (Takaoka Universal Vaporizer) [52] allowing the use of any of the available volatile anesthetics: ether, chloroform, trichlorethylene, halothane, or methoxyflurane.

In 1988, Alberto Torrieri of Buenos Aires, with the help of J Antonio Aldrete, introduced a needle for combined spinal-epidural block (First global communication) [53].

Intravenous Anesthetics: Somnifene—Pernocton—Eunarcon—Hexobarbital—Thiopental

Several barbiturates played small roles in anesthesia in South America in the early 1900s, including Somnifene® (a combination of barbital and diallylbarbituric acid), Eunarcon, Evipan, and hexobarbital. These vanished from clinical use after the arrival in the 1930s of the ultra-short-acting thiopental.

Uruguay

In 1925, A Langón [54] published his experiences with Somnifene® (first used intravenously in 1924) for obstetric analgesia (nine cases), caesarean section (one case), and hernia surgery (one case). In 1934, MB López, A Stábile, M Albo and P Martincich, presented their experiences with hexobarbital. No reports indicate the commercial introduction of thiopental [55].

Venezuela

Leopoldo Aguerrevere gave Pernocton® (the first barbiturate used frequently to provide intravenous general anesthesia) in 1933, at the Maternity “*Hospital Vargas*” of Caracas. The first to use hexobarbital in Venezuela were P Gásperi, A Castillo and L Santana. Santana [14] also was the first to administer thiopental, giving it in 1942.

Argentina

In 1934, Germán Wernicke introduced hexobarbital for short-term anesthesia. In 1939, two anesthesiologists from the “*British Hospital*” of Buenos Aires, Leslie Cooper and Alberto Daniel, conducted the first trials with thiopental sodium, writing that “*The turbulent induction caused by inhalants has been left behind us*” [46].

Peru

In 1934, P Nagaró [8] presented his thesis “*Anesthesia of sodium Evipan*” (hexabarbital), and N Pareja wrote “*Sodium Evipan in short-term obstetric interventions*”. In 1940, commenting on the current status of anesthesia in Peru, R Rubatto said that general anesthesia was widely accepted, but its delivery lacked anesthesiologists. He then stated that adoption of gas anesthesia had failed while intravenous general anesthesia had been widely accepted. In 1943, M Falvi presented his doctoral thesis “*About childbearing analgesia with sodium pentothal*”, a trial performed at the “*Maternity Hospital*” of Lima. In the 1950s, the use of thiopental became widespread.

Colombia

An advertisement, printed by Abbott Laboratories de Colombia in 1934, suggests that thiopental was introduced as an anesthetic agent in 1934. According to Herrera Pontón [6], the first anesthesia procedures using cyclopropane and thiopental were performed in 1938.

Ecuador

In 1938, hexobarbital was first used in Riobamba [24].

Muscle Relaxants

As in the rest of the world, the arrival of the first muscle relaxant (Intocostin®) to South America, fundamentally changed anesthesia and surgery. This was literally a drug that had come home. The obvious advantages of paralysis on demand were balanced by the less obvious drawbacks of this first neuromuscular blocking drug (e.g., histamine release, arterial hypotension, bronchospasm, and, most importantly, residual paralysis after anesthesia). These effects stimulated the search for safer synthetic compounds.

Brazil

In 1942, Oswaldo Vital extracted alkaloids from the *Strychnos* plant, which had a relaxing effect on striated muscle. Purified, this substance became *chondodendrum platyphyll*, and was marketed in 1945 as “*Condrocurare*”®. This drug was marketed only in Brazil, and had the merit of having been discovered by a Brazilian.

Venezuela

Pascual Scannone [14] trained in the US and introduced the use of curare in Latin America in 1942, performing the first tracheal intubation at the “*Hospital del Algodonal*” in Caracas, in a patient paralyzed with curare.

Argentina

Roberto Elder (1904–1969), was a founder of the Argentine Association of Anesthesiology. In 1945, he published an article in “*La Semana Medica*” [56] “*The use of curare in surgery and anesthesia*”, noting the importance of “*highly experienced anesthesiologists with a perfect notion of directed ventilation and equipped with a suitable anesthesia machine to do it*”.

Uruguay

Walter Oría, Juan Scasso and Antonio Cañellas administered the muscle relaxant Intocostin®, the first commercial curare extract, in 1945 [57].

Colombia

Herrera Pontón [6] wrote that cyclopropane was first used in 1938, adding that curare was later incorporated, but not specifying the date.

Ecuador

In 1950, in Guayaquil, Rafael Comte performed naso-tracheal and oro-tracheal intubations after injecting muscle relaxants.

Peru

In the 1950s, Peter Safar visited Peru, promoting tracheal intubation and the use of muscle relaxants.

Specialization in Anesthesiology

Argentina

In 1921, Arce founded a “*School of Anesthesia Specialists*” at the “*Hospital de Clínicas*” in Buenos Aires, the first in Latin America. He taught “*Anesthesia for all practical physicians*”. The thirty attendees learned spinal anesthetic techniques with procaine, and the use of ether with Ombrédanne’s apparatus.

In 1936, Arce with Oscar Ivanissevich organized the second course in “*Anesthesia for all practical physicians*”. Mexican Federico Vollbrechthausen, who had trained at the Mayo Clinic, taught the course. It was also held at the “*Hospital de Clínicas*”. Attendees learned to intubate, and to use Foregger’s anesthetic machine with an open, semi-open, or closed circuit, using mixtures of cyclopropane, ethylene, and nitrous oxide with ether.

In 1961, in Buenos Aires, Roberto Elder introduced a “*Graduate Course*” of two years duration, the beginning of a residency in anesthesiology. Later, the School of Medicine

of the University of Buenos Aires agreed to the development of a four-year program leading to award of the “*Degree of Medical Specialist in Anesthesiology*”. In 2008, the course was extended to five years.

Brazil

Mario d’Almeida, Oscar Ribeiro and Ivo Thiago, established some aspects of training in anesthesia, in 1934 in Rio de Janeiro. They expanded this to the first Brazilian specialty school in 1941. After 1955, “*Centros de Ensino e Treinamento*” opened in major Brazilian states to train qualified specialists. These centers were key to the development of anesthesia in Brazil.

Colombia

In 1947, Juan Marín [6] founded the first “*School of Anesthesia*” for physicians in the “*Hospital de San José*”. In 1948, supported by the School of Medicine in Antioquia, Iván Sánchez organized a course on anesthesia. The first residency began in 1958.

Uruguay

Teaching in the clinical practice of anesthesiology began in 1947. In 1954, Alfredo Pernin established the first course for graduate anesthetists at the School of Medicine of Montevideo. In 1976, he created the Chair of Anesthesiology at the Medical School [58]. In 1981, Pernin and Dardo Vega authored the book, the History of Anesthesiology in Uruguay.

Venezuela

In 1950, José Mazziotta taught the first official postgraduate course in anesthesia at the “*Hospital Central*” in Valencia, marking the first official academic recognition of anesthesiology.

In 1959, Argentine anesthesiologist, Juan Nesi (1909–2001) from Buenos Aires, and Venezuelan Carlos Larrazábal (1924–1988) (both founding members of their societies) established the Postgraduate Course in Anesthesia at the University Hospital of Caracas. In 1962, Nesi and Larrazábal created the Chair of Anesthesiology in the School of Medicine of the Universidad Central de Venezuela. In 1966, the Postgraduate Course became the Latin American Center of Anesthesiology [59] and in the following year, the first International Training Center of Anesthesiologists of the World Federation of Societies of Anaesthesiologists (WFSA).

Peru

In 1964, a university level Anesthesiology Residency (Postgraduate training) was established in the Hospital of the “*Universidad Nacional Mayor de San Marcos*”, Lima [8].

Bolivia

In 1968, Carlos Castaños [60] established an anesthesia residency in the University Hospital in La Paz.

Ecuador

In 1971, a Chair of Anesthesiology was created at the School of Medical Sciences in Quito.

General Anesthesia with Intravenous Procaine: An Argentine Invention

During the Second Argentine Congress of Anesthesiology and First Latin American Congress, in 1949 in Buenos Aires, Gregorio Aranés and Ivar Castellanos gave a paper on “*Brief observations on anesthesia with Pentothal Sodium and Procaine*” [61]. They noted that Fraser and Hamilton had combined thiopental and intravenous procaine (as an analgesic agent), with continuous spinal analgesia or other anesthetics (cyclopropane, ethylene or nitrous oxide) and muscle relaxants to supply anesthesia. They then described their experiments at the Institute of Surgery in Haedo, Buenos Aires, using thiopental-procaine as a general anesthetic, adding a muscle relaxant in some cases. The authors concluded that: “*We believe that procaine, as an anesthetic agent, deserves dedication and studying from all anesthesiologists in the world*”.

Several things recommended this technique to South American anesthesiologists. First, the technique was effective, supplying smooth anesthesia with analgesia that extended into the postoperative period. Second, the ingredients were inexpensive and easy to deliver. Third, the material needed for delivery of anesthesia was compact and therefore easily transported and stored. Thus, with several variations, use of intravenous procaine became widespread in South American countries, including Argentina, Uruguay, Bolivia, Chile, Peru and Paraguay.

For several subsequent decades, anesthesiologists studied intravenous procaine, presenting papers at conferences and in international journals. For example, Jaime Wikinski, José Usubiaga, and others presented “*Clinical evaluation of procaine as a general anesthetic*” at the Third World Congress of Anaesthesiologists, in 1964 in Sao Paulo, Brazil. The Peruvian anesthesiologist, Hernández de la Haya [8] wrote, “*intravenous procaine technique was widely accepted. It is highly used in Argentina and Uruguay and broadly accepted in our field, especially in health hospitals*”.

The First Latin American University Professor of Anesthesiology

In 1948, the School of Medicine of the University La Plata, Argentina, created the first university course in anesthesiology for graduates, appointing Gregorio Aranés (1908–1996) as Professor and Course Director [46].

The first Latin American Anesthesiologist Appointed as Professor of Anesthesiology and Pharmacology in the United States

Jose Usubiaga (1931–1970) was born in Buenos Aires, earning his degree in medicine in 1953. In 1964, after publishing outstanding work—116 papers in his lifetime—he settled in the US with his wife, Lilia Usubiaga, also an anesthesiologist. In 1967, he was appointed Associate Professor of Anesthesiology and Pharmacology, at the School of Medicine of the University of Miami and, in 1970, he was appointed Professor [62, 63]. Sadly, he died a few months after this appointment. LJS, one of the editors of this book was a faculty colleague of “Dr Jose” at the University of Miami and comments that he was “highly respected not only for his scientific accomplishments but also for the remarkable kindness and obvious respect showed to all with whom he worked”.

Corporate and Scientific Activities

Founding of Anesthesiology Societies in South America

Most Latin American Societies in individual countries arose immediately after World War II (Fig. 33.1)

Founding of the Latin American Confederation of Societies of Anesthesiologists (CLASA)

CLASA was founded at the VI Latin American Congress of Anesthesiology, held in Lima, Peru, in October 1962, and was primarily the result of the efforts of Argentine anesthesiologist José Delorme [18]. Founder countries were Argentina, Bolivia, Brazil, Colombia, Chile, Ecuador, Peru, Uruguay and Venezuela [64]. In October 1987, the Confederation became a Regional Chapter of the WFSA.

Participation in the Founding of the World Federation of Societies of Anaesthesiologists (WFSA)

The WFSA was founded in 1955 in Scheveningen, the Netherlands, during the First World Congress of Anaesthesiology. Founders were the Societies from 28 countries, including five from South America: Argentina, Brazil, Colombia, Chile and Uruguay. The Brazilian representative, Olegario Laranjeiras, was named Vice President for Latin America. From 1984–1988, Brazilian anesthesiologist, Carlos Parsloe (1919–2009; Fig. 33.2) was President of the WFSA. According to Almiro dos Reis Júnior, Parsloe was “the most important and popular Brazilian anesthesiologist, and the one with the highest global impact”. His career spanned all of modern anesthesia, starting in the 1940s and continuing to his death. He was a student, teacher, politician

Fig. 33.1 Most Latin American Societies formed in the decade immediately following World War II. (Data kindly supplied by the World Federation of Societies of Anaesthesiology.)

(in the best sense of that word), and traveler all his life, a kind humane man with a consummate interest in worldwide anesthesiology [65].

In 1964, Brazil hosted the World Congress of Anaesthesiologists in Sao Paulo. The 2012 Congress was held in Buenos Aires.

South American Federation of Anesthesiology (FASA)

FASA was established in Paysandú, Uruguay, in 1987, by delegates from Argentina, Brazil, Paraguay and Uruguay. Bolivia, Chile, and Colombia subsequently became members.

Latin American Congress of Anesthesiology

During the Second Argentine Congress of Anesthesiology in Buenos Aires, in October 1949, Argentine José Delorme suggested that the event should become the first Latin American Congress of Anesthesiology, a suggestion unanimously approved by the representatives of those Latin American Societies present [66]—Argentina, Brazil, Colombia, Cuba, Chile, Mexico, Uruguay and Venezuela. Thus, the Latin American Congress antedated the First World Congress of Anesthesiology, held in 1955 in Holland. The First Latin American Congress took place in 1949, in Buenos Aires, and the Second in 1954, in Sao Paulo, Brazil.

Anesthesiology Journals Published in South America

The first Spanish language journal, “*Revista Argentina de Anestesia y Analgesia*” (today “*Revista Argentina de Anes-*”

Fig. 33.2 A photograph of Carlos Parsloe and his wife, Edith. Both are remembered with affection by all who knew them, including the three editors of this book. (Courtesy Dr. Kester Brown.)

tesiólogía”), was founded in Buenos Aires by Argentine, Alberto Gutiérrez [67] in 1939, preceding the launch of “Anesthesiology” (1940) and “Anaesthesia” (1946). Daniel D’Almeida started publication of the oldest specialty newsletter in Latin America, the Portuguese language newsletter, “*Boletim de Anestesia*”, in 1903. Currently, anesthesia societies in Argentina, Bolivia, Brazil, Colombia, Chile, Ecuador, Peru, Uruguay, and Venezuela, all publish journals.

Emblems of the CLASA and the WFSA

The Sixth General Assembly of the CLASA, held in 1971 in Rio de Janeiro, Brazil, adopted the emblem of CLASA suggested by Juan Marín, pioneer from Colombia. That year, Francis Foldes, President of the WFSA, proposed that Marín’s emblem should also be adopted as the Presidential Medallion of the World Federation, a suggestion accepted during the Fifth World Congress of Anaesthesiologists held in Kyoto, Japan in 1972. The then elected President, Otto Mayrhofer from Austria, was first to wear the new medallion.

Jeanette Thirlwell

Summary

The *Lancet* first appeared in 1823. The Boston Medical and Surgical Journal (later the New England Journal of Medicine) followed in 1828. These were the principal journals describing medical discoveries, particularly ether's anaesthetic properties. The *Lancet* in 1838 called Elliotson's performance of operations under mesmerism "humbug". Undeterred, Elliotson published *The Zoist: A Journal of Cerebral Physiology and Mesmerism, and their Applications to Human Welfare* from 1843 to 1855.

Were *'Current Researches in Anesthesia and Analgesia'* (1922) and the *'British Journal of Anaesthesia'* (1923) the first anaesthesia journals? In 1891, US dentist Samuel Hayes published *'Dental and Surgical Microcosm'*, arguing for the provision of oxygen to avoid 'asphyxial (nitrous oxide) anaesthesia'. Hayes and *Microcosm* died in 1897.

From 1914, Francis McMechan edited a 'Quarterly Supplement' *'Anesthesia and Analgesia'* for the *'American Journal of Surgery'*. In 1922, he founded the National Anaesthesia Research Society with the supplement as the Society's journal. He renamed it *'Current Researches in Anesthesia and Analgesia'* in 1925 when the Society became the International Anaesthesia Research Society.

Hyman Cohen soldiered in the US Army, married a Manchester girl in 1904, and became a full-time anaesthetist after completing medical school at St Bartholomew's Hospital. *The British Journal of Anaesthesia* was first published in 1923 with Cohen as the editor. He introduced the journal as a publication "devoted entirely to the interests of anaesthesia and its practitioners".

German surgeons edited *'Schmerz, Narkose und Anesthetie'* which appeared from 1928 to 1943. The *'AANA Journal'* was published in 1933, as a report of the first annual meeting of the National Association of Nurse Anesthetists. In 1935, the French Society of Anaesthesia and Analgesia launched *'Anesthésie et Analgésie'*. Perhaps the first multinational anaesthesia journal, *'Revista Argentina de Anestesia y Analgesia'*, was published in 1939. Out of respect for McMechan, the American Society of Anesthesiologists refrained from publishing its own journal until McMechan died in 1939. *'Anesthesiology'* appeared in 1940. More journals in various languages appeared after World War II, reflecting the establishment of anaesthetic societies or specialist societies. That is, the rise of subspecialties and associated journals, beginning with *'Pain'* in 1975, mirrors the continuing growth of anaesthesiology. The successive contents pages of journals reveal the chronological development of anaesthesia.

Assisted by Roger Eltringham, Iain Wilson founded and edited the on-line journal *'Update'* in 1992 to support the safe scientific practice of anaesthesia in the developing world. The WFSA adopted *'Update'* as its official journal.

Ethical misconduct in medical publishing has recently received great publicity. Three cases of spectacular deliberate deceit were uncovered, one resulting in prison for fraud. More plagiarism has been detected and eradicated by use of electronic software that can compare submissions to texts in huge databases.

An Overview

Scientific journals allow communication among individuals in all fields of learning, be they general and popular sciences, pure sciences such as mathematics, or pursuits as diverse as astrology, psychology or linguistics. New ideas, discoveries, and inventions are documented, theories proposed and

phenomena documented. Details of experimentation and their results and applications are offered for discussion among peers, furthering collaboration and progress. Specialty journals such as those for anaesthesia and its many subspecialties have a more singular focus than those serving broader fields. There follows a history—the stories—of the evolution of some of the more important journals devoted to anaesthesia.

J. Thirlwell (✉)

Executive Editor, *Anaesthesia and Intensive Care*,
Australian Society of Anaesthetists, Sydney, Australia
e-mail: jeanette@thirlwell.com.au

The Early Anaesthesia Journals

Modern anaesthesia began with the 1840s introduction of nitrous oxide, ether, and chloroform. At that time, newspapers or early medical journals such as the *Lancet* (first appearing on October 5, 1823) disseminated written communications of discoveries which could produce analgesia with or without unconsciousness. In *Lancet*'s first issue, the editor Thomas Wakley wrote of his aims: "A *Lancet* can be an arched window to let in the light or it can be a sharp surgical instrument to cut out the dross, and I intend to use it in both senses" [1].

But the story begins earlier. In the late eighteenth century, the Austrian physician Anton Mesmer, introduced and popularised mesmerism, or hypnotism with his 1779 monograph, "Mémoire sur la Découverte du Magnétisme Animale" [2]. After marrying a wealthy young French widow, Mesmer lived comfortably in Parisian society. His monograph argued, in less than idiomatic French, that his technique might provide adequate analgesia for even radical surgery. Mesmer's publication, a forerunner of a journal, and word of mouth, spread his views from France to England and Scotland. James Esdaile and James Braid, both Scottish surgeons excised tumours and amputated limbs under this early form of "anaesthesia", publishing books documenting their operative cases.

John Elliotson was first an Assistant Physician at St Thomas's Hospital, London in the 1830s, then at the University College Hospital. He performed operations under mesmerism, but not without challenge and criticism. In the *Lancet* in 1838, Wakley, true to his aim to "cut out the dross", famously pronounced mesmerism as "humbug", prompting John C. Warren, the surgeon at Morton's 1846 demonstration of ether anaesthesia in Boston, to declare "Gentlemen, this is no humbug!" [3].

However, Wakley's rebuke did not stop Elliotson in his practice of mesmerism, and with a considerable cult following, Elliotson began a journal titled 'The Zoist: A Journal of Cerebral Physiology and Mesmerism, and their Applications to Human Welfare'. Publication extended from April 1843 to December 1855, with complete volumes annually for thirteen years. An international journal, it was published by Bailliere in London and Paris and by Weigel in Leipzig. It reported on mesmerism as used for chronic aches and pains, psychological and psychiatric disorders, superficial tumour excisions and major surgical procedures such as leg amputations [4]. Was this the first anaesthesia journal?

The First "True" Anaesthesia Journals

Until recently it was generally believed that the first anaesthesia journals were published in the early 1920s, with Volume 1 of 'Current Researches in Anesthesia and Analgesia'

appearing in August 1922, closely followed by Volume 1 of the 'British Journal of Anaesthesia' in 1923–4. But the Reverend Samuel Hayes, a Pittsburgh Pennsylvania dentist and former preacher in the Church of the United Brethren of Christ, published the first true anaesthesia journal in 1891. Hayes, like many dentists of the time, practised nitrous oxide analgesia for his patients. He criticized the technique used by some of his colleagues, preaching against their 'asphyxial anaesthesia'. Hayes argued for the provision of oxygen with nitrous oxide (or any other inhaled anaesthetic) in the administration of anaesthesia. In 1881 he therefore devised a foot-operated bellows to 'aerate' the gas delivered via the bubble-through vaporisers which he had also invented for ether and chloroform.

As a dentist, Hayes knew of a handbook published by the SS White Dental Manufacturing Company (SSW-DMC) of Philadelphia. From the 1880s the company published its proprietary journal, 'Dental Cosmos'. Hayes decided to confront Cosmos with his own quarterly, titled, with tongue-in-cheek, 'Dental and Surgical Microcosm' (DSM; Fig. 34.1). Hayes was 'Proprietor and Controlling Editor' of this challenging new volume. George Bause noted that "Hayes prided himself on defining 'anaesthesia' as distinct from 'asphyxia'" [4].

In 'Microcosm', Hayes publicised various design modifications of his "generators" (vaporisers), with thermoregulation to control the rate of vaporisation of chloroform and therefore the dosage received by the patient. Hayes died of tuberculosis in 1897 and with his demise, his journal ceased publication.

Anesthesia and Analgesia

'Current Researches in Anaesthesia and Analgesia Research Society Inc.' was first published bimonthly by the National Anaesthesia Research Society Inc., with Francis McMechan (Fig. 34.2) its instigator and editor. Though wheelchair-bound by rheumatoid arthritis, McMechan was a dynamic and enthusiastic advocate for the advancement of anaesthesia practice and research. Described as one of "the most militant figures of the history of the speciality" [5], he realised the need for a journal that would promote the specialty and disseminate the results of research. McMechan's involvement in editing and publishing began with his appointment by Managing Editor, Joseph McDonald, in 1914 as editor of a 'Quarterly Supplement' ('Anesthesia and Analgesia') to the 'American Journal of Surgery'. McMechan recruited the transactions of meetings of anaesthetists worldwide to publish in his Supplement. In the process he became known to medical researchers and leaders in the development and manufacturing of anaesthetic agents and commercial design of equipment.

Fig. 34.1 The cover of the summer quarter, 1891, issue of the *Dental & Surgical Microcosm* issue, published and edited by SJ Hayes of the Hayes Dental and Surgical Manufacturing Co. (Courtesy of George S Bause, MD, MPH, Case Western Reserve University, Cleveland, OH.)

Fig. 34.2 The cover of a 1923 issue of *Current Researches in Anesthesia & Analgesia*, edited by Francis H McMechan, MD, published by the National Anesthesia Research Society, predecessor of the international Anesthesia Research Society

With McDonald's death in 1922, McMechan campaigned to establish a formal anaesthesia research organisation to continue the activities of the supplement. Thus in August of that year McMechan founded the National Anaesthesia Research Society which then published its own journal. McMechan was justifiably proud of this journal, actively discouraging the establishment of an alternative. *Anesthesiology's* first edition in 1940, had to await McMechan's death, as mentioned below.

The second page of Volume 1, Number 1 of 'Anaesthesia and Analgesia' lists the members of the Board of Convenors of the National Anesthesia Research Society and the research committee. It contains many notable names such as McKesson and Guedel. The journal's title changed in 1925 when the National Anesthesia Research became the International Anesthesia Research Society.

In 1909 McMechan married actress Laurette van Varsveld (Fig. 34.3), who assumed the role of constant carer/companion of her husband. McMechan, with Laurette at his side, travelled nationally and internationally to Canada, England, and the European continent. In his travels, McMechan met a young Australian, Geoffrey Kaye. On McMechan's strong recommendations, in 1934 Kaye became the principal instigator and founder of the Australian Society of Anaesthetists, initiating the long path to establishing the Australian Journal, 'Anaesthesia and Intensive Care', in 1972. McMechan inspired similar actions by others in Canada. Laurette, in the 1920s and 30s, became widely known and highly regarded for her contribution to her husband's journal, so much so that after his death in June 1939, she was appointed Assistant Editor and continued in that role until her death in 1970.

There were relatively few editors-in-chief of 'Anesthesia and Analgesia' over its almost 90 years of existence, promoting continuity of style. Its second editor, Howard Dittick was succeeded by Thomas Seldon (1959–1976), then Nicholas Greene (1976–1990), Ronald Miller (1990–2006), and currently, Steven Shafer.

The 1940 November–December issue of 'Anesthesia and Analgesia' published a eulogy to McMechan by Omar Ranney, followed by tributes from Kaye, the then Secretary of the Australian Society of Anaesthetists. McMechan was more than founder of Anesthesia and Analgesia. As Kaye wrote to Laurette McMechan:

"He was an inspiration. We admired his courage, which rose superior to every physical disability. We admired his amazing knowledge of anaesthesia. We recognised in him a man of culture, with the wide and tolerant outlook which was capable of converting a national into an international endeavour... Above all, I think we admired his vision and the ideal to which it led him. He was not the parent of American anaesthesia, although he was, more than any man, its co-or-

Fig. 34.3 Francis and Laurette McMechan. (Courtesy of the Geoffrey Kaye Museum of Anaesthetic History, Australian and New Zealand College of Anaesthetists.)

dinator. Of international anaesthesia, however, he was both co-ordinator and parent" [6, 7].

Other journals appeared between the first issues of 'Current Researches in Anaesthesia and Analgesia' in 1922 and its rival 'Anesthesiology' in 1940. In 1923–4 the 'British Journal of Anaesthesia' arrived, followed in 1935 by the French journal, 'Anesthesie et Analgesie' and the Argentinian journal 'Revista Argentina de Anestesia y Analgesia'.

British Journal of Anaesthesia

The 'British Journal of Anaesthesia' was the second major English language journal. It was first published in July 1923 and edited by Hyman Cohen until 1928. Initially a soldier in the United States Army, Cohen married a Manchester girl in 1904, then entered medical training at St Bartholomew's Hospital in London. He graduated in 1916 and became a

full-time anaesthetist. He introduced his journal as a publication “devoted entirely to the interests of anaesthesia and its practitioners”, saying that the journal “anticipates acting, not only as the mouthpiece for those who desire to give public expression to the results of their research and experience, but to place before its readers, an account of what is being done generally in the anaesthetic world” [8].

In 2002, J Norman of Southampton, UK published a paper entitled “The British Journal of Anaesthesia—An Informal History Of The First Twenty-Five Years”, listing the pioneer founders in this developing medical specialty as SR Wilson and HEG Boyle, of the University of Manchester, F Shipway, J Bloomfield, DW Buxton from London, HB Fairlie from Glasgow and AJ O’Leary from Liverpool [9]. Although of necessity reducing publication from quarterly to twice a year for most of World War II, this journal flourished thereafter, rising high in the ranks of anaesthesia journals.

Anesthésie et Analgésie

In 1935, ‘Anesthésie et Analgésie’, the official publication of the French Society of Anaesthesia and Analgesia was launched. In the first issue, the chief editor, Robert Monod explained that the Society aimed to create a “review of anaesthesia in the French language” [10], and that, like anaesthesia journals established before and after, it sought to document research in the laboratory and in clinical practice, impartially and without bias.

Revista Argentina de Anestesia y Analgesia

Volumes 1 and 2 of ‘Revista Argentina de Anestesia y Analgesia’ were published in 1939–40 (Fig. 34.4). Articles came mostly from Argentina, but also included one paper each from France and Italy, making ‘Revista Argentina de Anestesia y Analgesia’ possibly the first journal with an international list of contributors. In his introductory editorial, Emilio Forgue, a Member of the Academy of Surgery and a Corresponding Member of the Institute of France, noted the widely differing techniques of anaesthesia used in different countries in the late 1930s, the choices varying according to the medical school and hospital traditions and the results of their research. He argued that the safest anaesthesia is “the one with which the anaesthetist has most experience” [11]. He acknowledged the originality and leadership of Americans at the time in the use of inhalational agents, while anaesthetists in Germany led the way in the use of regional techniques. Forgue was a protagonist of regional anaesthetic techniques. In contrast, in France he noted that particularly in Lyon, preference was given to intravenous induction.

Antonio Gutierrez, a Member of the National Academy of Medicine and Honorary professor of the Faculty of Medicine in Buenos Aires, wrote an editorial in the second issue of ‘Revista Argentina de Anestesia y Analgesia’, May–August 1939 titled, ‘What is a Surgical Operation from the physiological point of view?’ In answer, he described the ‘offence, injury and aggression’ inflicted, and the subsequent responsibility of the anaesthetist to support the patient [12]. Both editorials were forthright and apposite, applying equally well in the present day.

Anesthesiology

In March 1935, John Lundy approached Maurice Fishbein, editor of the ‘Journal of The American Medical Association’, to suggest establishing a second American anaesthesia journal under the auspices of the American Medical Association (AMA). Lundy was keen to increase the quality and quantity of scientific papers published in the field of anaesthesia. He believed that his anaesthetic colleagues would back this venture, and wrote to fifty-five of the most prominent of these to gather their support. The response was mixed. Although agreeing that another American anaesthesia journal would be an otherwise appropriate venture, Arthur Guedel expressed concern that establishing a second journal might offend McMechan. In contrast, Guedel’s friend, Ralph Waters, then professor of the world’s first academic Department of Anesthesiology at Madison, Wisconsin, agreed with Lundy that a second journal would be an “excellent idea” and that contributions from his department would support the venture. Other responses were less positive, so the project was temporarily shelved. Lundy suspected that McMechan had negatively influenced some of those surveyed [13].

After McMechan died in June 1939, plans quickly proceeded for establishment of ‘Anesthesiology’. On November 4, the Journal Committee and the Publishing Committee of the American Society of Anesthesiologists met, appointing Henry Ruth as first Editor in Chief with Ralph Tovell and E.A. Rovenstine as Associate Editors and Paul Wood as Managing Editor. An Editorial Board was then appointed with four Contributing Editors and nine Consulting Editors. An Editorial Policy Committee was then established to act as a steering Committee to determine editorial policy. The first issue opened with an unusual essay by Howard Haggard, Director of the Laboratory of Applied Physiology at Yale University. His article entitled “The Place of the Anaesthetist in American Medicine” was a transcript of a paper presented at a meeting of the Society of Anaesthetists at the New York World Fair, New York City on October 12, 1940. This was a newly established Section on Anesthesiology of the AMA, held during its ninety-first annual session in New York City,

Fig. 34.4 A picture of the Volume 1, April, 1939 issue of *Revista Argentina de Anestesia y Analgesia*. (Courtesy of the Geoffrey Kaye Museum of Anaesthetic History, Australian and New Zealand College of Anaesthetists.)

October 10–14, 1940. Haggard's essay neither praised nor faulted anaesthesiologists [14]. His intent was to impress on the listener/reader that public opinion and an appreciation of the practice of anaesthesia as a professional skill were crucial to the development of the specialty. He maintained that the anaesthetist must shape public acceptance of the specialty of anaesthesia by the achievements of the anaesthetist in education, training and scientific development in physiology, pathology, biochemistry and general scientific endeavours. Haggard believed that good practical skills and professional personal presentations of anaesthetists to their patients were essential to the acceptance of the specialty of anaesthesia in its own right [14].

Volume 1, Number 1 continued with Guedel's review of his use of cyclopropane over the previous eight years in more than eight thousand cases, discussing controlled respiration, the production of abdominal relaxation, the presence of cardiac arrhythmias and techniques of administration. A readable, uncontrolled study of practice by one of the "great" anesthesiologists of the day [15].

Anaesthesia

'Anaesthesia', the Journal of the Association of Great Britain and Ireland, was established in 1946, remarkably soon after World War II. Its Editor was Cecil Hewer and Sub-Editor R. Blair Gould, with J.F. Gillies representing Scotland. Alfred Webb Johnson, President of the Royal College of Surgeons of England provided an introduction to this inaugural issue [16].

"I am grateful for the invitation to write a Foreword to this first number of the Quarterly Journal 'Anaesthesia', for it not only gives me the opportunity to wish the Journal every success, but also to say how pleased I am that the Association of Anaesthetists of Great Britain and Ireland has decided to launch a periodical publication on this important subject.

"The year of the celebration of the centenary of the first operation under general anaesthesia in this country is a most opportune time for the institution of a Journal which will make British teaching and records of discovery and achievement available to the medical profession throughout the world. It is very fitting that the country which made such valuable contributions in the early days of anaesthesia by the pioneer work of Hickman, Simpson, Snow and Clover should be represented in the medical literature of the subject."

Hewer's editorial followed in the same vein, justifying the establishment of this new publication: "...the rapid advance in all types of anaesthetic and analgesic technique requires fuller and quicker expression than can be provided in the overloaded columns of the general medical press. The full and accurate presentation of observations, theories, new

methods etc., is essential if true advance is to be maintained and if unprofitable detours are to be avoided."

Henry Featherstone, the first President of the Association of Anaesthetists, wrote of the "Inception and...Purpose" of the Association and its aims, objectives and formulated rules as set out at its establishment in 1930, and the subsequent successful introduction of a Diploma of Anaesthesia. This first issue also included a nine-page article by President AD Marsten on the "Centenary of Anaesthesia in Great Britain" in 1946, chronicling the events preceding the launch of "Anaesthesia" [17].

Thereafter followed twenty pages of dissertations on curarisation, local anaesthesia for abdominal operations, and an assessment by Noel Gillespie from Canada of the effect that World War II had on the "Position of the American Anaesthetist". The journal also included a case report, a review, abstracts and Association news. A small volume descriptive of anaesthetic interests of the time, 'Anaesthesia' quickly grew in stature and physical dimensions, from a small A5 quarterly booklet, half the size of its currently conventional A4 format, now issued monthly.

However, with the establishment of 'Anaesthesia' with such self-confidence it would be wrong to assume there was no rivalry between the long-established British Journal of Anaesthesia and this newcomer to the scene of anaesthesia journals. It was as if an unfair advantage of opportunity was being taken to rise above the British Journal of Anaesthesia which had suffered badly as a consequence of World War II because of a severe lack of papers offered for publication and a shortage of paper for printing of many medical journals at the time. It is fair to say that not all representatives of the Association of Great Britain and Ireland were in agreement with this proposal. This rivalry that the commencement of a second British journal aroused is clearly set out in a work by Thomas B. Boulton, titled 'The Association of Anaesthetists of Great Britain and Ireland 1932–1992, and the Development of the Specialty of Anaesthesia'. Ultimately the British Journal recovered from the ravages of wartime, while Anaesthesia maintained popularity as a more clinically orientated publication [17].

'Revista Brasileira de Anestesiologia'

'Revista Brasileira de Anestesiologia', the official publication of the Brazilian Society of Anaesthesiology, commenced publication in 1951, its first editor being Oscar Ribeiro. Ribeiro's introductory editorial was in Portuguese, while the second, by Ralph M. Waters, was in English. In nine pages, Waters congratulated his Brazilian colleagues for their inauguration of the first journal of anaesthesiology in a Portuguese-speaking country and the second in Latin

America. Waters gave a broad overview of the development of the specialty of anaesthesia from the latter part of the nineteenth century when, in the US, the administration of anaesthesia was largely entrusted to the temporarily idle medical student, intern, general practitioner, nurse or any individual who happened to be nearby. He then described the development of the specialty of anaesthesia through the 1940s, listing in detail the obligations of service, teaching and research. He also described the qualities of the “Good Anaesthesiologist”, citing the physical strength needed to practise well, moral obligations to the patient, the obligation to display a spirit of friendly cooperation with those with whom he works, and how he must “serve as the balance wheel which governs the smooth running of the machine of which he is a part. In short, he can make or break the success of the surgical team His pronouncement is as true today as it was some sixty years ago [18].

‘Masui’ (The Japanese Journal of Anesthesiology)

From 1951 to 1960, a profusion of anaesthesia journals emerged in Europe, the Middle East and the Far East. In April 1952, the first issue of the Japanese Journal of Anesthesiology was published. There were five Editors of this first issue; Shichiron Isikawa, Myoshi Urabe, Kingo Shinoi, Tikashi Suzuki and Shinobu Myamoto. In his Foreword, Tamotsu Fukuda, Professor of Surgery at Juntendo University in Tokyo, stated that several factors increasingly allowed surgeons to successfully perform major surgery, attributing their growing success to the development and availability of antibiotics including penicillin, and to “aggressive” pre- and postoperative management of their patients. He observed that regional anaesthesia had in the past, been the preferred technique, with reasonable results, but emphasised that it was now time for his anaesthesia colleagues to emulate anaesthesiologists in Europe and the United States, to allay not only the intraoperative pain of surgery but to continue their management of the patient as a whole, through surgery and the postoperative period. Generally known as ‘Masui’, the ‘Japanese Journal of Anaesthesiology’ is a Japanese language journal and is still in regular production [19].

The Japanese word ‘masui’ has an interesting story in itself. The news of the administration of successful anaesthesia in 1846 and the developments which followed spread quickly around the world with the publication of books such as Schlesinger’s German book on ether anaesthesia. By 1848, six copies of the Dutch edition of this book had reached Japan and a Japanese edition was published in 1850. Seikei Sugita, an official translator of the Shogunate, executed the translation, coining the Japanese word ‘masui’, meaning ‘paralysis and unconsciousness’.

Journal of Anaesthesia

The ‘Journal of Anaesthesia’, the journal of the Japanese Society of Anaesthesiologists is published in English. This journal made its debut in March 1987, its first Editor-in-Chief being Keisuke Amaha, with Kenjiro Mori (Kyoto University), Takesuke Mateki (Kurume University) Ryo Ogana (Nippon), Reiji Shimizu (Jichi) and Jurichi Yoshitake (Kyushu University) as co-founding editors. Indexed from Volume 17 in 2003, it achieved citation status in 2010. In parallel with other well-known journals, it has increased its publication from an initial two issues a year through four and now six issues per year.

In June 2010 at the Asian Australasian Congress of Anaesthesiologists in Fukuoka, Japan, Professor Akitomo Matsuki of the Department of Anesthesiology, Postgraduate School of Medicine of Hirosaki University, presented a paper entitled, ‘Seshu Hanaoka’s Philosophy of “Safety and Challenge”’. Hanaoka was a highly regarded Japanese surgeon in the late 18th and early nineteenth centuries. In 1804 he performed one of the earliest reported general anaesthetics, using an extract of *Datura stramonium* in an oral preparation, enabling him to excise an advanced tumour of the left breast. The patient, Kan Arya, expressed feeling no pain during the procedure, but died four and a half months later from dissemination of the original pathology. The successful anaesthesia and surgery which resulted is celebrated in the adoption of the flower of *Datura*, as the basis of the logo of the Japanese Society of Anaesthesia, appearing on the front cover of all issues of their ‘Journal of Anaesthesia’ since its inception. *Datura* has been used in South America, the Middle East and Far East in particular, for its ‘medicinal’ properties, and while it is not an anaesthetic, it is a known hallucinogen and is also known to alter the appreciation or memory of pain. The plant is recognized as containing scopolamine, hyoscyne and atropine.

‘Schmerz, Narkose und Anesthesie’

The first German language journal of anaesthesiology, ‘Schmerz, Narkose und Anesthesie’ (Pain, Narcosis and Anaesthesia) was published from 1928 to 1943. The title emphasised pain, anticipating the later development of pain as an anaesthesia subspecialty. The chaos of World War II ended publication of this journal.

Der Anaesthesist

In 1952/1953, Volume 1 of ‘Der Anaesthesist’ appeared, the journal of the Austrian Society for Anaesthesiology, its three editors being R. Frey of Heidelberg, W. Hugen of

Basel and O. Mayrhofer of Vienna. In 1953, it developed into the first multi-national society journal, in that with its Volume 2, Issue 3 it became the journal of the German Society for Anaesthesiology, while in Issue 4, it also became the journal of the Swiss Society for Anaesthesiology. Thus, 'Der Anaesthetist' has served the German-speaking fraternity of Europe while promoting co-operation with central European countries as well.

In 1979, *Der Anaesthetist* added a twenty-page journal-within-a-journal. Appearing every three to four months, this supplement, 'Regionale Anaesthetese' supported the sub-specialist field of regional anaesthesia. Subsequent supplements commemorated pioneers of 'Regional Anaesthesia' such as Karl Koller, the discoverer of the local anaesthetic effects of cocaine, then Carl Schleich who developed infiltration anaesthesia, and August Bier, the champion of spinal anaesthesia. Many editors of 'Der Anaesthetist' and its included journal, 'Regionale Anaesthetese', have written editorials and articles on the history of both journals, and the importance of developments in regional anaesthesia as a peculiarly German-based subspecialty.

Canadian Anaesthetists Society Journal

The 'Canadian Anaesthetists Society Journal' was established in July 1954. An introductory page listed the executive officers and council of that society, including the president, Russell Fraser. The founding editor, Roderick Gordon, headed a three-member editorial board: Alan Noble, Louis Lamoureux and Ted Gain. The journal was printed in Toronto and published by the Society itself. An accompanying editorial described the evolution of the journal from the Society's newsletter, which had published papers presented at previous meetings [20]. The journal evolved over time from a quarterly to a monthly publication in 1993 and grew in international prominence within the specialty. In 1987, the name of the journal was changed to the Canadian Journal of Anesthesia. Reflecting the two official languages of Canada, articles in the Canadian Journal of Anesthesia are printed either in English or in French, according to the language of submission. In early 2012 the Journal's circulation was just under 6000, two-thirds external to Canada—from a modest beginning, as the successor to an anaesthesia society newsletter, it had grown to become a mainstream international journal.

Acta Anaesthesiologica Scandinavica

In 1940, a young anaesthetist, Torsten Gordh, returned to Sweden from training in the US, where his tutor Ralph Waters advised him to establish a Nordic Society of Anaesthe-

siologists. It took nine years to evolve, but in 1949, Gordh, Otto Mollestad (Norway), Henning Poulsen (Denmark) and Eero Turpeinen (Finland) founded, in Helsinki, the 'Nordisk Anesthesiologisk Forening' (NAF), that is, the Nordic Society of Anaesthesiologists [21].

Establishment of a journal was the next step, but this required interminable discussion to clarify the journal's aims. In 1950, after the Society's first congress in Oslo, approaches were made to various publishers with however, no general agreement on the proposed publication by the time of the General Assembly of the Society in 1952. There was still dissention concerning the nature of the contents and the scientific standard to be achieved. Finally, in 1956, at the General Assembly in Helsinki, a decision was made to proceed, with Bjorn Ibsen and Henning Poulsen as Editors, and Eric Nilsson (Sweden) as Editor-in-Chief. The name chosen for the Journal, 'Acta Anaesthesiologica Scandinavica' (AAS), conforms to the usual Latin style of other Scandinavian medical journals. Four issues appeared in 1958, with Olaf Norlander then added as Associate Editor for Sweden. The first issue was small, an A5 format, with a conservative creamy-coloured cover.

By 1971 it was noted that two-thirds of subscribers were non-Scandinavian, *Acta Anaesthesiologica* having effortlessly become an international journal. As with many journals in their first years, the editors did much of the editing and preparation of papers, while A. Ronsing, a lecturer in English at Aarhus in Denmark, and Armstrong Davison of Newcastle-upon-Tyne, UK translated submissions in Scandinavian languages into English, and Otto Mayrhofer of Vienna translated abstracts into German.

Jan Eklund, Editor-in-Chief from 1985 to 1993, has described the history of this journal in a dissertation, 'Acta Anaesthesiologica Scandinavica—The First Fifty Years (From Lead to Electrons)'. Sven Gisvold followed Eklund as Editor-in-Chief in 1993, and in 2008, he was succeeded by Lars Rasmussen [21, 22].

In December 1971, when the AAS had grown sufficiently, Munksgaards became the publisher on contract to the Scandinavian Society. The journal format changed to the more conventional American A4, and a bright orange-red colour cover made it immediately identifiable. Each journal has a unique and readily identifiable cover, as well as a registered name and ISSN, but the individual appearance helps recognition on a library rack of journals side by side.

Middle East Journal of Anaesthesiology

Bernard Brandstater, an Australian graduate who was Professor at the American University of Beirut Medical Centre, pioneered the 'Middle East Journal of Anaesthesiology' in 1966. This journal was included in *Index Medicus* in 1976.

Brandstater, the first Editor-in-Chief, drew from Hamlet, Act III, Scene II for the journal's motto, "Some must watch and some must sleep". On the home page of its website, Brandstater also chose its symbol, the poppy flower (*Papaver somniferum*), first cultivated in the Middle East, a flower that has given unique service to suffering mankind for thousands of years. This journal is published three times a year, its consultant editors representing various Middle Eastern countries. Each volume consists of six issues and is therefore the sum of two years' publications. The journal is dedicated to promoting research and education in anaesthesia in these countries.

Anaesthesia and Intensive Care

In 'Fifty Years, The Australian Society of Anaesthetists 1934–1984', Gwen Wilson presented the history of the establishment of 'Anaesthesia and Intensive Care', the Journal of the Australian Society of Anaesthetists [23]. In 1934, Geoffrey Kaye, of Melbourne, acting on McMechan's recommendation, gathered six like-minded colleagues to found the Australian Society of Anaesthetists. One stated aim of the Society was to establish a journal. However, the long distances between cities and towns in a vast and thinly populated continent limited growth of the Society in those Depression years. Kaye first established a series of 'Anaesthetic Numbers' in the Medical Journal of Australia, and later wrote infrequent memoranda which developed into the Newsletter of the Society. The Newsletter contained some articles of a scientific nature, almost all written by Kaye himself, a demanding ongoing project. Most other Australian anaesthetists of that time sought greater exposure and recognition, sending their scientific articles to established overseas journals. The Newsletter was rightly regarded as a carrier of society news rather than a vehicle for scientific communication.

During World War II, many Australian medical graduates, including Kaye, were deployed overseas in the defence forces. Communications within the Society virtually ceased, and no scientific congresses were held in those years. At the Annual General Meeting of the Society in Perth, Western Australia in April 1954, the question of an Australian Journal of Anaesthetics, as it was referred to then, was raised again. However, a postal referendum by the Victorians revealed a consensus that the project was premature, and the proposal was abandoned.

In 1969, Ben Barry was appointed Honorary Federal Secretary of the Society. Barry favoured the establishment of a journal and quietly laid much of the groundwork, promoting the idea among members and accurately assessing costs with quotes from publishers. A motion to publish a journal was put to the Executive Committee in May 1971 and passed unanimously. Barry was appointed founding Editor, with an

editorial board of twelve members. 'Anaesthesia and Intensive Care' was established, after four decades from its first consideration, with Volume 1 Number 1 appearing in August 1972. Barry continued as its editor for ten years. He was followed by B Horan, then J Roberts, A Duncan, and in 2007, N Gibbs. Barry continued to take a keen interest in the publication, opening each new issue and immediately calculating the income from advertisements contained within its pages to assess its continuing viability. Now in its fortieth year, 'Anaesthesia and Intensive Care' continues to be published in-house at the Australian Society's headquarters, employing a printer for the hard copy production only. It enjoys the official support of the Australian and New Zealand Intensive Care Society and the New Zealand Society of Anaesthetists (Fig. 34.5).

Since 1984, when the Australian Society of Anaesthetists celebrated its fiftieth year, an aspect of the history of anaesthesia has been featured as a cover photo, with a short informative covernote in the prepages. From 1984 to 1988, they were prepared by Gwen Wilson, followed by Rod N. Westhorpe and Christine Ball who have continued to provide the covernotes to this day. (Fig. 34.5) Other journals have also given prominence to history. 'Anesthesiology' has included a series of historical vignettes contributed by George Bause, curator of the Wood Library-Museum, Douglas Bacon and others. 'Anesthesia and Analgesia' recently included the cover image and story "The Amazing Nitrous Oxide", written by Naveen Nathan. For many years, the Newsletter of the Association of Anaesthetists of Great Britain and Ireland has included a "History Page."

Journals in Anaesthesia-Related Fields

Pain

In 1973, John Bonica was instrumental in organising the first International Symposium on Pain, held in Issaquah, Washington, US. Bonica's interest in pain began in the late 1930s and 1940s, during World War II, with his involvement as Chief of the Anesthesia and Operating Section of Madigan Army Hospital, Fort Lewis, Tacoma, Washington, where he was primarily involved in the treatment of pulmonary conditions and severe pain caused by war wounds. There, he taught himself regional anaesthetic techniques, and after the War initiated a training program in anaesthetics, first at Tacoma General Hospital in Tacoma Washington and then at the University of Washington.

Along with like-minded colleagues, Bonica established the International Association for the Study of Pain (IASP) in May 1974. At its first meeting in Washington DC, Bonica proposed the establishment of the journal, 'Pain'. Elsevier published the first issue of this quarterly journal in 1975 with Patrick Wall as its first Editor-in-Chief, while Bonica headed

the list of the Editorial Board. Definitions of pain were established and published in 1979 in 'Pain'. Publication expanded from a quarterly to a monthly in 1982. The IASP widened its base over the past 40 years to involve neurologists, neurosurgeons and other medical specialties, reflected by the increasingly range of articles published in the journal. It has become an interdisciplinary journal. In 2011, 'Pain' had an Impact Factor of 5.371 (the highest of all journals classified as related to anaesthesia by ISI) and a 5-year Impact Factor of 6.125 [24].

Other notable journals specialist fields are 'Critical Care Medicine', established in 1972 'Regional Anesthesia and Pain Management' established in 1975.

'Thoracic and Cardiovascular Anesthesia', 1986, 'Journal of Neurosurgical Anesthesiology' 1989 and the 'International Journal of Obstetric Anesthesia', 1991 have also been established, following on closely since the original pioneering publications in new subspecialties.

Other Established Journals

These include the 'Indian Journal of Anaesthesia' which recently celebrated its fiftieth year of publication, having commenced in 1956, while the 'Romanian Journal of Anaesthesia and Intensive Care' was established in 1994.

Reasons for Writing

The British Medical Journal of 9 October 1965 contained a report of the nineteenth General Assembly of the World Medical Association held in London in that year. This session was in fact a conference of medical editors. Russell Brain made the first presentation. Brain was a British neurologist, principal author of Brain's 'Diseases of the Nervous System', and for many years, Editor of the journal, 'Brain'. His address, discussed the shortcomings of the presentations of scientific papers, pointing to poor construction of hypotheses and faulty reasoning, leading to erroneous deductions [25]. Austin Bradford-Hill followed with another paper, this in a more constructive vein, titled, "The Reasons for Writing" [26]. Bradford-Hill, or Hill as he called himself and preferred to be known, commenced by posing the question, "Why does the scientific worker write at all?" After dismissing examples of "authors who write to gain notoriety or to climb another rung or two on the ladder", he stated that the object of a scientific worker was to communicate to other workers in the field, just two things: "what was it the worker thought he had found out and how did he find it out". Hill was reacting to the loose and long-winded presentations of many papers published at the time. He declared that papers should have four sections which clearly answered the ques-

tions, 'Why did you start, what did you do, what answer did you get, and what does it mean anyway?' He argued that 'this seems to be a logical order of a scientific paper'. These four questions of Hill's, to be answered in the structure of the paper, constitute our now universally accepted format of Aims, Methods, Results and Discussion. Hill's basic guide to good scientific writing is clear and authoritative and continues to be quoted in "how-to" manuals such as the popular 'How to Write a Scientific Paper' by George Hall, the most recent edition being reprinted in 1999 [26].

'Update', Journal of the World Federation of Societies of Anaesthesiologists

The published reports in anaesthesia journals indicate the globalisation of the understanding and practice of anaesthesia. The spread of the English language as the language of science has facilitated communication of knowledge and ideas, of the results of drug trials, of new techniques and new equipment to facilitate the practice of these techniques. The prize for the journal published most broadly in geography and languages surely must go to 'Update', the Journal of the World Federation of Societies of Anaesthesiologists (WFSA). This Federation was formed in 1955 and its first World Congress held in 1957 in Scheveningen in The Netherlands. The World Congress of Anaesthesiologists has since been held at four-yearly intervals in cities worldwide. The original funding for the production of an international journal was given by the World Federation of Societies of Anaesthesiologists in 1992. UK aid from the Overseas Development Administration then added 16,000 Pounds Sterling over four years. 'Update' was launched, founded and edited by Iain Wilson in England, generously assisted by Roger Eltringham. The journal was then adopted by the WFSA as its official journal.

Since its beginning, this journal has aimed to spread the knowledge of the science and safe practice of anaesthesia throughout the developing world, its editors now being the Members of the Publications Committee of the WFSA, and its current Editor-in-Chief Bruce McCormick. This small band of volunteers from UK, US, Australia, Argentina, France, China and Togo edit all copy and translate the contents of every issue, resulting in its publication not only in English, but also Spanish (web), Russian (web and hard copy), Mandarin (hard copy) and French. At the time of writing, Portuguese and Persian editions are underway. Now fully funded by the WFSA, this journal is distributed in various countries where medical libraries and the Internet are not readily accessible or are prohibitively expensive, and has from the start, been available via the internet for free download. The journal reaches many anaesthetists, anaesthetic technicians and nurses in remote parts of South American

countries, in sub-Saharan Africa, and in China, Southeast Asia and Mongolia and many other places where facilities for clinical practice and educational development are scarce, and textbooks and journals few or out of date. In terms of the populations they serve, collectively these countries are better termed ‘the real world’. The aim of the WFSA and its committees is altruistic, supported by membership fees and donations of the individual societies of the WFSA.

Support and Survival

Why did some Anaesthesia Journals evolve as they did? Why, for instance, did ‘Anesthesiology’ eclipse ‘Anesthesia and Analgesia’? Part of the answer may well lie in the economic and scientific dominance of the US after World War II. Relatively unscathed and growing economically, the US drew ahead in many aspects of science and its support, including that for anaesthesiology. NIH support increased markedly in the 1950s and 1960s. As part of this general development, the science of anaesthesia developed more in the US than in other countries, and perhaps being vulnerable to provincialism, researchers in the US submitted the results of their work to American journals. But probably most significant was that all members of the American Society received ‘Anesthesiology’ as part of their membership and the membership of the ASA quickly surpassed that of the IARS. The excellence of the selection of the editors-in-chief and editorial staff added greatly to Anesthesiology’s prestige, and it became the journal of choice for research reports. Anesthesia and Analgesia was pejoratively referred to as the ‘Yellow Peril’ until its standards were raised by editors such as Nicholas Greene and those who followed.

Ethics of Publication—Plagiarism and Fraud

Regrettably we can’t believe everything we read. Newspapers publish untruths which can result from inaccurate reporting, or deliberate misrepresentation of the facts for political or publicity purposes. Similarly in medical publications, be they in general articles or specialist fields of reporting or original research such as anaesthesia, there may be instances of either genuine mistakes or deliberate modifications of a study’s results, to gloss over a defect in the collection of data or to prove a point that the author had as the original aim of the study. Unfortunately, it falls to the editor’s lot or that of the reviewer to identify fraud before acceptance for publication. This is not an easy task, and inevitably some papers slip through the net.

Plagiarism is a well-recognised transgression in publication. Most journals request assignment of copyright by the authors on acceptance of the submission by that journal. Any part of another paper may be quoted as long as acknowledgement of the source is included. But the exact copy of text without

acknowledgement of the source and permission being granted by the copyright holder is plainly illegal. Self-plagiarism is certainly not unknown, where an author repeats verbatim his or her own already published text, whether it be originally in a journal or a paragraph in a major work such as a textbook.

A sharp-eyed and well-read editor or reviewer may recognise phrases or whole sentences in familiar subject matter that alerts him or her to the possibility or probability of plagiarism. More recently with the development of electronic software, such a submission may be scanned and compared to texts in the huge databases available such as Pubmed. Examples of software are eTblast, Deja-vu, DocCop and Turnitin, the last mentioned of these being in regular use in universities and schools when assessing students’ examinations and ‘original’ essays. However, these electronic programs are helpful but not perfect; they assist in identifying closely similar text but must ultimately be used with caution. At best, they are useful tools, and editorial boards of anaesthesia journals are rapidly adopting the practice of scanning all submissions before acceptance for publication.

In the 1990s, various editorials were published on double publication and self-plagiarism to draw authors’ and readers’ attention to the serious nature of the problem. ‘Anesthesia and Analgesia’ and ‘Anaesthesia and Intensive Care’ have used these editorials to expose the practice, by instancing several cases within their own pages. In the ‘British Journal of Anaesthesia’ in April 1991, G Smith, R Miller, LJ Saidman and M Morgan published an editorial titled “Ethics in Publishing”, which was closely followed by another in the same vein by JG Roberts in ‘Anaesthesia and Intensive Care’ the following month, the latter titled “Publishing in our Journals: Ethics and Honesty” [27, 28]. Similar editorials were published around the same time in Anesthesiology, Anaesthesia and the Canadian Journal of Anesthesia when it appeared that there was emerging an “epidemic” of double or multiple publication of data from a single study, and an increasing awareness of lack of ethics approval (of informed consent). As a result of this widely recognised and unacceptable incidence, the International Committee of Medical Journal Editors revised their document of ‘Uniform Requirements’

Editors of journals in the same specialty fields communicate freely with one another when suspicion about the originality of a paper arises or when fraud is suspected; for instance, when no registration of a trial or clinical study is documented. For most journals, documented registration of a study or clinical trial is obligatory before acceptance for publication. An editorial by Martin Tramèr in the ‘European Journal of Anaesthesiology’ in 2011 describes a series of 88 clinical trials which were published in various medical journals from 1999 to 2011, all by the same author, Joachim Boldt [29]. Originally the total number of articles was 102, but at least 12 of these could be verified as approved by the Institutional Review Board (IRB) of the State Medical Association of Rheinland-Platz, Germany, where Boldt conducted

his research. However, 88 remained without IRB approval, the research consequently could not be verified and to date is plainly unacceptable for publication. In his Editorial, Tramèr describes how the authors of the eighteen well-known medical journals have signed an “Editors-in-Chief Statement Regarding Published Clinical Trials conducted without IRB Approval by Joachim Boldt”.

But to return to the beginning, Joachim Boldt, a German anaesthesiologist and former Head of the Department of Anaesthesiology at the Klinikum Ludwigshafen, a hospital which is not university-affiliated, published his 102 articles in various journals including the ‘European Journal of Anaesthesiology’ and ‘Anesthesia and Analgesia’. Of these 102 articles, 12 were verified as having been approved by the IRB. The remaining 88 articles in question had no ethics committee approval as there was no ethics committee or IRB at this non-university-affiliated hospital at the time, and any claim published in these papers that the authors had such approval was plainly false. In another four articles in this series of 102, Boldt and his co-workers positively claimed that these studies had the approval of the IRB of the hospital, but no such committee has ever existed. However, there was in place until 2001, an arrangement whereby an author wishing to gain permission to proceed with some planned research could apply to the Landesartzkammer Rheinland-Pfalz, with a letter of approval from an ethics committee (IRB) together with patients’ signed consent forms.

Scott Reuben graduated from the State University of New York Medical School at Buffalo in 1985 and trained in anaesthesiology at Mount Sinai Medical Center in New York. In 2009 he held the position of Professor of Anaesthesiology and Pain Medicine at Baystate Medical Center in Springfield, Massachusetts. Suspicion of fraudulent publication first occurred in 2008 when it was discovered that he had not submitted an application for IRB approval for two pieces of research which he planned to present at an in-hospital research week. In 2009, it was revealed by a staff member at Baystate that Reuben had admitted to failing to subject his proposed trials to an IRB, fabricating the results of trials and never even conducting the trials he wrote about in 21 articles he published in journals.

Reuben’s first paper in a series of 21 clinical trials of doubtful validity appeared in 1996. Reuben fabricated some of the listed patients, no doubt wishing to add weight to the clinical “proof”. He also listed co-researchers, some of whom knew nothing about the trials and had their signatures forged on submitted documents.

In 2009 Reuben also admitted to a member of staff that he had fabricated volunteers for his research and therefore the data in the results of his research in trials of various pain-killer preparations and an antidepressant drug for which Pfizer had made major grants for Reuben to perform the studies. The editors of the journals which had published Reuben’s studies were obliged to retract these 21 articles. In 2010, Reuben was

charged and sentenced for health care fraud. He was relieved of his professorship at Baystate and sentenced to six months in gaol to be followed by supervised release for three years. He was also fined heavily and ordered to provide an enormous amount of monetary restitution [30]. According to Steven Shafer, Editor of ‘Anesthesia and Analgesia’, doctors had been applying his findings in their clinical practice, and thereby likely putting their patients at risk of serious and undocumented effects of the drugs. Shafer described Reuben’s publications as “the biggest case of fraud in the history of Anaesthesiology”.

Some institutions such as the colleges of the medical specialties have their own systems to assist in the management of cases of plagiarism or fraud. One such is the General Medical Council of the United Kingdom. The recently established Committee on Publication Ethics (with the neat acronym of COPE) welcomes medical journal editors to join its international membership and to enjoy the full benefits it offers, assisting editors dealing with apparently insoluble issues with difficult authors and other problems of non-compliance with instructions [30].

But the history of this organisation is interesting in itself. In 1997 Michael Farthing, at that time Professor of Gastroenterology at St Bartholomew’s Hospital in London, was appointed Editor of ‘Gut, International Journal of Gastroenterology and Hepatology’. Within his first year as Editor, Farthing was surprised to encounter four cases of misconduct among the submissions received. This prompted some informal meetings of editors who were similarly concerned, where cases were discussed behind closed doors. In November of that year, a formal meeting of like-minded editors where anonymised cases were discussed, and the Committee on Publication Ethics was thus established. In his first annual report of the group meeting in May 1998, Farthing stated that “COPE is an experiment”, adding that he would be delighted if the international response to research into misconduct significantly reduced its incidence. By the year 2000 COPE had a constitution, elected officers and a council. COPE is now a fully established organisation which has not only issued its ‘Guidelines on Good Publication Practice’, but assists individual editors personally and through its flowcharts (algorithms or guidelines), thereby directing editors in sorting out their problems with difficult and non-compliant authors. COPE’s membership is currently around 350 editors worldwide, with a Code of Conduct and a quarterly newsletter.

Development of an Organization of Journal Editors

The International Committee of Medical Journal Editors (ICMJE) is a group of general medical journal editors worldwide. Originally known as the Vancouver Group after its first meeting in 1979 in Vancouver, British Columbia in Canada, the group now meets annually to discuss such items as rec-

ommendations for Instructions for Authors, a guide which all journals publish either once a year or regularly in each issue. These clearly set out the obligations which authors should observe for ready acceptability of their submissions. The committee also advises on such matters as registration of clinical trials and conformity.

Accessibility of Journals—HINARI

Lack of access to scientific journals has been recognised as a major hurdle to improvement in world health. After much deliberation and planning, in the year 2000 the World Health Organisation and the United Nations organisation agreed to co-operatively fund a program “Research for Life”. One of the three programs under this banner is the Health Internet Access to Research Initiative, “HINARI”. Under the HINARI banner, publishers who agree to allow their journals to contribute to this initiative donate one online subscription to the organisation. Microsoft Ireland provides free password-controlled access for approved institutions in low- and middle-income developing countries. This gesture is aimed at improving standards of health care and is already providing guidance to researchers in these countries as demonstrated at a combined meeting of General Partners, (the publishers) and recipients in London in July 2011.

All anaesthesia journals contribute to the distribution of the latest advances in the specialty, thus serving the needs of their readerships. But because of the wide range of their focus and differing readerships, direct comparisons and comparisons over the history of our specialty are inappropriate. As Nicholas Greene, a former Editor of ‘Anesthesiology’ indicated in a cautionary note in 1992: “Measuring something as subjective as the quality of the written word is as fraught with dangers as attempting to measure beauty” [31].

Publications as Measures of Progress

Each anaesthesia journal in its sequential issues reflects the development and progress of anaesthesia in a chronological order. By reading the contents pages of each issue of a journal, the titles of articles being very brief summaries, we can follow the chronological development of anaesthesia and form an accurate picture of trends and progress over the years. This is a different, but valid, way of looking at the history of anaesthesia.

Acknowledgments My thanks are due to Dr George S. Bause MD, MPH, Clinical Associate Professor, Case Western Reserve University, Cleveland, Ohio, USA, for his own photograph of the cover of the first issue of “Microcosm” and for the information relating to this journal; to Dr Gustavo Elena, Associate Professor of Anaesthesiology, Universidad Nacional di Rosario, Totoras, Argentina, for his translations of editorials; to Dr Shingi Sasaki, for also arranging translations; and to

Ms Tereza Jimenez and Ms Karen Bieterman, Librarians at the Wood Library-Museum of the American Society of Anesthesiologists, Park Ridge, IL, USA, without whose generous assistance this small chapter would not have eventuated.

A History of the American Board of Anesthesiology Certifying Examinations

35

Stephen Slogoff

Summary

The American Board of Anesthesiology (ABA) incorporated as a sub-board of the American Board of Surgery, held its first written examination in 1938, and certified 9 diplomates by examination in 1939. In 1941, the ABA became a primary board. Its first written essay-style examination tested anatomy, pathology, pharmacology, physics and chemistry, and physiology. The unstructured oral examination aimed to test a candidate's clinical proficiency. A practical examination, held at the candidate's hospital, was used for 15 years—until growth in the candidate pool made it impractical. As a substitute, in 1975, the ABA required that a faculty clinical competence committee prepare an annual Certificate of Clinical Competence (CCC) for each resident in training.

In 1944, Saklad questioned the reliability of essay examinations, and after 1947 the written examination consisted of multiple choice questions. Other suggestions by Saklad, and later by Slocum, increased the reliability of the examination. In 1955, the ABA employed the Educational Testing Service (ETS) to provide psychometric support. Discussions between the ASA's American College of Anesthesiology (ACA) and the ABA, led to creation of an in-training examination for all residents in 1975. The 1979 introduction of the Rasch Model for grading examinations, permitted the Board to apply an ability-based standard rather than percent correct or a normative pass rate (i.e., the same level of knowledge was required each year to pass the written examination). In 1982, the ABA hired Francis Hughes as Executive Director. Hughes participated in every important decision concerning the Board's examination system until he retired in 2009.

In 1940, oral examiners chose the questions asked. In 1961, Adriani became chair of the Examinations Committee and in 1964 prepared a landmark guide for oral examiners. Paralleling one of Adriani's ideas, in 1969, Keats proposed using "suggested topics", forcing all test candidates to discuss the same subject. The resulting structured examination was first administered in 1970.

In 1995, the ABA sought the help of psychometrician Mary Lunz, to deal with concerns (first expressed in the mid 1980s) about how to control for reliability of individual guided questions, examiner grading, and the impact of new examiners giving their first examinations. In 2003, the ABA implemented multifactorial analysis scoring for its oral examination, to correct for question difficulty and examiner grading severity. During the 1980s and 1990s, the Board developed and refined certification in Critical Care and Pain Medicine subspecialties, and recertification for its primary (now Maintenance of Certification in Anesthesiology) and subspecialty certificates.

Over the course of 70 years, the ABA has provided increasingly objective certification of candidates in anesthesiology. The scoring system is now as objective as present methods and human frailty allow.

Introduction

The 1930s saw a sustained appeal to the American Medical Association (AMA) and its Advisory Board of Medical Specialties, to establish a certifying process for anesthesiology specialists. Advocates for this goal included Ralph

Waters, who founded the first university-based residency in anesthesiology at the University of Wisconsin in 1927, Paul Wood of the New York Medical College, and John Lundy of the Mayo Clinic (Lundy also lobbied successfully for the creation of the Section of Anesthesiology within the AMA). Complex motives prompted these men and those whom they represented. They believed that certification would bring legitimacy to this new medical specialty. Perhaps of equal importance, they believed that the recognition implied by certification would limit the intrusion of nurse anesthetists and minimally trained family physicians into the medical

practice of anesthesia. Through their efforts, the American Board of Anesthesiology (ABA) was incorporated in 1938 as a sub-board of the American Board of Surgery.

The ABA acted quickly, giving its first written examination in 1938, and certifying nine diplomates by examination in 1939. Certificate #41, (the first to be awarded by examination), went to Rolland Hastreiter from University Hospital in Augusta, GA. He was certified on 3 Feb 1939. Certificate #1 (not by examination) went to T Drysdale Buchanan. Paul Wood became the first secretary of the Board and chair of the Examinations Committee. His considerable organizational and leadership skills qualified him for both positions. The Board modeled its process on that of the American Board of Surgery: written and oral examinations followed by a practical examination at the home site of the candidate. Based on national recognition of their expertise, 40 “Founders,” including all the directors (Table 35.1) of the first ABA, were certified without examination. No further diplomates were certified in that manner. Those participating in the first oral examination included the ABA Directors and some of the other Founders.

In 1941, the ABA became a primary board, no longer a sub-board of the American Board of Surgery. Then, as now, the Board existed primarily to credential (confirm their suitability to enter the certification process) and certify candidates. In the past two decades, the ABA assumed certification of practitioners in two subspecialties within anesthesiology (Critical Care and Pain Medicine). It developed recertification for its primary and subspecialty certificates and, most recently, the conversion of recertification to maintenance of certification in anesthesiology (MOCA). Notwithstanding these diverse activities, certification remains its primary business.

This essay will describe the evolution of the examination process for the primary certificate through to approximately 2005, the date where my direct source material ended. This process has radically changed from the first examinations in 1938 and 1939. Logistics have changed because of the dramatic growth of anesthesiology and the consequent enrollment of increasing numbers of candidates for examination. A sustained commitment of the ABA to fairness in the evolution of the process, provided an underlying platform.

Fairness requires that every candidate is treated equally, but how could that be done for oral examinations by examiners with diverse qualities—some more demanding, some less demanding? How could that be done if the questions asked by different examiners differed? How does one factor into the process, the experience of the examiner or the time of day of the examination? And do the written and oral examinations test relevant knowledge and skills? This history of the ABA describes the struggle to answer these questions, and to achieve the best, if imperfect, answers.

Early Examinations

The ABA modeled the examination process on the written, oral, and practical components of the American Board of Surgery examination. Thus, the original Directors created a written essay-style examination with five basic science components: anatomy, pathology, pharmacology, physics and chemistry, and physiology [1]. In turn, each component consisted of five questions. Candidates had to answer three of the five questions in each component, within 45 minutes. Three directors on the Examinations Committee: the first ABA president Thomas Buchanan, Wood, and Emory Rovenstine, the fabled chair at Bellevue Hospital and a disciple of Ralph Waters, graded all examinations. All lived in the New York area and shuttled papers among themselves to complete the grading. As is the case today, in that first examination, graders were blinded to the name, personal information and location of the candidate. As the candidate pool grew, restricting grading to a small committee of directors became impossible, but at least one ABA director read every examination and retained final say over grading. Within a few years, Ralph Tovell and Lundy, both original directors, noted that teaching programs had obtained examination questions, and in response had changed their curricula. Some critics complained that the ABA gave the hardest basic science test of all specialties; Waters and Kenneth Woodbridge, the first Anesthesia Chair at Temple University accepted that as a compliment.

Initially, oral examinations were intended to test the candidate’s proficiency in clinical anesthesiology, but were unstructured—examiners could ask questions about any area of anesthesia they chose. Unlike the written examination, examiners reviewed the candidate’s application and list of publications before the test, and often asked the candidate “what he thought he did best.” Not surprisingly, examination content varied widely. Each candidate was tested for 10 minutes in each of three rooms with two examiners in each room. ABA directors gave the first sets of examinations, but other “Founders” soon came to help, although only the directors graded the content. Then and subsequently, no one with personal knowledge of a candidate could examine that candidate.

After satisfactory completion of the written and oral examinations, a director or Founder went to the candidate's hospital, watched him/her provide anesthesia care, observed their interactions with patients and surgical colleagues, and even investigated whether they worked for a fee or were salaried by a hospital—salaried anesthesiologists were then considered to be acting unethically because all other physicians billed fee-for-service. On completion of the practical examination, the Board voted to award or not award a certificate to the candidate. By 1940, the ABA was already wavering on the feasibility of continuing the practicum phase of the certification process. Discussion in the ABA minutes focused on the impracticality of the exercise, particularly after the influx of candidates from World War II. There was no official end to the practical examination, nor was there mention of the last candidate so examined.

Rather than describe the evolution of all three components of the examination process simultaneously, the narrative now will follow each separately.

The Written Examination

The enormous surgical demands imposed by World War II, mandated drafting many young physicians into anesthesiology. Most of these became on-the-job trainees. For those few who were formally trained and eligible for examination after credentialing, the ABA initially provided written and oral examinations in Europe and the Far East, but that practice soon became unworkable.

In 1944, Meyer Saklad (Fig. 35.1), one of the first nine diplomates, and one of the creators of the original American Society of Anesthesiology's Physical Status Classification, became a director of the Board and the Board's first innovator. He questioned the reliability (the likelihood that the same candidate would get the same grade if taking a similar test at a different sitting) of essay-type examinations, arguing that the questions were too open-ended and responses too broad to establish true knowledge. Regardless, the horde of returning military anesthesiologists made the grading of essay examinations impractical. With little fanfare, the 1948 written examination of the ABA morphed into 125 multiple choice questions, and the next year into 300 questions, divided equally among the original five areas. The passing (the cut) score was arbitrarily set at 67% correct.

In 1950, administration of the written examination was decreased from twice to once a year. The multiple choice format was now firmly entrenched, although ABA minutes described the directors agonizing about teaching programs gearing their didactic material to passing such tests. When Fred Haugen of the University of Oregon succeeded Saklad as chair of the Examinations Committee, he opted to add more questions requiring reason and logic, rather than just

Fig. 35.1 Meyer Saklad. (Courtesy of the Wood Library-Museum of Anesthesiology, Park Ridge, IL.)

memory. By now, the written examination had a normative passing score, i.e., a certain percentage of candidates would pass independent of an arbitrary percent correct. In 1955, Saklad questioned this approach and suggested the imposition of a minimum pass score, regardless of the success rate. Saklad challenged the Examinations Committee to evaluate the test questions, to decide which should be answered correctly by a passing candidate, but little happened with this proposal. Prompted by such controversies, the ABA contracted with the Educational Testing Service (ETS) in Princeton to provide psychometric support. Two years later, ETS recommended eliminating the rigid five content sections, and reducing the length of the test from 300 to 180 items.

A “reliability index” provides a statistical assessment of the consistency or precision of a test; i.e., the likelihood that the same candidates taking a parallel, but different examination at another time would generate the same score. It ranges from zero (no reliability) to 1.0 (perfect reliability.) The changes instituted by Saklad and ETS dramatically increased the reliability index from 0.70 in 1956, to greater than 0.90 in 1957. However, “validity” (does the test examine what you hope it does) was a more elusive goal to assess,

and had to be based on “content validity.” This psychometric assessment, content validity, is based on the examination having a clearly defined content outline as the basis of its creation, and that test takers who are qualified in that domain perform better than those who are less well prepared in the content domain.

In 1960, Harvey Slocum, chair of Anesthesiology at the University of Texas Medical Branch in Galveston, became chair of the Examinations Committee. He enacted major changes in the written examination. First, the test would include 50 previously used questions from the 1957 and 1958 examinations for equating purposes. Equating would permit comparison of performance of examinees from different years on the same questions, and thereby allow psychometric conclusions about new items. Second, to allow reproducible analyses, statistical evaluations would only be made for data from first-time takers. With the benefit of these changes, the ABA went from a normative scoring system, in which a predetermined pass rate was used, to a criterion-based scoring system in which a predetermined cut score was used, resulting in a pass rate of 84% the first time it was used. But these low failure rates produced discomfort for the Board and two years later the Board returned to normative scoring.

In 1965, the examination included more equating questions and increased to 210 items to prevent dilution by previously used questions. One year later, the ABA switched from ETS to the National Board of Medical Examiners (NBME) for psychometric support. The NBME distrusted equating, causing removal of all previously used items. The cut score was again now normative with a pass rate set arbitrarily at 75% for first-time takers. Despite such arbitrariness, considerable data suggested that the written examination was performing well. The reliability index (see above) equaled 0.94 and director James Matthews noted that the current examination had never had a reliability index less than 0.86, a success level not yet achieved by any other specialty board. In that year, the “discrimination index” (comparing performance on items in aggregate by those who passed and failed the test) was 0.37; a good score is considered anything greater than 0.25. The Board was increasingly satisfied with the state of the written examination.

In 1967, two seemingly minor events changed the Board forever. An ad hoc committee of delegates from the Association of University Anesthetists, the American Society of Anesthesiologists (ASA), the AMA section on Anesthesiology, the Academy of Anesthesiology, and the ABA met to consider the possibility of an in-service examination for all US anesthesiology residents. David Little, secretary of the ABA, was the Board’s delegate. Nothing came of the effort initially, but the seed for this concept was planted. The other event was election to the Board of the then chair of anesthesiology at Baylor Medical College, Arthur Keats (Fig. 35.2). Over the next twelve years, Keats changed the

Fig. 35.2 Arthur Keats. (Wood Library-Museum of Anesthesiology, Park Ridge, IL.)

Board’s written and oral examination more than any director before or since. No challenge was too great, no detail too small.

Keats became chair of the Examinations Committee in 1971, the same year that he became editor-in-chief of the journal, *Anesthesiology*. The committee immediately started discussions of computer-based examinations. He opined that such technology would not be appropriate for the primary examination, but “if recertification (an idea he and the rest of the Board opposed) ever came to pass, a computer-based examination might be ideal.” He accurately foresaw the future.

Also in 1971, a second discussion of an in-service examination for all US anesthesiology residents was initiated between representatives of the ASA’s American College of Anesthesiology (ACA) and the Board. For decades, the College had run a shadow certification process for anesthesiologists. Both the ACA and the ABA certified many practitioners, but the ACA also certified many who the ABA considered unqualified by training or who had failed the Board’s examination. These competing certificates were a source of confusion to hospitals and their credentialing committees. Keats and Little represented the ABA and proposed that leadership of any in-service examination for all US anesthesiology residents must remain in the hands of the ABA, that the

examination should be administered annually, and that participation would be a certification requirement of the ABA. At the next ABA meeting (1972), this enormously controversial proposal was discussed. First, the ABA had reservations about creating examinations with outsiders from the ASA and, secondly, they recognized the enormity of the undertaking. Albert Betcher declared opposition to the plan if the ACA continued its certification. Keats assured the Board that if the proposed plan were enacted, the ACA would cease awarding certificates, which it did a few years later.

In 1973, an ABA/ACA Liaison Committee for In-Training Examinations was formed. Membership from the ASA included Harry Bird, Charles Coakley and William Eggers. William Hamilton, Robert Patrick, and Keats as chair represented the ABA. Note the change in title from “in-service” to “in-training,” a distinction that persists between surgery and anesthesiology to this day (surgical residents are in “servitude” and anesthesia residents are in “training”). The committee was charged with creating an examination that could be administered to all residents by 1975. Ultimately the ABA planned to use a subset of that examination as the written ABA examination. The challenge was so enormous that both organizations prepared their own examinations to use if creation of the in-training examination failed.

A key challenge for the committee was that a written certifying examination needs to test only a sample of knowledge from the field to be valid; but a useful in-training examination must be comprehensive; i.e., truly examine the total content of the domain of knowledge. No one had previously focused on the scope of the specialty. The liaison committee immediately went to work on creating a content outline (grid) that defined the entire contemporary scope of anesthesiology. Concurrently, Keats asked the NBME to help him create a new metric to assess whether the examination would test what was actually learned during residency training, as opposed to other educational experiences.

In the spring of 1975, amazingly on schedule, 1700 residents at multiple centers across the U.S. took the first in-training examination. The test had 350 questions, 140 from old ABA and ACA examinations, and 210 generated by writers solicited by Keats from US program directors. Performance on that examination would serve as the comparator for future examinations. In that year, the ad-hoc committee petitioned its two parents to change its status to a permanent council. The ABA-ASA Council on In-Training Examinations resulted. Keats (chair), Bird, Benson and Slogoff represented the ABA. Eggers, Howard Zauder, Coakley and Alan Sessler represented the ASA. As part of its charter and as a requirement of the ABA, the chair of the Council would always reside in the Board.

In the early days of the In Training Examination (ITE) Council, all examination questions were reviewed and edited by the 8 Council members. Disagreement about which

of the five choices for the answer was correct, was not atypical. It then usually went like this. Keats, as chair, would let the discussion go on for several minutes during which one distinguished member would argue for answer "A," another for answer "C," and another for "D." After 10 minutes, Keats would say, “Time’s up. The answer is ‘E’. Let’s move on.”

The second examination in May 1976, was also given to all Canadian residents and was equally successful. Several enhancements were added. First, the “grid” was formalized as the “Content Outline of Anesthesiology,” a description of the scope and breadth of the specialty, a document updated every several years with the appointment of a new Council chair, and provided to every anesthesia training department and resident.

Second, the Council debated over the feedback to departments and residents. In a qualifying test, only a score is required, but to have educational value, feedback had to be more meaningful. Options ranged from no feedback to providing the entire examination with answers. The latter was rejected for two reasons: all of the questions would be lost for future use and, more importantly, giving the questions and answers would suggest that those 350 items reflect all that you have to know about the domain, a flawed conclusion. The Council settled on a “keyword” feedback. The resident would receive a keyword phrase describing the essence rather than the point of the question, for each item they had answered incorrectly. This directed attention to an area of study rather than the more circumscribed correct answer to a specific question. An example might be a question dealing with drugs that do and don’t cross the placenta with the correct answer being a muscle relaxant. The “keyword” phrase might be “placental transfer of relaxants.” To avoid overwhelming junior residents with too many keyword phrases, feedback was limited to questions answered correctly by at least half of the graduating (CA3) residents. Keywords were created in advance, but could be modified if the responses to the question suggested a deficiency in knowledge different than expected. Program directors could therefore easily see what proportion of their residents incorrectly answered a question related to a specific keyword phrase, and draw conclusions about deficits in their departmental curriculum.

Third, the examination performed wonderfully by psychometric standards: reliability and discrimination indices (see above) were high.

The Council soon grew to 14 members, too unwieldy to review questions as a full group, so Keats divided us into three groups led by him, me (SS) and Phil Larson. Arthur always took the most opinionated people in his group. At the end of the first day of meeting in groups, we spilled out of the small rooms into our great room, and I noticed that a distinguished chair of a New England program emerged looking ashen. I asked him what was wrong. He said “for the past eight hours, Arthur splained (sic) anesthesia to us!”

And the new metric that Keats had requested of the NBME, the PGY (post graduate year of training) Index, demonstrated enormous utility. This index did not measure discrimination between high and low scorers, but between CA-3 residents and incoming residents. A high PGY Index suggested that the material tested was actually learned “in training” and a low or negative PGY Index suggested that the material was well known to residents just leaving medical school and/or not reinforced during training. A question about the Krebs cycle supplies an example that would contribute to a negative PGY Index. Such questions were dropped from the examination. A large corps of question writers and editors helped the Council prepare first-rate questions. At every Council meeting, Keats reminded us that every question should be answered correctly by a “good, not great resident graduating from a good, not great program.” Keats also saw to it that there were no “PQ” (one paper-one question) questions and no “PAP” (piss-ass picayune [sic]) questions.

In 1977, the In-Training Examination moved from the spring to the second Saturday in July. This facilitated the ABA using a subset (about 250 questions) of the in-training examination for the written portion of its certification process after full completion of residency training, while still collecting data on the performance of the graduating CA3 residents on the entire ITE. (The examinations were administered together until 2008, when the ABA started computerized testing for its candidates and the ITE remained a pencil and paper examination.). The ABA applied two criteria for the subset: each question had to be clinically relevant and non-controversial. The change in date to July also provided baseline examination data from residents with no training.

Feedback concerning the In-Training Examination to departments, and the regularly updated Content Outline have likely improved training, and by extension advanced the specialty. The examination results prompted curricular changes, and books have been written based on the keyword phrases. Scores of question writers have become part of the Board’s oral examination system based on their efforts for the Council. By 1980, the chair of the Council met regularly with all directors of the nation’s residency programs at the annual meeting of the Society of Academic Anesthesia Chairs/Association of Anesthesia Program Directors, to review the examination and its performance and to describe widespread misinformation detected by the examination that might “surprise” these educators. Residents and their teachers received feedback indicating where those residents stood in their knowledge base, compared to their nationwide peers.

In 1979, the ABA reintroduced a criterion-based cut score for the written examination, which had become a subset of the In-Training Examination. The introduction of the Rasch Model [2] for grading examinations, a model that could

Fig. 35.3 Frank Hughes. (From the author’s collection)

separate candidate ability from item difficulty, facilitated application of a truly defensible criterion-based cut score. It again required a pool of equating questions be included in each test from previous examinations, questions for which the difficulty was already known. The model measures difficulty and ability on a logit scale. A logit is a number without dimensions or boundaries and is an exponential transformation (a log scale) derived from the percent correct score of a test item. Using a cut score on the logit scale, permitted the Board to set a standard, arbitrary as it was, based on actual ability rather than percent correct or some normative pass rate. While understanding the Rasch Model is a challenge for even the most sophisticated examination committee, its usefulness is critical to objective scoring of examinations. With its use, the same level of knowledge is required to pass the Board’s written examination from year to year, regardless of the actual pass rate.

At its winter meeting in January 1982, the ABA decided to hire an Executive Director to manage its administrative functions. The list of candidates numbered one. Francis Hughes (Fig. 35.3), a psychometrician at the NBME, had been the ITC (The In-Training Council) and ABA liaison for several years. His personal style and characteristics seemed to perfectly fit the administrative requirements of the job, and his psychometric skills and insight into the Board’s examination system were a monumental plus. He was ready

Fig. 35.4 Stephen Slogoff. (From the author's collection)

for a change and the rest was, as is said, history. Hughes became instrumental in every important decision concerning the Board's examination system, until he retired in 2009. Frank has been a close friend of this author since 1978 and I rarely remember anything funny about him, except when Harry Bird, in reference to Frank's obsessive compulsive behavior about details observed, "Frank is Catholic with both a capital C and a small c."

In 1982, I (Fig. 35.4) became a Board director and immediately migrated to full involvement in the examination process. A year later, Hughes and I "validated" the standard (cut score) for the written examination. To do so, we created the "borderline candidate" standard [3]. Each Board director received a 100 item sample of identical A-type (five choice) questions from the ABA subset, with varying, but known difficulties and was asked to assign a value to each item based on their expectations for the candidate who would just barely pass the examination, rather than the one who would excel. Correct answers were not provided. If they believed this imaginary borderline candidate would surely get it right, a value of one would be assigned. If they believed the borderline candidate would fail, then a score of 0.20 (a pure guess) was assigned. If they believed the candidate could narrow the choices to two, three or four possibilities (an educated guess)

then respective scores of 0.5, 0.33 or 0.25 were assigned. Scores for the 100 items were summed and then averaged for the 12 directors. The resultant score was converted to a logit level of ability based on the known difficulty of the 100 items and became the cut-score for the Board's written examination. Interestingly, this score was almost identical to the arbitrary score put in place a few years earlier. This standard was first used in the 1988 test. Over the ensuing decades, the Board repeated the "borderline candidate" exercise several times as it fine tuned and refreshed the standard for the written examination. In 1986, I became the chair of the Examinations Committee and the In-Training Council.

Originally, the ITC reported a standard score, placing the test takers along a continuum of success compared to their peers at training level. Starting in 1990, it reported a scaled score, a logit value of ability independent of the cohort taking the test. Since logits actually range narrowly above and below the number zero to several decimal points, and are hard even for those who understand them to conceptualize, the logit value was converted to a linear scale from 1-61 to make understanding easier for the trainee and program director. Henceforward, residents could track their own ability as training progressed, independent of cohort ability or test difficulty. By being able to track growth in knowledge of their residents individually and in aggregate, independent of these variables, educators have used these data to evaluate their residents and the effectiveness of their didactic programs.

In 1990, the Board and ITC administered the first non-standard examination to comply with the Americans with Disabilities Act. Examples of such disabilities might be dyslexia for the written examination or severe stuttering for the oral examination; each one requiring a longer test period. Every year since, a handful of candidates receive disability-specific non-standard written and oral examinations.

The Oral Examination

Although a grid of more than 100 suggested topics for the oral examination was created in 1940, the examiners had complete discretion in their choice of the actual questions asked. Two Board members in each of four rooms examined the candidates and assigned a grade from 0 to 100. The examiners then met to review the grades. By the mid-1940s, the ABA relied on an increasing pool of associates needed to administer the oral examination.

In 1945, Saklad questioned the validity of the oral examination, stating that he "frequently wasn't sure what the questions meant and what a correct answer was." In 1947, he became the first chair of the combined written and oral Examinations Committee. That fall, for the first time, grades of associate examiners were included in the final score, although they counted less than those of the

Directors. At that session, 29 candidates passed, 15 failed and 2 “conditioned,” i.e., had to retest in one or more sections. The ABA began populating its examiner pool with a corps of “national” examiners, rather than local volunteers. Diplomates were only invited if they were expected to be effective examiners, and only re-invited if they demonstrated the requisite skills. The ABA believed that this change enhanced reliability, i.e., the likelihood that a candidate taking the examination at another time with different examiners would get the same grade.

Starting in 1950, four associate examiners and two directors examined each candidate, and all grades counted equally. For the first time, associate examiners were divided into “senior” and “junior”, based on experience. Senior examiners were specifically expected to ensure the proper conduct of the examination. Saklad prepared a written outline of what the Board expected of a passing candidate, and introduced 3”×5” question cards to facilitate inter-room reliability, provide a progression of easier to harder questions, and encourage examiners to stay on topic. However, use of these cards was not mandatory. After three years on the Board, Stuart Cullen, chair of Anesthesiology at the University of California San Francisco, said the Board should stop worrying about the questions, but focus on the issue that we “are examining physicians, not technicians and we need more than a safe anesthetist.” He was demanding that questions focus more on the theoretical basis of clinical anesthesiology, rather than on issues of safe administration of anesthetics, an expectation that is consistent with the current examination. Midway through the decade, Frederick Haugen, the then chair of the Examinations Committee, began meeting with the associate examiners to describe what the ABA expected of the process and of a successful candidate, an important first step in standardizing expectations for a successful candidate. In 1956, the Board ruled that each examiner had to record the candidate’s grade, independent of their co-examiner and before any discussion of the examination could occur, a policy that persists today.

As with the written examination, a cut score defined the difference between pass and fail for the oral examination. The Board agonized over whether the passing grade should be 75, or a little higher or lower. In 1957, ETS recommended recording grades in multiples of five from 65 to 85, and that the passing grade should be 75. In 1958, Forrest Leffingwell moved that the grade of 75 not be used, thus avoiding fence sitting by an examiner. Further, a director in the examination room would audit the performance of all associate examiners. It was suggested but not pursued, that case histories should be provided to examiners (shades of the coming structured examination). However, the only resulting change was that henceforward, examiners would list all topics discussed in the first examinations on a yellow sheet of paper,

to be taken by the candidate to subsequent rooms to ensure that topics were covered only once.

In 1961, the oral examination format was decreased to two rooms with two examiners in each, its current form. The grading system became 70, 73, 77, or 80 (i.e., low fail, fail, pass and high pass, respectively) with fence sitting (75) still not an option. The cut score settled at greater than 75 (e.g., 77, 77, 77, and 70 representing the lowest passing score of 75.25), the Board believing that no candidate should pass the examination having received failing grades from two of the four examiners.

During his tenure as chair of the Examinations Committee (1961-2), Robert Dripps refined the training and auditing of new, junior and senior examiners. Quality control was of prime importance to the Board, which didn’t hesitate to terminate an underperforming examiner.

John Adriani became chair of the Examinations Committee in 1964, and prepared a landmark guide for oral examiners entitled “The Oral Examination of the American Board of Anesthesiology” [4]. He described (1) what characteristics an ABA diplomate should possess, (2) the requisites of a good examiner and (3) the type of questions an examiner should ask. A good examiner must have an adequate knowledge base, a clear understanding of what he/she expects from a diplomate, and the ability to elicit gradable information from the candidate. Questions should be easier at the beginning of the examination, should be modified by the style of the candidate’s responsiveness, and should sometimes focus on depth and at other times on breadth of knowledge. Adriani’s document, culled from observations by Board members, could serve as the basis for instructions to examiners today. However, Adriani was noted for opening his examination by handing the candidate a piece of paper and asking for the formula for atropine. I suppose that in the 1960s, he thought that was an easy question.

Ted Eger, one of the editors of this book remembers:

“Adriani was one of my Board examiners in the early 1960s. The other examiner was Bernard Briggs who asked me why the Ohio Chemical Co. had brought out the anesthetic fluroxene. Adriani quickly asked Briggs if he didn’t mean halothane (but that couldn’t be because halothane was produced by Imperial Chemical Industries.) No, Briggs insisted, he meant fluroxene. And I was caught in the middle with my mind frozen on the only reasonable answer: To make money—which was the answer I finally gave. It got a frosty reception from Briggs who elaborated that he wanted to know what qualities fluroxene had that recommended it. Oh, those. They passed me anyway [5].”

In 1966, Robert Patrick—a brilliant and gentle man who was a professor at the Mayo Clinic—suggested that a candidate could question the validity of their examination and request a repeat examination at the end of the day. Such a request would void the results of the first test; only the grades from the second examination would count. Few availed themselves of the opportunity and the opportunity lasted but one year.

Forrest Leffingwell—chair of Anesthesiology at Loma Linda University and president of the ASA in 1962 had “a great sense of humor, but came across as formal and thus highly respected but not feared [6].” In the 1968 ABA minutes, he opined that “It is apparent that the validity of the written examination is based on a good scientific foundation. It is equally apparent that the validity of the oral examination is based on quicksand.” While the Board has persisted in its belief that the oral examination has a unique value, much remained to do to challenge Leffingwell’s perception. In 1969, the ABA tested the correlation between results on the two different examinations and found a coefficient (r^2) of 0.45. That analysis suggested, but didn’t prove, that the two examinations tested different attributes.

In 1969, Keats observed that Board directors and associate examiners never had an opportunity to mingle socially, since the Board met every day after the examinations. His suggestion that there be a formal reception for associate examiners and their spouses on the Sunday evening before the examinations started was unanimously adopted. That same year, Keats noted that the examiner pool lacked African-Americans, a rapidly corrected oversight.

In 1969, Keats was asked to standardize the oral examination. He “suggested topics” for each examination period so that all test candidates and examiners would discuss the same subject, albeit with the actual questions left to the individual examiners. This paralleled Adriani’s suggestion and represented a revolutionary change. The first structured examination was administered in 1970, and in 1972, the first actual guided question was used. Before entering the examination room, each candidate received for review a brief summary describing the patient, the planned procedure, relevant medical problems and possibly some laboratory data. The examination focused on the preoperative, intraoperative, and postoperative issues of that case. This author took his oral examination in that year and was asked to deal with the anesthetic management of a child with a full stomach who had aspirated a peanut and required bronchoscopy for its removal. I was sure I had failed, but didn’t.

Keats continued his assault on the examination process. He recommended redefining of the four grades (70, 73, 77, 80): 70 and 80 would represent a definite fail or pass, respectively, regardless of how poorly or well the candidate performed. 73 and 77 was to be used only when the examiner was uncertain. Fence sitting (75) was still not allowed. The lowest passing score remained 75.25 (e.g., 77, 77, 77, 70). No longer was there a concept of “high pass” or “low fail.” Such inability to reward exemplary performance dissatisfied many examiners. This scoring system continued until the Board eliminated grading of the entire examination by the examiners in 2003 (see below). In 1972, examiners were instructed to grade candidates on five attributes: facts, application, judgment, adaptability, and organization and clarity

of response. “Facts” were later removed as a grading issue, since the written examination covered these, and the stress associated with the oral examination could cause facts to be forgotten even though the candidate had an excellent grasp of important concepts.

In 1976, the Board introduced “Suggested Topics,” (later called “Additional Topics” to reflect their mandatory use), which dealt with anesthetic issues not covered in the guided question. These brief vignettes were to follow the guided question to provide real topical breadth when all of the questions in the two examining rooms were combined. In an early use of these suggested topics, Jim Arens, a director from Galveston, was examining a poorly prepared candidate and got onto the subject of electrical safety in the operating room. He asked the candidate what he would do if the isolation monitor in the operating room turned from “green” to “red.” Expecting the candidate to say that he would start unplugging pieces of electrical equipment to determine which one had a potentially dangerous ground fault, he was amazed when the candidate replied, “I will take my shoes off.” Flustered, Arens replied, “I’m not worried about you, I’m worried about the patient!” The candidate quickly responded, “Don’t worry about the patient, he already has his shoes off.”

In the same year, a library of guided questions and suggested topics was initiated for use in future examinations. Also in 1976, the Board stopped discussing candidates at the end of the examination day; the grades generated were the final score. By then a rigorous system had been created to ensure that a candidate was never examined by someone who knew or had previously examined him/her. Occasionally the system failed, but a candidate could always be assigned a new examiner if, on entering the room, either the candidate or one of the examiner recognized the other in a way that could compromise the integrity of the process.

To ensure that every resident in the country had access to adequate oral examination preparation, the ABA, in 1982, started inviting faculty from programs not represented in the associate examiner pool, to training sessions and observation opportunities at real examinations, a program that continues today.

In 1983, the Board began examining reliability of individual guided questions, examiner “agreement” in grading, and the impact of “dubious” grades by new examiners giving their first examinations. Regarding the last of these issues, inspection of test results indicated that even if the new examiners’ grades differed significantly from those of the other examiners, as long as a candidate was examined by only one new examiner out of the four, the impact was nil. Scratch that concern. Over the next five years, the Board, guided by Hughes, studied the psychometric reliability of the oral examination (i.e., assessed whether candidates would get the same grade if they took the examination with a different set of examiners or with a different pair of guided questions.)

These efforts by the ABA reflected its concern for any potential unfairness in the system: guided questions of differing complexity and difficulty, administration by better or poorer examiners and variability of grading among examiners.

For the next several years, these issues drove the Board to investigate numerous modifications in examination content, as well as examiner training and auditing, to ensure fairness in a process that was becoming increasingly important and less voluntary for practicing physicians. It would still be several years until true objectivity was achieved (see below).

Around 1975, external forces increasingly demanded that specialty boards not only certify diplomates, but also periodically recertify them. Some boards almost immediately acquiesced to this demand. The ABA resisted, not because it was opposed to the concept of recertification, but because it felt it still needed to better validate its primary certification before demanding recertification. "Validation" refers to whether the process of certification—credentialing, written and then oral examinations—meant that a diplomate was a better specialist than those who failed in the certification process or never attempted it. This was a major problem for most specialty boards. Recertification was also a threat to those anesthesiologists practicing without certification, but that consideration was never an issue or deterrent for the ABA. Wendell Stevens, the gentle, soft-spoken chair of anesthesiology at the University of Oregon and a new director, was assigned the unenviable task of stonewalling the external organizations, including the ABMS, pressuring for recertification.

Several years later, the Board published the results of an investigation that took over five years to complete, examining whether certification correlated with better skills and practice [7]. In each residency program, a faculty member familiar with the clinical attributes of all the residents, completed a questionnaire detailing the qualitative competence of their residents independent of their knowledge base and Certificate of Clinical Competence (which only documented minimally acceptable criteria; see below). The participating faculty member was blinded to the purpose of the questionnaire. Those residents were followed through the examination process over the next several years. The study was repeated with the next year's class as well. Success in the Board's oral examination clearly and significantly correlated with the earlier assignment of higher competence by the candidates' faculty. This appears to be the only validation of any specialty board's primary certification process.

However, the correlation is imperfect. That is, the oral examination does not reveal all the factors important to clinical excellence. Thus, these data, while statistically significant, are "soft". They reflect subjective data, collected from over 120 sources in more than 120 different programs. The only reproducible thing is the examination process. Consider-

ing all of these factors, the data and their implications are powerful. And, again, nobody else has attempted such a validation or come close.

With this study complete, and external pressure mounting, the ABA initiated its recertification process. One of the last holdouts, Robert Stoelting, chair at the University of Indiana, opined that "at least recertification will finally get people to read again after they passed their boards."

Attempts to strengthen and increase the fairness of the oral examination continued. In 1988, the Board declared that all programs should offer practice oral examinations to their residents. A parallel was added for new examiners. For the first few examinations in each week's cycle of the real thing, two directors served as the formal examiners, while new examiners observed these "real pros" before they started examining. While the Board continued to audit all examiners regularly, it also recognized that auditing examining style and content was different from evaluation of grading. The inherent differences in expectations of different examiners did affect candidate success. To deal with this concern, in June 1995, the ABA asked a psychometric consultant, Mary Lunz, to apply the Rasch model to the oral examinations with some common examiners over two examination cycles. Although candidate ability was the most powerful determinant of outcome, she identified four factors that influenced outcome: difficulty of the guided question, grading severity of the examiners, session of the day or week, and candidate ability. She recommended considering a Rasch model for the oral examination to control for those variables, a decision that would place the standard in the Board's hands, rather than the examiners.

A year later, led by Myer (Mike) Rosenthal of Stanford University, chair of the Examinations Committee, the ABA changed the format of the examination to emphasize the perioperative medicine nature of the practice, a name and focus anticipated by Saidman's 1994 Rovenstine Lecture, published a year later [8]. Time in each of the two rooms was extended to 35 minutes, and while intraoperative care was still stressed in the guided questions in both rooms (10 minutes in one and 15 minutes in the other), 10 minutes in one was devoted to preoperative evaluation and, in the other, 15 minutes was devoted to postoperative and intensive care. The new format was introduced in April 1997. The change included a requirement that each examiner had to provide scores for the individual components of each examination as well as the final, overall holistic grade.

In 1998, the Board started to explore the use of modular grading to replace the holistic grade. One year later, led by Jane Matjasko, chair at the University of Maryland, and by Hughes, the ABA began development of a plan for grading of the oral examination that used the Rasch model and considered three components: question difficulty, examiner

severity (i.e., the harshness or leniency of grading), and candidate ability. A criterion-based passing score could then be derived by scoring the evaluation on each module of the examination. The new scoring system changed the thought process for grading from holistically and non-linear (see Keats' definition of score above), to grading on a ranked scale of performance. Examiners now graded each module as one in which a candidate (1) rarely, (2) sometimes, (3) often, and (4) almost always, demonstrates attributes of a board certified anesthesiologist. After three practice years with the multifactorial analysis, the ABA implemented multifactorial analysis scoring for its oral examination in 2003. The cut score was set at 3.0 ("often demonstrates attributes of a Board certified anesthesiologist") minus the standard error of the mean. Subtracting the standard error of the mean gave the benefit of doubt to the candidate. For the first time since its inception, grading of the certifying examination of the ABA corrected for the difficulty of the questions and the severity of the examiners. At least some of the objectivity that Leffingwell couldn't find in 1968 had now been realized.

The Practical Examination

From 1940 on, the ABA viewed the practical examination with ambivalence. On the one hand, the directors believed that they needed evidence that the potential diplomate was a good practitioner as well as a good test taker. They also recognized the impracticality of the task with an increasingly large candidate pool. Between 1945 and 1949, many candidates were certified without a practical examination if their practices were "well known" to a director of the Board, a practice necessitated by the large numbers of as yet uncertified anesthesiologists returning from WWII. By 1949, diplomates rather than directors performed practical examinations, and failed candidates could appeal for a second examination by a director.

By 1950, a "survey" of practice and references by a committee of certified anesthesiologists who lived and worked in the vicinity of the candidate, rapidly replaced the practical examination. Three years later, only one candidate underwent a practical examination. Less than five years later, a candidate-generated form describing what they had done since residency training and a list of diplomate references, replaced the survey. In 1957, practical examinations were formally discontinued and the survey committees were disbanded. Part of the credentialing process, the candidate-generated form of practice activity and references remained in place for the next two decades.

In 1975, the ABA required an annual Certificate of Clinical Competence (CCC) for each resident in training. The CCC, prepared by a knowledgeable faculty member and

signed by the chair and resident, replaced all other sources that documented the candidate's clinical skills, personal characteristics, professional behavior and integrity. The CCC for the final six months of training became the primary credentialing tool for entering the examination system, and the candidate-generated form and list of references were retired.

Conclusions

Over the course of 70 years, the Board has moved towards an ever more objective and fair means of certifying candidates in anesthesiology. During the last decade, the Board developed and refined certification in its two subspecialties, Critical Care and Pain Medicine, and added recertification for its primary (now Maintenance of Certification in Anesthesiology) and subspecialty certificates. The primary examination process has never been better. The perfect examination remains the Board's (desired but unattainable) goal, and both the written and oral examinations continue to undergo refinement.

The scoring system is now as objective as present methods and human frailty allow, and standards for both examinations are criterion-referenced with solid evidence indicating the appropriateness of both cut scores. In the near future, the Board is likely to pursue further advances in the written and oral examinations with the use of computers and simulators.

While every Board director contributed to the examination process, I believe three people had the greatest impact: Meyer Saklad in the 1940s and 1950s repeatedly challenged the status quo and did something about it; Arthur Keats from the middle 1960s through to the 1970s led sea changes in both examinations; and Frank Hughes from his days with NBME until his retirement in 2009, guided the board through the complex task of creating defensible and valid criterion-referenced cut scores for both examinations. With the help of many Board directors, these three men contributed to making anesthesiology's certification process one of the fairest and most psychometrically defensible systems in organized medicine. I base this conclusion on numerous discussions with members of multiple specialty boards and am personally convinced that few, if any, boards have achieved the degree of fairness attained by the ABA.

Acknowledgments I thank the current directors of the American Board of Anesthesiology who gave me complete access to all of the minutes of that organization. Thanks also to Mary Post, the Executive Director of Administrative Affairs for the ABA, and Shirline Fuller, her Executive Assistant, who facilitated that access. I greatly appreciate the support of the late Patrick Sim and Felicia Reilly of the Wood Library Museum. I am also most grateful to the many former directors of the Board who gave me wonderful insights into the history and people described, as well as for critically reviewing this manuscript.

Summary

The first US nurse anesthetists appeared in the 1870s. First directed by surgeons, these Catholic sisters later adding their own education and techniques. In 1908, surgeon Crile at Cleveland's Lakeside Hospital (later Cleveland Clinic) asked Agatha Hodgins to become his personal anesthetist. Hodgins developed a school of nurse anesthesia and promoted formation of the Lakeside Alumni in 1923, leading in 1931 to organization of the National Association of Nurse Anesthetists (NANA). In 1933, NANA president Fife proposed establishing a national board examination for nurse anesthetists, a proposal furthered in 1934 by appointment of an Education Committee to study establishment of the examination, and set standards for schools of nurse anesthesia. In 1939, the NANA became the American Association of Nurse Anesthetists (AANA). In 1941, Shupp suggested that passage of a certifying examination could define eligibility for AANA membership, and by mid 1940s new AANA members had to be certified by examination. The number of AANA-approved schools of nurse anesthesia progressively increased in the 1940s, but World War II delayed implementation of the qualifying examination until 1945. The title Certified Registered Nurse Anesthetist (CRNA), came into use in 1956.

To obtain GI benefits for training in nurse anesthesia, returning Korean War veterans had to apply to accredited schools. The AANA petitioned the Department of Health, Education and Welfare (HEW) for recognition as the accrediting agency for schools, receiving formal recognition from HEW Commissioner Brownell in 1955. In 1974, the HEW Office of Education required 12 new criteria to recognize AANA accreditation policies and procedures. By 1975, the AANA responded successfully to these mandates.

In 1978, the AANA adopted by-law amendments, establishing an independent Council on Recertification (COR), separating the AANA from certification and recertification processes, and separating membership from certification. In 1982, the "Qualifying Examination" became the *Certification Examination for Nurse Anesthetists*, because passing the examination certified an individual for entry into practice, not for AANA membership.

In the 1980s, attention focused on increasing the objectivity and quality of the examination process. Content validation procedures were documented through a 1987 analysis, with subsequent professional practice analyses in 1992, 1996, 2000, and 2007. Also beginning in 1987, examination scores were reported as scaled rather than raw scores, ensuring neither an advantage nor a disadvantage to taking the Certification Examination at a particular time.

In the mid 1990s, the Council on Certification of Nurse Anesthetists (CCNA) moved from paper and pencil test administration to a computer format, thereby allowing computer adaptive testing (CAT). This process objectively assessed the difficulty level that each examinee could pass.

Introduction

Delivery of anesthesia increased rapidly after Morton's demonstration of the effectiveness of ether as an anesthetic, at the Massachusetts General Hospital in 1846. Lacking qualified anesthesia personnel, delivery of anesthesia passed to whomever was available, leading to considerable morbidity and mortality in Europe and the US. American surgeons believed that use of the untutored "part-time anesthetist"

Fig. 36.1 Magaw at the head of the table, giving what appears to be ether anesthesia. (Courtesy of the American Association of Nurse Anesthetists Archive.)

explained the untoward effects. Surgeons wanted clinicians dedicated to the delivery of anesthesia, and nurses eagerly answered the call [1].

Virginia Thatcher's *History of Anesthesia with Emphasis on the Nurse Specialist* suggests that surgeons turned to nurses because they

“wanted a person who would: (1) be satisfied with the subordinate role that the work required, (2) make anesthesia their one absorbing interest, (3) not look on the situation of anesthetist as one that put them in a position to watch and learn from the surgeon's technique, (4) accept relatively low pay, and (5) have the natural aptitude and intelligence to develop a high level of skill in providing the smooth anesthesia and relaxation that the surgeon demanded [1, 2].”

The earliest known nurse anesthetist was Sister Mary Bernard (1860–1924), a Catholic nun who administered anesthesia at St. Vincent's Hospital in Erie, PA, in 1877. By 1889, nine sisters of the Third Order of the Hospital Sisters of St. Francis had become nurse anesthetists [1].

The Sisters of St. Francis established St. Mary's Hospital in Rochester, Minnesota, in 1889, with the understanding that William Mayo (1819–1911) believed nurses would make fine anesthetists and that he would undertake their instruction. His sons, surgeons William (1861–1939) and Charles Mayo (1865–1939), “decided that a nurse was better suited to the task because she was more likely to keep her mind strictly on it, whereas the intern was naturally more interested in what the surgeon was doing [3].” Two sisters, Edith (1871–1943) and Dinah Graham (1860–1947), were the first nurse anesthetists at the Mayo Clinic.

In 1893, Alice Magaw (1860–1928, Fig. 36.1), the most famous nurse anesthetist of the nineteenth century, replaced

the Graham sisters at Mayo Clinic. In her biography of the Mayo brothers, Helen Clapsattle noted that Magaw “won more widespread notice than that of any other member of the Rochester group apart from the brothers [3].” She earned international respect, and Charles Mayo dubbed her “the mother of Anesthesia” for her outstanding contributions [3]. She was the first nurse anesthetist to publish articles on anesthetic practice, beginning with “Observations on 1092 Cases of Anesthesia from Jan. 1, 1899 to Jan. 1, 1900,” in the *St. Paul Medical Journal* [4].

In the article, Magaw said:

I gave in a brief way our method of administering ether and chloroform. This is a method we have found, after several years' experience, to be the most satisfactory. I shall only report the cases on whom this method was used during this last year. I can report that out of this number, 1092 cases, we have not had an accident; we have not had occasion to use artificial respiration once; not one case of ether pneumonia; neither have we had any serious renal results.

Magaw also wrote, “That it is believed that if ether is given with plenty of air and the drop method, there are few, if any, bad results...the mortality can be much diminished by the careful selection of the anesthetic [4].”

Magaw reported administering open-drop chloroform and ether without a fatality attributable to the anesthesia, a considerable feat given a death rate due to anesthesia of perhaps 1:2000 in later years. Surgeons sent nurses to observe and learn from Magaw [4]. In December 1906, she published a review of her work in *Surgery, Gynecology, and Obstetrics*:

“At St. Mary's Hospital our preference has always been ether. In 14,380 anaesthetics given by me, I have yet to see a death directly from the anaesthetic, but, no doubt, have had my share

of trouble in its administration, although artificial respiration with us is almost unheard of. In my series of cases, the ‘open Method’ has been the method of choice. We have tried almost all methods advocated that seemed at all reasonable, such as nitrous oxide gas, as a preliminary to ether (this method was used in 1,000 cases), a mixture of scopolamine and morphine as a preliminary to ether in 73 cases, also chloroform and ether, and have found them to be very unsatisfactory, if not harmful, and have returned to ether ‘drop method’ each time, which method we have used for over ten years. [5]”

In 1908, surgeon George Crile (1864–1943), at Lakeside Hospital in Cleveland, subsequently the teaching hospital for Case Western Reserve University, asked Agatha Hodgins (1877–1945) to become his personal anesthetist. Hodgins perfected administration of nitrous oxide-oxygen anesthesia, and Crile recalled,

“In 1909 I was able to report before the Southern Surgical and Gynecological Association that Miss Hodgins had administered nitrous oxide in 575 major operations, and in August 1911, I reported before the American Surgical Association, 10,787 surgical operations performed by me under either ether, or nitrous oxide supplemented by ether, with no anesthetic death. I reported also the use of morphine and scopolamine as adjuncts to ether or nitrous oxide anesthesia in over three thousand operations. [2]”

Between 1909 and 1915, local and visiting surgeons at Lakeside Hospital were sufficiently impressed by Hodgins’ talent that they sent their nurses to be trained by her. She thus became a major participant in the education of physicians and nurse anesthetists at Lakeside Hospital [6, 7].

The contributions of America’s nurse anesthetists to care in surgical units and hospitals during World War I increased the demand for nurse anesthetists after the war. The war prompted the first US military effort to train anesthetists. Nurses were taught anesthesia in 6-month on-the-job training programs, at four formal educational centers: St. Vincent’s Hospital, Portland, OR (1909); St. John’s Hospital, Springfield, IL (1912); The New York Post-Graduate Hospital, New York City, NY (1912); and Long Island College Hospital, Brooklyn, NY (1914). A diploma was issued upon completion, but there was no mention of an assessment or graduation examination.

After World War I, new nurse anesthesia educational programs moved into university hospitals and major community hospitals [1]: Johns Hopkins, Baltimore, MD (1917); the University of Michigan, Ann Arbor, MI (1919); Charity Hospital, New Orleans, LA (1917); Barnes Hospital, St. Louis, MO (1917); Presbyterian Hospital, Chicago, IL; Grace Hospital, Detroit, MI (1918); Grady Memorial Hospital, Atlanta, GA (1918); St. Joseph’s Hospital, Tacoma, WA; St. Mary’s Hospital, Minneapolis, MN; and Lakeside Hospital, Cleveland, OH (1915). The programs took 3 to 6 months, and there were no certification examinations upon completion.

The 6-month training programs initiated by the Armed Forces in World War II, and the subsequent 3- to 6-month civilian programs noted in the preceding paragraph established

Fig. 36.2 Beginning with World War I, the required duration of training for nurse anesthetists was approximately 6 months, growing in roughly 6-month increments consistent with the need for progressively greater knowledge and skills

the minimum duration of required training (Fig. 36.2). In 1951, the requirement increased to a minimum of 1 year, and in 1962 became 18 months. This trend continued to the 1990s, at which time programs required a master’s degree that demanded 24 to 36 months of training [8].

In 1930, at the biennial American Nurses Association (ANA) convention, Agatha Hodgins asked the ANA for recognition of nurse anesthetists as a subgroup within the organization. The ANA declined, as the ANA organizational structure did not envision such a possibility. Hodgins then led in the formation of a national professional organization for nurse anesthetists. The process began with the formation of the Lakeside Alumni in 1923. At the first Alumni meeting, Hodgins presented a plan for a national organization of nurse anesthetists. A tentative constitution and bylaws were drawn up, but not until 17 June 1931, in the Department of Anesthesia at University-Lakeside Hospital in Cleveland, was the organizational meeting for the proposed association held. A motion was proposed that a national association be formed, and the motion passed to form the National Association of Nurse Anesthetists (NANA). The NANA became, thereby, the oldest specialty nursing organization in the US. The early aims of the NANA were to place qualified anesthetists, supply continuing education, and provide professional recognition [1].

The 1930s

Because Hodgins became ill, Gertrude Fife (1902–1980), assistant director of the School of Anesthesia at University Hospitals in Cleveland, assumed a leadership role in the newly formed NANA. As president of the NANA at its first meeting in September 1933, Fife spoke on “The Future of the Nurse Anesthetist.” She called for “establishment of a national board of examination for nurse anesthetists, argu-

ing that such an examination would certify to surgeons that nurse anesthetists' knowledge in their field met the approval of an examining board – a board chosen and functioning to safeguard the interests of surgeons, hospitals, and the public [9].” At this first convention, the trustees established minimum standards for schools of anesthesia, specifically: duration of course, 4 months; number of cases of clinical experience, 250; and hours of class instruction, 75.

The second annual NANA meeting, in 1934, saw the appointment of an Education Committee to study the feasibility of establishing a national examination for nurse anesthetists, and standards for schools of nurse anesthesia. Fife observed that:

“We must find a way whereby the hospitals and surgeons who employ nurse anesthetists can be assured that they have received the proper training, and are qualified to do the work” [10]. “An examining board should be chosen and every applicant applying for membership in the organization should be required to pass an examination. The examining board would be responsible for the preparation of the examination – the arrangements whereby the examination would be taken within the State – and responsible for the final decision which would allow the National Association to issue to the individual who successfully passes the examination a certificate signifying that the individual is sanctioned by this organization.” [10]

Although state board registration could have accomplished this end, Fife reasoned that such registration was impractical; a national solution was needed. The national examining board she envisioned would (1) prepare the examination, (2) arrange for examination locations in each state, and (3) award certificates to successful candidates [10].

At the fourth annual meeting, in 1936, the NANA Education Committee continued to pursue its goal of establishing a national board of examiners, one that would be recognized by organizations that depended on nurse anesthetists. The Committee's report emphasized that a national examination and certification of nurse anesthetists should be compatible with professional trends in associated branches of medicine, including the newly created American Board of Surgery and the Council on Dental Education. Both organizations had been established in part for certification purposes [11]. The Education Committee's discussions with members of the American Board of Surgery and the American Hospital Association (AHA) suggested that those organizations would endorse the proposed examination for nurse anesthetists, and the inspection and accreditation of schools in anesthesia, as well as an examination and/or certification of currently active nurse anesthetists [12].

By the sixth annual meeting, in 1938, the Education Committee had (1) compiled a list of schools offering training in anesthesia to graduate nurses; and (2) obtained AHA endorsement of NANA plans for the inspection of schools of anesthesia for nurse anesthetists. On the basis of that inspection, the NANA foresaw that the AHA would approve

those schools having curricula equivalent to the standard already adopted by the AHA [13].

In 1939, interest in nurse anesthesia as a career received a major endorsement in “Anesthesia – a Career,” in the August issue of *RN Magazine*. The article drew 400 inquiries [14]. That year also saw formalization of a vital aspect of the anesthesia curriculum: Training in anesthesia programs had to be at least 6 months, and a NANA Curriculum Committee was formed to evaluate and present a curriculum in keeping with progressive education. Finally, in that year, the NANA resolved to change its name to the American Association of Nurse Anesthetists (AANA) [15].

From 1933 through the 1940s, the AANA studied ways to ensure the quality of the programs offered by schools of nurse anesthesia. In cooperation with the American Hospital Association, education committees of the AANA initiated efforts to establish a program for the inspection of schools. In 1945, the AHA's Council on Professional Practice proposed to put the program into operation. Representatives of the AANA and the AHA met in 1946, and recommended that the AANA, rather than any other agency, initiate the program. To undertake this action, the AANA board of trustees appointed an Approval Committee (to certify the quality of each school). Workshop conferences and the preparation of questionnaires preceded initiation of the program of school inspections. For the initial inspection of schools, the AANA board of trustees would appoint advisors from the field of adult education, and these advisors, with a nurse anesthetist, would visit each school of anesthesia to recommend accreditation. As originally envisioned, schools would be revisited at three-year intervals. This program of school evaluation was put into effect in the 1950s [8].

The 1940s

In 1940, AANA president Miriam Shupp (1901–1988), noted that a national examination of applicants could be used to measure their eligibility for AANA membership. “We have,” she said, “arrived at that period in our development when this project can and should be put into effect to assure the members of AANA and those who employ nurse anesthetists that only properly qualified people are being admitted to membership [16].” Such a requirement had immediate appeal. It would motivate schools of anesthesia to improve their instructional programs, and the success of their graduates on the national examination would provide a measure of each school's quality [16].

At the ninth annual meeting, in 1941, AANA president Helen Lamb (1899–1973), envisioned development and operation of a national examination program by early 1943. The Education Committee laid the groundwork by requesting question sets from schools of anesthesia for use in the

examination. Selection of the actual questions for the examination would be the responsibility of the yet-to-be-named examining board [17].

The AANA board of trustees appointed a Certification Program Committee, to plan for the examination of association members. A potentially contentious plan was to test anesthesiologists who had extensive experience in administering anesthetics but were not graduates of an approved school of anesthesia [18]. A 1942 resolution by the Certification Program Committee avoided this controversy, and was adopted by the AANA. The resolution required all AANA members to be certified by examination, except that the examination requirement would be waived for currently active members [19].

World War II, A Turning Point

World War II accelerated the coming of age of all anesthesia providers, nurses and physicians alike. Because the war drained the country of such providers, hospitals all over the US scrambled to fill the void, coping with the shortage in diverse ways. Some looked to the AANA's standards as criteria for training their students. However, because the AANA had no control over the quality of instruction, it was deeply concerned that those standards might not be met. How could the AANA ensure that these variously trained practitioners possess the skills required to safely provide anesthesia? [20]

Until the Examination Program came into being, the AANA knew little about the anesthesia programs being offered by schools around the country. What knowledge the AANA did have, was pieced together from questionnaires completed by program directors, information on applications for membership, and a fledgling school-visit program that the war had curtailed. There was great uncertainty about the adequacy of graduates applying for membership, because of doubts about the quality of training received in newly organized and older courses, and because of the lack of standards for approval of courses and schools. World events now added urgency to fulfillment of plans for a national board of examinations, plans that had been under discussion since 1933 [20].

The plan for the Certification Program, approved at the 1942 AANA meeting, was submitted to the Council on Professional Practice of the AHA. The AHA voiced reservations about what it saw as a conflict between the goal of raising the quality of service provided by nurse anesthetists and the exemption of those who were practicing. The AHA was also concerned that waiving the certification requirement for currently active members might weaken the program by including unqualified anesthetists. Finally, because the certification examination would only test theoretical knowledge, the AHA remained skeptical of the examination's ability to

test the practical skills of the candidates [21]. Some AANA members also objected to paying a fee for an examination that gave successful candidates no advantages over anesthetists who remained uncertified.

The examination program was approved at the 1944 AANA meeting, and the bylaws were amended to make successful completion of the qualifying examination a requirement for AANA membership. A Committee on Examinations was established, consisting of five members appointed by the board of trustees. The Committee's charge was to prepare a master set of questions for each examination, to prepare instructions for test-takers, and to grade the examinations [21]. The revised bylaws also established the Committee on Credentials, which replaced the Membership Committee. This new committee would accept or reject the qualifications of each applicant for the examination [21].

As 1944 drew to a close, the AANA invited 34 schools of anesthesia to participate in creating the examination. Thirty-four were selected perhaps on the basis of being better known to the educators, and perhaps because 34 was a workable number for construction of examination questions. Twenty-four schools submitted examination questions; all but two sent essay-type questions. The examination questions were drawn from these submissions. The Certification Program Committee then worked jointly with the Committee on Examinations, to prepare application forms for AANA membership, to create a transcript for each student, to refine the logistics of the program and examination, to prepare revisions of bylaws, and to develop test questions and a study outline [22].

Therefore, 12 years after it was proposed, the first qualifying examination was administered on June 4, 1945. A passing grade was a prerequisite for AANA membership, thus justifying the term "qualifying examination." This one aspect of eligibility set it apart from a state board examination or a certification examination [23].

Overseen by examination proctors chosen by the chairman of the Committee on Examinations and AANA's executive secretary, the examinees tackled the 38-page examination, which included true-false, fill-in, essay, and multiple-choice questions. There was no oral or practical component. The examination consisted of five parts: I, anatomy and physiology; II, anesthetic agents and medications; III, clinical aspects; IV, principles and techniques in administration of therapeutic cases; and V, miscellany, which included history, ethics, terminology, organization and management of an anesthesia and gas therapy department, and explosion hazards and safeguards [20, 24]. It consisted of true-false, short essay, and fill-in-the-blank questions about the uses (including those beyond anesthetic administration) of helium, carbon dioxide, nitrogen, oxygen therapy, and cyclopropane. The five content areas carried equal weight, and passing or failing the test was based on the average score [20, 24].

The grades for the first group of examinees were not revealed to them or their schools. However, after the second examination, the AANA provided percentile ranking reports to each anesthesia school [24].

Ninety-two nurse anesthetists from 39 hospitals in 28 states and Hawaii took the first examination. Eighty-nine passed with a grade of 70% or more. One was disqualified for not having been authorized to sit for the test [24].

At last, 12 years after it was first proposed, the nurse anesthesia profession had established criteria enabling the AANA to “raise the standards of membership and the educational standards of schools of anesthesia, as well as increase the excellence of the services individual nurse anesthetists provided to patients, surgeons and society [20].” Comments from some of those taking the first examination reveal the diverse impact of this test on these new professionals [20]:

JH, Charity Hospital, New Orleans: “We had been well prepared by our instructors at Charity Hospital, so I did not find the questions overly difficult. I did not take anesthesia lightly. I worked and studied very hard...the examination was a definite step forward.”

EC, Grace Hospital, Detroit: “I thought the examination was a good idea...Nurse anesthesia was a very hard job. I started at \$250 a month and was on call every day and every other weekend...The examination was hard, too, considering the 9-month course I had taken in anesthesia. It took me all day to write it.” (Note: Course length was a minimum of six months, but each program could impose a longer, but not shorter time.)

MD, Mercy Hospital, Chicago: “That examination was so difficult that I remember thinking if I ever took another one it would be for a medical degree...Nevertheless, it was a good idea.”

BM, Grace Hospital, Detroit: “I can’t recall a single question. Although the limited academic training I had received was not helpful in the examination, my hands-on experience served me well, not only on the examination but throughout the 35 years I practiced.”

AM, Charity Hospital, New Orleans: “I had just finished my anesthesia course the year before, so many of the answers to the questions were fresh in my mind...I was afraid that if I didn’t pass I would lose my job.”

The qualifying examination was administered subsequently in November and May, for the next 30 years. In 1976, administration of the examination was changed to June and December.

After the third administration of the qualifying examination in 1946, Adam Gilliland (d.1952), professor of psychology at Northwestern University, Evanston, IL, was appointed as an educational consultant to the AANA. Two key changes resulted from his consultation: (1) objectivity increased, because of the use of recognition-type test items rather than recall; and (2) examinees were not penalized for incorrect responses in multiple-choice test items [25].

Scoring and statistical analysis of the examination was now done by clerical workers under Gilliland’s supervision.

This change hastened analysis of the results. Each program director received complete statistical reports on the performance of each graduate of the school. The reports included the name of each examinee, the percentile rank on each part of the examination, and the percentile rank on the total examination and on the General Information Test (GIT; see below). This information allowed school directors to correlate the successes of students while at the school with their performance on the qualifying examination [24].

The AANA now used percentiles to report grades on the qualifying examination. This method diminished problems resulting from questions that were too difficult or too easy, and it eliminated the differences in the grades reported by strict versus lenient examiners. The board of examiners determined the passing score for each examination in relation to the difficulty of questions and the quality of the group of applicants [26, 27].

In 1947, Gilliland suggested adding administration of a standardized general information test (GIT) to the qualifying examination, in order to establish the validity and reliability of the qualifying examinations. Since the duration for the fourth qualifying examination (November 11, 1946) had already been allotted, a short GIT was selected. Scores from this test correlated poorly with those from the fourth qualifying examination. Gilliland thought that the brevity of the GIT may have contributed to the low correlation, and at his suggestion, a longer GIT was used with the fifth qualifying examination. The correlation between the scores on the fifth examination seemed sufficiently high to serve as a fair basis for evaluating the examination [28, 29].

Next, Gilliland recommended administering the Bennett Mechanical Comprehension Test (BMCT), to determine whether a test could indicate manual skill in manipulating anesthetic equipment and in administering anesthetics. A questionnaire was sent to the director of each school of anesthesia asking for an estimate of the manual skill of each candidate from the school taking the ninth examination (May 1949). The information gathered from these questionnaires was compared with the results of the mechanical comprehension test [29, 30]. The BMCT was used with the next two examinations (November 1949 and May 1950.) Another questionnaire was sent to the directors of schools of anesthesia, asking for estimates of the manual skills of the candidates [30, 31]. It appears that the correlation with the BMCT results was insufficient, and the minutes and yearly reports do not mention the use of the BMCT after 1951.

The 1940s began a progressive increase in the number of schools of nurse anesthesia approved by the AANA (Fig. 36.3), reflecting the progressively increasing attractiveness of nurse anesthesia as a profession. The development of the examination and a certifying process could not have hurt the reputation and desirability of a career in nurse anesthesia.

Fig. 36.3 By the 1920s, there were fewer than 20 schools training nurse anesthetists. However, starting in the 1940s, the numbers grew progressively in successive decades. Nurse anesthesia may have become increasingly attractive because of the aura of official approval conferred by the examination and certification process developed in the 1940s

The 1950s

The use of machine-scored answer sheets changed the content of the exams. Beginning with the fifth qualifying examination in May 1947, exam items were constructed to have only one possible correct answer. This allowed members of the committee to prepare a scoring key for each part. This was sent to the educational consultant, Gilliland, who oversaw the scoring and statistical analysis of the examinations. An important consideration in using machine-scored answer sheets was that effectiveness and validity of the test could be evaluated by statistical procedures that are largely inapplicable to essay tests. The machine-scored tests facilitated comparison of the scores of groups, and objective and precise evaluation of individual scores [32].

The Personnel Research Institute from Western Reserve University, developed a job description for the work of an anesthetist. This became a basis for the test outline and was used to test validity of the examination. The job description was constructed from interviews with anesthetists and observation of their work in hospitals in Cleveland and nearby Detroit and Cincinnati. An outline of major subject areas was prepared from the job description [33].

In 1951, in order to increase security of the test, testing agencies in cities throughout the country and abroad were employed. Because most of these agencies were connected to colleges and universities, the day of test administration was changed from Monday to Saturday. Candidates could now select any of the test cities, whereas previous candidates had been assigned to a test city near their place of residence [34].

In January 1952, the AANA adopted the first set of standards for accrediting schools of nurse anesthesia, and the

program of accreditation went into effect. Subsequently, the standards were subjected to major and minor revisions. The compliance of schools with the standards is the basis for accreditation decisions made by the AANA Council.

Members attending the 1953 AANA annual meeting adopted an amendment that allowed experienced nurse anesthetists who did not have formal training, but were working in a recognized school of anesthesia, to take the qualifying examination after completing a specific refresher course. Only nonmembers of the AANA could take the refresher course [35]. The amendment also required that any candidate graduating from any recognized school more than five years before the date of application, had to present evidence of current clinical ability for evaluation by the credentials committee. This requirement was included so that a person who had administered only one type of anesthesia (e.g., for dentistry or obstetrics) could not qualify for membership [35].

In 1955, a bylaw was adopted in response to the misperception that membership in the AANA licensed an anesthetist to administer anesthesia. The bylaw sought to ensure compliance of all AANA members with the laws of the state in which they worked as nurse anesthetists. Through this bylaw, the AANA took the stand that administration of anesthesia was a practice of nursing, and that all AANA members should maintain active registration as professional nurses in the state in which they worked [36].

Because each state had its own Veterans Administration policy concerning so-called “accredited schools,” veterans returning from the Korean War faced problems obtaining GI benefits for training in schools of nurse anesthesia. The AANA applied to the Department of Health, Education, and Welfare (HEW) for recognition as the proper agency for accrediting these schools. On 20 November 1955, commissioner Brownell of HEW formally recognized the AANA as the accrediting agency for schools of anesthesia for nurses, thereby facilitating receipt of veterans’ benefits [37].

In 1956, the initials CRNA, standing for certified registered nurse anesthetist, came into use. This title now signified to employers and the public that an individual nurse anesthetist had met the standards required for AANA membership [38].

The 1970s

From 1955, the AANA had been the recognized accrediting agency for schools of anesthesia. On August 20, 1974, the HEW Office of Education announced a change in the criteria for accreditation agencies [39]. The AANA formed a task force to assess and meet the requirements for compliance needed to successfully petition for continued recognition as the accrediting agency for nurse anesthesia educational programs. HEW mandated that 12 new criteria become part of

the AANA accreditation policies and procedures. Three of the more important mandates included: (1) construction of due process mechanisms for students and faculty, including a mechanism for resolving grievances; (2) avoidance of possible conflicts of interest by separation of the decision-making body responsible for the accreditation of educational programs from the body responsible for the certification of graduates of those programs; and (3) public accountability to include representatives of the public and the community of interest in decision-making bodies, both at program and accrediting agency levels. New requirements also were imposed to ensure quality education [39].

In response to these mandates, the AANA made major revisions to its organizational structure to ensure absence of conflict of interest, autonomy in decision-making for the accreditation and certification bodies, and due process. The revisions supported the inclusion of public members of the community of interest on selected decision-making bodies [39]. The AANA acquired support for their petition from the American Nurses Association, the American College of Nurse-Midwives, the Association of Operating Room Nurses, the Federation of Nursing Specialty Organizations, the National League for Nursing, and the US Public Health Service. Many individual anesthesiologists, surgeons, and hospital administrators also supported the AANA's endeavors [39].

In August of 1975, AANA members adopted a restructuring that included the formation of three councils within the corporate structure of the AANA—councils on accreditation, certification, and practice. These official groups affirmed AANA's compliance with the criteria mandated by HEW's Office of Education [40].

Autonomy of the Council on Accreditation (COA) eliminated the possible conflict of interest between the accrediting authority for educational programs, and the credentialing authority concerned with the initial certification of graduates. The Council on Certification would act independently in the initial certification of nurse anesthetists, and would be responsive to public interest. The Council on Practice would act as the appellate body for both the Council on Accreditation and the Council on Certification.

The Council on Accreditation assumed responsibility for establishing the standards and policies for nurse anesthesia educational programs, subject to consideration by its communities of interest. The standards addressed administrative policies and procedures, institutional support, curriculum and instruction, faculty, evaluation, and ethics. Thus, the COA (1) established standards, guidelines, procedures, and criteria for the accreditation of nurse anesthesia educational programs; and (2) accredited entry into nurse anesthesia practice educational programs. The Council's scope of accreditation applied to institutions and programs of nurse anesthesia at all levels of education—the post-master's degree certificate, the master's degree, and the doctoral degree [41].

Accreditation of an established program was based on self-evaluation by the program, and a site visit by a team of two or three reviewers. The process was repeated at intervals of up to 10 years, and might be supplemented by progress reports. A summary report of the review and the program's response to the report were presented to the Council for an accreditation decision. Accreditation signified that programs had completed the accreditation process successfully. Accreditation might be awarded for periods of from 2 to 10 years [41].

Responsibility for program accreditation by the AANA has been maintained without interruption since 1955. Today the Council for Higher Education Accreditation and the US Department of Education continue to recognize the Council on Accreditation as the accrediting agency of nurse anesthesia educational programs.

In September 1975, The Psychological Corporation in New York City assumed responsibility for the qualifying examination, including selection of testing centers, scoring and processing of test results, and consultation for examination development. The "bank" of examination questions remained the property of the Council on Certification, but was maintained by the testing agency.

The Council on Certification of Nurse Anesthetists (CCNA) first met on September 8–10, 1975. Over the next several years, it made several changes:

1. Candidates whose religious beliefs precluded taking an examination on a Saturday, took Sunday examinations;
2. Dates of the test administration changed to the second Saturday and Sunday in June and December;
3. New qualifying examination application forms and new transcripts were prepared;
4. The examination fee increased from \$20 to \$125;
5. An individual could apply for eligibility to take the qualifying examination regardless of the number of previous failures (previously, the candidate could not apply after failing three times);
6. Students enrolled in a program that had been placed on probation or had its accreditation status revoked, could apply for eligibility to take the Council's qualifying examination; but
7. Students admitted to a program that was on probation or had its accreditation status revoked, could not apply for such eligibility.

At the AANA annual meeting in 1978, the membership adopted the bylaw amendments that restructured the AANA. An independent Council on Recertification of Nurse Anesthetists (COR) was established, officially separating the AANA from the certification and recertification processes. The existing autonomous Council on Certification assumed responsibility for the initial certification of nurse anesthetists. Previously, after a graduate had passed the qualifying examination, he or she was certified, could become an AANA member, and could use the CRNA designation. No voluntary membership was available. The new bylaw sepa-

rating membership from certification made voluntary membership available. An individual could be certified, and could use the CRNA designation, without becoming a member of the AANA [42].

Establishment of the Council on Recertification eliminated the need for external agencies (specifically, the US Office of Education, the Council on Postsecondary Accreditation, and the American Society of Anesthesiologists) to address the question of requiring AANA membership and recertification. Independence of the COR also allowed the AANA to increase political, economic, and government relations (lobbying) activities, and to engage a labor relations consultant to assist members and states. It separated evaluation of professional competence from association activities. It made AANA membership voluntary and no longer tied to initial certification or recertification [42].

The 1980s

On March 26–27, 1982, the “qualifying examination” became the “certification examination for nurse anesthetists,” because formation of the Council on Certification eliminated the need to pass the certification examination in order to qualify for AANA membership. An individual passing the examination was certified by the Council on Certification for entry into practice, not for membership in the AANA [43].

In conjunction with the testing agency, the Council updated the nurse anesthesia examination process, and built a job-related examination. Nurse anesthesia programs had evolved from on-the-job training programs, to established hospital and university programs meeting the criteria of the Council on Accreditation for Accreditation of Nurse Anesthesia Programs Standards and Guidelines. Although differences in academic and clinical experiences existed among programs, standards and guidelines now identified the minimum requirements for nurse anesthesia educational programs.

Content validity refers to the degree to which examination content represents the area of work. A high degree of validity means that the questions on the examination accurately reflect requirements and expectations of the actual job, and that scores on the examination accurately indicate the examinee’s mastery of those requirements. Content validation studies assess whether questions on an examination adequately represent a performance domain. Content validation procedures for the certification examination were documented through an analysis in 1987, and through subsequent professional practice analyses (PPAs) in 1992, 1996, 2000, 2007 and 2011 [44, 45].

For example, following the 1992 PPA, the Council revised the content outline and percentages of questions in each area to reflect current entry-level nurse anesthesia practice. These changes were justified by the consistency in the responses of the practitioners surveyed, in the major

domains of knowledge and skills identified in the PPA. Knowledge was divided into five major areas related to anesthesia practice: basic sciences (30%); equipment (5%); basic principles of anesthesia (31%); advanced principles of anesthesia (30%); and professional issues (4%). The examination committee would use the new content outline to develop new questions for the certification examination as well as reclassify those currently in the repository of questions to meet the new specifications [45]. The examination content and percentages changed modestly after analysis of the results of the 2007 PPA: basic sciences (25%); equipment (10%); basic principles of anesthesia (30%); advanced principles of anesthesia (30%); and professional issues (5%) [46].

In April 1986, the Council accepted the Angoff method for “cut-score” determination, scaling, and equating of the certification examination. Psychometrically sound standards were used to set the passing score [44, 45].

Beginning with the December 1987 certification examination, scores were no longer reported as raw scores but as scaled scores. The use of a scaled score facilitated the equating of examination scores to ensure that candidates had no advantage or disadvantage based on having taken the test at a particular time [47].

In response to requirements of employers and states, that nurse anesthetists be certified in order to work, the Council implemented a certification-eligible status for applicants waiting to take the certification examination. As long as the certification-eligible status could be verified through the Council, the applicant could be employed [47].

The 1990s

The June 1990 certification examination included questions using graphs, diagrams, and electrocardiogram (ECG) strips. These questions facilitated testing of clinical knowledge and skills. The Examination Committee and the Council on Certification of Nurse Anesthetists worked collaboratively to ensure that the certification examination assessed the entry-level knowledge and skills necessary to perform the tasks identified in the on-going job analyses. Ongoing reassessment of the tasks, knowledge, and skills demanded by the test items, was a vital part of the process [44]. Graduates were increasingly pressured to pass the certification examination. States now required certification in order to be licensed as an advanced practice nurse, and Medicare required certification/recertification for reimbursement.

In 1993, suspected cheating prompted the Council to implement new policies ensuring the integrity of the certification examination:

If the Council determines that there is reason to believe that one or more applicants have engaged in cheating or other improper behavior, or otherwise violated the security of the examination,

the Council may, at its discretion, (1) order one or more of those applications to retake the Certification Examination at a time and place to be determined by the Council, or (2) refuse to release the scores of one or more of those applications and thereby, deny their applications for certification [48].

The protection afforded by copyright was inserted into all levels of the instructions received by the candidates, forbidding the dissemination of copies of the examination by “review courses” claiming to prepare students for the examination using actual questions from the examination. The CCNA determined that all current council and committee members must sign a Work for Hire Statement, and that former examination and committee members must sign an Assignment of Copyright statement [48]. Candidates were warned that violation of the copyright not only subjected them to possible legal action but also endangered their credentialing.

In 1992, the CCNA considered changing its current paper-and-pencil test format to a computer format. The Council project manager, Karen Plaus, provided Council with information from the National League for Nursing regarding a new testing technology. It had recently been adopted by the National Council of State Board of Nursing, and was known as computer adaptive testing (CAT). CAT is based on the psychometric framework of the Item Response Theory (IRT) developed at the University of Minnesota in the 1960s. IRT is used to determine the difficulty of test questions and to estimate the ability of candidates [49]. Plaus advised Council of the advantages of this new technology – namely, more flexibility in test administration dates, the immediate availability of results, increased test security, and the possibility of self-paced administration of the test. By 1994, after meeting with experts in testing and with individuals from professional associations who used the computer for certification and licensure testing, Council began preparations for the transition [49, 50]. Implementation of CAT was approved in June 1996. Implementation required the development of educational materials for students and program directors, including three item-writing workshops and related lectures on CAT and IRT [49, 50].

Several advantages accrued from using the CAT format rather than the traditional paper-and-pencil format. The National Certification Examination (NCE) would be individualized for each candidate. The candidate would be examined individually at test administration sites, sitting at individual stations and taking the test at his or her own pace. The NCE would be offered up to four times a year, enabling a year-round test administration schedule. Candidates could schedule their own date, time, and test location. This advantage was more than simply a convenience, as many states required certification to practice. Because candidates could be promptly notified of their certification status, this flexibility accelerated their entrance into the workforce. Most important, the competence of candidates would be more accurately and fairly measured than before [49, 50].

How does CAT work? Each test is individualized and assembled interactively as the candidate is tested. Test questions are stored in a large item bank and are classified by content category and level of difficulty. After the candidate answers a question, the computer calculates an estimate of competency and chooses for the next question an item of appropriate content and difficulty. This process is repeated for each question, thus creating an examination that is both tailored to each individual’s knowledge and skills, and fulfills the CCNA test plan requirements. The CAT NCE is fair to all candidates and conforms to the CCNA NCE outline content areas of basic sciences, basic and advanced principles of anesthesia, equipment, instrumentation and technology, and professional aspects. The passing score is identical for all candidates, ensuring a consistent difficulty level necessary to pass the NCE for all examinees [49].

The features for the CAT differed from those for the previous certification examination administered since 1945. (1) The test varied in length, with a minimum number of scored questions of 70 and a maximum of 140. Twenty pre-test questions were not included with the minimum 70 that were scored. (2) The maximum length was three hours. (3) There were no options for review of previous answers. (4) The scores were reported as pass/fail [49].

On December 9, 1995, the last paper-and-pencil examination was administered to 820 individuals as the 102nd Certification Examination. On 15 April 1996, the first CAT was offered at the Sylvan Technology Centers. Student applicants now selected the date and location for their examination. Twice yearly administrations and the assembling of eligible candidates at university test centers on a Saturday were a thing of the past, incidentally eliminating the possibility of a cancellation due to a snowstorm.

Students and prospective employers pressured the Council to release results directly to the student upon completion of the examination. The Council rejected this request for three reasons. (1) The test agency first needed to verify all test results. (2) Each applicant needed to confirm that all criteria for certification criteria had been met. (3) Test center security required verification that the computer functioned properly, that the integrity of the data was maintained, and that the test session occurred under controlled conditions.

A New Century Arrives

By the twenty-first century, computer use affected most aspects of daily living. Every student had a computer, and nurse anesthesia programs placed many of their internal documents on such devices. Accordingly, the Council sought to make most documents available to students and program directors via the Web, including portable document format (pdf) files for transcript forms and examination information. By 2003, 55% of all CCNA candidates registered on-line.

By 2004, all CCNA forms, including the official CCNA transcript and candidate handbook, were available as interactive pdf files.

The new systems for examination came none too soon. With the arrival of the new millennium, the popularity of nurse anesthesia as a profession continued to increase, with the number of graduates and clinical sites more than doubling in the years 2000 to 2009 (Fig. 36.4).

The Test Today

AANA bylaws originally stated that the examination should include written, oral, and practical portions. According to Thatcher, the difficulty of conducting more than a written examination led to the elimination of the oral and practical portions of the examination [6, 51], leaving only the written examination.

From its inception in 1945 to 2012, 68,784 students have taken the certification examination. The test evolved from a five-part, 38-page paper-and-pencil examination that used true-false, fill-in, essay, and multiple-choice questions, to a streamlined computer-format test having a maximum of 140 questions. The evolution resulted from concerns regarding the adequacy of the test instrument, and the equality and fairness of its application to all candidates.

Today diverse test designs, such as multiple correct responses, calculation, “drag-and-drop” and “hotspot” questions, enable a better test of issues difficult to pose in the traditional multiple-choice question format. Candidates now receive a preliminary pass/fail report as they leave the test center. This preliminary report is validated, and the National Board of Certification and Recertification for Nurse Anesthetists (NBCRNA) sends the official results within 2 to 4 weeks after the test (as opposed to the 3 months after the old paper-and-pencil test). Applicants now select the day, the time of examination, and the test site location. They register online. Some students say that one of the greatest benefits is that they are able to join the ranks of the employed more quickly.

What About the Future?

The NBCRNA continues to consider the use of simulation and other testing modalities. Looking into the future, by 2025, doctoral education for nurse anesthetists will become a requirement for entry into nurse anesthesia practice. With today’s changing healthcare environment, providers must continue to expand their knowledge and skills. To position nurse anesthetists to meet this ongoing challenge, the AANA and NBCRNA support doctoral education as one way to incorporate technological and pharmaceutical advances, informatics, evidence-based practice, systems approaches to quality

Fig. 36.4 The number of nurse anesthetist graduates and clinical sites for training more than doubled in the first decade of the new millennium. Computerization of examinations facilitated such rapid growth. (Data courtesy of the American Association of Nurse Anesthetists.)

improvement, healthcare business models, teamwork, and public relations. These are all subjects that will shape the future for anesthesia providers and their patients [52].

In 2011, the NBCRNA introduced the Continued Professional Certification (CPC) program that embraces lifelong learning for nurse anesthetists. Following initial certification, each nurse anesthetist will be required to complete continuing education and core competency modules every four years. A recertification examination is required every eight years.

Manuel Pardo

Summary

In 1850, four years after Morton's demonstration, Surgeon Warren described adequate anesthesia care: Have a dedicated person continuously deliver anesthesia to a fasting supine patient; administer anesthesia sufficient to produce relaxation; beware of obstructing breathing; and don't set fire to the operating room. Between 1847 and 1858, Snow documented how to safely give and assess ether and chloroform anesthesia. From 1860 to 1900, no formal training programs in anesthesiology existed. Surgeons, interns, medical students, nurses, and orderlies gave anesthetics. In 1916, surgeon Gatch, President of the American Association of Anesthetists, advocated training medical students and interns in anesthesia. In the 1910s–1920s, a few physician anesthetists, such as Botsford and Herb, established teaching programs.

In 1927, Ralph Waters became chairman of the world's first academic department of anesthesia. He created a 3-year post-graduate residency program: 2 years of clinical training and 1 of research. Because his graduating residents served as leaders, his vision for academic anesthesia influenced the country and world.

The American Board of Anesthesiology (ABA) conducted its first written examination in 1939. Three years of post-graduate training, 3 years in practice, and passage of written, oral, and practical examinations were required to become diplomates.

During World War II (1941–1945), many physicians were drafted into anesthesia after a few months of training. Finding that they liked what they were asked to do, along with improved remuneration, they found anesthesiology to be attractive. The number of US anesthesia residency programs grew five-fold in the decade after the war, and the number of residents increased.

In 1945, the American Society of Anesthesiologists created a "Committee on Postgraduate Education." A half decade later, the Committee recommended at least 2 years in residency training, increasing to 3 years (plus internship) in 1984. Created in 1972, the Liaison Committee on Graduate Medical Education began formal accreditation of graduate medical education programs in 1975, after reviewing the recommendations of individual Residency Review Committees.

Believing that an organization of teachers could improve education in anesthesia, junior anesthesia faculty in the US founded the Society for Education in Anesthesia (SEA) in the early 1980s. From the late 1990s to 2010, training and recertification with computerized simulators grew rapidly despite limited evidence of sustained efficacy. Since the 1990s, the most notable changes in anesthesia education have been the increase in specialty operating room experiences and non-operating room clinical experiences. In 2000, the ABA established time limited certification.

The Early Nineteenth Century

The US had four medical schools in 1800: University of Pennsylvania, Harvard University, Dartmouth College, and King's College (subsequently Columbia University). Twenty-six more schools were added by 1840. The curriculum typically occupied two four-month blocks, covering

seven courses: anatomy; physiology and pathology; materia medica, therapeutics and pharmacy; chemistry and medical jurisprudence; theory and practice of medicine; principles and practice of surgery; and obstetrics and diseases of women and children [1]. Six to eight hours of didactic lectures occupied each day, lectures focused on practical rather than scientific concerns. Few effective therapies were available.

This mid-nineteenth century medical education had many deficiencies. Except for a few schools teaching anatomy with dissection, none offered laboratory instruction. Students were generally illiterate (even at Harvard), and few had a college degree. A brief and informal oral examination

e-mail: pardom@anesthesia.ucsf.edu

qualified the student for graduation; there was no written examination. The medical school diploma was the sole document required to practice medicine; no state or national licensing procedures existed. Most medical schools were independent, “proprietary” institutions without any affiliation with a hospital or university. Most existed to make money, and the ability to pay entrance fees was the major criteria for admission.

Some physicians supplemented their training with apprenticeships, but the quality of instruction was generally poor, and many apprentices merely performed household chores. Nonetheless, starting in the early 1800s, the “house pupil” experience became an increasingly popular feature of American medical education. A few physicians or medical students spent a year in a hospital, rotating through all the hospital wards, helping staff physicians provide bedside care of patients. The terms “house pupil,” “intern,” and “resident” were used to describe these postings. The increasing number of surgeries performed after the introduction of anesthesia in 1846, significantly enlarged the work of the house pupil.

At this time, European medical training was considered the finest in the world. In the first half of the nineteenth century, Americans who could afford it chose Paris as a place for postgraduate medical study. What was special about French medicine at this time? French clinicians developed many approaches that became widely accepted, including modern approaches to pathology, physical diagnosis, and the use of statistics in clinical research. They placed the hospital at the center of medical teaching and research [1]. Their strength was astute clinical observation, eschewing speculative theories such as humorism that had crippled medicine. According to humorism, the human body was composed of four humors: black bile, yellow bile, phlegm, and blood. In health, the humors were balanced. Deficiency or excess of one of the humors explained all disease. Treatment could include bleeding (to reduce a surplus of blood) or applying a hot cup to a patient’s skin, called “cupping” (to reduce a surplus of bile). French clinicians of this era did have a weakness: a distrust of experimental laboratory investigation [1]. By the mid-nineteenth century, German medical scientists had embraced experimental methods and subsequently made major discoveries such as cell theory, which eventually ended humorism’s grasp on medical thinking. In the second half of the nineteenth century, Americans desiring additional medical training began to choose Germany instead of France, because of strengths in new clinical subspecialties (such as dermatology, ophthalmology, laryngology) as well as in the laboratory.

Good Advice

At the Massachusetts General Hospital, on 16 October 1846, William Morton publically demonstrated the capacity of

diethyl ether to provide surgical anesthesia. John Warren presided as the operating surgeon. Four years later, Warren addressed the American Medical Association, reviewing the progress of surgery during the previous fifty years with a particular focus on how to administer ether safely [2].

“...I am in constant apprehension of some serious occurrence; and I would therefore venture to give a solemn warning to all surgeons who may have an occasion to use ether, not to omit any possible attention calculated to prevent a mischievous or dangerous accident. Our mode of application for the Hospital is very simple. First, The patient is not allowed to eat freely within three or four hours before an operation. Second, He is placed, if possible, in the horizontal posture. Third, If the operation is to be bloodless, the patient should be bled from the arm before it begins. Fourth, The pulse, respiration, and countenance should be carefully watched by an assistant, whose special duty it is to perform this office. Fifth, A large sponge, of a conical form, is filled with ether, and applied over the nostrils of the patient, but not in such a way as to prevent him from getting a quantity of atmospheric air into the lungs. Sixth, The application should not be too severely pressed upon the patient; and, if he coughs or exhibits symptoms of distress, the sponge should be raised for a moment, and then re-applied. Seventh, A perfect relaxation of the muscles is the test of full etherization, such as is required in every important surgical operation. Eighth, We generally continue the ether, with slight intermissions, till the operation is terminated, unless there is some reason for the contrary practice. Ninth, We avoid approaching the patient, during the administration of ether, with a light, the actual cautery, or any thing capable of setting fire to the vaporized ether.”

Sensible observations: Have a dedicated person continuously deliver anesthesia to a fasting supine patient. Administer anesthesia sufficient to produce relaxation (no movement?). Beware of obstructing breathing; and don’t set fire to the operating room. Education for the budding anesthetist.

1847–1858

John Snow, the first and arguably the greatest anesthesiologist, witnessed the use of ether for dental extraction in London on 28 December 1846 [3]. Over the next nine months, he designed a vaporizer that stabilized the temperature of the liquid ether and thus delivered a near constant (albeit high) concentration that he could crudely dilute by admitting more or less air to the inspired mixture. He developed an active ether administration practice, and published a monograph, *On the Inhalation of the Vapour of Ether in Surgical Operations*, that served as a comprehensive guide to the clinical use of ether anesthesia. In particular he described the “degrees” of anesthesia, a prerequisite to the control of the extent of anesthesia. He next applied his technical, clinical and educational skills to chloroform [4]. Reference works such as these were rare. The medical world learned the latest

medical events through lectures, medical society meetings, journals, and newspapers.

1860–1900

Formal training programs in anesthesiology did not exist in the nineteenth century. Personnel with little or no experience, including medical students, interns, and ward nurses provided anesthesia. Occasional editorials in medical journals advocated teaching anesthesia to medical students. In 1900, one such editorial in *The Lancet* [5] noted that “Since the examining bodies apparently think little of the importance of the administration of anaesthetics, the medical schools, which naturally take their cue from these bodies, cannot insist upon much attention to the subject.” The editorial mused on the importance of that omission: “A student may attend all the lectures available and read all the books, but until he has himself given an anaesthetic he can never become a safe anaesthetist.” An understatement, indeed.

A 1900 editorial in *The Philadelphia Medical Journal* remarked [6]:

“The faculties of our medical schools should recognize the tremendous responsibility of the anesthetist and the fact that all graduates are likely to be called upon to use anesthetics and in most cases quite frequently. Lack of knowledge or skill may jeopardize the patient’s life and frustrate the surgeon’s skillful endeavors. The facilities for teaching this subject should be increased; it should be made compulsory and the opportunity for hospital training should be given. In this way the students of the future will graduate much better equipped in a very important requisite than their predecessors have been.”

Because medical schools did not attend to the training of anesthetists, the door was open for nurses to fill the gap. Indeed, at the Mayo Clinic in Rochester, Minnesota, surgeons William (1861–1939) and Charles Mayo (1865–1939) “decided that a nurse was better suited to the task because she was more likely to keep her mind strictly on it, whereas the intern was naturally more interested in what the surgeon was doing [7].” Edith (1871–1943) and Dinah Graham (1860–1947) became the first nurse anesthetists at the Mayo clinic. Their successor, Alice Magaw (1860–1928) is regarded as the most famous nurse anesthetist of the nineteenth century. Surgeons sent nurses to observe her practice and learn what they could.

1910: The Flexner Report

The American Medical Association (AMA) was founded in 1847, and in 1904, the Association formed the Council on Medical Education. Although the AMA was a practitioner-based organization, academic physicians advocating higher

educational standards dominated the council [1]. In 1906, the council surveyed US medical schools, but never published the unflattering results of the survey, thinking it politically unwise for a medical organization dominated by practitioners to publicly criticize the nation’s medical schools. Instead, the council invited the Carnegie Foundation for the Advancement of Teaching, to survey US medical schools. Abraham Flexner (1866–1959), an obscure educator at the Carnegie Foundation, led this survey. From 1908 to 1910, he visited every medical school in the US and Canada. His famous and widely distributed 1910 report, *Medical Education in the United States and Canada*, described the shortcomings of North American medical education compared to European education [8]. Describing each school’s laboratory and clinical facilities, Flexner’s observations were vivid and often critical. For example, he remarked on the laboratory facilities of the Kansas Medical College in Topeka:

“The school occupies a three-story building, on the upper floor of which there have been improvised laboratories for pathology and bacteriology. They contain the necessary equipment for routine teaching, but are poorly kept...The dissecting-room is indescribably filthy; it contained, in addition to the necessary tables, a single, badly hacked cadaver, and was simultaneously used as a chicken yard.”

The descriptions of individual facilities made for interesting reading—unless your school was criticized. The report contained much more than gaudy descriptions. Flexner first discussed principles underlying modern medical education. He then provided a detailed description of entrance requirements, attendance, teaching staff, resources for maintenance, laboratory facilities and clinical facilities available in each medical school. He advanced several tenets essential to medical education: 1) the medical student should be prepared by at least two years of college, including coursework in biology, chemistry and physics; 2) scientists rather than practitioners should teach basic sciences; 3) research should play a central role in the medical school; 4) medical schools needed financial resources to decrease their dependence on student fees; and 5) the schools needed ready access to hospitals for teaching purposes. While European schools possessed many of these elements, few American schools did. To Flexner, the model system of medical education was Johns Hopkins Medical School, and his report extolled its virtues repeatedly [8]. The Flexner report changed medical education over the next 10 years, leading to elimination of approximately one-third of US medical schools.

World War I (1914–1918)

There were few developments in anesthesia education during World War I. One outstanding example was Arthur Guedel (1883–1956), who served as an anesthesiologist with the

American Expeditionary Forces in France [9]. Because he was the only anesthesiologist in the region, he had to quickly train nurses, orderlies, and others to administer ether. Based on his observations from a decade of anesthesia practice, Guedel developed a chart describing stages of ether anesthesia based on patterns of respiration and the appearance of the patient's eyes (see Fig. 39.2). His trainees used this chart as they worked independently. Guedel was known for visiting his trainees at various hospitals using a motorcycle to navigate the muddy battlefields. This earned him the moniker “the motorcycle anesthetist of World War I.” After the war, Guedel published the chart, which became widely used. Many modern anesthesia textbooks reproduced the chart as an example of the utility of clinical observations in evaluating depth of anesthesia.

1916

Although anesthesia continued to be taught in an unstructured manner, seeds of change had been sown. Anesthesia organizations in the US, including the American Association of Anesthetists, the predecessor to the American Society of Anesthesiologists (ASA), gained footing. In 1916, Willis Gatch, Professor of Surgery at the University of Indiana Medical Department, was elected president of the American Association of Anesthetists. In his presidential address, “Instruction of Medical Students and Hospital Internes [sic] in Anesthesia [10]” he remarked that

“Nothing can do more to improve your standing as specialists than to educate physicians generally in this subject, and the best place to begin this course of instruction is with the medical student. Unless our leading medical schools give instruction in anesthesia not described in their catalogues, the training of students in this subject must be either entirely lacking or very inadequate...I am convinced that in most of our medical schools the student receives practically no instruction in anesthesia and that the instruction therein of internes [sic] in our hospitals is usually haphazard and frequently resented by its recipients.” In his plan for supervision of interns, Gatch proposed “... that the duties of the anesthetist should not be limited to the actual conduct of the anesthesia, but should cover also the preliminary examination and preparation of the patient and his immediate post operative care.”

1920

Gatch's address may have prompted the American Association of Anesthetists to form a committee to investigate the teaching of anesthesia in medical schools, and to develop plans for advancing anesthesia teaching and establishing a standard approach to training hospital interns in anesthesia. Isabella Herb (1863–1943), was on the committee, as one of the few individuals in the US with an academic appointment

Fig. 37.1 Isabella Herb administers ethylene anesthesia while the discoverers of ethylene as an anesthetic, J. Bailey Carter and Arno Luckhardt, observe. (From [12]. Photo provided by Dr. John B. Stetson. Reprinted with permission)

in anesthesia. She was Assistant Professor of Surgery (Anesthetics) at Rush Medical College, and Chief Anesthetist at Presbyterian Hospital in Chicago (Fig. 37.1). Herb presented her teaching method at the annual meeting of the Interstate Association of Anesthetists, held in October 1920 in Pittsburgh, PA: “Anesthesia in Relation to Medical Schools and Hospitals [11].” She noted that “instruction in the art and practice of anesthesia is altogether absent from the curriculum of the majority of medical schools, or totally or inadequately dealt with...Nothing can improve the status of anesthesia, or bring about the proper recognition of anesthetics as a specialty, as the education of physicians and surgeons generally in this branch of medicine, and the proper place to begin instruction is in the medical schools when, true to the Arabian proverb ‘A man knows not and knows that he knows not.’” Herb outlined her approach for teaching medical students at Rush Medical College and the Presbyterian Hospital in Chicago. Physiology, and the chemistry and pharmacology of anesthetic agents were taught during the first two years of medical school. During the senior year, a required didactic

course in anesthetics was given, along with demonstrations and supervised administration of anesthesia. Her course topics resembled many of those that might be taught today. She began with the history of anesthesia and ended with legal matters. Between these bookends, she discussed the pharmacology of and the basis for the selection of the then used anesthetics (e.g., ether, chloroform, nitrous oxide). She continued with descriptions of the implications of patient pathophysiology, premedication with alkaloids, optimum patient position, resuscitation, how to deal with untoward events, and pulmonary complications following anesthesia.

Regarding interns and their training, she only admitted graduates of Rush Medical College, who thus had the anesthetic training outlined above. They became preceptees, with gradually increasing responsibilities. Herb noted “it is an exceedingly rare thing to find an interne [sic] who is not interested in this phase of his hospital work, in fact there is frequently considerable rivalry, in the desire to be considered the best anesthetist among the internes [11].”

Herb was among the first women physicians to specialize in anesthesia [12]. Beginning in 1899, she served as the first “physician anesthetist” at the Mayo Clinic in Rochester, working directly with Charles Mayo. Until that time, the Mayo Clinic used nurses or surgical residents to administer anesthesia. Herb also served as a pathologist at Mayo Clinic, in charge of the Section on Pathology. She left in 1904 for further study in Europe, and then returned to Chicago a year later to perform infectious disease research. In 1909, she became the chief anesthetist at Presbyterian Hospital in Chicago, a position she held until her retirement in 1941. She had a distinguished anesthesia career, reaching the rank of Professor of Surgery (Anesthesia) at Rush Medical College, and serving in many leadership positions in the specialty. She was the tenth president of the American Association of Anesthetists.

Mary Botsford (1865–1939) was another woman physician who specialized in anesthesia. Just as Herb was the first physician anesthetist at the Mayo Clinic, Botsford was the first physician anesthetist at the University of California Medical School in San Francisco, appointed in 1910 [13]. Botsford’s anesthesia skills were self-taught, and Botsford herself was a charismatic and inspiring teacher. She educated women physicians, and many became interested in anesthesia practice. Indeed, in Botsford’s time, the group of physician anesthetists at the University of California was composed entirely of women, reaching a peak of five from 1921 to 1928.

1921–1930

The 1910 Flexner report focused on medical student education because the prevailing view held that four years of medical school provided adequate preparation for the practice of medicine. That view changed as medical practice evolved

in the years after World War I. Long available but few in number, internships had no consistent format. An increasing recognition of the importance of post-graduate training prompted growth in the number of internship positions and the development of common internship structures, including the addition of formal didactic elements such as conferences, teaching rounds and lectures. The AMA Council on Medical Education, which had underwritten the Flexner report, and subsequently examined and approved medical schools, now extended this role to internships [14]. Reflecting the importance of the hospital setting to the internship, the council changed its name to “Council on Medical Education and Hospitals.” While many internships lasted one year, others lasted two or even three years. Inconsistency in the internship experience was common, as interns were a source of service to the hospital as much as they were trainees learning to care for patients. Also, there was disagreement amongst medical educators about the role of the internship; some thought of internship as the end of medical school whereas others believed it was the start of post-graduate training. The AMA Council authorized three internship structures: rotating, straight, and mixed [15]. The rotating internship, considered the best overall training, allowed experience in the major specialties of medicine, surgery, obstetrics, and pediatrics, as well as some training in anesthesiology, radiology, and pathology. The straight internship, consisting of experience in only one major clinical area (e.g., medicine, surgery, pediatrics, radiology, or pathology), was considered more limited in scope, but was typically conducted in medical school teaching hospitals with increased access to educational activities [15]. The mixed internship offered experience in more than one clinical area, but in fewer disciplines than the rotating internship.

The term “residency” denoted training after the internship in a specific field of medicine. At that time, the residency was for the elite trainee, and programs only accepted the best students and interns [14]. Most had a pyramid structure, with more junior residents than senior residents, and only one achieving the position of “chief resident”. In 1927, the list of hospitals with residency programs, under the AMA Council on Medical Education and Hospitals, contained 270 hospitals and 1699 residency positions. Of those, 15 hospitals offered anesthesia programs, with 19 residency positions in total [16].

1927—Waters Comes to Madison

In 1927, Ralph Waters joined the University of Wisconsin as the chairman of the world’s first department of anesthesia. He sought to create an academic department that had four pillars: optimum patient care, education of medical students and interns, post-graduate education, and research into the

scientific foundations of anesthesia [17]. While Herb and Botsford's programs taught medical students and interns, there was no provision for extended post-graduate anesthesia education in a university setting. Waters created a 3-year post-graduate residency program, with the first and third years dedicated to clinical training, and the second year to laboratory research. Reflecting on his career, Waters wrote:

“When I quit Kansas City to come here I had one idea in mind. That was that Anesthesia's great need was recognition by, and teaching in medical schools so that all M.D.'s would know what every doctor ought to know about it. So the residencies here came to be at least three years in duration.... [18]”

The choice of three years as the duration of his anesthesia residency may have reflected the duration of other specialty training. In 1923, three years of graduate medical education was required in general surgery, orthopedic surgery, obstetrics and gynecology, pediatrics, medicine, and neuropsychiatry. Specialties requiring only two years of graduate medical education at that time included ophthalmology, otolaryngology, and dermatology.

Waters started twice weekly departmental meetings: one reviewed the week's cases (at first such sessions were called M&M or Morbidity and Mortality Conferences; later they became more elaborate, morphing into Grand Rounds), and another reviewed current medical literature. Resident responsibilities included patient care, research, literature reviews, and teaching and supervision of medical students and interns. Waters acted to expand his vision for academic anesthesia across the country, expecting his graduating residents to serve as leaders. In a letter to Lincoln Sise (anesthesiologist at the Lahey Clinic in Boston), he wrote “my ambition is for the men who spend some time with me here to get eventually in teaching positions in other universities because I think that is the only way we can hope to improve the specialty in the future. It has therefore been a disappointment to me each time that one of my boys has gone to private practice [19].” Several of his graduates, and in turn, graduates of their programs, established most of North America's academic programs using Waters' approach. These included Emery Rovenstine, Robert Dripps, Stuart Cullen, and Emanuel Papper, each of whom spawned academic anesthesiologists and chairs. The University of Wisconsin residency program also served as a model for early programs in the United Kingdom and Canada [20].

1930–1940s

1937—Rovenstine's Address

Rovenstine's 1937 presidential address to the Associated Anesthetists of the US and Canada was titled “Anesthesia:

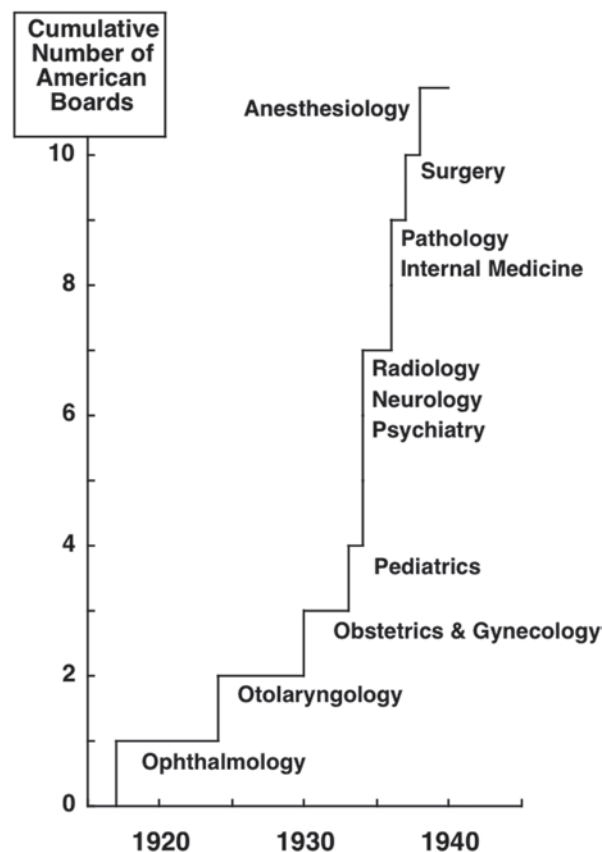

Fig. 37.2 Formation of many of the major examining boards took place in the 1930s, culminating with the formation of the American Board of Anesthesiology in 1938

Organization for Teaching.” He advocated elements underlying contemporary anesthesia training programs, namely supervised clinical instruction in the operating room, didactic sessions, anatomy laboratory teaching for regional anesthesia, case conferences to review results and complications, and discussions of the current anesthesia literature. Further, he argued that “A teaching institution will not fulfill the spirit of service by the mere dissemination of knowledge but must accept as an integral part of its assignment, the accumulation of new knowledge... The attention of those responsible for postgraduate instruction must also be directed toward the preparation of students for teaching, administration, and organization.”

1938–1939

Specialty board organizations demanded increased standardization in specialty training in the 1930s. The American Board of Ophthalmology and the American Board of Otolaryngology, were founded in 1917 and 1924, respectively. Several additional boards followed in the 1930s (Fig. 37.2) [14]. The American Board of Anesthesiology was established in 1938 as a board subordinate to the American Board

Table 37.1 Sample essay questions in the first written examination of the American Board of Anesthesiology, March 1939. (From [23], with permission)

Field	Essay question
Pharmacology	Define the term “secondary saturation” and give your opinion of its importance in the administration of nitrous oxide
Anatomy	Describe a method for producing block anesthesia for a surgical procedure involving a bunion
Physics and Chemistry	What safeguards do you advise against the hazard of explosion when inflammable anesthetic agents are being employed?
Pathology	If you had a patient suffering from marked cirrhosis of the liver and an intra-abdominal operation were necessary, what anesthetic agents would you avoid for this patient?
Physiology	Outline the protective mechanism which is called into place when acute hemorrhage occurs

of Surgery, becoming an independent board in 1939. An umbrella organization, the Advisory Board for Medical Specialties guided these specialty boards.

The boards required at least three years of post-graduate training, a few years in practice, and the successful completion of an examination (written, oral, and practical) to achieve diplomate status. Thus, while medical schools and teaching hospitals controlled the undergraduate educational experience, the professions themselves greatly influenced graduate medical education. In 1937, the Advisory Board for Medical Specialties created the Commission on Graduate Medical Education, with a mandate to “formulate the educational problems and principles involved in the continuation of medical training for a period of years after graduation and the adequate training of specialists, and to make recommendations for methods whereby those in practice, general and limited, may keep abreast of new developments in diagnosis, treatment and prevention [21].” The distinguished composition of the commission (albeit without a single anesthesiologist) strengthened the influence of its report. The report summarized what it believed were the basic principles of a residency:

1. The residency should be the most satisfactory method of graduate training for specialized fields of practice.
2. The residency should be organized as a real educational experience provided by qualified teachers who are willing to assume responsibility for adequate instruction.
3. The residency should provide preparation in the sciences basic to the specialty as well as sufficient clinical experience, under supervision, to ensure real competence.
4. The residency should be a joint responsibility of medical schools and of those hospitals able to provide residencies of a satisfactory educational character [21].”

In 1939, 30 approved anesthesia residency programs in the US trained a total of 58 residents [22]. The American Board of Anesthesiology’s 1937 Booklet of Information specified a requirement for three years of training after internship (like the other specialty boards), but this did not become mandatory until 1986. Eligibility for board certification also included a four-year period of practice limited to anesthesiology.

The first written examination conducted by the American Board of Anesthesiology, took place on 28 March 1939 [23]. It

consisted of sections on pharmacology, anatomy, physics and chemistry, pathology, and physiology. Each section contained five essay questions, and the candidate selected three questions to answer (Table 37.1). Three directors of the American Board of Anesthesiology graded each examination, but the logistics of grading would grow in proportion to the number of candidates and the practicalities of duplicating and tracking the essays. The large number of post-World War II military anesthesiologists seeking ABA certification put an end to the essay examination, and the 1948 written examination changed from an essay to 125 multiple choice questions [24].

1941–1957

World War II changed attitudes toward medical specialization. Military physicians with specialty training received increased recognition, compensation, and responsibility. Anesthesiology in particular, benefited from the urgent need to enlarge the then small pool of anesthesiologists, to manage great numbers of casualties. A “crash” program to train many anesthesiologists (and non-physicians) resulted. Stevens Martin conducted the first armed forces anesthesiology didactic courses. These were offered to officers of station or general hospitals, officers of evacuation hospitals, and enlisted men of the Medical Corps on mobile auxiliary surgical teams [25]. The brief courses led students through the requisite basic sciences, anesthetic techniques and recognition of the stages of anesthesia (after all, they would be using ether!), how to recognize and treat cardiorespiratory complications, and the avoidance of fires and explosions (ether, again). The nitty-gritty of everyday anesthesia.

Daily lectures were given for 2–6 weeks, complemented by demonstrations of techniques, and practical instruction given as a preceptorship. Trainees were given unstructured assignments to an operative schedule, and were to undertake preoperative and postoperative rounds. Those assigned to evacuation hospitals learned techniques in inhalation anesthesia, intravenous anesthesia, some regional anesthesia, and tracheal intubation. Enlisted men only learned to deliver open drop ether anesthesia. The objective for all personnel was to learn enough to manage the technical demands of safe

Fig. 37.3 The number of approved residency programs increased from the mid-1930s to the mid-1940s, consistent with the rising interest in a career in anesthesia. That interest was magnified by the enforced recruitment of physicians to anesthesia during World War II and the development of the means to pay anesthesiologists well. (Data taken from [27])

anesthetic delivery. The academic veneer was necessarily thin. By the war's end, many physicians had performed learned the trade we call anesthesia, learned it well, and learned that they liked the requirements placed on them.

After World War II, increasing demands for medical specialization led to a growth in specialty residents at teaching hospitals [14], and the number of US anesthesia residency programs increased almost five-fold over a decade (Fig. 37.3). As would be expected, the numbers of physicians subsequently recruited as residents, reflected this rapidly expanding interest in anesthesiology (Fig. 37.4) [26]. The total number of residents in training in a given year increased more than 4-fold between 1959 and 2006. There was however, a transient decrease in the early to mid 1990s, a dip reflecting a temporary focus on primary care rather than specialty training.

In 1945, the ASA created a "Committee on Postgraduate Education" (chaired by Stevens Martin) whose purpose was "to conduct a thorough study of the possibilities for postgraduate education in anesthesiology [28]". It was designed primarily to serve two groups: 1) returning veterans seek-

Fig. 37.4 The total number of residents in anesthesiology (all) more than quadrupled in the period from 1959 to 2006. The graph also presents the numbers in the CA1 year and the numbers graduating in a given year (grad; from data provided by [26])

ing further training in anesthesiology, and 2) new initiates into the field. Approximately half a decade later, the Committee issued "Recommendations for a Curriculum in Anesthesiology [29]". The committee recommended two types of training: post-graduate refresher courses, or residencies and fellowships in anesthesiology. The term "fellow" was the most variable of the post-graduate training positions during the two decades after World War II, as the fellow could be assigned to one division or even one faculty member in a given department [14]. At some teaching hospitals, the resident was referred to as a "fellow" or "graduate fellow [14]".

The groups served by postgraduate refresher courses included World War II veterans seeking further training. The courses lasted three months or more, and covered general anesthesia, all forms of regional anesthesia, or a combination of both. The courses provided lectures, demonstrations, and group discussions on basic anatomy, physiology, pharmacology, physics, and chemistry. They were supplemented with weekly conferences to discuss "interesting cases and current literature" (M&M plus journal club). Perhaps most impor-

tantly, the participants were preceptees providing supervised anesthetic management of diverse cases. These courses were not a requirement for entrance to the ABA written examination, since the ABA began to require two years of post-internship training, starting in 1945. Instead, these “short courses” were part of the growing recognition that medical knowledge was progressing rapidly, and were designed to help physicians keep up with the latest developments in one’s field [30]. As medical specialties (including anesthesiology) began to develop more rigorous residency training models, these short courses were eliminated as a means of learning a new specialty.

In contrast to the Postgraduate Refresher Courses, recommendations for residency or fellowship prescribed a minimum of 2 years spent in training for candidates with no prior instruction. Diplomates or Fellows in Anesthesiology would supply instruction. Candidates anticipating a position in a university or large institution, were urged to spend 3–4 years in residency or fellowship training.

The committee provided a 96 line “master and all-inclusive” list of subjects in outline form, that had four major headings: Introduction, General Anesthesia, Regional Anesthesia, and Related Subjects. The Related Subjects included topics contained in twenty-first century subject outlines, such as resuscitation, obstetric analgesia, and patient positioning. One subject, “psychology: surgeon–patient–anesthesiologist relationships” is notably absent in present-day subject outlines.

The Committee recommended a minimum case volume of “750 anesthetics per year under direct or indirect supervision, using all established agents and techniques for general and regional anesthesia performed for (all ordinary operations). They should be thoroughly familiar with the principles and practice of preoperative medication, postoperative rounds, bronchoscopy, fluid and inhalation therapy, diagnostic and therapeutic nerve blocks. A maximum of 14 days vacation per year should be given to each resident or fellow in Anesthesiology.” Finally, the committee also encouraged all residents and fellows in anesthesiology to do original laboratory or clinical research, or write a thesis. It is not clear whether the encouragement had any impact, although subspecialty fellowships, in general, provided a greater opportunity for scholarly activities than residencies, which were clinically oriented by nature.

Who might review and regulate residencies? Return to 1940, when representatives of the American Medical Association’s Council on Medical Education and Hospitals, and the American College of Physicians, formed the Conference Committee on Graduate Training in Internal Medicine. This Conference Committee appraised residency programs in internal medicine [31].

During World War II, members of the American Board of Internal Medicine also participated in these reviews. In

June 1948, representatives of the three organizations met to reactivate the Conference Committee on Graduate Training in Internal Medicine. The Committee was charged with the establishment of standards for internal medicine residencies and the evaluation of internal medicine residencies. In May 1950, a parallel organization for surgeons arose. Representatives of the AMA, the American College of Surgeons, and the American Board of Surgery met to discuss a procedure for coordinated approval of surgical residency programs. They sought to, 1) encourage the adoption of uniform standards for residency training in surgery, 2) sponsor an “inspection service” for hospitals offering surgery training, and 3) approve and publish a list of acceptable surgical residency programs. The joint committee was called the Conference Committee on Graduate Training in Surgery. In 1953, the Conference Committee on Graduate Training in Internal Medicine officially changed its name to the Residency Review Committee (RRC) in Internal Medicine, in order to better describe its activities [31].

These experiences prompted the establishment of RRCs in other specialties. The AMA Council on Medical Education and Hospitals proposed that each RRC consist of representatives of the Council and the specific specialty board (“bipartite groups”). A few tripartite RRCs were established, similar to medicine and surgery, by incorporating a specialty society as a third sponsor. By 1957, all but a few of the established specialties had formed RRCs with the goal of formalizing accreditation in graduate medical education [31]. The RRC in Anesthesiology was formed in 1957, with three members representing the AMA Council on Medical Education and Hospitals, three members representing the American Board of Anesthesiology (ABA), and a Secretary who was a member of the Council staff. Residencies were surveyed by Council field staff or Diplomates of the ABA, who represented the RRC. In later years, the ASA sponsored committee members, thus making anesthesiology a tripartite RRC.

1957–1967

In 1962, the Anesthesiology RRC allowed residency programs to be approved for three years of training instead of two. The program had to offer research approved by the program director, subspecialty training in clinical anesthesia more advanced than the “usual” experience, or study in another clinical discipline. There was a benefit to participating in a three year program—the candidate was eligible to take the ABA written examination immediately after completion of training. Candidates who completed two years of anesthesia training were required to submit proof of four years of anesthesia practice over and above residency or fellowship training, prior to taking the written examination.

1966—The Citizen’s Commission

In 1962, the Board of Trustees of the AMA appointed a Citizen’s Commission on Graduate Medical Education, to study the problems in the graduate education of physicians. In 1966, the Commission, led by John Millis, president of Western Reserve University, issued its report. Five issues of paramount importance were highlighted [32]:

1. Discontinuity of the educational process
2. Persistence of apprenticeship in the process of education and training
3. Ineffectiveness and inadequacy in the organization of existing institutions of medical education
4. Failure to decide the role of the university in graduate medical education
5. Unsatisfactory balance between generalization and specialization

Accreditation of internships by the Internship Review Committee of the AMA, and accreditation of residencies by a separate RRC for each specialty, was cited as an example of discontinuity in the educational process. The Citizen’s Commission also recommended that a new Commission on Graduate Medical Education be established, to review and approve standards for graduate medical education. Although the recommendation was never applied, this illustrated an early attempt to demonstrate accountability in the training of physicians.

1972—Birth of the Accreditation Council for Graduate Medical Education

In 1972, discussions between the AMA, the Association of American Medical Colleges, the American Board of Medical Specialties, the American Hospital Association, and the Council on Medical Specialty Societies, led to the creation of two new accrediting bodies in medical education [33]. The Liaison Committee on Graduate Medical Education (LCGME) was established to serve as the official accrediting body for graduate medical education, and the Coordinating Council on Medical Education (CCME) was established to consider policy matters for both undergraduate and graduate medical education. In 1980, the CCME was disbanded after years of disagreements among the five parent organizations.

The LCGME first met in December 1972, and was charged with the responsibility for accrediting graduate medical education programs, after reviewing the recommendations of individual RRCs. In 1975, the LCGME began to formally accredit programs. In 1981, the LCGME adopted a new name, the Accreditation Council for Graduate Medical Education (ACGME) [33]. The number of residency programs grew over the intervening years. In the academic year 2008–2009, there were 8,734 ACGME-accredited residency

programs in 130 specialties and subspecialties. The number of active full-time and part-time residents for the academic year 2008–2009 was 109,482 [34].

1980s—Society for Education in Anesthesia

Believing that a broadly based organization of teachers of anesthesiology could improve education in anesthesia, a group of junior anesthesia faculty in the US founded the Society for Education in Anesthesia (SEA), in the early 1980s. Philip Liu, an anesthesiologist at the Massachusetts General Hospital, was “chairman pro tempore” of the fledgling organization. In the first SEA newsletter in February 1984, he expressed his hope that “members of this Society will develop a genuine sense of fellowship, so that individuals with an interest and vocation in the teaching of anesthesiology will find a network of support and a resource for communication.” The first annual meeting and workshop of the SEA was held in October 1985, in San Francisco, with a meeting theme of “Training Residents for Competence.” Over time, the SEA has served as an organization promoting the teaching of anesthesiology to medical students and residents. While individual members of SEA have served on the Anesthesiology RRC, the SEA has not asserted itself as an influential organization with respect to oversight or direction of anesthesia education.

The Duty Hours Era—1980s to Present

Training demanded extreme amounts of interns’ and residents’ time. For many years, it was common for an intern or resident to take “call” (staying in the hospital to admit and care for patients) every other night. On the post-call day, the intern or resident would remain in the hospital until the evening in order to tend to patient care needs. In this manner, over 120 hours of a possible 168 hours per week might be spent at work. While the culture of dedication to patients and one’s professional work had its advantages, there was no doubt about the associated fatigue, and eventually about the limitations of performance that accompanied sleep deprivation. In the 1950s and 1960s, psychologists defined some of the effects of sleep deprivation, including reduced vigilance and cognition. A 1971 study showed that sleep-deprived interns (0 to 4 hours of sleep, mean of 1.8 hours) were twice as likely as a rested intern (7 hours sleep) to miss cardiac arrhythmias on an electrocardiogram [35].

However, it was the 1984 death of college student Libby Zion that brought resident duty hours to the national spotlight [35]. Zion was admitted to New York Hospital with fever, tremors and disorientation. She was diagnosed with a “viral syndrome”, i.e., effects of a viral infection, and given intravenous hydration. She also received the painkiller and

sedative meperidine, which likely caused a drug reaction with an antidepressant drug that she was taking, phenelzine. She developed extreme fever (107 degrees) and died of a cardiac arrest. Zion's father was Sidney Zion, an influential journalist with the *New York Daily News*. After learning more about his daughter's care, he became convinced that her death was the result of poor staffing at the hospital, including residents working too many hours, and covering too many patients with inadequate supervision [36]. A Manhattan grand jury investigation criticized the 36-hour duty periods worked by the residents, and the inadequate supervision by attending physicians [36, 37]. The New York Health Commissioner formed a committee that became known as the Bell Commission, led by primary care physician Bertrand Bell, a long-time critic of the lack of supervision of interns and residents [36]. The Bell Commission's 1987 report recommended an 80-hour per week limit on resident duty hours, a maximum of 24 consecutive hours on duty, and the requirement for senior physicians to be present in the hospital [37]. These recommendations were incorporated into the New York State Health Code in 1989, making New York the first (and so far, only) state that has adopted regulations for resident duty hours [36, 37].

The ACGME and the AAMC also formed task forces, and provided position statements on duty hours. However, progress was slow. In 1992, the ACGME approved requirements that all programs require one 24-hour period per week without patient care responsibilities, with call limited to every third night. While the 1992 ACGME rules did not specify hourly limits on resident duty hours, many individual specialty RRCs imposed such limits, including internal medicine, dermatology, ophthalmology, and emergency medicine. Most of these RRCs chose 80 hours as the weekly limit, with emergency medicine setting a limit of 72 hours [37]. The pressure mounted, however, when a 2001 petition requested that the Occupational Safety and Health Administration (OSHA) regulate duty hours of residents because of its potential role as a workplace health hazard. Also in 2001, the US Congress considered legislation to limit resident work hours [37]. Finally, in 2003, the ACGME set a maximum limit on the duty hours of residents in all specialties, of 80 hours per week. They also set a maximum of 24 hours of continuous duty, plus 6 hours for continuity and transfer of care.

Were patients safer as a result of these changes? The answer is not clear, given the many factors that impact on patient outcomes, and the complexity of the modern health care system. The Institute of Medicine (IOM), the health arm of the National Academy of Sciences, is an independent organization that advises the public and national decision makers, both private and governmental. Congress requested that the IOM study the relationship between resident duty hours and patient safety. In 2008, the IOM released a report titled "Resident Duty Hours: Enhancing Sleep, Supervision, and

Fig. 37.5 Sim One, the first computer-controlled patient simulator lies on the table, attended by Judson Denson (*left*) and Stephen Abrahamson in the 1960s at the University of Southern California. (From [41]. Copyright (c) 1969 American Medical Association. All rights reserved)

Safety.” The report “asserts that revisions to medical residents’ workloads and duty hours are necessary to better protect patients against fatigue-related errors and to enhance the learning environment for doctors in training. The report recommends that residency programs provide regular opportunities for sleep each day and each week during resident training [38].” Subsequently, the ACGME revised its common program requirements to include additional restrictions on duty hours, the most notable being a reduction of continuous duty for interns to 16 hours maximum. However, the ACGME also addressed other aspects of patient safety, including new standards for supervision, teamwork, transitions of care, fitness for duty, alertness management, and fatigue mitigation [39].

Late 1980s—The Simulation Era

In the mid 1960s, the first computer-controlled mannequin simulator was created at the University of Southern California. Underlying its development was the question “how can computers be used in medical education?” Anesthesiologist Judson Denson and engineer Stephen Abrahamson received a \$272,000 grant from the US Office of Education, and created the simulator (nicknamed “Sim One”) in collaboration with Aerojet General Corporation and Sierra Engineering (Fig. 37.5) [40, 41]. Lifelike features of the simulator included a chest wall that moved with respiration, blinking eyelids, anatomically correct airway structures, and palpable carotid and temporal pulses.

Sim One was used for an educational study of tracheal intubation skill acquisition, by new anesthesia residents. In the study, the investigators trained ten new anesthesia residents in how to check their anesthesia equipment, provide oxygen to a patient, induce anesthesia, intubate the patient's trachea, and stabilize anesthesia after intubation. Five residents were trained with Sim One, and the other five were trained in the operating room with real patients. A checklist of required actions was used to give the resident feedback on the relevant steps in the process. Once training was complete, the investigators determined the number of days until a resident completed nine consecutive successful tracheal intubations. Simulator-trained residents took 46 days on average, while conventionally trained residents took 77 days [41]. In other words, the simulator-trained group took less time to achieve the same performance benchmark. Because of limitations in computer technology at the time, Sim One was never commercialized.

Fast-forward to the 1980s. David Gaba at Stanford University Medical School created the Comprehensive Anesthesia Simulation Environment (CASE), to investigate human performance in anesthesia [42]. Michael Good and JS Gravenstein at the University of Florida developed the Gainesville Anesthesia Simulator (GAS) to help teach basic clinical skills to anesthesia residents [40]. The two groups were also influenced by the desire to improve patient safety in anesthesia. Over the next decade, these two simulators were produced commercially. The CASE system ownership changed repeatedly, eventually being sold to Medsim Ltd in Israel. GAS was licensed to Loral Data Systems, Inc, and a new company called Medical Education Technologies Inc (METI) in Sarasota, Florida. The CASE system was used by Gaba to create a training curriculum called Anesthesia Crisis Resource Management (ACRM), which was based on the aviation model of crew resource management [43]. The initial description was even published in an aviation journal.

From the late 1990s through to 2010, training with computerized simulators grew rapidly despite limited evidence of sustained efficacy. In the year 2000, there were less than 200 of these simulators in the world, but by 2011, the METI company reported that over 7000 institutions use its simulation products worldwide [44]. During this time, the cost of a computerized mannequin simulator decreased from \$250,000 to \$30,000. In 2009, the American Board of Anesthesiology required simulation training as part of its Maintenance of Certification in Anesthesiology (MOCA) recertification process. In 2010, the Anesthesiology RRC instituted a requirement of at least one simulated clinical experience per year.

Several factors led to the widespread adoption of simulators for training. Trainees generally reacted positively to

this form of teaching, and many studies showed that learning objectives could be achieved at least as effectively as with traditional teaching methods. In addition, management of rare events such as malignant hyperthermia could be "practiced" repeatedly in a controlled setting. However, no large-scale randomized trial of simulator-trained clinicians versus non-simulator trained clinicians has examined the impact on patient outcomes. Because of the low morbidity rate attributable to anesthesia, such a study would involve large numbers of patients. To this criticism, Gaba has argued that "no industry in which human lives depend on the skilled performance of responsible operators has waited for unequivocal proof of the benefits of simulation before embracing it. In my opinion, neither should anesthesiology [45]."

The costs of developing a simulation education program are substantial. A typical budget would include the acquisition cost of the simulator, clinical equipment to promote realism, audiovisual equipment to facilitate video-based debriefing techniques, and personnel to teach and administer the simulation courses. While simulation programs are clearly part of the fabric of modern anesthesia training, the cost/benefit ratio may be quite high.

1990s–2010—The Development of Subspecialty Anesthesia

Since the 1990s, the most notable changes in anesthesia education have been the increase in sub-specialty and non-operating room clinical experiences. Beginning in the 1980s, the ABA required subspecialty anesthesia training, including obstetric anesthesia, pediatric anesthesia, cardiothoracic anesthesia, neuroanesthesia, anesthesia for outpatient surgery, recovery room care, regional anesthesia, pain management, and critical care medicine. Initially, the required duration of each experience was not specified by the ABA or the RRC, except for critical care, which had a 2 month minimum [46]. In 1985, the ABA began to issue certificates in critical care medicine to candidates completing one year of specialized training, the first subspecialty in anesthesia to receive such recognition [46]. In 1991, the ABA began issuing certificates in pain management. The recognition of these two subspecialties was indicative of the increased attention to subspecialty training in anesthesia, which occurred at both residency and fellowship levels. It was also a reflection of the ever-increasing complexity and specialization of medicine in general.

In the course of residency, the RRC now requires two month-long rotations in obstetric anesthesia, pediatric anesthesia, neuroanesthesia, and cardiac anesthesia. Non-OR required rotations include critical care medicine (four

months), post-anesthesia care unit (2 weeks), preoperative medicine (one month), and pain medicine (one month each of acute, chronic, and regional). The increase in non-OR rotations, combined with the increased complexity of the specialty OR rotations, has resulted in the need for fellowship training to properly prepare for certain anesthesia subspecialties. Fellowships have become much more rigorous, especially if they must conform to the requirements of the ACGME. Currently, the ACGME accredits one-year fellowships in several anesthesia subspecialties: critical care medicine, pain medicine, pediatric anesthesia, cardiothoracic anesthesia, and obstetric anesthesia. In addition, some departments offer non-ACGME fellowships in areas such as obstetric anesthesia, regional anesthesia (including ultrasound), liver transplant anesthesia, and operating room management.

What does this mean for anesthesiology training in the twenty-first century? The “general” anesthesiologist, capable of caring for patients in any subspecialty will be a relic of the past. Increasingly, anesthesiologists will focus their practice in one or more subspecialties, and if a particular subspecialty is governed by an ACGME fellowship, then the fellowship will be the only path for training.

Summary

In 1932, the Association of Anaesthetists of Great Britain and Ireland (AAGBI) was founded. Shortly thereafter, anesthesia societies arose in France and Italy. In 1935, the AAGBI established a Diploma in Anaesthetics (DA) and in 1940, Torsten Gordh introduced instruction in anesthesia in Sweden. World War II isolated Europe from anesthetic advances in the US and UK. However training programs began in many European countries soon after 1945, and European countries increasingly recognized anesthesia as a medical specialty.

In 1957, six countries signed the Treaty of Rome, creating the European Economic Community (EEC) that grew into today's European Union (EU) with 27 member states. Increasing mutual recognition of medical qualifications and harmonization of medical education accompanied this political process. In 1958, the European Union of Medical Specialists (UEMS) was founded, and in 1962 Specialist Sections were created, including one for Anaesthesiology. In 1963, the UEMS stipulated a minimum of 3 years training in anesthesia, increasing to 4 years in 1969. By 1973, training varied between 3 and 7 years in EEC countries and 2 and 6 years in non-EEC countries.

Before 1960, relatively few European anesthesiologists existed, nurse anesthetists giving most anesthetics (under a surgeon's direction). From 1960 to 1970, France, Sweden, Finland, Germany, Norway, the Netherlands, and Switzerland established formal educational programs for nurse anesthetists. From 1970 to 1990, growing numbers of anesthesiologists allowed increasing supervision of all non-physician anesthetists.

Beginning in the 1960s, national anesthesia training programs gradually incorporated intensive care, emergency medicine, and pain management, with variations among countries in duration and design of curricula. Founded in 1982, the European Society of Intensive Care Medicine (ESICM) created the European Diploma in Intensive Care (EDIC) in 1988.

Founded in 1978, the European Academy of Anaesthesiology (EAA) established the European Diploma in Anaesthesiology and Intensive Care (EDA) in 1984, with a two part, multi-lingual Diploma examination. In 1993, the Specialist Sections of the UEMS formed educational Boards, leading to the European Board of Anaesthesiology (EBA) which became the specialty's monitoring authority within the EU. The EBA developed guidelines for training anesthesiologists, coordinating activities with the EAA until 2005, and with EAA's successor, the European Society of Anaesthesiology (ESA), since 2006. Established in 1986, the Foundation for European Education in Anaesthesiology (FEEA) promoted Continuing Medical Education (CME). Since 1990, recertification required evidence of annual CME in about 60% of European countries.

Growing demands for and on anesthesiologists may lead to relative shortages in Europe. With increasing cost constraints and the EU Directive decreasing working hours, this may increase reliance on nurse anesthetists.

The Development of Anesthesia as a Specialty in Europe

Marked variations among European countries characterized the development of educational programs in anesthesia, before and after 1945. In the 1930s, a few dedicated physicians directed their professional activities towards anesthesia. In the UK, general practitioner anesthetists, junior hospital doctors, or medical students gave most anesthetics. General practitioner anesthetists received no fee for their work in "voluntary" hospitals and relied on general practice to earn

their living. Founded in 1932, the Association of Anaesthetists of Great Britain and Ireland instigated an examination for a Diploma in Anaesthetics in 1935, and trained full-time anesthetists during World War II. These Diplomates were already in place when anesthesia was recognized as a medical specialty in 1948.

In France and Italy, anesthesia societies were founded and instruction in anesthesia sporadically organized in the mid 1930s, on the personal initiative of surgeons dedicated to anesthesia. In Germany, demands for independent professional recognition of anesthesia were made in 1928 and again in 1939, but failed due to the opposition of surgeons, the dominant force in the operating room. Most powerful was Ferdinand Sauerbruch from Berlin, who rejected modern anesthetic techniques like endotracheal intubation and opposed initiatives to remove anesthesia from the surgeon's control. His influence extended beyond Germany to much of continental Europe. In addition, medicine in Europe was cut off from the advances in anesthesia occurring in the USA and UK during World War II. These circumstances delayed the recognition of anesthesia as an independent specialty, and the introduction of training programs in continental Europe, except in Scandinavia where specialists were already practicing and teaching anesthesia by the first half of the 1940s.

In the first postwar decade, virtually all European countries established training programs in anesthesia, the duration of training varying between 1 to 3 years. The curriculum included specialties like surgery, internal medicine and/or basic sciences because these were, and are, considered important for the practice of anesthesia. Over the ensuing 3 decades, the length of training in anesthesia increased, equalling that in other specialties such as surgery and internal medicine (Table 38.1 and Fig. 38.1). The following paragraphs describe examples of these developments in selected European countries.

United Kingdom

From its founding in 1932, a primary objective of the Association of Anaesthetists of Great Britain and Ireland (AAGBI) was the provision of a Diploma in Anaesthetics (DA). Since only a registered examining body could certify such a Diploma, the Diploma was placed under the Conjoint Examining Board of the Royal Colleges of Physicians and Surgeons. Candidate diplomates had to provide evidence of qualifications in medicine, surgery or midwifery, resident appointments in recognized hospitals for at least 12 months, including 6 months as a resident anesthetist, and delivery of at least 1000 anesthetics. The first examination took place in November 1935 [1, 2]. During World War II, the UK Armed Forces created Field Surgical Teams with surgeons, anesthetists, and supporting staff. The AAGBI oversaw their train-

ing and assessment, fortunately ensuring that by the end of the War, there were sufficient physician anesthetists to meet the needs of the nascent National Health Service (NHS) in 1948 [3, 4]. To ensure the independent eligibility of anesthetists for full consultant status, the President of the AAGBI approached the Royal College of Surgeons, requesting the formation of a Faculty of Anaesthetists. The Council of the College approved this request in February 1948 [1, 2, 4, 5]. The DA was quickly upgraded to a Fellowship Diploma with a two-part examination, a Primary in basic sciences and a Final in clinical anesthesia, medicine and surgery. Medical graduates could apply for Part I after completing 6 months as a House Physician or House Surgeon; Part II could be sat 2 years after passing Part I and after completing at least 12 months of specialty training in anesthesia. In 1953, the new DA became the Diploma of the Fellowship of the Faculty of Anaesthetists of the Royal College of Surgeons (FFARCS).

The Royal College of Surgeons retained responsibility for the FFARCS until 1983, when it passed to the Faculty of Anaesthetists. In 1988, the Faculty of Anaesthetists became the College of Anaesthetists, still based at the Royal College of Surgeons. In 1992 the College received Royal status, thereby achieving independence as The Royal College of Anaesthetists (RCoA) [4, 5].

Since 1992, the training leading to a Certificate of Completion of Training (CCT) in Anaesthetics has had a duration of 7 years. A trainee must follow a competency based program covering basic, intermediate, higher and advanced training in anesthesia, pain medicine and intensive care medicine (ICM). Basic, intermediate and higher training each normally last 2 years, followed by advanced training, normally lasting 1 year. Trainees are expected to pass the Primary FRCA examination during the basic, and the Final during the intermediate levels of training. Those who pass are inducted as Fellows of the College and can use the letters FRCA after their name.

France

In the 1930s, French surgeons and anesthetists sporadically organized training in anesthesia. Anesthesia became an independent medical specialty after World War II [6]. In 1946, two anesthetists, Ernest Kern and Nadia du Bouchet, who had trained during wartime in England and the US, held the first course in anesthesia in Paris. In 1947, surgeons Pierre Moulouquet and Jean Baumann, with anesthetists Louis Amiot, Geneviève Delahaye-Plouvrier, du Bouchet and Kern, organized a formal, one-year, university-based course of training and theoretical study. A Diploma of Anesthesia was granted after success in an examination.

In 1948, the Ministry of National Education created a Certificate of Specialized Studies in Anesthesia (CES, Certificat

^ 1955-1969 two years and 1970-1976 one year of internship had to precede the specialist training program (not included in this table)

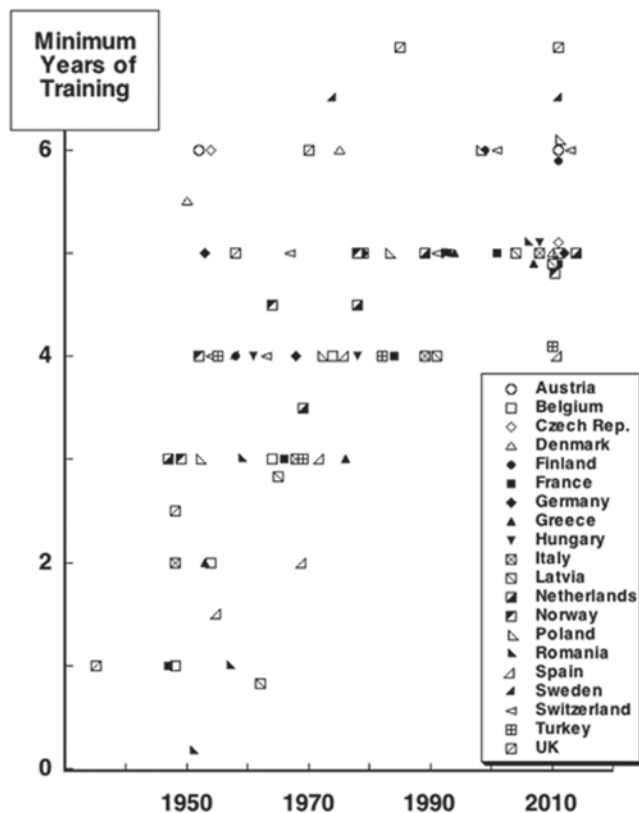

Fig. 38.1 The minimum years of training in anesthesia and related areas in 20 European countries progressively increased from the 1940s to the 1990s

d'études spéciales d'anesthésie) to be granted by the Faculties of Medicine. Training lasted for at least 2 years and included 70 lessons, hospital training and a final examination. In 1966, mandated training increased to 3 years. In 1988, the Diploma of Specialized Studies (DES, *Diplôme d'études spécialisées*) replaced the CES. Admission to this new postgraduate specialist training program (now called "internat qualifiant"), required doctors graduating after 1984 to take a competitive entry examination common to all specialties, the specialty that candidates could ultimately choose being dependent on their ranking success. In 2002, the required duration of postgraduate training in anesthesia increased to 5 years. Trainees receive theoretical training (basic sciences 60 h, anesthesia-pain 150 h, intensive care and emergency medicine 150 h), while pursuing practical training (3 years anesthesia and 2 years ICM; 1 year of which can be replaced by a specialty related to anesthesia).

Admission of medical students to a specialist educational program, after their 6th year, now requires passage of a national classifying examination (introduced in 2004) in lieu of the examination for the "internat". Based on the test results, the student may select a specialty for training. After 5 years of training, a trainee must submit proof of having met the

requirements specific to his/her specialty, and must present a thesis to a regional jury to receive the final Diploma (DES). A supplementary Diploma (DESC, *Diplôme d'études spécialisées complémentaires*) in non-surgical ICM, emergency medicine, pain and palliative medicine, hemobiology and transfusion, or clinical pharmacology may be obtained with 2–3 years of additional training.

Sweden

In Nordic countries, anesthesiology emerged earlier than in the large countries of continental Europe. One of the most influential pioneers was Torsten Gordh, who trained in Ralph Waters' Department in Madison, Wisconsin in 1938, and in 1940 became the first full-time anesthesiologist (at Stockholm's newly opened Karolinska Hospital) – not only in Sweden, but also in continental Europe. He immediately introduced training programs for doctors, students and nurses [7]. The National Medical Association recognized anesthesiology as a separate specialty in 1953. In 1960, the National Board of Health and Welfare officially followed suit. Initially, 3 years of anesthesia training were required to be included as a specialist on the register of "License to Practice". In the early 1970s, this changed to 5 years and included 6 months training in both a medical and surgical specialty, as well as 6 courses in basic sciences. The National Board of Health and Welfare determined the general rules for education of specialists, but the Swedish Society of Anaesthesiology and Intensive Care Medicine determined the details [8]. The European Diploma in Anaesthesiology and Intensive Care (EDA) examination, though voluntary, has been regarded as the national examination since 1989 [9].

Denmark

In Denmark the first doctor to undertake specialist training in anesthesiology was Trier Mørch, in 1940 [10]. Willy Dam-filled the first anesthesiologist appointment, established in 1944 at Bispebjerg Hospital in Copenhagen. The National Health Service recognized anesthesiology as an independent specialty in 1950. Training requirements included 2 years of anesthesiology, 1.5 years of surgery, 1 year of internal medicine, and a 1 year course at the WHO Anaesthesiology Centre in Copenhagen (see below), followed by an examination. Training in pharmacology, physiology or biochemistry could replace 6 months of internal medicine. The requirements changed on several occasions. In 1975 they were: 4 years of training in anesthesiology, consisting of 2 years of theoretical training, and 2 years of training common to all specialties [11]. In 2004, the Danish Society of Anaesthesiology and

Intensive Care Medicine's Postgraduate Training Manual prescribed 5 years of training, including 13 months in Intensive Care Medicine (ICM), 3 months in pain therapy, and 3 months in emergency medicine and trauma care. No compulsory specialist examination has existed since 1971. Since 2000, a performance-based assessment developed in detail for the first years of training has increasingly replaced the end-of-training examination [12]. A national hospital visiting program was introduced concurrently, to ensure that all centers fulfilled the conditions needed to provide adequate training.

The early 1950s saw development of two important events in anesthesiology in Copenhagen. First, a training center in anesthesiology was established in response to a request by the World Health Organization (WHO) to the Faculty of Medicine of the University of Copenhagen. The Centre organized 23 one-year courses, the first commencing 1 May 1950. Foreign instructors included Ralph Waters and Stuart Cullen, followed by Robert Macintosh, Henry Beecher, Jack Moyers, Leroy Vandam, Francis Foldes, and Torsten Gordh. From 1952 to 1974, 220 Danish and 205 European trainees, and 218 trainees from outside Europe, attended the courses [11, 13]. The second event was the 1952 poliomyelitis epidemic in Denmark. Led by Danish anesthesiologist Bjørn Ibsen, patients with life-threatening poliomyelitis were concentrated in one area and treated with controlled ventilation. These actions markedly decreased deaths, and their imitation led to the establishment of the first intensive care unit one year later [14].

Norway

The Norwegian pioneers were Otto Mollestad, who trained and qualified in Oxford with Macintosh, and Ivar Lund, who trained in Boston with Henry Beecher. Mollestad took the first anesthesiologist appointment at Rikshospitalet in Oslo in December 1946, and Lund joined the Ullevål Hospital one month later. Anesthesiology was recognized as a separate specialty in 1949. Training requirements for qualification as a specialist developed in parallel to those in other Scandinavian countries [8, 15]. Currently, education is based on a curriculum of 5 years including 6 months in ICM and 6 months served in any specialty other than anesthesiology, preferably internal medicine or pediatrics, or in research. There are 260 mandatory course hours in specific topics. As in Denmark and Sweden, the Norwegian Medical Association has not adopted examinations although the Norwegian Society of Anaesthesiology voted for a national examination in the early 1980s. A hospital visiting program introduced in the early 1980s evaluates the adequacy of training programs.

Finland

In 1940, Eero Turpeinen studied new methods of anesthesia with Torsten Gordh in Stockholm, but World War II cut short his stay. In 1945, he completed his anesthesia training in the US, and in 1948 he became the first Finnish specialist in anesthesia. From 1950 to 1967, most Finnish training in anesthesia occurred at the WHO courses in Copenhagen. The first dedicated residency posts in anesthesiology were founded during 1952 to 1955, and the post of chief anesthesiologist at Turku University was established in 1954. Criteria for training and accreditation were devised in 1955, based on a proposal by the Finnish Society of Anaesthesiologists. Anesthesiology was officially recognized as a separate specialty and a training program started in 1958 [4, 16]. Today the duration of training is 6 years, including 15 months in general practice and supporting disciplines, 4 years in anesthesiology, and 9 months in ICM. Of the 4 years in anesthesiology, a maximum of 3 years may be spent in a university hospital. The EDA examination can replace a written examination at the end of training, but no hospital visiting program exists.

Germany

Pressure in Germany for an independent professional identity for anesthesia arose in 1928 and again in 1939, but failed due to opposition from surgeons. World War II separated German medicine from the outside world [17, 18]. Soon after the War, many surgeons realized that anesthesia had enabled enormous advances in surgery, and consequently began sending young doctors to anesthesiology centers in the US, UK, Scandinavia, France and Switzerland [19]. Conversely, foreign anesthetists like Jean Henley (New York) and Karl Müllly (Zurich) visited German hospitals and taught modern anesthesia [20, 21]. In September 1953, the German Medical Assembly voted to include anesthesia as an independent discipline in the official list of medical specialties. The German Society of Anaesthesia had been founded just five months earlier. The duration of training was set at 5 years: 1 year of general medicine (as for every specialty at that time), 1 year of surgery, 6 months of internal medicine, 6 months physiology or pharmacology, and 2 years of anesthesia. In 1968, adapting to the widening responsibilities of anesthesiology, the duration of training specifically devoted to anesthesia increased to 4 years. Training in physiology, pharmacology, internal medicine, a lung function laboratory or a blood bank could replace 6 months of the 4 years. Trainees had to document the successful administration of 1200 anesthetics, and experience in ICM including artificial ventilation. Between 1955 and 1969, graduates from medical schools had to serve 2 years as an intern before being entitled to enter a specialist

training program. This period was shortened to 1 year in 1970 and after 1976, the internship requirement ceased.

In 1987, training in ICM was set at 6 months and the minimum number of anesthetics was increased to 1800, including 100 regional blocks. In 1992, the duration of training continued to be 5 years: 4 years anesthesia and 1 year anesthesiology based ICM. An anesthesia-related specialty could replace 1 year of anesthesia training [18]. A final oral examination was introduced in 1978, organized by the State Chambers of Physicians (*Landesärztekammern*), which are officially responsible for both postgraduate medical training and continuing medical education. They also govern the recognition of training centers.

Austria

In the summer of 1947, the non-profit Unitarian Service Committee, sought to assist European refugees subjected to Nazi persecution, and sent a group of American anesthesiologists to Austria. They visited the Faculties of Medicine, gave lectures and demonstrated modern anesthetic techniques. This prompted some visionary surgeons to send assistants to the US and the UK [22]. In 1951, the Austrian Society of Anaesthesiology was founded, and in June 1952, the Federal Ministry of Social Administration recognized anesthesiology as an independent medical specialty. Training lasted 6 years, and consisted of 3 years of general medicine and 3 years of anesthesia, including basic sciences. Training in anesthesia increased to 4 years in 1981, and to 5 years in 1994, including 2 years of ICM. In addition, 6 months of surgery and 6 months internal medicine were required, resulting in a total duration of 6 years. At this time, the specialty was renamed “Anesthesiology and Intensive Care Medicine” [22]. A compulsory examination was introduced in 2002, and candidates could replace about half of the final examination with the Part I Examination for the EDA [23]. Since June 2010, all candidates have had to take the EDA Part I. If they pass, the number of oral examinations they must take during the final examination decreases from 8 to 4. In addition, the EDA Part II examination can be taken instead of the final national examination.

Switzerland

After World War II, the Swiss Academy of Medical Sciences recognized the need to adopt new developments in medicine in general, and anesthesiology in particular. It granted a clinical fellowship to Werner Hügin (Basel), who trained in Beecher’s Department in 1947–1948. Others followed, and in 1952 they formed the Swiss Society of Anaesthesiology. They successfully petitioned the Swiss Medical Association to recognize anesthesiology as a specialty in January

1954. Training lasted 4 years, including 2 years in anesthesia (18 months in Switzerland and, until 1962, 6 months in a foreign training center). After 1961, training in anesthesia could be entirely undertaken in Swiss anesthetic departments. In 1963, training in anesthesia increased to 3 years at the expense of non-anesthetic training, and in 1967, to 4 years resulting in a total duration of 5 years (4 years in anesthesia and one year in non-anesthesia training). In 1991, 3 months of ICM became mandatory, increasing to 6 months in 2001 with a total duration of training of 6 years [24]. By 2013, the one year non-anesthesia training will be cancelled upon request of the Federal Government and the total duration of training will again be 5 years. The Swiss Society of Anaesthesiology and Reanimation (SSAR) introduced an optional examination in 1979. The SSAR persuaded the Swiss Medical Association to make the examination compulsory in 1986. One year later, the Part I EDA examination was adopted as the national written examination. Part II was organized as a national oral examination by the SSAR from the outset [25].

The Netherlands

Doreen Vermeulen-Cranch, from University College Hospital in London provided the first formal teaching in anesthesia, doing so in Amsterdam in January 1947. The first national training curriculum was proposed and accepted in 1947, with 2 years’ training in anesthesia following 6 months in each of basic internal medicine and basic surgery. The Netherlands Society of Anaesthesiology (NSA) was founded in January 1948, and anesthesia was recognized as a medical specialty in that year. Training duration in 1954, 1969 and 1974 stepwise increased to 4.5 years and included training in basic sciences, ICM (6 months) and pain medicine (3 months) [26]. A five-year training program was established in 1989. Training guidelines were revised in 1996 and again in 2004, with the addition of specific learning goals. Examinations were offered from the beginning, but met with resistance. In 1989, a basic written and a final oral examination became mandatory. These examinations evolved into annual examinations A, B and C for training years 1, 2 and 3, with a final oral examination on three clinical cases. With the installation of new training guidelines in January 2011, competency based training in modules was implemented and changes to the EDA examination are planned. A delegation of the Board of Accreditation of the NSA inspects all medical specialist training institutions, at least once every five years.

Belgium

Belgian pioneers William De Weerd and Jan Van de Walle, both trained in Macintosh’s Department in Oxford. They

established anesthesia services in the two University Hospitals of Leuven in 1947 and 1948 respectively, and began training courses in 1948. Two years training and conduct of a scientific project entitled trainees to the Diploma of Specialist in Anaesthesiology. In 1951, Van de Walle's division became an independent Department, and regular payment of anesthetists was introduced. Admission Boards for medical specialties were established in 1958 [27]. Anesthesia was officially recognized as an independent specialty in 1964. Postgraduate training in anesthesia existed in University Hospitals. The curriculum lasted 4 years, but a Diploma was not essential for specialist recognition. A Decree of the Federal Minister of Health issued in September 1979, prescribed the requirements of training centers, setting the duration of training in anesthesiology at 5 years. If post-anesthesia training included 12 months of training in ICM, anesthesiologists could be accredited as anesthesiologists specializing in ICM. Anesthesiologists and other specialists could obtain a supplementary certificate of competence in emergency medicine after an additional training of 1 to 2 years. This option was replaced by the creation of 2 new separate specialties, acute medicine and emergency medicine, in 2005.

Italy

Italian anesthesia evolved from 1947 to 1950 when open-minded surgeons encouraged young assistants to learn modern anesthetic techniques, some in the US, and some in the UK. "Schools of specialization" in anesthesiology formed within medical schools. The first, in Torino in 1948, offered a postgraduate training program of 2 years. A parliamentary bill in July 1954, created independent anesthesia services in hospitals, thereby granting the specialty formal recognition [28]. The duration of training increased to 3 years in 1968, and to 4 years in 1989. Anesthesia services became strongly connected with ICUs, and in 1979, the Italian Society of Anaesthesia changed its name to the Italian Society of Anaesthesia, Analgesia, Reanimation and Intensive Therapy. In 2008, anesthesia training was harmonized with that of the European Board of Anaesthesiology, and the duration of training increased to 5 years, including training in basic sciences. The specialty now officially became Anaesthesia, Reanimation and Intensive Care Medicine. Trainee assessment relied on annual oral examinations in each of the training centers, and the evaluation of skills by the responsible tutors.

Spain

Civil War (1936–1939) and World War II markedly delayed the development of anesthesia in Spain. After 1945, some physicians trained as anesthesiologists in the UK, especially

in Oxford, and in the US. In 1952, the Spanish Army recognized the position of specialist in anesthesia, establishing regulations for training. In the same year, the public health system (Seguridad Social) called for the establishment of the first positions for specialists in "anaesthesiology and reanimation". "Anaesthesiology and reanimation" first appeared as a medical speciality in the Official Bulletin of the Government (Boletín Oficial del Estado) in July 1955. In 1969, the Universities of Granada, Valencia and Barcelona opened the "University Schools for Professional Education of Anaesthesiologists" (Escuelas Profesionales de Anestesiología). Diplomas of anesthesiology were given after programs lasting 2 years.

In 1972, an official postgraduate program called MIR, "Médicos internos y residents" defined training in anesthesiology and reanimation, as well as all other specialties [29]. Many public hospitals then offered positions for residents in anesthesiology with a training duration of 3 years. 1976 saw the first 4 year residency program in the MIR system, and the 1996 guidelines for training in anaesthesiology and reanimation mandated 4 years of training. While there is an annual entry examination for every specialty, no final examination is required to obtain the relevant specialist diploma. With the inception of the MIR system, ICM was recognized as an independent specialty. Until then however, anesthesiologists or cardiologists directed ICUs, and the separate specialist recognition of ICM is considered a major problem for anesthesia. Spanish anesthesia trainees still devote at least 6 months of their training to ICM, and are legally allowed to work in the ICU.

Poland

Many Polish surgeons and anesthetists trained in the UK during World War II, returning to Poland when the war ended. They petitioned health care organizers to encourage the development of anesthesiology. In 1951, Mieczysław Justyna, Assistant Professor, was appointed as the national consultant for anaesthesiology and devised a program for specialization in anesthesiology. Based on this program, the Ministry of Health mandated 3 years training in anesthesia, of which 5 months would be spent in internal medicine and 11 months in surgery. In 1973, training increased to 4 years. In 1978, the name of the specialty became Anaesthesiology and Resuscitation and, in 1983, changed to Anaesthesiology and Intensive Care. Between 1983 and 1998, training in anesthesia and intensive care took 5 years, 3 years in the former and 2 years in the latter. In 1998, training increased to 6 years: anesthesia for 4 years and ICM for 2 years. From 1978 to 2008, the national examination comprised three parts: written, practical and oral. In autumn 2008, the EDA Part I examination replaced the written part of the National Specialization Examination [30, 31].

Table 38.2 Evolution of Anesthesia Training in the USSR (until 1991) and the Russian Federation (after 1991)

Year	Description	Duration of training			
		Total	Anesthesia	ICM	Public health and basic sciences
1956	Primary specialization (“pervichnaya spezializacija”)	2 months	2 months	–	–
1958 to date	Primary specialization (“pervichnaya spezializacija”) Now: professional re-training	5 months or 10 months	approx. 80 %	approx. 20 %	–
1960–1993	Clinical residency (“klinicheskaya ordinatura”)	2 years	approx. 70 %	approx. 30 %	–
1982 to date	Internship (“internatura”)	1 year	approx. 35 %	approx. 35 %	approx. 30 %
1993 to date	Clinical residency (optional: additional 3 years)	2 years (+ 3 years)	approx. 40 %	approx. 40 %	approx. 20 %

USSR and the Russian Federation

World War II probably devastated the USSR (Soviet Union) more than any country in Europe, greatly delaying progress in medicine in general and anesthesia in particular. The introduction of modern techniques such as endotracheal anesthesia began in 1946. In 1956–1957, leading surgical departments began training anesthesiologists, with training lasting 2 months. The first academic department and chair of anesthesia was established at the SM Kirov Military Medical Academy in St. Petersburg, in 1958. In that year, courses for primary specialization of 5 or 10 months duration were introduced and still exist today. In 1960, a so-called residency, i.e., 2-year training in anesthesia, was established as a second route, which since 1993, could be optionally extended to 5 years. The option of extending the residency from 2 to 5 years is virtually never taken up. In 1982, a one year-training program was introduced as a third alternative and called an internship (Table 38.2). Remarkably, these variants are equal from a legal point of view. Although the Professors, Chairs and the All-Union Society of Anesthesiologists played a consulting role, the Ministry of Health independently issued regulations for training and practical work of anesthesiologists. In 1986, the last decree of the former USSR made departments of anesthesiology and intensive therapy mandatory for every hospital. Today, there is no national examination. Efforts continue to persuade the Government to increase the duration of clinical training from 2 to 3 years, with the aim of eventually reaching the European standards of 5–6 years.

The system of parallel methods of qualification in anesthesia was also established in several former satellite states for a period following World War II. Countries which became independent after dissolution of the Warsaw Pact and the Soviet Union in the years 1989–1991, and who subsequently became members of the EU (Baltic States, Czechoslovakia, Hungary, Romania, Bulgaria) abandoned the parallel programs, instead assuming programs consistent with those in the EU.

The Evolution of Educational Components of Anesthesiology

In the 1950s and 1960s, anesthesiologists progressively expanded their expertise in the emerging fields of intensive care, emergency medicine, and pain medicine. Increasingly, these became constituent elements of education and clinical practice in anesthesiology, but anesthesiology was not the only base specialty through which these fields could be approached and certification obtained.

Intensive Care Medicine (ICM)

The 1952 poliomyelitis epidemic in Copenhagen and the initiatives instituted there by Ibsen [3, 4, 14], led to the establishment of one of the world’s first ICUs in December 1953, under Ibsen’s direction. Less well known, the anesthesiologist Åke Bauer had established an ICU in Borås (Sweden) at the same time. Anesthesiologists increasingly led the treatment of patients suffering from respiratory failure from all causes, and also the care of patients with compromised vital functions. These roles made anesthesiologists the leaders of ICM in many European countries, ensuring that ICM became a significant part of training in anesthesia. In the following decades, all European countries developed structures and regulations for education and training in ICM, but with significant differences identified in an international survey of 37 training programs within 28 European countries [32]:

Supra-specialty model: Multidisciplinary access to a single common training program leading to dual specialist certification in a base specialty and ICM was the most frequent type of training (15 countries), e.g. Netherlands, UK, France, Belgium, Finland, Portugal.

Multiple sub-specialty model: ICM training provided by multiple parent specialties, each with their own training programs provided dual certification or base specialty certification, including ICM (Austria and Germany).

Single sub-specialty model: Single parent specialty without multidisciplinary access provided ICM training. Dual certification or base specialty certification, including ICM (13 countries), e.g. Scandinavia, Italy, Poland, Czech Republic, Slovakia.

Primary specialty: Base specialty with access directly after graduation from medical school, leading to specialist certification (Spain and Switzerland).

At present, the duration of training usually ranges between 12 and 24 months, but is at least 36 months in Spain and Switzerland [33]. Some typical training programs will be briefly described.

United Kingdom

In 1992, the Royal Colleges of Anaesthetists, Physicians, and Surgeons formed the Joint Advisory Committee for Intensive Therapy which became the Intercollegiate Board for Training in Intensive Care Medicine (IBTICM). The RCoA was designated as the lead college. In 1999, the Specialist Medical Order was modified to include ICM as a joint Certificate of Completion of Training (CCT) with a base specialty. The IBTICM evolved into the Faculty of Intensive Care Medicine of the RCoA at the end of 2010. At the request of the General Medical Council, a primary specialty program for ICM was developed by January 2011, and runs in parallel with dual certification [34]. Another option for advanced training is pediatric ICM. In the UK, 80% of consultants leading adult ICUs are anesthetists by primary training [2]. The standard curriculum for anesthesia incorporates basic and intermediate training in ICM.

France

The first French ICUs opened in 1954, rapidly following the lead taken by Denmark. In the 1950s, ICM (réanimation) also became part of the practice of, and education in, anesthesia. Today, the training program for anesthesia-ICM includes 18 months practical training in ICM. Anesthetists, surgeons, internists, cardiologists, and neurologists can obtain an additional certificate (DESC) in non-surgical ICM (réanimation médicale). This requires 3 years of training beyond that for the base specialty.

Scandinavia

As seen in Table 38.1, Scandinavian training programs in anesthesiology include ICM training of 6-12-months duration [8]. In addition, the Scandinavian Society of Anaesthesiology and Intensive Care Medicine (SSAI) initiated a 2-year Scandinavian training program in ICM, in 1998.

Germany

The anesthesiology curriculum has included training and experience in ICM since 1968. A minimum training period of 6 months was introduced in 1979. In 1992 this increased to

12 months, and a multidisciplinary approach to ICM was officially established, i.e. supplementary training in specialty-related ICM was introduced for anesthesiology, surgery and its branches, internal medicine, pediatrics, neurosurgery and neurology. Training lasted 24 months, of which 12 months (anesthesiology) or 6 months (other specialties) could be set against training time in the base specialty [35].

Emergency Medicine

In the 1960s, many European anesthesiologists increasingly focused on emergency medicine. They took leading roles in cardiopulmonary resuscitation and formed physician-equipped ambulances providing a pre-hospital rescue service for critically ill patients – emergency medical services (EMS). Consequently, the German, Swiss and Austrian Societies of Anaesthesiology added “Reanimation” to their names in 1965, 1967 and 1972, respectively (in German, reanimation denotes resuscitation whereas it stands for ICM in the Romance languages). In the 1980s and later, several countries introduced supra-specialty qualifications. In 1984, a Certificate of Qualification in EMS in Germany could be acquired even before completion of specialization. The requirements were 12 months (later 18 months) of clinical training, 80 h of theoretical courses and 10 practical pre-hospital experiences as a supervised EMS physician. From 2003, mandated training increased to 24 months, and the number of pre-hospital supervised experiences to 50. The diploma became the Certificate in Emergency Medicine [36, 37]. In 2000, the Swiss Medical Association introduced a Certificate as an Emergency Physician, and a Certificate in Clinical Emergency Medicine was added in 2009 [25]. In France, an additional certificate (DESC) in emergency medicine could be obtained by anesthetists, surgeons, internists, and pediatricians. It required 2 years of training beyond that for the base specialty [38]. These specialists control both the pre-hospital EMS (SMUR, Service Mobile d’Urgence et de Réanimation) and the emergency departments in hospitals. Belgian anesthesiologists and other specialists could obtain a supplementary certificate in emergency medicine after an additional training of 1 to 2 years. A separate specialty status replaced this in 2005. For Scandinavian anesthesiologists, the Scandinavian Society of Anaesthesiology and Intensive Care Medicine (SSAI) offers a two-year masters course in advanced emergency medicine [8].

In the UK, a new specialty, Accident and Emergency Medicine, developed from casualty surgery in the 1970s, but never became part of anesthesia training. In 1991, an Intercollegiate Board in Accident and Emergency Medicine was established with representation from 8 Colleges and the British Association for Accident & Emergency Medicine [38].

Before this, a training program was available to those who had completed their specialization and the additional training lasted for 3 to 4 years. In 1993, the Board became the Intercollegiate Faculty and, in 2006, the College of Emergency Medicine. The minimum duration of specialist training in emergency medicine is now 6 years.

Pain Medicine

From the early 1970s, their expertise in treating acute post-operative pain drew anesthetists into pain therapy, and most European countries incorporated pain therapy into the core curriculum in anesthesiology [39]. Some countries established 1 to 2 year training programs in pain medicine, as a multidisciplinary supra-specialty. In Switzerland, an applicant must attend a given set of lectures and courses and perform a minimum number of interventions under supervision. In 2001, the SSAI opened a Nordic Education in Advanced Pain Medicine to its members, with training lasting 2 years [8, 40]. In the UK, the RCoA defines pain management as a special interest area for advanced training. Trainees in anesthesia may apply for a 6 to 12 month advanced training course in pain management. Within the RCoA, the Faculty of Pain Medicine was established in April 2007, replacing the previous Pain Management Committee. Doctors starting their Advanced Pain Training (APT) from 2011, are required to take the Fellowship of the Faculty of Pain Medicine of the RCoA examination, in addition to achieving the competencies of their APT.

Subspecialties of Anesthesia

Formal training programs in subspecialties such as cardiac/thoracic, pediatric, obstetric or neurosurgical anesthesia, are uncommon in Europe. The core curriculum includes these as it does acute pain therapy, management of chronic and malignant pain, emergency medicine and trauma care, ACLS training, and last but not least, ICM. Scandinavian anesthesiologists who recently obtained their specialist diploma in anesthesiology and intensive care can apply for the advanced Inter-Nordic education program in Paediatric Anaesthesia and Intensive Care, which is coordinated by the SSAI and lasts 12 months [8, 41]. In the curriculum organized and supervised by the RCoA, cardiac/thoracic, obstetric, pediatric anesthesia and neuroanesthesia are defined as special interest areas for advanced training, each lasting 6-12 months. However, the opportunity for trainees to gain such expertise depends on the availability of training posts in teaching hospitals, and the perceived demand for consultants trained in these fields.

Undergraduate Teaching

In most European countries, education of medical students in anesthesia began in the 1950s, when anesthetists first obtained posts as specialists and developed Anesthesia Divisions in University Departments of Surgery. In subsequent decades, university anesthesiologists increasingly committed themselves to the education and examination of students. Whether a student's surgical training included anesthesiology or whether anesthesiology was separated from surgical training varied, and still does, among European countries. National societies and their leading members increasingly appreciated the correlation of the quality of undergraduate teaching and the choice of anesthesiology as a professional career [8, 42, 43]. Some National Societies took special measures to familiarize medical students with anesthesiology and its various facets, e.g. the German Professional Association of Anaesthetists set up a website and a summer school for students and a "road show" at teaching hospitals. Based on the experience that courses in advanced life support using full-scale simulators proved particularly attractive to students if given by anesthesiologists, the German Society of Anaesthesiology and Intensive Care Medicine enabled 30 University Departments in 2003 to purchase full-scale anesthesia simulators for use in undergraduate teaching [44].

Continuing Medical Education (CME)

CME in anesthesiology developed simultaneously in most European countries and in some, evolved into Continuing Professional Development (CPD). Since 1990, about 60% of European countries require a given number of annual credits as a prerequisite for recertification. In most countries, national Medical Associations and national Societies of Anesthesiology jointly organize and control CME activities. In the UK, the RCoA developed guidelines for CPD based on a so-called CPD matrix, specifying the knowledge and skill areas needed for revalidation (recertification). In France, the CME concept recently evolved into an evaluation of professional practices (EPP), integrated into a compulsory CPD system for all healthcare workers. For this purpose, in 1994, the scientific and professional associations of anesthesia formed the French College of Anaesthetists and Intensive Care Providers (CFAR, Collège Français des Anesthésistes Réanimateurs).

Harmonizing Education in Europe

The diverse systems of European medical education reflect European heterogeneity in history, language, political, legal, economic, and medical systems. In 1957, six countries signed the Treaty of Rome, creating the European Eco-

conomic Community (EEC), which subsequently developed into today's European Union (EU) with 27 member states out of 47 European countries. The protracted and continuing process of harmonizing medical education will be described below, beginning with a description of the professional bodies guiding this development.

The European Union of Medical Specialists (UEMS) and the European Board of Anaesthesiology (EBA)

One year after the signing of the Treaty of Rome, medical specialists from the six member countries formed the UEMS (Union Européenne des Médecins Spécialistes) to serve as a source of discussion and consultation for EEC legislation [45–47]. Today the UEMS is the umbrella organization of the national associations of medical specialists of the 27 EU member states, together with 2 non-member states, Norway and Switzerland. Non-EU states can join as observers (Fig. 38.2). In 1962, the UEMS created the first Specialist Sections to offer expert advice to the EEC Commission. Representatives from the six initial member countries constituting the Section of Anaesthesiology, held their first meeting in September 1962. At that time, training in anaesthesiology in these six countries ranged from 2 to 7 years. In 1963, the Section stipulated 3 years as the minimum period of training. In 1969, a re-assessment of training requirements for all EEC countries, including those about to join, again showed that training varied from 3 to 7 years. In 1969, the Section agreed on a minimum training period of 4 years, and in 1980 proposed a 5 year minimum period [48, 49]. In 1973, the periods of training still varied between 3 and 7 years in EEC countries, and between 2 and 6 years in non-EEC countries [47].

The Specialist Sections of the UEMS acted to harmonize specialist training, and proposed criteria that might allow the mutual recognition of specialists. These were established by “Doctors Directives” 75/362/EEC and 75/363/EEC in 1975, and were updated in 1993 by Directive 93/16/EC, which included requirements for recognizing training institutions and a minimum duration of training. In Directives 2005/36/EC and 2006/100/EC regulating the recognition of professional qualifications, anaesthetics is named as one of the medical specialties with a minimum period of training of only 3 years, contrary to the proposal made by the Section of Anaesthesiology and endorsed by the Council of the UEMS.

Chapter 6 of the 1993 UEMS Charter on the Training of Medical Specialists stipulated individual input from each specialty. Accordingly, the Sections formed educational boards. Initially a separate European Board of Anaesthesiology (EBA) was formed. The Section and Board soon coalesced, with Section members normally also being Board members [46]. Two delegates represented each country in

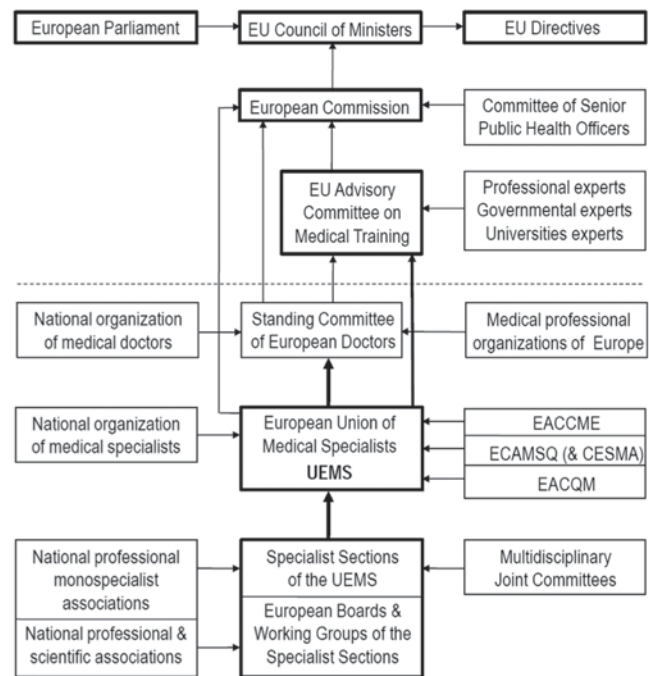

Fig. 38.2 The European Union of Medical Specialists (UEMS) and associated organizations are separated from the governing European political and professional structures (upper boxes) by the broken horizontal line. EU = European Union; EACCME = European Accreditation Council for Continuing Medical Education; ECAMSQ = European Council for Accreditation of Medical Specialist Qualification; CESMA = Council for European Specialist Assessment; EACQM = European Advisory Council for Quality Management of Specialist Medical Practice

the Section and on the Board. In 1993, the Section adopted requirements for the Specialty of Anaesthesiology and incorporated these in Chapter 6 of the Charter in May 1995. The Charter defined the tasks of the Board and confirmed it as the EU monitoring authority of the specialty [46].

The principal aims of the EBA, and procedures undertaken to achieve these were:

The publication of training guidelines in anaesthesia, in booklet form in 1996, with revisions in 2001, 2008 and 2011 [50–52]. These produced changes, moving training programs in European countries, particularly in Eastern Europe, towards harmonization. In all versions, 5 years was recommended as the minimum duration of training.

Three guidelines were published in 2007: Directions for a core curriculum in emergency medicine integrated in the specialty of anaesthesiology [53]; Guidelines for anaesthesiologist specialist training in pain medicine [54]; and Guidelines for safety and quality of anaesthesia practice in the European Union [55].

EBA endorsement of the examination for the European Diploma in Anaesthesiology and Intensive Care Medicine (EDA) of the European Academy of Anaesthesiology (EAA). In an editorial published in 2010, recommendations were made for trainee evaluation and assessment in Europe [56].

The Joint Hospital Visiting and Accreditation Programme of the EBA and EAA.

Medical specialties failing to fulfill given criteria were not listed as independent in the EU Directives on the recognition of professional qualifications (2005/36/EC and 2006/100/EC). They therefore could not form UEMS Specialist Sections and Boards. To overcome this problem, the Council of the UEMS was permitted to ask one or more Sections to create a Multidisciplinary Joint Committee (MJC) for defining competences or spheres of activity associated with several specialties. MJCs with active participation of the Section of Anaesthesiology were created for Intensive Care Medicine (MJCICM), Emergency Medicine (MJCEM), and Pain Medicine (MJCPM).

Based on its 1994 Charter on CME, in 1998 the UEMS Council developed a system for the exchange of CME credits at European level for countries recognizing credit points. For this purpose, the European Accreditation Council for CME (EACCME) was created one year later, becoming operational in 2000. UEMS/EACCME and several national accreditation authorities as well as the American Medical Association signed agreements on mutual recognition of credits. The EBA published guidelines on CME/CPD in 2007 [57].

To harmonize the assessment process in Europe, 11 Sections already conducting a European examination convened in 2007, and founded a Council for European Specialist Assessment (CESMA) with active participation of the Section of Anaesthesiology. They proposed the “Glasgow Declaration” on the significance and conditions of European Board Examinations.

A major challenge to the UEMS will be the revision of the EU Directive on Mutual Recognition of Professional Qualifications (Directive 2005/36/EC), which is expected in 2013. This revision will do the following:

Update the list of specialties recognized in the EU.

Update the content and length of training. This is of utmost importance for anaesthesiology since in the Directive 2005/36/EC currently in force, the minimum duration of training is still 3 years despite the minimum of 5 years recommended in the 1996–2011 EBA guidelines [50–52].

Introduce the concept of “Particular Competencies” in intensive care and other specialties instead of defining them as independent specialties [58].

The European Academy of Anaesthesiology (EAA)

The EAA was founded in Paris in September 1978. Its main educational activities were to grant the European Diploma in Anaesthesiology and Intensive Care (EDA) and support the EAA/EBA Joint Hospital Visiting Programme (HVP). The latter role was to ensure that academic institutions met the criteria for teaching and training anaesthesiologists in Europe, expressed in the training guidelines of the EBA [49, 59]. The

EDA was established in 1984 as an annual two part multilingual postgraduate (end-of-training) Diploma examination. Part I was a written multiple choice examination which European medical graduates could take even before training in anaesthesia commenced. Eligibility for the Part II (final) examination required that candidates pass the Part I examination, complete 6 years of medical practice, including 4 years of training in anaesthesia. They had to be eligible for specialist registration in a European country. The latter criterion was later modified insofar as candidates had to be certified anaesthesiologists in any country, or trainees in the final year of training in anaesthesiology in a European member state of the WHO. Part II consisted of four 30-minute oral examinations, each with a different pair of examiners. Successful candidates became Diplomates of the European Academy of Anaesthesiology (DEAA). Initially, this title was not officially recognized and was simply one of distinction. The Diploma neither replaced national specialist accreditation nor conferred the right to practice in another country.

In Switzerland, the EDA Part I examination became mandatory for all trainees in 1987, but the final (oral) examination remained in the hands of the National Society (SSAR). Malta accepted the European Diploma as a criterion for specialist status. From 1990, in a reciprocal agreement with the RCoA, those holding the EDA were exempt from passing the Primary FRCA when applying for the Final FRCA and those holding the FRCA were exempt from sitting the Part I EDA. In addition to the EDA examination, the EAA introduced an In-Training Assessment (ITA), which took place simultaneously and used the same multiple choice questions as the Part I Diploma examination. The ITA could be held in every European training centre accredited by the EEA examination committee [9].

In 1989, the EAA created a voluntary Hospital Recognition Programme. Although not accepted by the UEMS, it was supported and recommended by the Specialist Section of Anaesthesiology [49]. In 1996, it became the Hospital Visiting Programme (HVP) administered by a permanent Joint Committee of the EBA and the EAA. This program was mainly intended for training centers in countries without a national hospital visiting and accreditation program [59].

The European Society of Anaesthesiology (ESA)

The EAA limited the number of its members and was frequently regarded as a “closed” organization. To provide a broader forum, the European Society of Anaesthesiologists was formed in 1992, and was open to all practicing anaesthesiologists. A parallel organization, the Confederation of European National Societies of Anaesthesiology (CENSA), evolved from the former European Regional Section of the World Federation of Societies of Anaesthesiologists. The

Fig. 38.3 Annual number of candidates sitting for Part I (written) and Part II (oral) Examinations for the European Diploma in Anaesthesiology and Intensive Care Medicine increased from 1984 to 2010 (*upper graphs*), whilst the percent passing each examination remained roughly constant at 60% for Part I and 75% for Part II (*lower graphs*)

complementary and partially overlapping nature of these three bodies led to an amalgamation which was realized in January 2005, by the formation of the “new” European Society of Anaesthesiology (ESA). CENSA became the National Anaesthesia Societies Committee (NASC) of the ESA. All activities of the combined organizations continued in the “new” ESA.

The Examinations Committee of the ESA governs the conduct of the EDA examination. New and past Diplomas have equal value. The title of Diplomate changed from DEAA to DESA. Candidates sitting the Part I and II examinations have steadily increased in numbers (Fig. 38.3). The Glasgow Declaration of the CESMA was approved by the Board of Directors and Examination Committee of the ESA and supported by the EBA. Article 6 of this document makes candidates of any nationality, i.e. also non-European nationals, eligible to sit European Board Examinations, and the EDA eligibility criteria had to be adapted accordingly. Article 7 allows candidates who pass a European Board Examination and who are certified specialists, to call themselves Fellows of the respective Board. This complies with a request made by the Section and Board of Anaesthesiology to the Council

Fig. 38.4 From its inception in 1989, the Joint Hospital Visitation Programme has accredited 62 European training centers

of the UEMS in 2002 [60]. The EBA, with support of the ESA, prepared criteria for Membership and Fellowship that included more than just being a Diplomate: candidates must have been admitted to the Specialist Anaesthesiology Register of a European member state, have been in clinical practice for 5 years, and have fulfilled the national or future European requirements for CME/CPD in the preceding 5 years. Implementation is scheduled for 2013. In 2007, Hungary joined Switzerland, in making the EDA Part I examination mandatory. In 2008, Romania and Poland followed suit [31], as did Slovenia and Turkey in 2009, and Austria in 2010. In February 2009, the Austrian Medical Chamber recognized the EDA Part II examination as equivalent to the Austrian national final examination in Anaesthesiology.

The Joint Hospital Visiting Programme of the EBA and EAA continued as the Hospital Visiting and Training Accreditation Programme (HVTAP), organized and supervised by a Joint Committee of EBA and ESA. It is offered on a voluntary basis to academic departments of anesthesia that apply for teaching accreditation, in accordance with European training guidelines. Figure 38.4 shows the cumulative number of training centers accredited since the program’s inception.

In 1986, Johan Spierdijk (Netherlands), Philippe Scherpereel (France), George Rolly, Guillaume Hanegreefs and Maurice Lamy (all Belgium) founded the Foundation for European Education in Anaesthesiology (FEEA, Fondation Européenne d’Enseignement en Anesthésiologie). Initially, the FEEA aimed to provide CME in anaesthesiology within the European Community by organizing refresher courses. Growth in the number of member countries progressively extended the area of activity of the FEEA, especially into Eastern Europe [61]. Since 1995, the FEEA also established educational centers outside Europe. In

January 2009, the ESA formally assumed the FEEA's activities with the creation of the CEEA (Committee for European Education in Anaesthesiology). The CME program of CEEA is based upon a cycle of six courses, and is accredited in Europe by the national systems of accreditation and the EACCME [62].

Subspecialties of Anesthesiology from the European Perspective

In most European countries, ICM, emergency medicine both inside and outside hospital, acute and chronic pain treatment, and palliative care, are considered special and essential areas of expertise in anesthesiology [8]. Note however, that ICM, critical care and pain medicine are not sub-specialties attainable exclusively by anesthesiologists, rather they are supra-specialties accessible from different base specialties including anesthesiology, surgery, and internal medicine.

Intensive Care Medicine

The European Society of Intensive Care Medicine (ESICM) was founded in March 1982, and created the European Diploma in Intensive Care (EDIC) in 1988. This became widely accepted and, according to a web-based survey published in 2009, was used by 10 European countries, with a mandatory exit examination [58]. The CoBaTrICE (*Competency-Based Training in Intensive Care medicine*) collaboration was formed by the ESICM in 2003 to develop an internationally acceptable competency-based training program in ICM, and harmonize training standards across national borders [58].

As a multidisciplinary medical specialty, ICM could not be represented in the UEMS by a specialist section. Therefore a Multidisciplinary Joint Committee of Intensive Care Medicine (MJCICM) was established within the UEMS in 1999, with representation by delegates from 9 Sections, including anesthesiology. Delegates without voting rights represented the ESICM and the European Society of Paediatric and Neonatal Intensive Care. The MJCICM endorsed the EDIC, created an Intensive Care Unit Accreditation Visiting Programme in 2001, and published guidelines on structure, organization and training in 2002 [63]. To harmonize ICM training across Europe, the UEMS created a specialty Board for ICM (EBICM) in 2006, with representatives drawn equally from the MJCICM and from the ESICM, thus ensuring representation for the various national models of training. In April 2008, the Council of the UEMS supported the proposals made by the Chairmen of the MJCICM and EBICM, that ICM should be included in the revised version of Directive 2005/36/EC on the recognition of professional qualifications, as a particular medical competence/qualification. The

Council advised that the training content should be defined and managed through CoBaTrICE collaboration and monitored by the EBICM [33, 58].

Emergency Medicine

Currently, 15 members of the European Union (nine listed in EU Directive 2005/36/EC) recognize emergency medicine as an independent specialty. It is not yet a Specialist Section of the UEMS but, like ICM, it has been represented by a Multidisciplinary Joint Committee (MJCEM) since 2005. The MJCEM adopted a comprehensive Core Curriculum in Emergency Medicine, which the UEMS Council formally endorsed in April 2010. EU Directive 2005/36/EC sets European specialty training in emergency medicine at a minimum of 5 years of full-time training as a primary medical specialty. Within the 5 years, at least 3 must be spent in an Emergency Department accredited for training [64]. In October 2010, the Council of the UEMS agreed that the MJCEM and the European Society for Emergency Medicine should jointly form a European Board of Emergency Medicine.

Pain Medicine

Established in 1993, the European Federation of IASP Chapters (EFIC) is a multidisciplinary professional organization in the field of pain science and medicine, composed of the 30 European Chapters of the International Association for the Study of Pain (IASP). The EFIC aims to create a framework for European training and certification standards in pain medicine, including a core curriculum and subspecialty training. The typical duration of such a training program would be 2 years. At UEMS level, a MJC on Pain Medicine was established in April 2012.

Additional Competencies

The Federation of European Associations of Paediatric Anaesthesia (FEAPA) has developed guidelines for training, including the recommendation that all anesthetic trainees complete a minimum of 3 months of continuous training in pediatric anesthesia, regardless of their intended specialization [65].

Certification in transesophageal echocardiography (TEE) is a joint initiative, begun in 2005, between the European Association of Cardiothoracic Anaesthesiologists (EACTA) and the European Association of Echocardiography (EAE).

In 2006, the European Society of Regional Anaesthesia & Pain Therapy (ESRA) launched the European Diploma in Regional Anaesthesia & Pain Therapy, which certifies

clinicians involved in regional anesthesia who achieve a uniformly high standard of knowledge. The Diploma is awarded to candidates who have passed a two-part examination.

Non-physician Anesthesia Team Members; Workload and Working Time

In Europe, responsibility for anesthetic services lies with trained physician anesthesiologists who may delegate anesthesia delivery to non-physician members of the anesthesia team. The degree of delegation varies enormously among countries, but independent delivery of anesthesia by nurse anesthetists is not allowed in any European country. Basic education, training, certification, roles, tasks and responsibilities of non-physician anesthetists differ due to the diversity in the historical development of health care systems in general, and anesthesia services in particular [66]. A recent study identified 4 models of non-physician anesthesia personnel: nurse anesthetists, circulating nurses, anesthesia technicians, and anesthesia physician assistants [67]. This paper describes the ways in which nationally certified nurse anesthetists can work alongside and under the responsibility of anesthesiologists. In most countries, they assist the anesthesiologist in giving anesthesia. In Denmark, France, Netherlands, Norway, Sweden, and Switzerland, nurse anesthetists perform both nursing and a delegated anesthesia practice. The number of nurse anesthetists equals 100 to 160% of the number of anesthesiologists including residents, or between 105% and 205% without residents [67]. These numbers differ to some extent from those reported in a paper published 3 years earlier (45 to 230% when residents are included and 50 to 320% when they are not) [68]. Either way, nurse anesthetists clearly contribute substantially to patient care.

Reliable data on the contribution of each group to the provision of anesthesia in the decades after World War II are not available. Since few anesthesiologists practiced in European countries in the 1950s and 1960s, it is reasonable to assume that during that period nurses gave far more anesthetics than did doctors, the former nominally working under the supervision of the surgeon. Formal educational programs for nurse anesthetists were established after 1960 (1960 in France, 1962 in Sweden, 1963 in Finland, 1964 in Germany, 1965 in Norway, 1966 in The Netherlands, 1969 in Switzerland). From 1970 to 1990, the number of anesthesiologists increased to such an extent that virtually all non-physician anesthesia providers worked under the supervision of a certified anesthesiologist [66].

Although standardization of training and practice of nurse anesthetists or other anesthesia team members in Europe do not currently exist, such standards are becoming increasingly likely and necessary, given the existing or impending shortfall in numbers of anesthesiologists [69]. Escalating eco-

nomics constraints, increasing workload, growing demand for anesthetic care, demographic factors and inappropriate political decisions (e.g. too few places to study medicine or too few training positions in anesthesiology) underlie the likelihood of this impending shortfall [8, 68, 70–72]. However, it must not be taken for granted that sufficient numbers of nurse anesthetists will be available to compensate for a shortfall in anesthesiologists, because a lack of young doctors as well as nursing personnel, is becoming apparent in many countries.

Directive 2000/34/EC of the European Parliament and of the Council of June 2000, the so-called European Working Time Directive (EWTD) increases the need to train sufficient numbers of competent anesthesiologists. This limited the average working time for each 7-day period, including overtime, to 48 h (with a transitional period of 5 years from August 2004, for doctors in training). The effect of the EWTD on length and quality of training is not yet clear [73–75], but decreasing working time of trainees is a driving factor behind the replacement of the classical experience-based education of anesthesiologists by competency-based training programs [52, 56, 58].

Conclusion

Before 1945, anesthesia was not recognized as an independent medical specialty in Europe, due to the opposition from surgeons and the isolation of Europe during World War II. Influenced by developments in the US and the UK, modern anesthetic practice began in Europe after World War II ended. The growth of training programs between 1947 and 1958 supplied the basis for de facto or official recognition of anesthesiology as a separate, independent medical specialty. Not surprisingly, countries differed markedly in the clinical responsibilities of anesthesiologists and the content, quality and length of training. The principles of free movement of people, goods, services and capital underlying today's European Union of 27 Member States, stimulated efforts to harmonize the quality of anesthetic care and education. In the past 2 decades, this has enabled the mutual recognition of medical qualifications. The quality and uniformity of anesthesiology care and education has increased in Europe, not by lowering high standards, but by raising low ones, at first in the countries of Western Europe and then, following the dissolution of the Eastern bloc and the Soviet Union in 1989–1991, in most of the newly independent states of Eastern Europe.

Summary

Research in anesthesia has taken several forms. Other essays in this book supply detailed histories of those specific researches, including the discovery of new anesthetics and anesthetic adjuvant drugs, advances in anesthetic delivery and monitoring, measurement and codification of anesthetic pharmacodynamics and kinetics, and the development of vehicles for the exchange of information on research (societies, books and journals). We refer the reader to these chapters for details of the histories of specific researches. The present chapter supplies an overview, a summary of the progress in anesthesia research.

Research in anesthesia evolved from need and curiosity. Consider eight themes. Theme 1: The discovery of anesthetics and anesthetic adjuvants occupied the minds of anesthetists from the inception. Theme 2: The application of anesthetics demanded an immediate need to define and control the anesthetic state. The second theme demanded Theme 3: What did the body do to anesthetics (pharmacokinetics) and what did anesthetics normally do to the body—to breathing, circulation, indeed to all parts of the body (pharmacodynamics)? And what the anesthetics did to the body also led to Theme 4, outcomes. Sometimes these marvelous drugs did bad things, destroying the liver or brain and more; and sometimes they did good things, protecting the brain and the liver and more. Theme 5: How do anesthetics and anesthetic adjuvants accomplish their magic? The initial musings on mechanisms were far off the mark. I remember reading many books in my residency a half century ago. The one that excited me the most was *The Mode of Action of Anaesthetics* by TAB Harris published in 1951. It told how things worked and I was enthralled with the ideas, (almost) all wrong. In the past several decades that darkness seems to have lifted—but I wonder if a future reader will also say “all wrong.” Theme 6: Scratch an anesthetist and you’ll find a gadgeteer. Most anesthetists I know love gadgets and many have tried their hand at developing new ones. And Theme 7: who supplies support for research? Funding comes from many sources, but most comes from industry with lesser amounts coming from the NIH, anesthetic organizations (e.g., the ASA and IARS), and local sources (e.g., departmental and personal). Theme 8 makes use of the above seven themes: Translational research. How do laboratory discoveries move to the clinic—and vice versa?

Theme 1: New Drugs for Anesthesia

The discovery of new drugs began the history of anesthesia, and continues to the present. Figure 39.1 illustrates the chronology of the major drug discoveries. Some drugs are more equal than others, and the game changers are given in larger, bold type. For example, nitrous oxide, ether and halothane each moved anesthesia in giant steps. Although enflurane, isoflurane, and then sevoflurane and desflurane replaced halothane, they contributed much smaller steps.

The discovery/development of new drugs, and especially increasingly better anesthetic and adjuvant drugs, has often resulted from a collaborative effort between industry and academicians. Early on, such discoveries were often made by intellectuals. In 1774, Unitarian minister and genius Joseph

Priestley (1733–1804) synthesized nitrous oxide. Precocious Humphrey Davy (1778–1829) studied it, in 1800 noting that it might be used for surgery, and dentist Horace Wells (1815–1848) unsuccessfully attempted a public demonstration of its use as an anesthetic in 1845. Valerius Cordus (1515–1554) synthesized ether in 1540, and three centuries later, on 16 Oct 1846 (ether day) Morton (decidedly not an intellectual) used ether to publically demonstrate its anesthetic effect. Some additions arrived by trial and error (wild guesswork). Soubeiran, von Liebig, and Guthrie independently discovered chloroform in 1831, and Jean-Baptiste Dumas named and chemically characterized it in 1834. The obstetrician, Sir James Simpson discovered its anesthetic properties in 1847 by experimenting first on himself and then on his patients.

Ether, nitrous oxide, and chloroform supplied most of the needs for general anesthesia (some would add ethyl chloride) for the better part of a century, and the search for a better inhaled anesthetic was delayed. Discovery went elsewhere. In 1884, Carl Koller, (1857–1944) demonstrated that cocaine produced conjunctival anesthesia and within the year,

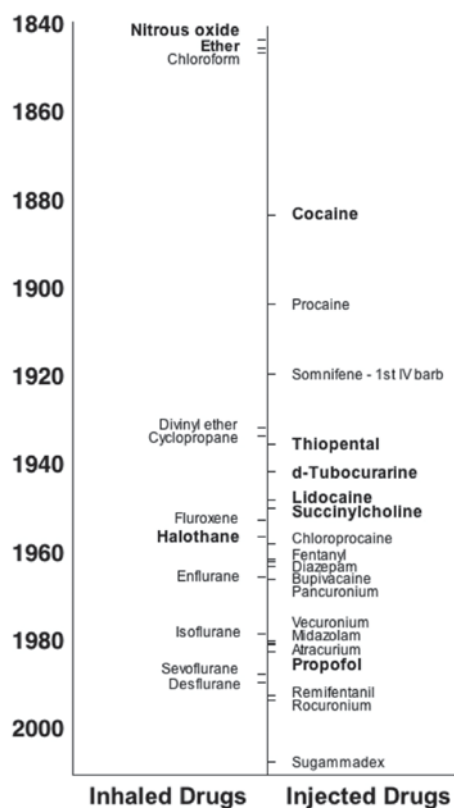

Fig. 39.1 The chronology of the major anesthesia drug discoveries began in 1844 with nitrous oxide. Some drugs were more equal than others, and the game changers are given in larger, *bold* type

cocaine was widely used for topical, infiltration and regional anesthesia. However, the toxicity of cocaine prompted a search for a better local anesthetic, leading to the synthesis of procaine by Einhorn in 1904.

The search for a better inhaled anesthetic was revived in the 1920s. Ethylene was discovered to put carnations to sleep and when given to animals put them to sleep, too. In 1923, Luckhardt and Carter introduced ethylene as an inhaled anesthetic at Presbyterian Hospital in Chicago [1]. Some discoveries had the insight of genius; simple things like Prof. Chauncey Leake's (1896–1978) suggestion to produce an ether with two ethylenes, to obtain the advantageous properties of both ethylene and diethyl ether. This led to divinyl ether in the early 1930s.

August Freund discovered cyclopropane in 1881, and cleverly proposed the correct cyclic structure. George Lucas and Velyien Henderson in Toronto discovered its anesthetic properties in the late 1920s. Henderson was the first human subject anesthetized with the gas. Waters demonstrated its anesthetic properties in patients in the early 1930s, using it in a rebreathing system.

And parallel to the expanding interest in inhaled anesthetics, Weese and Scharpff synthesized the short-acting

barbiturate, hexobarbital, in 1932 [2]. It was widely used in Europe. In the early 1930s, Ernest Volwiler (1893–1992) and Donalee Tabern (1900–1974), working for Abbott laboratories, discovered thiopental (Pentothal®). In 1934, Waters gave thiopental to a patient, inducing anesthesia without the unpleasant, sometimes terrifying, suffocating sensation associated with an induction of anesthesia with ether. Thiopental allowed a quick and pleasant transformation from wakefulness to sleep. “Count backwards, please, from 100...” Sleep came before 90.

One problem surgeons faced in the first half of the twentieth century was that, under ordinary circumstances, muscle relaxation was not sufficient to allow certain forms of surgery. Relaxation could be produced with the anesthetics at hand, but only by imposing deeper levels of anesthesia, levels that increased the risk of anesthesia. We knew of Ecuadorian Indians who painted the tips of darts with a substance called *woorari* (‘poison’ in the Carib language of the Macusi Indians of Guyana), now called d-tubocurarine (‘curare’). An animal pricked by such a dart would become paralyzed, would die, and would be served for dinner. In 1780, Abbe Felix Fontana found that curare's action was not on the nerves and heart but on the ability of voluntary muscles to respond to stimuli. In the Nineteenth century, Claude Bernard demonstrated that paralysis resulted from an action on a small portion of the muscle, the so-called myoneural junction [3]. In 1811–1812, Benjamin Brodie (1783–1862) showed that curare does not kill by a direct effect, and that recovery eventually occurs if breathing is maintained artificially. In 1934, Henry Dale (1875–1968) showed that acetylcholine is the messenger mediating neuromuscular transmission, and that curare blocks such transmission.

Of course, one would not wish to permanently paralyze a patient, but what if the dose of curare were adjusted to produce just enough relaxation to facilitate surgery, a dose producing but a temporary paralysis? Stuart Cullen sought to test this possibility, injecting curare into dogs that promptly developed asthma-like symptoms. He abandoned curare. The credit for the discovery of the clinical usefulness of curare goes to the fearless Griffith and Johnson, who bypassed studies in animals, showing in 1942, that the bronchospasm found in dogs rarely applied in humans [4]. A new age had come to anesthesia, and curare was soon widely applied. Although it seemed safe, subsequent events suggested that the dangers implied by the deadly hunters of Ecuador might have some subtle application to humans (see below).

Cocaine and procaine had enabled topical, infiltration, and regional anesthesia, but neither was perfect. In the 1940s, local anesthesia was materially advanced by the introduction of the questionably safer, faster-acting amide, lidocaine. Lidocaine was synthesized by Nils Löfgren (1913–1967) and Bengt Lundqvist, and released for clinical use in 1948 [5].

It took World War II and advances in fluorine chemistry needed to enrich uranium isotopes, to give us modern inhaled anesthetics. The first successful modern anesthetic was halothane, synthesized by the British chemist Charles Suckling (b. 1920) for Imperial Chemical Industries. An inspired guess involved placing three fluorine atoms on one end of a two-carbon ethane, and adding a bromine and a chlorine atom on the other carbon. He thought the fluorine atoms would lend stability to and decrease toxicity of the molecule, and so they did. The bromine and the chlorine were probably included to secure a greater potency. In 1956, Michael Johnstone gave the first halothane anesthetic to a human [6]. Halothane quickly became popular because, unlike ether, the lack of pungency allowed a smooth, rapid, nonirritating induction of anesthesia.

And unlike chloroform—at least in the first years of its use—halothane did not seem to injure the liver. However, in 1958, a case of death in association with halothane use was reported, and more followed, leading to the National Halothane Study (see below). Enter Ross Terrell, a genius of a fluorine chemist, who was employed by the Ohio Chemical Company to find a replacement for halothane that would not injure the liver. He did that and more, synthesizing over 700 compounds in a search for the ideal anesthetic [7, 8]. First came enflurane, replacing halothane in the 1970s, particularly in the litigious US. Terrell's next anesthetic was isoflurane which replaced enflurane in the 1980s, and then he gave us desflurane in the 1990s. In parallel with Terrell, Bernard Regan, at Travenol Laboratories, synthesized sevoflurane [9]. This progression gave us and our patients increasingly safe and controllable anesthetics, nonflammable anesthetics with lesser blood solubilities allowing increasingly rapid awakening from anesthesia, with far less nausea than that from ether.

Further new drugs used in anesthesia resulted from the efforts of diverse clinicians, academicians and industry investigators. These included the muscle relaxants that replaced curare, increasingly safer and more controllable muscle relaxants. These newer muscle relaxants were made ever safer by better techniques for determining and eliminating any residual postoperative effects of such useful but potentially deadly drugs. Most recently we have, or nearly have, the reversal agent sugammadex, a drug eliminating the effects of particular relaxants by “hiding them from the muscle”.

The new drugs included propofol, an intravenous induction agent largely replacing thiopental through greater controllability, secondary to metabolism an order of magnitude greater than that of thiopental. Propofol had some problems at its birth. Being poorly soluble in water, it had to be dissolved (“formulated”) in an organic solvent. The solvent was initially cremaphor EL, and this combination was employed in 1977 in clinical trials. However, we soon learned that cremaphor might produce anaphylactoid (allergic-like)

reactions that could be life threatening. Oops! Try again in 1986, using an emulsion of soy lipids to dissolve the propofol. Success!

1846–1920: Theme 2—Defining and Controlling Anesthetic Delivery

The discovery of anesthesia mandated research to address a simple question—how to conduct the patient safely through the operative procedure, and how to satisfy surgical requirements without injuring or killing the patient? We needed a clinically relevant assessment of what we came to call depth of anesthesia, we needed a controllable way to deliver anesthesia to achieve the “correct” depth, and we needed it right away. John Snow gave it to us. Golly, he was good. He invented the notion of depth of anesthesia, and he expressed that as five “degrees”:

“I shall divide the effects of ether into five stages or degrees; premising, however, that the division is, in some measure, arbitrary...In the first degree of etherization I shall include the various changes of feeling that a person may experience, whilst he still retains a correct consciousness of where he is, and what is occurring around him, and a capacity to direct his voluntary movements. In...the second degree, mental functions may be exercised, and voluntary actions performed, but in a disordered manner. In the third degree, there is no evidence of any mental function being exercised, and consequently no voluntary motions occur; but muscular contractions, in addition to those concerned in respiration, may sometimes take place as the effect of the ether, or of external impressions. In the fourth degree, no movements are seen except those of respiration, and they are incapable of being influenced by external impressions. In the fifth degree...the respiratory movements are more or less paralysed (sic), and become difficult, feeble, or irregular.” (pp 1–2) [10]

Snow described how to achieve these degrees in his two books on delivery of the anesthetics of the day, diethyl ether [10] and chloroform [11]. We spent a century tinkering with the basic notions, Arthur Guedel being the greatest tinkerer. In World War I, he gave us not five degrees, but four stages, the third (surgical anesthesia; roughly equivalent to Snow's fourth degree) containing four planes (Fig. 39.2) [12]. Along the way, in 1895, Cushing (a neurosurgeon) and Codman added measurement of blood pressure and heart rate, and the anesthetic record [13].

1950–1980: Theme 3—Phenomenology: Pharmacokinetics

What Snow, Cushing, and Guedel taught us required attention to the patient's response to the anesthetic. What we saw in the patient, things such as the character of breathing, or the

Fig. 39.2 The figure shows what constituted most of the characteristics of the first three of four stages (denoted at the furthest *left*) of anesthesia that Guedel devised. Four, successively deeper planes lay within the third stage. Stages and planes go from lightest level (*top-most*) to deepest level of anesthesia. *Column 1* characterizes inspiratory and expiratory movements, the depth and smoothness. *Column 2* indicates the activeness of movement of the eye in the second stage and the first plane of the third stage. *Columns 3, 4, and 5* display the size of the pupil (*innermost circle*) and the iris (distance between the *innermost* and *outermost circles*) without (*column 3*) and with (*columns 4 and 5*) application of light to the eye. (From Guedel AE: *Inhalation anesthesia: A fundamental guide*. New York, Macmillan Co, 1937 pp 1-172)

size and responsiveness of the pupils to light, or changes in blood pressure, guided administration of more or less anesthetic or dictated cessation of anesthetic administration. Our observations had an enormous subjective element, meaning that delivery of anesthesia was as much an art as a science. This changed with our increased knowledge of anesthetic phenomenology in the 1950s, and the ability to deliver a precisely known amount of anesthetic that, additionally, we could directly measure.

In the mid-1900s we knew little about what we came to call anesthetic pharmacokinetics. We were ignorant about factors governing movement of anesthetics within the body (and thus we were hindered in our understanding of how to control and make use of such limits). Snow knew it was important, but could do little about it. In 1924, Howard Haggard explored the absorption, distribution and elimination of di-ethyl ether in dogs, dividing the distribution into that which went to the brain, and that which went elsewhere [14, 15]. In 1950, Seymour Kety (1915–2000) provided the first kinetic models, unintelligible for most mortals, and wrong in details (it failed, for example, to recognize the importance of differential distribution of the delivery of blood to different tissues) [16].

In 1954, John Severinghaus (b. 1922) started us properly down the pharmacokinetic road with his seminal study of

nitrous oxide, the first investigation of uptake of an inhaled anesthetic in humans [17]. His investigation led to a more general, but empirical, description of uptake known as the square root of time rule, a rule stating that anesthetic uptake decreases as a function of the square root of time. It applied to anesthetics other than nitrous oxide [18]. Hal Price improved on the concepts of tissue distribution of intravenous anesthetics, noting that tissue bulk and blood flow had to be accounted for in our thinking of the redistribution of an anesthetic like thiopental (Pentothal®) [19]. His concepts led the way with thiopental and injected anesthetics, and prompted a broader view, one applicable to the inhaled anesthetics. In parallel with Price, Eger (b. 1930) studied inhaled anesthetic kinetics, doing so with a vengeance, measuring solubilities and uptake of all clinically-used and many experimental anesthetics [20]. In the late 1950s, he developed an iterative mathematical model explaining how inhaled anesthetics move into and throughout the body [21], a model that with a few modifications applies to all inhaled anesthetics used today. Other investigators used analog models to accomplish a similar explanation [22, 23], but these could not describe the effect of the inspired anesthetic concentration on pharmacokinetics.

1960–1980: Theme 3 Continued— Phenomenology, Pharmacodynamics

In 1963, we got a measure of anesthetic potency, a measure that would provide a standard that allowed a comparison among anesthetic effects. The measure of potency was MAC, the minimum alveolar concentration of an inhaled anesthetic producing immobility in 50% of subjects given a stimulus such as a surgical incision [24, 25]. Three decades later, we got the equivalent of MAC for injected drugs such as propofol [26]. MAC allowed the comparative measurement of effects of inhaled anesthetics, everything from cardiorespiratory effects to what anesthetics did to brain and muscle and kidney and liver and pregnant ladies and infants and obese people and old people and... [27]. These phenomenology studies (“what does X do to Y?”) poured out and dominated research through the 1970s and 1980s. Such studies continue to the present.

1950–Present: Theme 4: Outcome Studies

For the most part, important outcome studies appeared in the second half of the 20th century. But we must acknowledge earlier work, for example, Snow’s careful dissection of the causes of death associated with chloroform anesthesia [11]. He repeatedly refers to a “sudden paralysis of the heart”,

possibly ventricular fibrillation or possibly severe myocardial depression. A less successful outcome study with the same theme was the work of the Hyderabad commission [28]. In 1902, echoing Snow's observations, Edward Embley provided support for the view that chloroform might cause sudden death by cardiac depression, believing that this resulted from a direct depressant effect of the vapor or by vagal irritability [29–31].

In 1954, at about the same time as we began to understand inhaled anesthetic pharmacokinetics, we got the first of the great outcomes studies, the work of Henry Beecher (1904–1976) and Donald Todd [32]. These investigators directed a consortium of 10 University hospitals in an investigation of the factors associated with death after anesthesia. Despite an absence of computers (after all, it was the early 1950s) they collected data on 599,548 patients coming to the astonishing conclusion that if a patient undergoing major surgery received curare, that patient was approximately 6 times more likely to die. The finding raised a ruckus, especially since it was published in a surgical journal and surgeons subsequently ordered anesthetists to stop using curare. No one likes being told what to do. Of course, the main problem was that apparently American anesthetists didn't understand that curare was apt to leave a residual paralysis that required reversal of the neuromuscular blockade [33]; the anesthetist did not recognize that although the patient might be breathing and appear grossly normal, he was still at risk from a remaining weakness, at risk of inadequate ventilation or an inability to react properly to vomiting—with vomit going into the lungs. You'd think we anesthetists would learn, but half a century later, another outcomes study again found that inadequate reversal of the effects of muscle relaxants grossly increased mortality [34].

Introduction of the inhaled anesthetic halothane, in the 1950s, was a smashing success. It quickly replaced all other potent inhaled anesthetics, including chloroform, cyclopropane and ether (halothane didn't explode but ether and cyclopropane did, and halothane had the added advantage of being less pungent than ether). Halothane also displaced the now infrequently used chloroform because chloroform injured the liver and halothane didn't seem to do so. Then in the late 1950s and early 1960s, sporadic cases of severe liver injury appeared after anesthesia with halothane, and we anesthetists feared that we might lose this new friend. The result was the National Halothane Study [35], a study of more than 800,000 patients given various anesthetics. The results suggested a rare, but believable connection between halothane and severe liver injury and death, a connection with signs and symptoms indicating that injury might be a consequence of an allergic response of the liver to halothane (or its metabolites).

The number of studies of outcomes, consequent to the activities of anesthetists, has increased dramatically. Outcome studies differ from phenomenology studies in that the outcomes intend to connect an action (of an anesthetic or a manipulation of some sort such as body temperature [36], oxygen concentration [37], or administration of beta blockers [38]) to either an adverse or beneficial outcome. In contrast, phenomenology studies connect an activity to a change where the change is neither inherently good nor bad. Sometimes outcome studies require data collection from large numbers of patients, as in the Beecher-Todd study or in the National Halothane Study, but more recent outcome studies might include just tens, hundreds, or a few thousand patients. Such small numbers were needed to demonstrate in the 1990s, that beta adrenergic blockage might provide long-term protection against postoperative myocardial injury [38].

One dramatic outcome study in the 1950s, was inadvertently conducted on patients suffering from tetanus [39]. These patients were given nitrous oxide to breathe, in order to decrease the pain of the muscle spasms produced by tetanus. The pain decreased, but after a few days, the number of white blood cells decreased and the patients began to die. The connection to nitrous oxide was clear, although the reason was not. The use of nitrous oxide continued in ordinary surgical patients because it appeared that the problem was only from prolonged breathing of the nitrous oxide. Anesthetists debated whether a more subtle noxiousness of this most ancient of anesthetics resulted from shorter exposures, with a consensus that the case was not proven, and the anesthetic had a long record of benefit and safety [40]. In 2007, an outcomes study of 2000 patients, given or not given nitrous oxide, suggested that nitrous oxide increased morbidity [41], possibly doing so for reasons related to the unique capacity of nitrous oxide to slowly inactivate a vital enzyme, methionine synthase [42]. However, not all recent outcome studies, even of 1000 patients, reveal an adverse effect of nitrous oxide [43]. The noxious effect of nitrous oxide continues to be debated, but the concerns over such noxiousness, including increased postoperative nausea and vomiting, have decreased the use of nitrous oxide in clinical practice.

The numbers of outcome studies are already large and will increase further. They will increase because of the need to supply better patient care, and to provide “evidence-based medicine.” Their application may not only increase patient well-being, but will likely decrease the cost of patient care by causing us to discard ineffective remedies that often have the additional disadvantage of being expensive. This latter issue also concerns research on the comparative effectiveness of medical treatments and whether the incremental benefit of more effective treatments justifies the added costs.

1980-Present: Theme 5—Finally, Studies of Mechanisms

As indicated above, the major anesthesia research in the 2–3 decades following World War II was phenomenological, plus an increasing, somewhat later interest in outcomes. The 1970s and 1980s saw the start of a third major focus: how did anesthetics and anesthetic adjuvants work? A few such inquiries had been made earlier. In 1846, Claude Bernard (1813–1878) demonstrated that curare acted by interfering with the transmission of nervous impulses to muscle, at what is called the motor end-plate, the juncture of nerve and muscle [3]. Around 1900, Meyer [44] and Overton [45] connected anesthetic potency to an affinity for fatty substances, implying that anesthetics acted by doing something to the lipid parts of neurons, perhaps something to the lipid bilayers that encircle all cells, including the cells of the brain.

But only sporadic discoveries were made until the 1980s, when we began to make use of the great advances in our understanding of receptors, and in genetic engineering. Nick Franks and Bill Lieb deserve credit for shifting our attention away from thinking that anesthetics, especially inhaled anesthetics, must work by some action on lipids in membrane bilayers. As noted above, Meyer and Overton had focused on the correlation of anesthetic potency with affinity to lipid. In 1984, Franks and Lieb demonstrated that an equally good correlation could be made with an effect on a protein [46]. Then the floodgates opened, with many investigators showing that anesthetics affected numerous and specific receptors (proteins) in ways that plausibly explained the actions of anesthetics and anesthetic adjuvants, such as opioids and muscle relaxants.

Some phenotypic results (i.e., specific anesthetic effects such as the production of immobility in the face of noxious stimulation) of injected anesthetics such as propofol or etomidate clearly result from an action on a specific receptor. An important study in 2003 demonstrated that for propofol and etomidate, the action was on the gamma amino butyric acid (GABA) receptor, an inhibitory receptor [47]. Etomidate and propofol enhanced this inhibition, doing so by increasing the response of the GABA receptor to normally released GABA. In another important study, genetic engineering made a mouse with a specific GABA receptor that responded normally to GABA but no longer responded to the presence of etomidate or propofol—the enhancement was muted or gone. The bioengineered mouse did not display the usual phenotypic response to etomidate; the response was also muted or gone [47]. This brilliant experiment showed that the GABA receptor mediates at least part of etomidate's and propofol's effects. Future studies must deal with a more difficult question: what is the mechanism(s) by which etomidate and propofol affect the receptor to enhance inhibition?

Propofol and etomidate affect only the GABA receptor. In contrast, the inhaled anesthetics affect nearly all receptors or other proteins that allow nerves to function, usually by opening channels and thereby allowing the passage of ions (charged particles). Most of these effects could plausibly cause anesthesia, but in fact, none can explain more than a small part of the capacity of inhaled anesthetics to produce anesthesia [48]. For example, as with propofol and etomidate, inhaled anesthetics enhance the response of GABA receptors to GABA, but the results of several studies suggested that the GABA receptor does not mediate at least some of the effects of inhaled anesthetics, like immobility [49]. We made magical mice, mice like those telling us so much about etomidate and propofol, mice in which one particular type of GABA receptor no longer responded to isoflurane, but the isoflurane MAC for those mice wasn't changed [50].

Theme 6: Gadgets

Ancient Times

Research developing gadgets is part of the history of anesthesia. There was the initial scramble to produce delivery systems allowing the anesthetist to control the anesthetic state. Again, Snow led the way, the greatest anesthetist who ever lived. He saw the need to provide better control over the concentration of anesthetic delivered, and he developed a vaporizer to meet that need [10, 11]. Despite its imperfections, his work anticipated much of what evolved into our present vaporizers.

However, most anesthetists ignored his insights. The curmudgeon, Simpson, thought Snow foolish. A handkerchief and a bottle of chloroform were all that was needed. And thus anesthesia was given with primitive devices delivering an unknowable concentration of anesthetic. Anesthetic sprinkled on gauze or a handkerchief. Both I (EIE) and one of my co-editors (LJS) vividly remember the horror of being anesthetized (twice) by an anesthetist placing a gauze mask on our respective faces and dropping liquid ether on that mask until our world disappeared. I think it took four strong men to hold me down.

So, with exceptions, we learned how to give anesthesia safely if not pleasantly, guided by our observations of the patient's response to what we gave. We slowly added improvements prompted by suggestions of people such as Edmund Andrews who noted that nitrous oxide might be given for more than a few moments if oxygen were added [51]. Implementing that observation required the development of iron tanks to hold large amounts of (compressed) nitrous oxide and oxygen. Such tanks promoted construction of anesthetic machines, and onto these were grafted vaporizers that, while crude, allowed delivery of graded concentrations of potent

inhaled anesthetics. Parallel developments were made in anesthetic delivery systems (to-and-fro and anesthetic circle systems), devices that accepted the gases and vapors made by the anesthetic machines, devices that enabled presentation of the gases and vapors to the patient to breathe and rebreathe—care being taken to remove the carbon dioxide from the rebreathed gases. Along the way in these developments, Cushing, after he killed a patient, led us to blood pressure monitoring and the recording of pulse rate and blood pressure in the 1890s [13].

Modern Times: So, for a century after the discovery of anesthesia, we made incremental improvements in anesthetic delivery systems and monitoring. World War II gave us the atomic bomb, and that invention required advances in fluorine chemistry—which, by the way, gave us Teflon® and modern (fluorinated) inhaled anesthetics. It also became crucial to better control the concentration of these powerful, potentially lethal, anesthetics. In the early 1950s, Lucien Morris invented the Copper Kettle, the first vaporizer intended to deliver a precisely known concentration of any volatile vapor, at any flow rate [52]. Control! Morris' approach was copied by other manufacturers (e.g., the Vernitrol produced by the Ohio Chemical Company.)

In a strange way, the atom bomb also gave us blood gas electrodes, devices allowing the measurement of oxygen and carbon dioxide partial pressures and acidity in small volumes of blood. John Severinghaus had begun a career in physics when the bomb exploded. His sense of the immorality of this device caused him to abandon physics and turn to a career in medicine and eventually anesthesiology. In the 1950s, this led to his invention of the carbon dioxide electrode and a device into which oxygen, pH and his newly invented carbon dioxide electrode could be placed allowing easy measurement of blood gases [53]. Severinghaus says he was given far more credit for the invention of the carbon dioxide electrode than was due. The real credit, he says should go to Richard Stow who thought of the basic idea (a slight pun), but couldn't make it work stably. Severinghaus supplied the additional thought needed to produce a functional electrode—Stow's electrode was simply a pH electrode covered with a latex film with distilled water separating the latex and the pH electrode. Carbon dioxide diffused across the latex and was read as a pH change. Severinghaus suggested adding sodium bicarbonate to the distilled water to ensure stability, and that worked like a charm. "The joke here is that I got the credit for inventing the CO₂ electrode but all I did was add soda."

At this time, we saw the development of analyzers of the gases that our patients breathed; anesthetic vapors and gases, oxygen and carbon dioxide. Because they absorbed infrared light (and thus were greenhouse gases—but I digress), the anesthetic gases and carbon dioxide could be analyzed by their absorption of infrared light at particular wavelength frequencies (the different frequencies allowed one gas to be dis-

tinguished from another). The German, Luft, had invented the device that used this principle right before World War II [54]. This analysis could be done on a breath-by-breath basis, and the results for the gas concentrations in the gases at the end of each breath closely correlated with the gases measured in arterial blood, using the blood gas analyzer. Thus, with each breath one could tell the concentration of these gases in the lungs and thus in the blood. Given a bit of time for equilibration, the concentrations in blood reflected the concentrations in tissues such as the brain. Such devices invited the determination of the anesthetic concentrations required to produce specific anesthetic phenotypes (i.e., the capacity of an anesthetic to produce a certain characteristic such as immobility or blockage of memory); as noted above, they facilitated the invention of MAC.

The realization that one could control the effects of inhaled anesthetics on vital functions such as breathing and blood pressure by controlling alveolar concentrations, in turn prompted an increasing demand for a clinical availability of monitors for respiratory (carbon dioxide and oxygen) and anesthetic gases. In the late 1970s, Severinghaus and Ozanne gave us such monitoring using a multiplexed mass spectrometer [55, 56]. (By now, dear reader, it should be clear that Severinghaus is the gadgeteer without peer [57]). Monitoring with the multiplexed analyzer usually worked well and was economical (it could serve a dozen rooms "simultaneously"), but the occasional breakdown of a system to which many anesthetists became addicted was unacceptable, and the multiplexed analyzer gave way in the late 1980s to the presently ubiquitous stand-alone infrared analyzers.

Not only could we now control the delivery, especially of inhaled anesthetics, we could measure and control what we did with those and other drugs. We controlled delivery in part by controlling ventilation. It sounds simple. When I (EIE) was a resident I usually controlled ventilation by squeezing a bag connected to the circuit which, in turn, was connected to the patient: when I squeezed, the patient got a breath. Because I was a graduate of much schooling, I (and every like anesthetist) was considered to have an "educated hand" that could precisely deliver the correct amount of breathing. Others decided that I was less educated than I thought [58, 59]. The educated hand wasn't. That, and a great interest in ventilating the lungs of patients suffering from polio in the 1950s, gave us ventilators, devices that continued to evolve, and gave us a precision over ventilation to the patient's great benefit. It also freed a hand that would otherwise be tethered to a bag.

And what about the heart? We could depress it with our drugs or stimulate it with other drugs. Increasingly, we measured various consequences of such depression and stimulation. As we've repeatedly noted, Cushing and Codman in the 1890s taught us to measure the blood pressure of patients indirectly, using the Riva-Roca method familiar to us in our doctor's office. But that didn't give us the pressure produced

by every beat of the heart, and increasingly we applied the pressure transducer [the strain gauge invented by Edward Simmons (1911–2004) and Arthur Ruge (1905–2000) in 1938] that investigators used in animals, an application that is commonplace today.

Perhaps the most fascinating development was that of transesophageal echocardiography, the use of ultrasound to supply beat-by-beat images of the heart, images that tell the anesthetist how well the heart is doing its job [60]. First developed as a crude instrument by Oka in the late 1970s [60], it evolved from producing a one-dimensional to a two dimensional image. Today, it tells the anesthetist how well and where blood is flowing in the heart—right and wrong. A second application of ultrasound, one still developing, now tells the anesthetist just where to place the tip of a needle when performing regional anesthesia—or when trying to cannulate an artery or a vein.

Finally, consider today's ubiquitous pulse oximeter, a device that measures the amount of oxygen carried by the hemoglobin in blood, doing so with each beat of the heart and announcing the content with a beep whose pitch indicates the amount (percent). Severinghaus tells this rich story in Chapter 55. Many contributed to the history. Glen Millikan devised a working model in 1941 and coined the term “oximeter” [61]. Earl Wood supplied a key control in the late 1940s [62]. But the person who put it all together, and is credited with the discovery of pulse oximetry, is Takuo Aoyagi, a most modest Japanese bioengineer who was driven to his invention by the serendipitous observation of artifacts he saw in his studies of cardiac dye dilution with an earpiece densitometer. He reported on his invention on 26 April 1974, “Improvement of the Earpiece Oximeter,” to the Japanese Society of Medical Electronics and Biological Engineering. The first report of Aoyagi's device was by the surgeon S Nakajima, in 1975 [63]. Anesthetists in all developed and many less developed countries use pulse oximeters, and many credit the device for decreasing the mortality associated with modern anesthesia. Curiously, attempts to prove this relationship have failed [64].

There are more inventions, gadgets devised by anesthetists, many trivial or potentially harmful (e.g., see my first publication) [65]. Some had considerable importance (e.g., transcutaneous measures of the partial pressure of carbon dioxide or oxygen). The reader is referred to Chapter 55.

1960-Present: Theme 7—Who Pays for Anesthesia Research?

For the era preceding WWII, the answer to the title question was “no one.” Little research was done except for that supported by industry or occasionally the well-endowed institution, or the curious individual who took money from his pocket.

The major support for research in anesthesia has always come from industry. Industry underwrote the research into new drugs (see above) and advances in equipment (see “gadgets”, also above). This relationship between industry and faculty investigators was symbiotic—industry got the data it needed to test and to gain approval for its' products. The investigators received support and the products required for clinical studies, and the subsequent academic recognition required for promotion, and the specialty gained access to marvelous (usually) new drugs. Most drug and equipment inventions were industry-inspired, but university investigators and practitioners often joined with industry in the evaluation of new products. Both developmental research and industry-investigator collaboration have decreased in the past two decades, as the cost of developing new drugs has increased and the perceived need for new products has decreased (as anesthesia as a specialty has matured). Rarely did industry support basic research in anesthesia, research into “how things worked”. This fell to the National Institutes of Health (NIH) in the US and similar institutions in other countries, and to various foundations

In the US, the first named National Institute of Health was born in 1930. The (pleural, now) National Institutes of Health grew dramatically after World War II, but little in the way of funding went towards research in anesthesia until the 1960s. In the 1960s, Emanuel Papper (1915–2002), the chair of the first Department of Anesthesiology at Columbia University, contributed to several NIH committees and in 1965–6 acted as a principal consultant in the establishment of the National Institute of General Medical Sciences, an Institute serving as a primary source of support for research in anesthesia from that time to the present. He played a major role in freeing more NIH dollars for research in anesthesia. In terms of increasing dollars in support of research for anesthesiology, the NIH has been generous (Fig. 39.3) [66]. NIH support for anesthetic research appears to have exceeded (by an order of magnitude) and be more consistent than that supplied by the UK from its Medical Research Council (MRC) (Fig. 39.4), differences that have persisted for the past two decades.

A crucial but small source of research support in the US increasingly came from professional anesthesia organizations. This support was crucial because it supplied seed money. In 1987, the American Society of Anesthesiologists (ASA) organized FAER (Foundation for Anesthesia Education and Research).

“From 1988 to 2009, FAER awarded grants of over \$24 million with another \$1.4 million committed for disbursement in 2010 and 2011. Most of this was underwritten by the ASA and private industry which has given FAER a total of \$24.9 million. The pace of donations and grants has increased in recent years. From 2005–2009, the ASA contributed \$8.8 million and FAER gave \$11.3 million in grants.” (personal communication from Dr. Denham Ward to EIE.)

Fig. 39.3 From 1975 to 2003, NIH support for anesthesiology grew by 1600%, to nearly \$100,000,000. This largely reflected increasing support of research in general, rather than acquisition of an increasing share of the research support pie by anesthesia researchers, which remained at less than 1% of the total grants funded by the NIH. (Data from Table 1 in Schwinn DA, Balser JR: Anesthesiology physician scientists in academic medicine: a wake-up call. *Anesthesiology* 2006; 104: 170–8)

Fig. 39.4 The Medical Research Council in the UK also supports “anesthesia research”. As the graph indicates, support has been uneven in the past two decades, ranging from zero to over 1 million pounds per year. Support in the past decade appears to be on the ascent. (Data kindly provided as a communication from Stephen Penton, Information Officer, Medical Research Council, 22 Nov 2012, to EIE)

The International Anesthesia Research Society has similarly contributed to the support of research, providing more than \$14,000,000 in support of research grants and fellowship training.

Conclusion: Theme 8

In greatest part, the seven themes exist to enhance clinical care. We have come to call this translational research, and the ASA has seen fit to emphasize its importance with an eponymous lecture named after one of the greatest contribu-

tors to such research, John Severinghaus—who was the first lecturer [57]. Such research does more than enhance clinical care. Not only does it move from bench to patient, but issues raised in the clinical care of patients lead back to laboratory work. Translational research is the eighth, and perhaps the most important, theme. Much of such research is described in great detail in Chapters 41–43, but I would argue that it appears in various guises in most of the chapters of this book.

Acknowledgment I thank Dr. John W. Severinghaus for his several suggestions.

Dennis M. Fisher and Steven L. Shafer

Summary

Before 1950, we little understood what drugs did to patients (pharmacodynamics) or what patients did to drugs (pharmacokinetics). In 1949, Faulconer et al correlated the EEG with the sedative/anesthetic effects of nitrous oxide. In 1960, Price simulated thiopental pharmacokinetics. In 1963, Eger extended the simulation to inhaled anesthetics and invented MAC. From 1972 to 1997, Sheiner and Rosenberg used computer models to predict pharmacokinetics in individuals, leading to the population principle.

In 1978, Hull used the effect site concept to understand the time course of pancuronium's effect. From 1978 to 1986, Sheiner and Beal defined methods for estimating the parameters controlling drug behavior, developing NONMEM to estimate population pharmacokinetics. In the 1980s, Schwidlen published models allowing control of anesthetic concentrations. With Stoeckel, he devised a target controlled infusion (TCI) system that could maintain a target drug concentration.

During 1983 to 1995, Rampil related his EEG "spectral edge" to response to noxious stimulation. Shafer developed algorithms to target plasma and effect site concentrations, measure the performance of TCI devices, and estimate pharmacokinetics. During 1990 to 1998, the Stanford group used TCI to study pharmacodynamics in a "pseudo-steady state", assessing the effects of constant brain concentrations of thiopental, midazolam, flumazenil, and propofol. In 1991, Hughes et al defined the time for a 50% decrease in plasma concentration, as the "context-sensitive half-time."

During 1992–2001, Glass and Sebel used TCIs to study fentanyl interactions with other anesthetic drugs. The Stanford group applied Sheiner and Beal's concepts to produce the "Minto" kinetic-dynamic model of remifentanyl, now used for TCI of remifentanyl. Fisher et al used the differential effects of muscle relaxants on adductor pollicis and respiratory muscles to create a dose-effect model that did not require measurement of plasma concentrations.

From 1996 to 2007, Sheiner used the population principle to show that population pharmacokinetic analysis does not require complete data. He proposed that a single clinical trial plus causal evidence of effectiveness can merit drug approval. Stanski in 2005 called this "Getting the Dose Right."

From 1989 to 1999, the Stanford group developed a pharmacokinetic—pharmacodynamic model of propofol incorporating age and gender as covariates, and yielding the "Schnider" model. With Glass et al. they developed TCI for sedating critically ill patients with propofol, midazolam, and lorazepam. From 1998 to 2004, Minto and the Stanford team initiated response surface methods to characterize drug interactions, including context-dependent time courses. From 1994 to 2005, Henthorn, Avram, and Krejcie demonstrated that accurate initial drug dosing required use of "front end" pharmacokinetics.

Prologue

Nearly four decades ago, Dennis Fisher and Steve Shafer independently encountered remarkable people changing the course of pharmacokinetic and pharmacodynamic

modeling. This chapter reflects their admiration of those individuals, and adds their personal experiences during an era transforming anesthetic clinical pharmacology and altering our understanding of and clinical practice with the drugs we use every day.

In the Beginning

Fisher spent the 1970s at the University of Pennsylvania in pediatric and anesthesia residencies, followed by a fellowship in critical care. His mentors, Ted Smith and Henry Rosenberg, introduced him to the prolific neuromuscular

Fig. 40.1 Lewis Sheiner—Visionary Pharmacologist (1940–2004)

research coming from Ron Miller's group at the University of California, San Francisco (UCSF). Following residency Fisher applied to Miller for a fellowship, primarily drawn to UCSF by the opportunity to work with Lewis Sheiner (Fig. 40.1), the god of pharmacokinetics and pharmacodynamics. Many years of NIH support followed.

Shafer started closer to San Francisco, enrolling in Stanford Medical School in 1978. In his last year at Stanford, Shafer worked with Stanski, a previous Sheiner fellow, who was building a program in anesthetic pharmacology. Here are the stories of people—exemplars—who changed the world of anesthetic-related pharmacokinetics and pharmacodynamics.

Sheiner trained in internal medicine but never did much clinical work. Following his residency he went to the NIH to study Clinical Pharmacology, focusing on computer programs to individualize the dosing of warfarin [1]. In the late 1960s, computers were expensive, and programs were tediously assembled with punched cards that the computer could read. Applying this cumbersome technology to individualize dosing was a radical concept: it seemed too expensive and difficult to be practical. It was but one of Sheiner's visions.

Soon after arriving at UCSF, Sheiner developed a collaboration with Barr Rosenberg, economics professor at Berkeley and the entrepreneur founding Rosenberg mutual

funds. Rosenberg told Sheiner that the econometrics community used sophisticated techniques to address problems inherent in issues such as warfarin dosing. Sheiner, Rosenberg and Ken Melmon (one of the founders of clinical pharmacology) proposed a general mathematical framework for optimizing drug dosage [2]. Sheiner's mother encountered problems with regular digoxin overdosing or underdosing, prompting his early study of computer aided digoxin delivery [3].

The "Population Principle"

Such modeling led to Sheiner's most important contribution, application of the "population principle" to pharmacology. According to the population principle, the behavior of drugs in individuals can be accurately predicted based on knowledge about how drugs behave in a population of patients with similar characteristics. The population principle defined drug behavior using "mixed effect" models combining the roles of "fixed effects" (e.g., dose, weight, height, age, gender), and the roles of "random effects" (things like the unexplained person-to-person differences in clearance, volume of distribution, or sensitivity to a drug) to explain drug behavior (pharmacodynamics). Further, the population principle separated the components of variability into those between individuals (interindividual variability, such as differences in clearance, which account for individual response to drugs) and those within an individual (intraindividual variability, such as assay noise). The aim was to predict drug effect as precisely as possible, taking known variables such as weight, height, gender, age, and other patient factors (e.g., genetics), to accurately predict the pharmacokinetic and pharmacodynamic factors controlling the response to a drug, factors such as clearance, volume of distribution, and potency. Thus, measurement of the right fixed effects should allow prediction of the response to a drug accurately, reducing the previously unexplained subject-to-subject variability. Reduction of residual inter-individual variability, things like assay noise, would require more precise measurements and perhaps refinement of models to more accurately describe the underlying biology.

Sheiner described the population principle in 1977 [4]. One of his insights was that pharmacokinetics in a population of patients could be estimated from routine clinical data. Sheiner's methods allowed the design of more efficient and informative clinical trials, optimizing dosing recommendations, and, via empirical Bayesian methods, optimizing individual therapy. The work transformed clinical pharmacology [5], the pharmaceutical industry [6, 7], and drug regulation [8].

A Fortuitous Bus Ride

Sheiner needed a statistician to develop his ideas, and a programmer to create software that would convert his concepts into research tools. In 1976, while riding on the UCSF

Fig. 40.2 Stuart Beal—Creator of NONMEM (1941–2006)

commuter bus to Marin County, he fortuitously sat next to Stuart Beal (Fig. 40.2), an aspiring statistician recently recruited to UCSF. Sheiner explained his ideas, piquing Beal's interest. A friendship and collaboration began that day and lasted a lifetime.

Beal expanded on Rosenberg's concepts for dose individualization [9], leading to his developing the statistical basis for mixed-effects modeling. Beal also wrote the program NONMEM, an acronym for non-linear mixed effects modeling. It is arguably the greatest intellectual advance in the history of clinical pharmacology. NONMEM's methodology opened the "population principle" of drug behavior to clinical pharmacologists, and became the standard modeling technique for the pharmaceutical industry. In the 1980s, Sheiner and Beal validated NONMEM against other popular approaches [10–12]. NONMEM outperformed those approaches.

In 1989, Ted Grasela approached Sheiner with a problem. Someone had sampled blood to determine theophylline concentration in neonates given theophylline to prevent apnea of prematurity. Each patient supplied a few samples. Grasela asked if a pharmacokinetic analysis could be done with such sparse sampling (compared to the standard of 10 samples or more). Sheiner realized that mixed-effects methods could be applied to Grasela's problem: the pharmacokinetic characteristics could be determined with a sufficient number of subjects (i.e., trading fewer samples per subjects for more subjects). The analysis succeeded [13], spawning a new approach to assessing population pharmacokinetics: study many subjects (thereby learning more about the population) but obtain few samples per patient (still learning about individual characteristics because of the large number of samples). This approach is known as sparse sampling coupled with population (mixed-effects) methods.

The "Effect Compartment"

Another novel Sheiner concept was mathematical modeling of the "effect compartment" in the context of a pharmacokinetic model. Clinicians have always known that a delay exists between drug dosing and drug effect. In 1960, Price described the time delay between thiopental concentration and drug effect [14]. Eger also provided insight into this delay or "hysteresis" for inhaled anesthetics [15]. However, this work did not link the delay to a pharmacokinetic model of the plasma drug concentration.

Stanski came to UCSF from his anesthesia residency at Massachusetts General Hospital. He wanted to develop a model explaining the delay between administration of a muscle relaxant and the resulting muscle paralysis. Immediately after receipt of a bolus dose, the plasma concentration of the muscle relaxant is at its highest concentration, but there is no drug effect. Over time the plasma concentration steadily decreases, and the level of muscle relaxation ("twitch depression") rises, reaches a maximum, and then recedes. This leads to the curious situation where there are two different plasma concentrations associated with the same twitch: one observed while the drug effect was increasing, and the other while the effect was decreasing. How could markedly different concentrations produce the same twitch depression?

Sheiner argued that the relevant concentration is the one at the neuromuscular junction (Sheiner chose the general term "effect site"). He linked it to the plasma concentration by simple "first order" diffusion down the concentration gradient. Sheiner and Stanski introduced the concept of the "effect site" in a manuscript describing the time course of d-tubocurarine [16]. It became Stanski's most cited manuscript. Interestingly, using the same principle of first order diffusion down the concentration gradient, Chris Hull, a British anesthesiologist in Newcastle, UK, developed an effect compartment model for pancuronium [17]. Although Hull's publication preceded Sheiner's, Hull did little to popularize his work, and the Sheiner-Stanski contribution is considered pivotal.

Sheiner's Legacies

Sheiner pursued other issues: nonparametric approaches making minimal assumptions [18], therapeutic drug monitoring [19], how to handle missing dose data [20], and modeling drug compliance [21, 22]. He was a formidable intellect engaging anyone having interesting questions. He loved data. He was never just the visionary. Sheiner formatted the data, wrote NONMEM control streams, fitted the data to models, created the graphs, and analyzed the outputs. Fisher or Shafer would call Sheiner with a question, and his answer was often "Let me see the data, and I'll get back to you." He rarely looked anything up in books. It might be faster, but if he forced himself to do the derivation, he would then understand it better. Besides, it was more fun.

Sheiner mentored more than a generation of investigators and clinical pharmacologists. Most clinical pharmacology papers continue to reflect his work. He mentored Carl Peck, former Director of the FDA Center for Drug Evaluation and Research which incorporated Sheiner's concepts into FDA work. Sheiner was Stanski's mentor and greatest friend. He mentored Fisher whose papers in the 1990s benefited from Sheiner's insights.

Beal's education at UCLA included a BA degree in mathematics with a minor in Logic and Fine Arts, and MS and PhD degrees in biostatistics. He started at UCSF in 1973 as a Senior Statistician in the Office of Information Systems, joining the faculty in 1976, the year of his bus ride with Sheiner.

Sheiner was the front man—meeting people, giving lectures, looking for good questions and informative data, and raising new ideas. Beal was the implementer, the developer of statistics, translating Sheiner's grand ideas into NONMEM. NONMEM was Beal's life. He created new methods in NONMEM to handle the challenges raised by Sheiner and others. NONMEM came to encompass all of statistics to Beal.

In 2001, Shafer asked Beal how to perform a repeated measures ANOVA. Not trained as a statistician, Shafer had no idea about the "right" way to approach it, but had coded the problem using NONMEM. Beal laughed. Like Shafer, he could perform a repeated measures ANOVA using NONMEM, but had forgotten how to do it with conventional approaches. Indeed, Beal used NONMEM for t-tests. That conversation speaks volumes about NONMEM's versatility. Why use anything else, if NONMEM can provide any statistical test?

Beal and Sheiner offered NONMEM for a modest user fee to colleagues in academia and industry. If you didn't renew your license, then Beal (yes, the same Beal who developed the code) would personally call and ask you to return your magnetic tape or, once that was obsolete, the floppy disks. A week later you got another call, again from Beal.

Sheiner's colleague, Malcolm Rowland, thought that making NONMEM available inexpensively was a terrible idea: if Sheiner and Beal didn't make NONMEM profitable, then there would be no posthumous support structure for NONMEM. Eventually Sheiner and Beal accepted Rowland's wisdom and turned over NONMEM distribution to Globomax (now ICON Development Systems). Rowland's suggestion proved prescient. Despite Sheiner's and Beal's premature deaths, NONMEM has grown in popularity, usability, and statistical power.

Beal and Shafer—A Relationship Built on Questioning

Although many found Beal to be distant and reserved, he and Shafer were unusually close. Their friendship grew from a 1990s disagreement about modeling. Shafer, whose research was in target controlled drug delivery, had numerous reser-

vations about NONMEM. NONMEM could not be used for TCI, which required changing infusion rate every 10 seconds. Shafer had modeled all patients' responses simultaneously, ignoring inter-subject variability [23]. Beal dismissed the approach as "naïve" but allowed Shafer to deluge him with data, graphs, and analyses. Eventually Beal agreed that the naïve approach had merits, and was sometimes powerful. In the process, Beal showed Shafer how data settle scientific debates. Beal's patient mentorship led to Shafer's interest in the role of data in evidential reasoning [24]. Their relationship is evident in a letter Shafer sent to Beal in January, 1995:

"I'm a physician with no formal training in mathematics or statistics. My role in clinical pharmacology is to bring the tools developed by your group to bear on questions important to me as a clinician. Your mentoring has allowed me to perform my work at a more sophisticated level than would otherwise be possible.

"Mentoring takes time and patience, and God knows I've sorely tested your store of each. You have been patient with me, careful in your explanations, and considerate of my lack of formal training in mathematics and statistics. With your permission, I'll continue to pester you with problems, bother you with bugs, quiz you with questions, and irritate you with irreverent e-mail."

Epilogue to Lewis Sheiner and Stuart Beal

In 2004, Sheiner had a heart attack on a train from Basel Switzerland. He had just received the Rawls Palmer award at the American Society of Clinical Pharmacology and Therapeutics meeting. He was resuscitated but never regained consciousness, dying several days later.

Two years later, without his friend, collaborator, and soul mate, Beal completed his testing and validation of NONMEM VI. He sent it to Globomax with the enigmatic comment that it was nearly done, and that it could be released even without a final OK. A few days later he died.

Sheiner and Beal invented concepts, methodologies, and tools that changed how we understand therapeutics. Every drug is dosed a little better because of their work.

Dennis Fisher and the UCSF group

Fisher (Fig. 40.3) arrived in San Francisco in 1980, his interests quickly attracting him to Sheiner's circle. A pediatric anesthesiologist, Fisher initially studied pharmacokinetics and pharmacodynamics of muscle relaxants and intravenous anesthetic drugs in children, infants, and neonates. He developed a model describing the kinetics of drugs like atracurium that were degraded in plasma [25]. Burroughs Wellcome (now GSK) repeatedly challenged the model without explaining their rationale. Their stance galled Fisher because they adopted a similar model for cisatracurium, and claimed that they developed the model [26].

Francois Donati obtained simultaneous measurements of twitch depression at the thumb (adductor pollicis) and the laryngeal muscles, leading Fisher to a remarkable insight:

Fig. 40.3 Dennis Fisher. (Courtesy of the author)

with two different rates of onset, both driven by the same plasma drug concentrations, he could estimate the relative potency of the two drugs, and the rate of plasma-effect site equilibration for each with no measurement of plasma concentrations. The manuscript [27] prompted a suggestion by “an anonymous reviewer” (Shafer) to validate the model by repeating the study with plasma sampling and computing the outcome with and without those data. Fisher did, the results confirming his thesis [28].

Fisher presently evaluates many new drugs, most having nothing to do with anesthesia. His software, PLT Tools (in which Shafer also has a commercial interest) provides a powerful environment for harnessing NONMEM. Fisher and Shafer have now taught several hundred pharmaceutical scientists how to model their data with NONMEM. Through his teaching, and development of PLT Tools, Fisher continues the tradition of teaching, innovation, and service to pharmaceutical development that characterized Lew Sheiner.

Anesthesia and Brainwave Pioneers

The EEG has long been used to measure anesthetic effect. In 1875, Caton observed electrical activity in the scalp of rabbits, and found that the currents on one side of the head

were influenced by light stimulation of the contralateral retina, suggesting the brain as a site of action [29]. Fifteen years later, Fleischl von Marxow demonstrated that chloroform extinguished the scalp electrical activity that Caton reported [30], confirming that the brain itself was the source of this activity. In the early 1930s, advances in amplification and recording allowed Berger to quantify EEG responses to chloroform-induced changes in consciousness [31]. In 1937, Gibbs observed that anesthetics changed the EEG from a low-voltage high-frequency pattern to a high-voltage, low frequency pattern, suggesting that the EEG could be used to measure the state of anesthesia [32]. In the late 1940s, Bickford at the Mayo clinic demonstrated the EEG effects of nitrous oxide [33]. In 1952, Faulconer correlated the arterial blood concentration of diethyl ether with specific EEG patterns, showing that the EEG responded predictably to a specific anesthetic [34]. Then as today, the finding was controversial. For example Galla and colleagues examined raw EEG signals for 43 patients and found a discrepancy between the clinical signs of anesthetic depth and the concurrent EEG [35]. Martin, Faulconer, and Bickford, later demonstrated the classic biphasic response of the EEG to sedative/anesthetic drugs [36]. Bickford continued his work for nearly 50 years, publishing his last paper in 1992.

The microcomputer revolution of the 1970s allowed numerous investigators to attempt to link the EEG with anesthesia effect. For example, Levy and colleagues tried to correlate anesthesia drug concentrations with EEG at 50% (median frequency) or 95% (spectral edge) of wave activity, and concluded that the behavior of the EEG prevented any single number from describing the anesthetic state [37, 38]. What wise men! Drummond and colleagues calculated median frequency, spectral edge frequency, a frequency band power ratio, total power, and dominance shift during states of patient arousal during anesthesia [39], and concluded that none of these descriptors reliably predicted imminent arousal. But Long and coworkers undertook a similar analysis, and found that an abrupt decrease in delta EEG power always presaged arousal [40]. Dwyer and colleagues found no difference in the EEG power spectrum between patients anesthetized with isoflurane who moved on incision and those who didn't move [41]. What these investigators did not appreciate is that different drugs used to produce the anesthetic state produce different effects on the EEG. Stanski sorted out that riddle.

Don Stanski

After Stanski (Fig. 40.4) completed his fellowship training with Sheiner, Phil Larson recruited him to Stanford University to continue Stanford's program in clinical pharmacology, a program founded by William Forrest, Ellis Cohen, and Ty Smith. With Ed Meathe, Stanski used EEG algorithms de-

Fig. 40.4 Donald Stanski

veloped by Ira Rampil [42] to calculate the “spectral edge” [43] of the EEG response to thiopental. Stanski sent his EEG recordings following thiopental administration to engineer Meathe at UCSD, who calculated the spectral edge using Rampil’s algorithm and returned the results to Stanski [44]. Stanski linked the EEG response to the effect site, the concept he developed at UCSF, to provide an integrated pharmacokinetic-pharmacodynamic model of thiopental [45]. His work disproved Dundee’s 1950s claim that there was acute tolerance to thiopental [46] and showed that elderly brains are more sensitive to thiopental because of a change in pharmacokinetics, not because of a greater sensitivity to thiopental [47].

Stanski’s success with the 95% spectral edge as a measure of thiopental drug effect was essential to his goal of creating integrated pharmacokinetic/pharmacodynamic models of intravenous anesthetic drugs. However, relying on UCSD to analyze his EEG recordings presented a significant logistical bottleneck. Shafer met Stanski in 1982, a year before Shafer completed medical school. Stanski needed a local programmer, and with help from Stanford Research Institute, Shafer wrote Fortran programs to digitize analog EEG data and calculate the 95% Spectral Edge. Stanski moved the EEG analysis to Stanford, and used Shafer’s software for his subsequent studies on thiopental, benzodiazepines, and intravenous opioids. Stanski paid Shafer the munificent sum of US\$ 1,000 at the end of the year for his contribution.

Stanford and “Ratsicles”

Stanski’s work eventually provided integrated pharmacokinetic/pharmacodynamic models for thiopental [48, 49], fentanyl and alfentanil [50, 51], sufentanil [52], etomidate

[53], ketamine [54], and midazolam [55, 56]. Stanski’s papers “hit” while Shafer pursued his residency (1984–1986) at the University of Pennsylvania. The papers garnered attention and befuddlement. Shafer was asked: “Do you know Stanski? Do you understand this effect site stuff?” Shafer answered “Yes” and “Maybe”. Stanski recruited Shafer back to Stanford after residency, seducing him with visions of an academic career in computerized delivery of intravenous anesthetics.

Over the next six years, Stanski’s laboratory became a center for clinical pharmacology in anesthesia. Stanski thought that defining the flow of drug to individual tissues could provide insights into the physical processes underlying common empiric pharmacokinetic models. He injected thiopental into rats, injected microspheres to identify regional blood flow then dropped the rats into liquid nitrogen. He dissected the tissues, counted microspheres, and assayed tissue concentrations of thiopental in twelve tissues from the frozen “ratsicle”. From these he constructed detailed physiologic models of drug behavior [57]. It was a colossal effort with a small return on investment. These mathematically complex, detailed models did not provide more insight than simple empiric models consisting of 2 or 3 compartments linked by first-order drug transfer [58].

G187084B Becomes Remifentanil

Stanski’s vision, partly implemented by Shafer, was that modeling and simulation could change drug development. In 1992, fortunate coincidences led Stanski, with Shafer in tow, to a paradigm changing experiment. Glaxo Pharmaceuticals had a new “ultra-fast” opioid, G187084B, later known as remifentanil. They recruited one of Sheiner’s former fellows, Keith Muir, to lead the remifentanil development program. Muir was well versed in pharmacokinetic and pharmacodynamic modeling. In preparing for his job interview, Muir read a paper by Shafer and Varvel summarizing the pharmacokinetic and pharmacodynamic parameters determined by Stanski for fentanyl, alfentanil, and sufentanil [59]. Muir took the modeling and data from the paper, and proposed to Glaxo that they use the EEG to guide the clinical development program for G187084B. Fortunately, the FDA assigned Dan Spyker as the medical reviewer for G187084B. Spyker was a toxicologist, but his PhD in electrical engineering probably drove his abiding interest in pharmacokinetic and pharmacodynamic modeling. He had formed a business, Cedar Systems, in the 1980s to develop software to model drug behavior. Spyker was convinced that Muir’s concept was sound. He also thought it was a revolutionary paradigm change. Muir then contacted Stanski and Shafer with a proposal: use the fentanyl, alfentanil, and sufentanil work as a template for studies of remifentanil, And use those results to simulate how the drug should be used clinically. Stanski and Shafer jumped at the opportunity.

Three Stanford fellows were assigned to the project: Tal-mage Egan, Charles Minto, and Thomas Schnider. Together they produced the highest resolution pharmacokinetic/pharmacodynamic model that had been created for an intravenous anesthetic [60, 61]. They then applied the pharmacokinetics in simulations showing what to expect clinically with remifentanyl [62]. These simulations reproduced the concentrations associated with different opioid effects, and provided precise guidance for clinical use.

The experiment worked. There were no failed clinical trials in the remifentanyl development program, because the doses, based on simulation, were correct in every trial. The FDA approved the drug a mere 4 years after the patent was granted, a record for a drug not on a fast track (e.g., HIV therapy). And, most critically, it set an example of how modeling and simulation could create a “fingerprint” of a new pharmaceutical [63], resulting in safer, faster, and less expensive clinical development. It was the first demonstration of Sheiner’s vision.

In retrospect, remifentanyl was an “easy” demonstration. Remifentanyl followed fentanyl, alfentanil, and sufentanil. For each of those opioids the EEG, a surrogate marker of effect, had already been mapped to clinical concentrations. Few other drug classes have such a clear relationship between a surrogate effect (EEG) readily measured in volunteers and the clinical effects.

Stanski Applies Sheiner’s Vision

Stanski wanted to see if Sheiner’s concepts could be more broadly applied. He left Stanford in late 1998 to work at Pharsight Corporation. Pharsight was founded to improve drug development using modeling. Stanski, Shafer, Fisher, and Sheiner were all involved in its early evolution. At Pharsight, Stanski directed a team applying modeling and simulation to drug development. Pharsight made some inroads in the area, but biological challenges (the difficulty of finding useful surrogate effects) combined with decreased FDA enthusiasm for modeling and simulation limited the implementation of Sheiner’s vision. Stanski then went to the Commissioner’s Office at the FDA to help them apply the kinetic/dynamic modeling skills developed at Stanford. In 2005 Stanski left the FDA for a position at Novartis Corporation where he built a team of approximately 80 clinical pharmacologists and modeling scientists. The concepts of quantitative drug development initially advanced by Sheiner and Beal, and refined for nearly 20 years at Stanford by Stanski, are being used today to develop new pharmaceuticals for human diseases. This is the wholesale application of Sheiner’s vision to drug development: multiple programs, ranging from pre-clinical to post-approval, all guided by mathematical models of pharmacokinetics and pharmacodynamics, with specific incorporation of patient covariates and models of intersubject and intrasubject vari-

ability. The whole shebang. And it works! In 2011, Stanski was awarded the first Sheiner-Beal Pharmacometrics Award by the American Society of Clinical Pharmacology and Therapeutics.

Stanski is not a mathematician, statistician, modeler, or computer programmer. He has no intuition with equations. Basic statistical concepts do not come naturally. He never programmed a computer or wrote an Excel macro, although he did run an early version of NONMEM using punch cards. Stanski is a visionary. He knows what the tools do, and can match the tools to important questions. He doesn’t need to model drug data. There are propeller heads like Shafer for that. Sheiner said it best, when introducing Stanski for the Rawls Palmer award in 1998: “I would rather hear a good question from Don, than a good answer from anyone else.”

Stanski was Shafer’s primary mentor, a lifetime relationship beginning nearly 30 years ago. Although Stanski is widely recognized for his scientific achievements, Shafer regards mentorship as Stanski’s greatest talent. Stanski mentored dozens of fellows, most having gone on to academic and scientific careers. Shafer regularly gives talks on mentorship. They are always dedicated to Stanski.

Helmut Schwilden and Colleagues

It is easy to compute the infusion rate required to maintain a constant concentration for drugs described by one compartment models: it is the target concentration times the clearance. However, by the late 1960s it was clear that one compartment models describe few, if any, drugs. Distribution of drugs between central and peripheral compartments influences the accumulation of drug in the peripheral compartment and thereby affects the infusion rate required to sustain a constant effect. In 1968, Krüger-Thiemer described the mathematics required to maintain a steady drug concentration for drugs described by more than one compartment [64]. However, the calculations were intractably difficult, and in 1968 nobody envisioned microprocessors. More than a decade passed before implementation of Krüger-Thiemer’s methodology.

Helmut Schwilden (Fig. 40.5) was a physicist who became an anesthesiologist. In the late 1970s, while Sheiner developed mixed-effects modeling and Stanski, modeled plasma-effect site relationships, Schwilden applied mathematics to instantly achieve and then maintain a constant drug concentration in the plasma.

The Beginnings of TCI

Schwilden published his *tour du force* in 1981 [65]. To implement the Krüger-Thiemer equations required a bolus injection of drug to nearly instantly achieve the desired plasma concentration, followed by an infusion that changed in rate

Fig. 40.5 Helmut Schwilden

every few seconds to maintain a constant concentration by replacing the drug that left the plasma. Schwilden's team built CATIA, Computer Assisted Titration of Intravenous Anesthesia [66], the first "Target Controlled Infusion" or "TCI" device. In the 30 years since TCI has become a standard technique to administer intravenous anesthetics worldwide, except in the US.

In the early 1980s, Max Ausems, a junior member of the faculty at Leiden University, created a new implementation of CATIA, "Titration of Intravenous Agents by Computer" or "TIAC" [67]. Ausems proved the accuracy of TIAC delivery of alfentanil [68] in human trials. He then used TIAC to "lock" the plasma alfentanil at a target concentration, and measured the effect of various alfentanil concentrations, thereby establishing concentration vs. response curves in the presence of various stimuli, and for spontaneous ventilation [69]. This pioneering work led to the development of TCI as a method of rapidly achieving a titratable steady state for understanding concentration vs. response relationships for intravenous drugs. It also led to a host of other "home-grown" TCI systems, only two of which are still in use: STANPUMP, developed by Shafer, and RUGLOOP (which was derived from STANPUMP), developed by Struys and De Smet [70].

The EEG and Feedback Control

Schwilden believed that such devices incompletely achieved the correct concentration in each patient. Adding the EEG would supply a continuous measure of drug effect that could be used to fine-tune drug delivery. Of course, there was precedent for this work. Bickford had implemented an EEG based closed loop system for anesthesia in 1950 [71], and Bellville followed suit in 1957 [72]. In 1962, Eger produced a constant EEG anesthetic level (burst suppression) in patients by adjusting and measuring the rate of an intravenous infusion of a 5% solution of ether [73]. Thus he combined a servo (human) titration of the level of anesthesia (pharmacodynamics) with an assessment of uptake (pharmacokinetics).

Schwilden improved on these pioneering efforts, concluding that the median frequency contained the information needed to control an infusion pump [74]. In 1987, he developed a pioneering closed-loop feedback system, using the EEG to titrate methohexital [75]. While many question whether the EEG means anything during clinical anesthesia, two decades ago Helmut Schwilden demonstrated that the EEG alone could be used to successfully guide methohexital anesthesia, convincingly answering the question.

Schwilden was not only a visionary, he was an international ambassador for using mathematics (i.e., computers) to control the delivery of anesthetic drugs. Schwilden ushered in the field in 1981, built the first devices, and demonstrated that they worked. He gave brilliant, insightful, and stimulating lectures. But he showed frustration at the pace of development. He had developed and implemented the mathematical framework for fundamental principles of anesthetic drug delivery. However, it was not until 1995, that TCI became commercially available in Europe. It is now popular worldwide, although it remains unavailable in the US. But the capacity of the EEG to guide anesthesia remains controversial, and closed-loop intravenous anesthesia delivery systems may never appear despite Schwilden's demonstration in the 1980s, and the pioneering demonstrations by Bickford [66] and Bellville [67] more than 50 years ago.

Paul White

While Don Stanski mentored Steve Shafer, Paul White mentored Shafer's wife, Audrey Shafer. Following residency, the Shafer's returned to Stanford as post-doctoral fellows. In her fellowship years with White, Audrey Shafer studied a novel drug, propofol, that ICI Pharmaceuticals thought would be a suitable replacement for thiopental. ICI sought FDA approval for induction of anesthesia, but White had other ideas. In his view, propofol should also be infused to maintain

anesthesia. ICI begrudgingly supported this research, which Audrey Shafer assumed as her fellowship project. Her resulting paper on the pharmacokinetics and pharmacodynamics of propofol [76] was the first definitive manuscript on propofol pharmacology.

Three Laboratories

Laboratories, like individuals, have a trajectory and a lifespan. To illustrate the history we provide an admittedly parochial description of three US laboratories contributing mightily to our understanding of the pharmacokinetics and pharmacodynamics of intravenous drugs. These three laboratories were populated by groups that we knew personally, and their selection does not mean that teams of investigators from other institutions (e.g., Emory University, Harvard University, University of Bonn, and the University of Leiden) made lesser contributions.

The Stanford Group

In the 1980s Stanski recruited fellows and investigators to characterize the clinical pharmacology of intravenous anesthetics. By 1986, Shafer, Pierre Maitre and Michael Buhner from Switzerland, and Bill Ebling, a PhD from Buffalo, New York had joined the laboratory. Maitre was an “expert” in NONMEM by virtue of getting the program to run [77], a superhuman task in 1987. Buhner studied benzodiazepine effects on the EEG [51, 52].

Stanski had a pleasant surprise for Shafer upon his arrival in 1986. While at the University of Alabama, Jerry Reves developed “computer assisted continuous infusion” or “CACI” [78]. Now at Duke University, Reves had joined with a young engineer, Jim Jacobs, to create CACI II [79]. Reves sent Stanski the software and Shafer was directed to test the CACI II device on patients. However, uncertain about the workings of the program, Shafer first tested the CACI II software. The resulting report [80] described numerous problems in the CACI II software, and Shafer was apprehensive about submitting such a critical manuscript for publication. Larry Saidman, Editor-in-Chief of *Anesthesiology*, asked Reves to review the submission. Reves was understandably annoyed by Shafer’s criticisms but supported publication, feeling that development of computer controlled anesthetic delivery demanded rigorous evaluation of software. In a rapprochement, Reves, Peter Glass (then a fellow at Duke), and Jacobs spent two days with the Stanford team in Palo Alto. Fellowship mixed with rigorous science, and Shafer found lasting soul mates in Jacobs (someone who loved programming and mathematics), and Glass (an avid clinical investigator).

Mathematical Simulation vs. Empirical Pharmacology

The difficulties with CACI (later fixed by Jacobs) prompted Shafer to write STANPUMP (“STANford PUMP”) to provide a competing platform, which he mostly completed from 1986–1990. Shafer noted that alfentanil, the drug with purportedly “rapid” pharmacokinetics, didn’t seem to work as promoted. Ebling, the resident genius, suggested that Janssen Pharmaceuticals had not positioned fentanyl, alfentanil, and sufentanil correctly: “Janssen says you should use alfentanil for short cases, but I don’t think it makes sense to use it for short cases. The drugs will look the same. The drug with the shortest half-life only makes sense for long cases, because there the rapid (terminal) half-life may pay off.” Shafer wrote software to simulate TCI infusions, and with John Varvel (his first fellow) demonstrated that Janssen Pharmaceuticals had not understood the clinical implications of the multicompartment pharmacokinetics of fentanyl, alfentanil, and sufentanil [55]. Jansson had not done the necessary simulations to see if the pharmacokinetics of alfentanil predicted unusually rapid recovery (they don’t). Shafer believed that pharmacokinetics might be widely misunderstood if a multibillion dollar pharmaceutical company had incorrectly positioned their product in the market. The paper provided a new framework to relate the time course of recovery to dose duration, (unknowingly having followed Eger’s work with inhaled anesthetics) [81] and subsequently given the name “context-sensitive half-time” by Glass and Jacobs [82].

In the early 1990s a series of novel opioids were in development. Shafer created a table of clinical and EEG potencies with the explicit intent of guiding the development of novel opioids. When Muir read the paper the following year, he immediately understood the implications for the development of GI87084B. He did not realize that Shafer planted the table in the paper for exactly that purpose.

It was a time of innovation. Orlando Hung dissected thiopental concentration vs. response relationships using TCI methodology [83]. Varvel developed metrics to measure TCI performance [84]. Shafer produced TCI algorithms to control effect site concentrations with TCI [85], and pharmacometric methods to estimate kinetics from TCI studies [23]. Keith Gregg, a statistician, developed a novel EEG based measure optimized for opioid drug effect [86].

At Work and Play

Shafer wrote of the personal relationships fostered by their work: “At home Audrey and I looked after Thomas, who was born in the middle of our fellowship year. John and Liz Varvel had two young children, and Jeanette and Orlando Hung had a son, Christopher, who was Thomas’ age and rapidly became his closest friend. We lived at each other’s houses, the kids entertaining themselves while we played

Pictionary—men against women. Liz, Jeanette, and Audrey were superior artists and skilled guessers. John, Orlando and I only won by inventing increasingly elaborate cheating schemes.”

New Kids on the Block Continue the Sheiner Legacy

In the mid 1990s a second influx of fellows initiated another productive period. Pedro Gambus (Spain), focused on a high-resolution study of intravenous dynorphin [87]. Valerie Billard (France) investigated plasma-effect site equilibration for propofol [88]. Thomas Schnider (Switzerland) undertook a high-resolution study of propofol pharmacokinetics [89] and pharmacodynamics [90] producing the standard propofol model for TCI. The work of Egan, Minto, and Schnider on remifentanyl has been mentioned. Juliana Barr (Stanford), Jacques Somma (Canada), and Katie Zomorodi (UK) performed pharmacokinetic studies of propofol, midazolam, and lorazepam for ICU sedation [91–93], informing the dosing guidelines in the FDA package insert for propofol and midazolam sedation. In a 6 week mini-sabbatical, Tim Short (New Zealand) created a model [94] that became the standard for describing anesthetic drug interactions. Minto demonstrated that one could “observe” effect site equilibration from the time to peak effect [95], providing a means to directly validate the equilibration between the plasma and the site of anesthetic drug effect proposed by Sheiner and Stanski decades earlier [16].

In 1997 Thomas Bouillon became the last fellow to join Shafer’s PK/PD research team at Stanford. The pharmacokinetic/pharmacodynamic underpinning of the potential of remifentanyl or propofol to depress ventilation and produce apnea had not been modeled. Bouillon created a model relating the dose of these drugs to ventilatory drive in patients breathing room air under non-steady state conditions. Bouillon directed the most complex human studies conducted by the Stanford team. It took 10 people to measure a volunteer’s CO₂—ventilatory response via a rebreathing circuit; set up and manage TCIs of propofol or remifentanyl; provide graded stimuli to assess pharmacodynamics; and gather blood samples and arterial blood gases every minute. At the day’s end, Bouillon always took the crew and the volunteer out for beer. Three papers published in *Anesthesiology* [96, 97, 98] years after Bouillon’s fellowship ended described his seminal work.

By 1999, clinical pharmacology no longer seemed sexy to Shafer. His VA Merit Review grant ran out after 11 years of funding, and he did not seek renewal. Stanski left for Pharsight. The fellows had gone. No new anesthetic drugs appeared. The research had achieved its goals. In two decades, Stanski, and then Shafer, had produced models characterizing the pharmacokinetics and pharmacodynamics of intravenous hypnotics and opioids. Shafer went to Pharsight for a sabbatical. Other investigators maintained a clinical pharma-

cology programs at Stanford, but since 1999, Shafer has not had a research laboratory.

The Duke Group

In the early 1980s Reves brought TCI technology from Schwilden and Ausems to the US, developing the first incarnation of CACI at the University of Alabama. Reves was evangelical about TCI, believing it would transform intravenous anesthesia. He had a particular interest in using CACI in cardiac surgery, believing TCI would improve patient safety [99]. He found that aging increased sensitivity to midazolam [100].

Reves recruited Glass from South Africa, to help him with this project, initially performing clinical evaluations with TCI [101]. Like Reves, Glass increasingly used TCI as a tool to characterize hypnotic—opioid interactions [102, 103]. In the 1990s Glass also became interested in the processed EEG as a measure of drug effect, with a specific focus on the bispectral index (oddly called “BIS” rather than “BSI”) developed by Aspect Medical Systems. Glass collaborated with Carl Rosow (Harvard) and Peter Sebel (Emory) in multicenter studies examining the clinical utility of BIS monitoring [104–106].

Reves brought Jacobs from the University of Alabama to develop and maintain CACI. Jacobs also provided pioneering work in TCI algorithms, insights into the “context-sensitive half-time” [82, 107], and novel pharmacokinetic models [108].

Some interests of the Duke laboratory mirrored those of the Stanford team, including TCI, novel drugs (propofol, remifentanyl), modeling, and simulation. The personal friendships formed at their meeting in Palo Alto fostered an environment of ongoing collaboration. However, the Duke laboratory had a different focus. The Stanford team pursued fundamental pharmacokinetics and theoretical development. Most Stanford studies were in healthy volunteers. The Duke group used TCI to characterize the clinical potency (called the “effective concentration” or “EC₅₀”) of anesthetic drugs in the tradition of Ausems. Nearly all of their studies were in patients. As at Stanford, a dearth of new drugs, and the departure of Reves, Glass, and Jacobs reduced the Duke team. Duke still has an active clinical pharmacology program, but one no longer focused on pharmacokinetics and pharmacodynamics.

The Northwestern Group

Three contemporaries of Fisher and Shafer created a laboratory in clinical pharmacology at the Northwestern University: Thomas Henthorn (the tallest of the group, and hence the presumed leader), Mike Avram (the pharmacologist), and

Tom Krejcie (the implementer). Classical pharmacokinetics characterized the disposition of drugs over many hours. However, in the mid 1980s, Henthorn, Avram, and Krejcie became obsessed with what happened seconds after an intravenous bolus injection. The classical model assumed that the concentration at zero minutes after bolus injection is the dose divided by the central compartment volume. That's the supposed peak, and it drops from there. But that's not how it works. Right after giving a slug of, say, propofol, the arterial concentration is 0, because it takes 30–60 seconds for drug to flow through the heart and lungs and reach the radial artery. After this initial delay the concentration abruptly shoots up as the main wave of drug passes down the radial artery. After the peak the concentration rapidly drops, but oscillates from the rapid return of a small amount of drug taken up by the heart and lung vasculature in the first pass. The oscillations subside in a minute or two, after which the concentration follows the smooth polyexponential decay described by classic models.

Like Price a generation earlier [109], Henthorn, Avram, and Krejcie focused on these “front end” pharmacokinetics, and gathered arterial blood samples during the initial moments after bolus injection. Shafer thought they were nuts. If the model is off for minute or two, but then works OK, that's good enough. Shafer didn't see a value in precise models for the first 2–3 minutes.

In the 1990s Henthorn, Avram, and Krejcie argued that plasma-effect site equilibration could not be properly modeled after bolus injection unless the model correctly defined the “front end” pharmacokinetics, particularly arguing that misspecification of the concentrations in the first 30–60 seconds drastically affected the equilibration occurring in the ensuing 2–5 minutes. They prevailed intellectually, but the Stanford group never incorporated “front end” pharmacokinetics into their PK models. The focus continued to be the “long term” pharmacokinetics for anesthetic drugs. Experimentally, the Stanford group sidestepped the issue (and greatly decreased the error) by using 10 minute infusions rather than bolus injections.

Henthorn, Avram, and Krejcie were right about the importance of front end pharmacokinetics [110]. Multiple investigators with slightly different research methodologies developed different estimates of the plasma-effect site equilibration rate (k_{e0}) for propofol because of inaccurate assumptions about drug behavior in the first 2 minutes after bolus injection. Indeed, Shafer published 4 different propofol k_{e0} estimates, because studies with slightly different arterial sampling schemes gave different results. These “dueling k_{e0} ” values created a nightmare for companies developing effect-site target controlled infusion algorithms for propofol. The approach of Henthorn, Avram, and Krejcie would have prevented this confusion.

Henthorn, Avram, and Krejcie have a nickname. In 1996 Shafer chaired a site visit for a T32 training grant in Clinical Pharmacology submitted by the Northwestern University. As part of the review process, Henthorn, Avram, and Krejcie described the hours of early morning preparation each investigator contributed to the arterial blood sampling every 5 seconds after drug administration. Impressed by the effort and coordination required, Shafer asked “at what ungodly hour does your SWAT Team arrive to make this happen?” The name stuck. The outside world knows these investigators as Henthorn, Avram, and Krejcie. However, to their academic colleagues, they are “the SWAT Team”.

The Industry Link

New drugs and devices benefit from the research conducted at Universities, but all products are eventually introduced by companies. Sometimes businessmen/scientists at these companies made significant contributions, as in the following two examples.

David Goodale

Dentist David Goodale was the propofol product manager in the US. for nearly 20 years, beginning in 1988. Goodale had pursued research before joining Stuart Pharmaceuticals. Throughout the 1990s Goodale worked with Shafer to characterize the fundamental pharmacokinetics and pharmacodynamics of propofol. In the early 1990s, Goodale asked Shafer to help ICI (previously Stuart, later Astra Zeneca) analyze the existing clinical database to provide dosing guidelines for propofol for sedation. Elderly patients had died because the wrong dose of midazolam was prescribed, and the FDA wanted to avoid similar problems with propofol. Goodale believed this could be accomplished with a thorough pharmacokinetic/pharmacodynamic characterization. After several months of modeling Shafer provided ICI with doses for MAC sedation, the adjustment in dose required for elderly patients, and the scientific basis of the dosing guidelines. Those doses are still in the package insert, affirming Goodale's belief that modeling would develop dosing guidelines that would withstand the test of time. Similarly, Goodale enabled Schnider's high-resolution pharmacokinetic/pharmacodynamic model of propofol for use in general surgery patients [89, 90]. and Barr's pharmacokinetic/pharmacodynamic model of propofol for use in the intensive care unit [91]. Much of this work was directly translated into the dosing recommendations in the propofol package insert—and every one has stood the test of time.

Nassib Chamoun

Around 1990, Nassib Chamoun, founder of Aspect Medical Systems, approached Stanski to discuss an improved method of EEG analysis. Virtually all prior EEG analyses had ignored the “phase” relationships in the signal, mostly because nobody had any idea what to do with them. Chamoun thought there was gold in the phase information, believing that the EEG consisted of multiple interlocking frequencies, and the phase information revealed which frequencies were interlocked. Sleep or anesthesia would decrease synchrony between interlocked frequencies, because the sedated brain could not sustain the connections. Stanski was intrigued, and introduced Shafer to Chamoun. Shafer agreed to share his EEG tapes so that Chamoun could test his algorithm.

Aspect Medical Systems recruited bright engineers and found investors to pay for the expensive research and development that Chamoun believed were needed to validate his bispectral analysis—BIS—as a measure of anesthetic effect. Based on promising results from the data provided by Stanski [111] and similar results from other investigators, Chamoun underwrote an ambitious series of clinical trials. Indeed, an enormous amount of what we know about the potency of anesthetic drugs, the pharmacodynamic interaction of anesthetic drugs, and the relationship of individual drugs to the EEG stems from the hundreds of millions of dollars that Aspect Medical Systems invested in research. Other vendors subsequently introduced processed EEG monitors to assess drug effect and “anesthetic depth”, but Chamoun did the heavy lifting, funding hundreds of clinical studies so that the use of BIS would be based on data.

The End of An Era

From the early 1970s through the end of the 20th Century our exemplars and their colleagues mathematically described the clinical pharmacology of most intravenous anesthetic drugs. All are older than 50 years. Few young investigators in anesthesia have arrived to replace them. Perhaps the paucity of drug development in anesthesia explains this drought. The excellence of drugs available to anesthesiologists (e.g., propofol, rocuronium, desflurane, sevoflurane) diminishes the incentive for pharmaceutical industry to develop new drugs. We may get sugammadex, but what then? Or perhaps all the important ideas have been offered? Is a lack of mentors the problem? Stanski moved to industry more than a decade ago. Shafer shifted his focus to his job as Editor-in-Chief of *Anesthesia and Analgesia*. Fisher left anesthesia to devote his efforts to early-stage drug development in other therapeutic areas. Henthorn, Glass, Schüttler, and Schnider became chairmen, an effective way to kill research careers. Schwilden, Reves, and White have retired. A few are still

active: Krejcie and Avram at Northwestern, Egan in Utah. However, perhaps it is the deaths of Sheiner and Beal, fountains of creative energy, that closed the era.

The era of innovation in pharmacokinetic/pharmacodynamic modeling in anesthesia peaked a decade or two ago. It was great fun while it lasted.

A Brief History of the Patient Safety Movement in Anaesthesia

41

William B. Runciman and Alan F. Merry

Summary

Approaches to safety began slowly. It took a century for ether to be fully accepted as a safer choice to chloroform and for PIN indexing for gas cylinders to be introduced as a safety design.

In the 1960s, Ross Holland in Australia and Gai Harrison in South Africa initiated longitudinal studies of mortality caused by anaesthesia, showing progressive declines over the next decades in first world countries.

In 1974, Cooper suggested applying the critical incident technique to identify the contribution of human behaviour to harm from anaesthesia, and in 1978 produced his seminal essay on preventable anaesthesia mishaps.

The medical indemnity crisis prompted the 1984 International Committee for Prevention of Anaesthesia Mortality and Morbidity (ICPAMM) meeting in Boston, at which Pierce conceived the Anesthesia Patient Safety Foundation, formed in 1985.

Cheney and others collected anecdotes from US “closed” malpractice claims, focussing attention on common errors, thereby pointing the way to their correction. A 1990 closed claims report found that respiratory events underlay 35% of total claims, largely preventable with better monitoring. Parallel approaches included Lunn and Devlin’s 1988 launch of the National Confidential Enquiry into Perioperative Deaths in the UK, the Runciman-led formation of the Australian Patient Safety Foundation, and the Australian Incident Monitoring Study.

In 1985, the 9 Harvard hospitals implemented monitoring standards, standards that other institutions then adopted. Similar movements arose in Australia, and the UK. The International Task Force of Anaesthesia Safety led to international standards adopted by the World Federation of Societies of Anaesthesiologists in 1992. In 1999, an Institute of Medicine report (“To Err Is Human”) found that anaesthesia-related mortality had decreased from 2 deaths per 10,000 anaesthetics in the 1980s to about 1 death per 200,000 for fit patients. The WFSA Global Oximetry initiative, begun in 2004, led to The Lifebox Foundation, making pulse oximetry available to every anaesthetised patient.

In 1988, Gaba described mannequin-based anaesthesia simulation at Stanford University. In 1991, he convened a conference focussed on human error in anaesthesia, and the organisational theory of safety in healthcare. This work led to the introduction of crisis management algorithms and checklists.

Retrospective medical record reviews by the 1991 Harvard Medical Practice study (and by a similar Australian study in 1995), prompted the development of a comprehensive classification of things that go wrong. Runciman developed a 12,000 category classification subsequently enlarged to the 20,000 category “Generic Reference Model”. With input from 250 international experts, this formed the basis for the International Classification for Patient Safety.

Arguably, improving the training and status of anaesthesia providers plays the key role in improving patient safety in anaesthesia.

Preface

Individual anaesthetists and others have advanced the safety of anaesthesia by improving drugs, devices, infrastructure, training, and techniques. These contributions have been supported by the strengthening of human factors such as teamwork, and the introduction of checklists, protocols and algorithms. To describe key elements of this story, we provide sketches of some key players, outline advances made by a few more, and mention and cite selected publications of some others. Our sketch relates only to clinical anaesthesia and largely to a few English-speaking countries. We apolo-

gise to the many who made important contributions not mentioned in our brief account.

The Past—A Framework of the History of Patient Safety in Anaesthesia

The potentially lethal effects of anaesthesia became known shortly after Morton's historic demonstration [1]. Ann Parkinson, of Spittlegate, Lincolnshire, died during ether anaesthesia in early 1847. The coronial inquest, reported in the Times of London, sparked a lively debate on the risks of etherisation [2]. Within three months of chloroform's introduction, Hannah Greener died suddenly whilst inhaling it for a minor procedure [3, 4]. This young girl had painful bilateral ingrown toenails. One had been successfully removed under ether, but she had been nauseated postoperatively and feared the second anaesthetic, 'crying continually and wishing she was dead rather than submit to it' [5]. Although chloroform had advantages over ether, its safe use required greater skill. Only a few practitioners (e.g., John Snow and Joseph Clover) possessed such skill, and deaths associated with chloroform dominated mortality from anaesthesia for the next 50 years, attracting considerable media attention. The use, and perforce the deaths from use, of chloroform, waned and then virtually ceased after a further 50 years [5].

The risks of anaesthesia soon after its discovery did not concern most patients. Pain consequent on disease or injury was commonplace, and patients remembered the horrors of operations without anaesthesia. Furthermore, the hazards of surgery eclipsed those of anaesthesia; before the 1860s advent of antisepsis, amputation carried a mortality of 30% and Caesarean section a mortality exceeding 80% [5].

Stories like those of Anne Parkinson and Hannah Greener powerfully influenced human behavior. Such reports provided the first of five parallel approaches to improving safety in anaesthesia.

Approaches to Improving Safety in Anaesthesia

1. Telling stories
2. Counting the dead (or injured)
3. Trying to understand what went wrong, and why
4. Developing preventive and corrective strategies
5. Evaluating the interventions

Progress in each of these occurred over three periods:

- The first century (1846–1945) after the discovery of anaesthesia, ending with the advances during World War II.
- The post war years (1946–1978), ending with Jeff Cooper's seminal paper on anaesthesia incidents [6].
- The recent years (1978–2012).

Table 41.1 A sample of the causes of death during the first 100 years of anaesthesia, selected to illustrate the diversity of causation

Uncalibrated chloroform dilution reservoir bag leading to overdose
Phosgene poisoning from chloroform decomposition with open gas lights
Misconnection of tubes leading to inhalation of liquid chloroform
Chloroform inhalers which when tilted, deliver liquid chloroform
Explosion with ether from open flames, electrical sparks, static
Explosions in patients' mouths or airways associated with ether
Ignition and burning of cuff of tracheal tube
Vomit forced into lungs by attempted resuscitation
Carbon dioxide instead of oxygen in a wrongly marked cylinder
Nitrous oxide instead of oxygen in a wrongly marked cylinder
Wrong volatile agent in bottle—no consistent colour coding
Toxic metabolites (phosgene) of trichloroethylene with sodalime
Percaine (nupercaine) confused with procaine (10-fold potency difference)
Ten times dose error because decimal point missed
Symbol for drachm (dram; 4.4 g) confused with symbol for ounce (28.3 g)
Death from infected anaesthetic agent for spinal anaesthesia
Air embolism during high pressure intravenous infusion
Cardiac arrest from combination of chloroform and adrenalin
Asphyxiation from poor positioning of patient with a lung abscess
Blocked tracheal tube
Airway obstruction due to impacting the epiglottis into the larynx with a gag
Electrocution by an ECG machine

From Sykes WS. Thirty seven little things which have all caused death. In *Essays on the First Hundred Years of Anaesthesia*. Volume 2, Chapter 1 (pp. 1–23), 1960. E & S Livingstone Ltd, London with permission

The pursuit of safety in anaesthesia is a work in progress: David Gaba argues that anaesthetic practice has yet to adopt many risk-reducing approaches accepted in other high risk environments (e.g., commercial aviation, mining and the nuclear power industry) [7].

Approach 1. Story Telling

Stanley Sykes collected anecdotes of lethal anaesthetic-associated errors during the first century of anaesthesia [5]. Table 41.1 documents the diversity of errors. Similarly, stories or 'cautionary tales' reported to medical indemnity organisations have been collected and published [8, 9]. They allow large numbers of practitioners to benefit from the experiences of an unfortunate few. This approach remains relevant today.

Approach 2. Counting the Dead

Death is a clear and objective endpoint, but several problems hinder attempts to monitor improvements in safety from the study of deaths nominally due to anaesthesia [10]:

- How much do surgery or pre-existing patient-related problems contribute?
- Are all deaths reasonably attributed to anaesthesia (i.e., the numerator) identified, recorded and reported?
- Has the total number of anaesthetics given (i.e., the denominator) been determined [11]?
- Does anaesthesia include sedation, analgesia or the use of other potent drugs, particularly when used by practitioners other than anaesthetists, or when not recorded as anaesthetics in emergencies and remote or unusual locations [12]?
- What time period between anaesthesia and death must be exceeded to exclude anaesthesia as a causal or associated factor? The number used has varied from a few hours to thirty days or longer [13].

A further confounder affects mortality rate comparisons at different points in history. Early studies of “anaesthetic deaths” typically examined deaths occurring in fit people having minor procedures. Increasingly, deaths included those in association with more complex and invasive procedures carried out in sicker patients, some at the extremes of age.

Several investigators counted deaths associated with anaesthesia in the first 100 years. John Snow collected 50 cases of chloroform associated deaths [5].

Sykes recorded that, in the early days, chloroform caused at least 1 death for every 3000 cases, whereas ether seemed to be associated with less than 1 in 12,000. An 1871 report cites a zero mortality from nitrous oxide, a rate of 1 in 2,723 for chloroform and a rate of 1 in 23,704 for ether [14].

After World War II and with the adoption of curare, more complex surgery was undertaken in increasingly sicker patients. Over a dozen studies of anaesthesia mortality were reported, and two important longitudinal studies commenced [12, 13]. In 1959, Ross Holland approached the Director-General of Health of the state of New South Wales, Australia, seeking and receiving ministerial support to obtain statutory immunity for a study of deaths associated with anaesthesia. With Douglas Joseph, he established The Special Committee Investigating Deaths Under Anaesthesia (SCIDUA), which began in 1960. This work continues to this day under the overall auspices of the Australian and New Zealand College of Anaesthetists (ANZCA) and the current chairmanship of Neville Gibbs. Since 1997, data has been garnered from each state and from New Zealand, providing the best longitudinal information on anaesthetic mortality in the world. Holland reported a mortality rate in the 1960s of around 2 deaths per 10,000 cases. This fell to 1 per 25,000 by the end of 1980, and is today thought to be about 1 in 50,000 overall, and perhaps 1 in 200 000 (approximately) for fit patients having minor procedures [15–20].

Gainsford (“Gai”) Harrison in South Africa recorded comparable figures from a 30-year longitudinal study

[21–23]. Mortality decreased from 1:1,000 in 1958 to 1:10,000 in 1986.

These results indicate that anaesthesia mortality has fallen progressively in high income countries, notwithstanding increasingly complex surgery in sicker and older people. Concurring with these observations, the 1999 report of the Institute of Medicine, “To Err Is Human”, stated that anaesthesia-related mortality had fallen from 2 deaths per 10,000 anaesthetics in the 1980s to about 1 death per 200,000 or even 300,000 [24].

Not everyone agrees that this reflects the overall picture. Robert Lagasse’s recent review calculated an overall rate of 2 deaths per 10,000 anaesthetics. A prospective study in The Netherlands found an overall rate of 1 death per 13,000 anaesthetics [10–25]. This is far better than the 15–40 times greater (0.3%) overall healthcare-associated mortality associated with admission to an acute care hospital [26, 27]. Of course, healthy patients having minor procedures have very low hospital- and anaesthesia-related mortality in high income countries today, and estimates of an overall rate are of limited value without some indication of casemix. Clearly, older people with serious co-morbidities undergoing major surgery have a higher risk of dying, but estimates of how much higher vary substantially, depending on factors including the reliability of denominator data, the time period included in the assessment, and the process of attribution of causality. Few would dispute the claim that anaesthesia is, in general, much safer today than it was a few decades ago, but two facts should counter any complacency. First, potentially avoidable deaths continue to occur, even in healthy young patients [19, 28]. Second, some low-income countries have anaesthesia mortality rates 100 times those cited here [29, 30].

The pioneering work in Togo, by Aboudoul-Fataou Maman, is anaesthesia patient safety history in the making. As a medical student, Maman found that, because of deficiencies in anaesthetic standards, many patients died after surgery in the hospital in which he trained, and so decided on a career in anaesthesia. He went on to initiate a classic quality improvement programme. With colleagues, he documented the very high rate of perioperative mortality in his institution, identified factors contributing to this [30] and introduced corrective strategies. These included preoperative evaluation by medical staff, protocols for nurses, triage of difficult cases to specialists, the promotion of local and regional anaesthesia, the creation of recovery rooms, and the training of nurses in the use of morphine. His data have made an important contribution to the World Health Organization’s Safe Surgery Saves Lives initiative [31] and the Global Oximetry Project [32] (now Lifebox: see www.lifebox.org).

In 1991, Pedro Ibarra was instrumental in seeing landmark legislation passed by the Colombian Congress (Ley 6

de 1991–Sixth Law of 1991) that, for the first time, defined a medical specialty (anaesthesia) in law. This set the stage for the introduction of minimal standards in Colombia in 1992 and, later, in the rest of South America (promoting, amongst other things, the widespread option of pulse oximetry) The impact of these minimal standards is evidenced by a drop in malpractice claims in Colombia where anaesthesia is now ranked 12th among medical specialties.

Approach 3. Understanding What Goes Wrong and Why

Anaesthetic agents, techniques, equipment—“the system”—or humans may underlie things going wrong. How do we identify the problems?

Implicating Drugs

For a century after chloroform’s introduction, its inherent toxicity was debated, especially in relation to lightly anaesthetised patients receiving noxious stimuli [5]. The landmark 1954 publication by Henry Beecher and Donald Todd supported the notion of the inherent toxicity of anaesthetic agents [33]. This report examined outcomes after 600,000 anaesthetics administered over five years in ten university hospitals, finding that the data “strongly suggests an inherent toxicity” for neuromuscular blocking drugs, particularly curare. A furore followed. Sixteen distinguished anaesthesiologists sought to refute the suggestion [34], and from a study of 33,000 cases, Dripps concluded that neuromuscular blockers did not increase risk [11]. It became clear that the use of curare without reversal by neostigmine placed patients at risk of fatal respiratory failure.

Halothane was introduced in the mid 1950s, and soon replaced all other potent inhaled anaesthetics. Although its hepatotoxicity was rare, it led to halothane’s replacement in the 1970s and 1980s by enflurane and isoflurane. In the 1960s and 1970s, volatile inhaled anaesthetics and succinylcholine were found to trigger malignant hyperthermia in susceptible individuals. In 1975, Harrison reported that dantrolene was an effective specific antidote and mortality fell from 80% to virtually nil [35]. It is now appreciated that the drugs used in anaesthesia today rarely contribute directly to mortality, provided they are used with adequate skill and care.

Implicating Equipment

As Sykes noted, inadequate equipment was identified early as a major cause of mortality and morbidity (Table 41.1) [5]. Understanding equipment became fundamental to safety in anaesthesia, with contributions from many anaesthetists, notably Jerry and Susan Dorsch in the USA [36] and John Russell in Australia [37], whose books have become established

as readily understandable references in this field. Equipment for anaesthesia has become more complicated, and the increasing incorporation of electronics and computers within anaesthesia devices creates new risks. There are particular challenges in providing equipment for low income regions of the world that is affordable, appropriate, and simple to maintain. Mike Dobson and Phoebe Mainland, working through the World Federation of Societies of Anaesthesiologists (WFSA), have advanced the case with the International Standards Organization (ISO), for standards that address these needs.

Implicating Techniques, Training and the System

Early academic leaders recognized that an environment conducive to safe anaesthesia required proper training, infrastructure and support. Robert Macintosh forcibly expressed the importance of proper training in 1949 [38]. These points were articulated in the 1993 International Standards for a Safe Practice of Anaesthesia [39], and repeated when these standards were subsequently revised [40]. Greater understanding has developed about techniques for airway management, patient positioning, ventilatory support, cardiopulmonary bypass, and crisis management.

Implicating People

In a lengthy, fascinating, and at times vitriolic paper (already cited above), MacIntosh argued in 1949 that there should be no deaths due to anaesthetics, and that those that did occur were mostly (if not all) attributable to failures on the part of the anaesthetist, rather than any inherent dangers in the drugs used or any underlying pathology that the patients might have [38].

Debate about the legitimacy of “anaesthetic death” as a default diagnosis for all otherwise unexplained perioperative deaths continued through the 1950s, 1960s and 1970s. Longitudinal studies by Holland [15, 16] and Harrison [22, 23] considerably increased our understanding of why things go wrong. In 1979, Arthur Keats published an important paper in which he criticised MacIntosh’s 1949 article. He accepted that a proportion of anaesthetic deaths are attributable to error but suggested that this proportion might be about 10%. He argued that many of the drugs and techniques used in anaesthesia are inherently hazardous (citing malignant hyperthermia and succinylcholine-induced hyperkalemia as examples) although he agreed that attribution of deaths to anaesthetic drugs was unacceptable, without demonstration of a cause-effect relationship [41]. In 1979, William Hamilton, a friend and hunting companion of Keats, followed with a very balanced editorial [42], accepting many of Keats’ points but suggesting that the proportion of deaths attributable to error might be closer to 90%. Clearly a better conceptual framework was needed to sort out the relative contributions of drugs, equipment, the “system”, patients, and anaesthetists themselves.

Incident Reporting, Mortality Committees and Human Factors

The earliest statement on the importance of critical incidents probably came from RH Todd, anaesthetist to the Prince Alfred Hospital in Sydney, who wrote the following in 1889: “An accident may be defined as any event in the course of the administration which interferes with the simple process of inducing and maintaining a state of surgical anaesthesia. Some of these accidents are of slight importance in themselves, but in as much as small accidents are often the forerunners of greater ones, successful results may depend on a readiness in anticipating, and failing this, a promptitude in remedying small accidents.” [43] He then went on to classify accidents as impediments to free respiration, and those in which cardiac failure occurs, with lists of causes.

In 1974, Jeffrey Cooper was a bioengineer at the Massachusetts General Hospital (MGH). Whilst helping carve a pumpkin at a Halloween party, he struck up a conversation which led to an invitation to speak on human factors in healthcare. The resulting lecture, ‘The anaesthesia machine: An accident waiting to happen’, led a listener to suggest that he use the critical incident technique pioneered by Flanagan in World War II. This led to the study which resulted in his landmark first paper on anaesthetist-reported incidents, demonstrating the multifactorial cause of most problems and the important contribution of human behaviour to things that go wrong [6].

In 1987, David Gaba introduced the concepts of “Normal Accident Theory” to the anaesthesia literature [44]. Gaba, Cooper [45], and then others, advanced the principles of a systems-based (rather than a person-based) response to error. At about the turn of the century, Alan Merry and Alexander McCall Smith (who was then Professor of Law in Edinburgh) extended these ideas into the debate about the most appropriate legal and regulatory response to human error [46].

Cooper’s seminal publication coincided with a medical indemnity crisis that had begun in the mid 1970s, characterised by increased litigation and steep rises in insurance premiums [47, 48]. These factors and others led Cooper, with Ellison (Jeep) Pierce—(then President of the American Society of Anesthesiologists) and Dick Kitz (then Chairman of Anaesthesiology at Harvard), to organise the first meeting of the International Committee on Anaesthesia Mortality and Morbidity (ICPAMM) in Boston in 1984 [48, 49]. This focused attention on how anaesthesia-related adverse events happened, and how they might be prevented. During the meeting, Pierce conceived the idea of the Anesthesia Patient Safety Foundation (APSF). With Cooper and others, Pierce formed the APSF in 1985 with the motto “to ensure that no patient should be harmed by anesthesia” [50]. The APSF became a potent advocate for preventing harm rather than cleaning up the mess after an (often tragic) event.

The Closed Claims Study

The Closed Claims Study also arose from the 1984 ICPAMM meeting, where preliminary findings were presented on “closed” malpractice claims [51]. Fred Cheney, then Chairman of the ASA Committee on Professional Liability, saw the value of such a study. He formed a team including Robert Caplan, Karen Posner and Karen Domino, and pursued the cooperation of medical indemnity organisations. Limitations notwithstanding [52], this approach produced an influential series of papers (from ICPAMM to the present) including a 1990 report showing that adverse respiratory events underlay the largest single class of injury (35% of the total), and an even larger percent of payouts [53]. It showed that better monitoring would prevent 75% of these injuries. Another landmark study showed the tendency of human beings to display “outcome bias”—the strong human tendency to find fault if there has been a bad outcome – even when there was no question of conciliation or compensation [54].

The ASA used the Closed Claims data to develop practice standards, guidelines and advisories which have increased safety. The Closed Claims Study now possesses the findings for 8,000 malpractice cases, from 34 insurance organisations that insure nearly 15,000 anesthesiologists.

A decrease in the cost of malpractice insurance for anaesthetists has been evident world wide. It is difficult to say how much of this is the direct result of the outcomes of Closed Claim Studies, or how much is due to improved training, newer and better monitoring, new drugs, crisis management algorithms etc.

The National Confidential Enquiry into Perioperative Deaths (NCEPOD)

John Lunn and Brendan Devlin launched NCEPOD in 1988, following a report on surgical and anaesthetic practice during 1985–86 in three UK regions. The report compared patients who had died in hospital within thirty days of a surgical procedure, with “index” (control) cases, using information from those who had cared for these patients [55]. Although frequencies could not be calculated, because of the voluntary nature of the data source and low response rates, NCEPOD reports led to substantial improvements in the availability of resources, supervision of junior staff, appropriateness of surgery and access to critical care facilities [55, 56].

The Australian Patient Safety Foundation

Inspired by developments in the US, William Runciman called a meeting in Australia of 65 influential anaesthetists in 1987. The group comprised department heads and academic leaders, together with past and current deans of the Faculty of Anaesthetists. Standards for anaesthesia monitoring were proposed, and the group decided to form the Australian Patient Safety Foundation (Aus.PSF) to promote patient safety in anaesthesia and, more ambitiously, throughout healthcare

[57]. An early initiative developed a voluntary national incident reporting system for anaesthesia – the Australian Incident Monitoring System (AIMS). In 1993, 30 publications resulted from analysis of the first 2,000 incidents [58]. This, with the US Closed Claims Study, established the utility of oximetry and capnography in anaesthesia, and influenced the promulgation of the International Standards for a Safe Practice of Anaesthesia, which were endorsed by the General Assembly of the WFSA in 1994 [59].

The International Classification for Patient Safety

Unexplained disparate results between retrospective medical record reviews by the Harvard Medical Practice study in 1991 [60], and by a similar Australian study in 1995 [61, 62], prompted the development of a comprehensive classification of things that go wrong in health care. This showed that there were, effectively, no qualitative or quantitative differences between adverse events in Australia and the US, but also confirmed how safe anaesthesia had become. Anaesthesia-related adverse events contributed less than 2% of the total events, compared with nearly 50% for surgery [61]. Anaesthesia related events were also, on average, less severe. Following this study, Runciman developed a 12,000 category classification (the Generic Occurrence Classification), subsequently expanded into “the Generic Reference Model”, with 20,000 categories [63]. With input from 250 international experts, this formed the basis for the new International Classification for Patient Safety (ICPS) [64]. The Australian team led by Runciman, now has responsibility for populating the ICPS framework with concepts and preferred terms on behalf of the World Health Organisation (from 2006 onwards). This is being done in collaboration with the “Common Formats” project for reporting to Patient Safety organisations in the US. To this end, Runciman was a member of the National Quality Forum—the group in the US which oversaw this project.

Several other anaesthesia patient safety experts have promoted patient safety across all of healthcare [65]. For example, Cooper participated in the Institute of Medicine report “To err is human...”; and was a key player in the formation of the National Patient Safety Foundation of the American Medical Association. In 2010, Alan Merry was appointed to chair the Board set up to establish the New Zealand Health Quality and Safety Commission.

Approach 4: Developing and Implementing Preventive and Corrective Strategies

As problems have been identified and understood, so preventive and corrective strategies have been developed and applied. Many problems listed in Table 41.1 were amenable to solution and were solved in the first century of anaesthe-

sia. Some, such as the correct identification of drugs with look-alike and sound-alike names, “decimal point” confusion, and problems with airway management continue to this day. Possible solutions to some of the causes of drug administration error have been developed and evaluated, but not yet widely implemented [66].

Improving the System Through Engineering

If it is possible to eliminate a problem by design, then this should be done. In the post war years, problems with equipment, particularly equipment used to deliver gases and vapours, were common [67–69]. In 1940, two patients died because carbon dioxide cylinders were substituted for oxygen cylinders, having had their green colour painted over with black [69]. The introduction of PIN indexing for gas cylinders in 1954 [69] is a classic example of an engineering solution to remove a latent factor [70] in the system that sets people up to make mistakes. Other examples include breathing circuits that can only be assembled in the correct manner [71, 72], and modifications to gas flowmeter systems of anaesthesia machines that prevent the administration of hypoxic gas mixtures.

Monitoring and Standards

By the mid 1980s, it became evident that some problems could not easily be “designed out” (inadvertent oesophageal intubation, breathing circuit disconnections, and adverse reactions to drugs or surgical stimuli), but more effective management was possible if they could be rapidly detected. Equipment monitors (the Ritchie Whistle was an early example of an alarm to warn of oxygen supply failure [73]) and highly effective patient monitors set the scene for the widespread promulgation of standards of care. These included pulse oximeters providing beat-to-beat measurements of arterial blood saturation (invented in 1972 by a bioengineer, Takuo Aoyagi and first used on patients by a surgeon, Susumu Nakajima, in 1975 [74, 75]) and capnographs providing breath-by-breath measurements of carbon dioxide concentrations (the modern infrared capnograph was developed in 1937 by Karl Luft [76]) In 1986, the nine Harvard hospitals initiated the Harvard Monitoring Standards as a standard of care, thereby beginning a wider adoption of monitoring; John Eichhorn and Jeff Cooper played major roles in this process [77]. Monitoring devices became de facto standards across the US and prompted the setting of standards in Australia, UK, and the rest of the world. Eichhorn was the organiser of the International Task Force of Anaesthesia Safety that led to the original 1993 international standards for safe practice of anaesthesia [39], and a major contributor to the revision of these standards in 2008 [40]. Anaesthesia safety standards were proposed for Australia during the 1987 meeting that gave birth to the Australian Patient Safety Foundation [58]. The 1980s Closed Claims Study and the 1990s AIMS, indi-

cated that half of all incidents could be detected by monitors, and that up to 90% of these would be detected by capnography and oximetry [53, 59]. These monitors have become the standard of care in high income regions of the world, but many operating rooms internationally are without them. In 2008, the revised International Standards for a Safe Practice of Anaesthesia [40] effectively elevated the use of pulse oximetry to a mandatory requirement for elective anaesthesia, in concert with the aims of the Global Oximetry project [32] (see below). National anaesthesia societies and the WFSA have endorsed these initiatives to enhance the safety of anaesthesia

Crisis Management.

It had long been recognised in the aviation industry, that if a cockpit crisis occurred, it was not managed effectively if dealt with through deductive reasoning. By the time a solution was found in increasingly complex aircraft control systems, it was invariably too late. Instead, pre-compiled responses, the basic steps of which could be learned by rote, were instituted. These algorithms enabled pilots to respond to crises in an ordered manner, and were designed to reach a management solution, with or without determining an immediate cause. In the early 1990s in the US, David Gaba spearheaded advances in the use of pre-compiled algorithms for the management of crises during anaesthesia [78]. This was followed in Australia by the development of a specific set of crisis management algorithms for anaesthesia, tested against 4,000 incidents [27]. The development of courses to pioneer the systematic management of crises in anaesthesia (including the use of algorithms when appropriate) was pioneered in the US, Australia and New Zealand [79].

The need to monitor things that might go wrong will persist. Each new initiative or technological advance contains new ways of making mistakes. An early example might be the introduction of the laryngoscope, that facilitated safe insertion of an endotracheal tube, but potentially damaged the patient's teeth. Unintended consequences, or "revenge effects", can have major implications [80].

A Just Culture-Speaking Out

In responding to accidents in healthcare, the focus has shifted from one on individual culpability, through one in which no blame is attributed, except in egregious circumstances, to a current view which emphasises a just culture [46]. There are times when "whistle blowing" is called for. Steve Bolzin exemplifies the importance of speaking up when things persistently go wrong. He is famous as the "whistle blower" whose actions changed the mortality of paediatric surgery at the Bristol Royal Infirmary from 30 to 5%. He conducted the Cardiothoracic Anaesthesia Audit in the UK from 1990, when he came to realise the high mortality rate in his own

unit. When his efforts to address this were blocked, he took his concerns to the media with the result that a major enquiry ensued. Many lessons were learned [81] and changes followed both at Bristol and in the United Kingdom generally [82]. His actions also had the less salutary effect of leading to his unemployment in Britain. This proved to be a watershed in the patient safety movement in the UK [83].

Human Factors and Simulation

In 1991, Gaba convened a conference on Human Error in Anaesthesia. Sponsored by the APSF and the United States Food and Drug Administration, the meeting brought together 30 experts in the field of human factors in patient safety, including James Reason and Jens Rasmussen. Reason, a psychologist from Manchester, had just published his classic book, *Human Error* [70], in which he advanced the view of accident causation that has subsequently become famous as the "Swiss Cheese Model." [84] He distinguished the role of active and latent failures in producing an accident, emphasising that latent failures lie dormant in a complex system, until by confluence of one or more additional failures, often triggered by an active failure, an accident occurs. The meeting launched important developments in the understanding of the role of human error in anaesthesia, and in the organisational theory of safety in healthcare, in particular the idea of learning from high-risk environments like aviation and nuclear power [7, 85]. The meeting accelerated the uptake of simulation as a tool for teaching and research in anaesthesia [86–89].

Engineer Stephen Abrahamson, and anaesthesiologist Judson Denson, in the mid-1960s, had created Sim One, the first anaesthetic simulator [90, 91]. Little came of this until 1986, when Gaba developed mannequin-based anaesthesia simulation at Stanford University and subsequently promoted its teaching and research potential. Soon after, Nik Gravenstein and Mike Good developed the Gainesville Anesthesia Simulator, along similar lines. Complex pathophysiological scenarios could be used in teaching human factors and crisis management [7]. Dan Raemer conceived of the Society of Simulation in Healthcare and chaired the "Board of Overseers" which established the Society in January 2004. *The Simulation in Healthcare Journal* began publication in January 2006, and the use of simulation for training, research and assessment in anaesthesia is now widespread.

Drug Administration Error in Anaesthesia

The "wrong drug" problem featured prominently in the 1993 AIMS reports [56], and has remained a recalcitrant problem in anaesthesia despite numerous case reports, high profile legal proceedings [92, 93] and calls for improvement [94, 95]. This probably reflects the fact that there is no simple solution to the problem, which is indeed multifaceted. In January 2008 and again in 2010, Bob Stoelting

chaired APSF consensus conferences to develop new strategies for safe medication delivery. The latter conference developed a new paradigm to reduce medication errors, based on four key principles: Standardization, Technology, Pharmacy/Prefilled/Premixed (medication), and Culture (STPC) [96]. Between 1972 and 1983, the DAME system at Duke University used technology to ensure correctness of anaesthetic drugs at the point of administration, but technological challenges led to the demise of the system. Many automatic anaesthesia record keeping systems are in use today but few have focused on improving the safety of drug administration. Alan Merry has led a team in New Zealand investigating drug administration error in anaesthesia over the last decade. The primary focus of this work has been the elucidation of the principles likely to enhance the safety of drug administration in anaesthesia, and the results provide support for the concepts of STPC [66, 97–99]. The challenge from 2013 onwards is to promote widespread uptake of these principles.

The Role of Anaesthesia Societies, Colleges, and Academic Departments

Arguably, improving the training and status of anaesthesia providers has been the most important factor in improving patient safety in anaesthesia in high and middle income countries.

Clover demonstrated early that specialisation is important to safety. He gave up general practice to pursue anaesthesia, and administered 10,000 anaesthetics (more with chloroform than ether) before losing a patient under chloroform in 1874 [2].

Improved training has resulted from the activities of many anaesthetists through academic departments, societies, colleges and other organisations. Academic departments have been critically important in providing a focus and home for researchers and educationalists, for advancing the scientific basis of anaesthesia through research, and promoting the standing of anaesthetists. Ralph Waters was appointed to the University of Wisconsin in 1927, with the challenge of creating an academic department of anaesthesiology. He had four major objectives: to provide the best possible anaesthetic care to patients; to teach interns and residents the fundamentals of clinical anaesthesia; to educate postgraduate doctors in anaesthesia; and to continue research into the scientific foundations of anaesthesia [100]. He appreciated the importance of establishing similar academic departments across the country and famous anaesthetists who promulgated the “Wisconsin model” included Emery Rovenstine and Robert Dripps. Lord Nuffield established the first Chair of Anaesthesia in Europe at Oxford in 1936, and Robert Macintosh (who had visited Waters) was appointed to this position. He too advanced teaching and research in anaesthesia, and many leaders in anaesthesia,

including academic anaesthesia, trained under Macintosh in Oxford and the first and subsequent generations of “offspring” of Ralph Waters. The detailed stories of the development of education in anaesthesia are told in other chapters of this book.

Organisations such as the American Society of Anesthesiologists (ASA) in the US, the Australian and New Zealand College of Anaesthetists (ANZCA) in Australia and New Zealand, the Royal College of Anaesthetists (RCA) in the UK, and several national anaesthesia societies have promulgated standards and have furthered their application through education and advocacy. The WFSA has been particularly important in this regard, because it provides a forum for all anaesthesiologists (i.e., medically qualified anaesthetists) to collaborate. The WFSA evolved from discussions at the International Anaesthesia Congress in Paris in 1951, and was established in 1955 with 26 founding member societies (there are now well over 100). Its primary aim was “to make available the highest standard of anaesthesia to all the peoples throughout the world.” The World Congress of Anaesthesiologists is arguably the premier international anaesthesia conference; it brings together anaesthesia providers from all over the world thereby advancing education and collegial support, both of which are critical for improving the standards, and therefore safety, of anaesthesia in low income countries of the world, if not everywhere. In particular, it provides a voice for many important contributors who might not otherwise be heard. The Education Committee of the WFSA, particularly under the leadership of Angela Enright has provided training and educational resources to thousands of anaesthesia providers, physicians and non-physicians, who would otherwise have had access to neither. Under Kester Brown’s presidency, the Safety and Quality of Practice Committee was established. This Committee was elevated to the status of a Standing Committee in 2004; amongst its other contributions to patient safety it initiated the global oximetry project and oversaw the first four pilot projects. This established the concept of combining education with the provision of affordable and robust oximeters, as a viable and effective strategy in advancing the standards of safe anaesthesia [32].

Global Initiatives to Improve Safety in Anaesthesia and Surgery

Anaesthesia and surgery are inextricably linked. The recognition that the delivery of healthcare is itself a science, has been pivotal to advancing the safety of patients undergoing surgery, as has recognition of the importance of teamwork, communication and collaboration between the members of the perioperative team [101–104].

Perhaps the greatest contribution from an anaesthesiologist in this context has come from Peter Pronovost, an anaesthesiologist and intensive care physician at Johns Hop-

kins [105]. In 2001, he began to study healthcare acquired infections, and demonstrated that implementing a five item checklist protocol dramatically reduced central line associated bacteraemia (CLAB) [106]. He extended this work to the state of Michigan. The mean rate of CLAB per 1000 catheter-days decreased from 7.7 to 1.4 at 16 to 18 months of follow-up [107]. This approach has now been adopted in many countries, undoubtedly saving many thousands of lives and millions of dollars. Pronovost established the Quality and Safety Research Group at Hopkins, and has been very effective in promoting the importance of rigour in research into patient safety (see below).

A major influence in this area has been the WHO Safe Surgery Saves Lives initiative, led by Atul Gawande. This initiative was undertaken in response to the problems of iatrogenic harm associated with surgery globally (a great deal of which is attributable to inadequate anaesthesia services in low income regions [108]). It resulted, amongst other things, in the development of the Surgical Safety Checklist and the advancement of the Global Oximetry project (now the Lifebox project) [32]. Olaitan Soyano, Jeff Cooper, John Eichhorn, Iain Wilson and Alan Merry formed the safe anaesthesia working group in this major interdisciplinary safety initiative. A landmark multicentre international evaluation of the Checklist, published in 2009, provides compelling support for believing that the widespread adoption of the Checklist has reduced avoidable harm to patients and indeed saved many lives [101]. Gawande's books [109–111] and regular articles in the *New Yorker* have been powerful instruments in advancing patient safety to a wide readership, extending an awareness of the importance of safety in healthcare well beyond the limits of those directly involved with the provision of healthcare.

The Lifebox Foundation was established in 2011, as a charitable organisation to further the Global Oximetry initiative of the WFSA. This initiative began at the 2004 Congress in Paris. Its aim was to sustainably improve safety in low income countries by providing high standard, robust, affordable pulse oximeters, supported by education and advocacy where appropriate. Since 2009, the project has included the WHO Checklist. The WHO Checklist explicitly addresses risks related to anaesthesia, and is designed to promote communication and teamwork within the operating room [101–104]. The inclusion of pulse oximetry within the checklist was intentional, to emphasise that its use during elective cases is viewed as mandatory (in line with the revised International Standards for a Safe Practice of Anaesthesia) [40]. Beneath this is a powerful message – that anaesthesia needs adequate resources, both in respect of its providers and their level of training, and the necessary equipment. In 2010, the global gap in pulse oximetry was estimated as 77,700 (95% confidence limits 63,195 and 95,533) [112]. By mid 2012, the gap has been reduced to 75,000 [113]. This very

substantial ongoing project has depended on close teamwork between many people, including in particular Gavin Thoms, Iain Wilson, Angela Enright, Isabeau Walker, Ellen O'Sullivan, Florian Nuevo, Alan Merry, and Atul Gawande [32, 114].

Approach 5: Assessing Preventive and Corrective Strategies

Measuring the effectiveness of preventive and corrective strategies in patient safety for anaesthesia is difficult because things go wrong so infrequently, making conventional prospective quantitative research costly, and/or a logistical nightmare [115]. Compounding the problem, anaesthesia-related “signals” tend to be lost amongst the “noise” produced by complex procedures and patient-comorbidities.

Nevertheless, measurement is integral to quality improvement (and safety is integral to quality in healthcare) [116]. Donabedian introduced the framework of structure, process and outcome for measuring quality in healthcare [117, 118]. In 2009, for the first time, as an interesting output from the WHO Safe Surgery Saves lives project, some basic metrics were defined to assist in estimating the quality of surgical services in a particular country. They included the number of operating rooms, number of operations, number of accredited surgeons, number of accredited anaesthesia professionals, day-of-surgery death ratio, and postoperative in-hospital death ratio [119, 120]. It is reflective of the challenge in improving the standards of anaesthesia globally, that to meet the definition for their respective structural measures, a surgeon has to be a physician, but an anaesthetist does not.

The difficulties in measuring outcomes in anaesthesia have been touched upon in Approach 2, above, in relation to studies of anaesthetic mortality. Nevertheless, indirect evidence suggests that progress has been made. In 1989, Eichhorn reviewed one million anaesthetics provided to ASA 1 and 2 patients at Harvard University hospitals between 1976 and 1985, finding eleven major intra-operative accidents, of which seven resulted from unrecognised lack of ventilation [121]. This finding prompted the introduction of the Harvard Monitoring Standards in 1985.

Indirect evidence from Australia supports the efficacy of introducing oximetry and capnography in the early 1990s. In 2005, Runciman noted that a five year study of medico-legal files, and an analysis of the last 2,000 incidents reported to AIMS had not revealed a single case of inadequate ventilation or undetected oesophageal intubation, although there had been several such problems resulting in brain damage or death each year before 1990 [27].

In Cooper's 1978 study on adverse events in anaesthesia, human errors in drug administration accounted for 19% of

events, equalling ventilation and breathing circuit errors at 19.5%. As noted, today's ventilation and circuit problems are passably low, but harm from drug administration error continues.

A major focus of the work by Merry's group into drug administration error (mentioned above) has been to quantify the extent of the problem. To this end they introduced a method of facilitated incident reporting in that a response is required after every anaesthetic, whether it be a simple negative reply or a more comprehensive account. This established, for the first time, realistic estimates of the likely rate of drug administration error in anaesthesia (about one error for every 130 anaesthetics) [98, 122]. This rate was orders of magnitude higher than most previous estimates, but is itself most likely to be an underestimate.

Amongst the many important contributions of Pronovost to advancing safety in healthcare are his recent contributions to articulating the importance of rigour in research in this field [123–125]. Lucian Leape, Donald Berwick and David Bates made an important point in 2002 [126]: they observed that safety in anaesthesia (as in aviation) had not been based on evidence but rather “by applying a whole host of changes that made sense, were based on an understanding of human factors principles, and had been demonstrated to be effective in other settings.” This idea was further advanced the following year by a (now famous) ironical “systematic review” of randomized trials of parachutes as an intervention to manage “gravitational challenge.” [127]

In 2011, Shekelle, Pronovost and their co-authors provided a more sophisticated analysis of these issues. They explain why randomized trials are clearly not needed for parachutes, but why rigorous empirical evidence (not necessarily from randomized controlled trials) might well be required for many of the interventions aimed at improving patient safety. Their key points are that an intervention to improve safety should be based on a sound theoretical construct; it should be sufficiently well described to be reproducible; desired outcomes should be clearly defined, the possibility of unintended consequences should not be overlooked; and the influence of context should be taken into account. This is really just a restatement of the essential elements of rigorous research into many other aspects of healthcare, but this important article underlines the point that there is no justification for abandoning rigour in research just because it happens to be in the field of patient safety.

This does not imply slavish subservience to artificial “hierarchies” of evidence [128]. Randomized trials certainly have a role but they are expensive, difficult to undertake, and may be difficult to interpret. Two examples of randomised controlled trials to investigate patient safety initiatives are the well known study by Moller and co-authors into pulse oximetry [129, 130] and a recent study in over 1000 patients by Merry's group investigating an intervention to

reduce error in the recording and administration of drugs in anaesthesia [66]. In their own ways each of these studies has provided insights into the challenges associated with evaluating safety initiatives. The negative result from the former study has contrasted with the almost universal perception of the value of pulse oximetry, and with other indirect evidence supporting its value. With the benefit of hindsight their result was predictable given that the outcomes for which the study was powered statistically would not be expected to be influenced by hypoxaemia [114]. In the latter study, the practical difficulty of getting compliance from a large number of participants in adhering to key elements of practice guidelines was well demonstrated.

If the randomized controlled trial is thought of as a hammer, not every problem is a nail. Research methods need to be appropriate to the questions to be answered, and to the context in which they are being considered [114, 128].

It is salutary to note that a number of recent, highly influential studies into checklists [101–104] and into the reduction of CLAB [107] have not been randomised trials. A very important incidental outcome from the Keystone project was some clarification, in the US context at least, of the distinction between quality improvement research and human-subject research involving novel interventions. There is a need for some pragmatism in regulatory requirements if the evaluation of large scale implementations of established best practice is to be affordable and practical [131].

Evaluation is fundamental to quality improvement, but uptake of best practices as evidence emerges is essential if gains in patient safety are to be realised. Despite the evidence supplied by studies such as those cited above, the adoption of initiatives supported by sound research to improve safety in healthcare has been patchy [132, 133], and anaesthesia has been no exception.

The Future

The history of the patient safety movement in anaesthesia is a proud one, with many fine achievements. Much progress notwithstanding, there remains much to be done. The biggest challenges lie in underfunded areas of the world but even in wealthy countries, preventable deaths continue to occur. The goal of the APSF, that “no patient shall be harmed by anaesthesia” has yet to be achieved.

Improving safety is an iterative process. At each iteration, the emphasis must be on identifying the most important of the residual problems, coming up with practical and affordable solutions, and implementing them. There is a place for pragmatism and for applying things simply because they make sense, but not for abandoning the commitment to the scientific foundations of anaesthesia that has been the hallmark of the contributions to patient safety of many of the

anaesthesiologists discussed in this chapter. Ongoing commitment to this fundamental principle will provide powerful impetus in adding to the impressive advances that have justified this speciality's reputation for leading the pursuit of patient safety. The goal of the APSF may be aspirational, but it has served our patients well, and will continue to do so, well into the foreseeable future.

Notable Names

The following list gives a brief insight into the contributions to patient safety, of some of the individuals mentioned in the body of this chapter. The list is in order of appearance, and is by no means exhaustive. Limitations on space have determined that many deserving contributors are omitted, and some appear elsewhere in this book. The authors offer their apologies to those people.

David Gaba (1954-) graduated from Yale University School of Medicine, in 1980. He introduced human factors and the organisational theory of safety into anaesthesia and healthcare, first by Normal Accidents Theory and then by High Reliability Organisation Theory. He is credited with inventing modern mannequin-based immersion simulation, work he conducted from 1986 to 1992. He subsequently introduced Crew Resource Management into anaesthesia (Anesthesia Crisis Resource Management), and then to healthcare in general (Crisis Resource Management). His ongoing research on human performance, cognition and human factors using simulation as a tool has been a model for the scientific advancement of patient safety.

W Stanley Sykes (1894–1961) served as an anaesthetist before and during World War II, including while a prisoner of war, for which he was awarded an MBE. He returned to general practice, but remained fascinated by things that go wrong with anaesthesia, becoming a prolific writer of matters medical and a series of thrillers. His “Essays on the first 100 years of Anaesthesia” [5] provide a rich tapestry of background, trivia, contemporary accounts, and important milestones in the development of anaesthesia and the safety of anaesthesia for that early period.

Gainsford “Gai” Harrison (1926–2003), a graduate of the University of Cape Town, contributed to the safety of anaesthesia in three areas: He conducted a 30-year longitudinal study of anaesthetic mortality; he was a world authority on anaesthesia for patients with porphyria; and he was pivotal in introducing dantrolene to treat malignant hyperthermia.

Aboudoul-Fataou Ouro-Bang’na Maman (1974-) was born in Tchalo (Sokode) and graduated from the University of Lome, Togo in 2002. He obtained a Diploma in pain management (“Capacité d’Evaluation et de Traitement de la Douleur”) from the University of Montpellier 2, in France,

in 2004, and a Diploma of anaesthesia from the Faculty of Health Science, Cotonou (Benin) in 2006. He worked in Togo, Martinique, and Guadeloupe. He translated the book “Safe Anesthesia” into French in collaboration with the WFSA publication committee.

Robert MacIntosh (1897–1989) was born in New Zealand and baptised with the Maori name Rewi Rawhiti. He pioneered the safety of anaesthesia in the English speaking world outside of the US. In World War I he served as a pilot in the Royal Flying Corps, was shot down in 1917, taken prisoner and escaped several times. After the war, he trained in medicine in London, and in 1937, became the first Professor of Anaesthesia outside the US. He was a proponent of “safe and simple” anaesthesia”. In the 1940s, he argued that most “anaesthetic accidents” were preventable. With William Mushin, he tried to launch research on this topic in 1944. Despite initial opposition, in 1949, the Association of Anaesthetists appointed a committee to investigate anaesthesia-associated deaths, a committee that is still active.

Arthur Keats (1923–2007) graduated from the University of Pennsylvania in 1946. Henry Beecher mentored him during his residency at the Massachusetts General Hospital from 1948–1951. He was the first Chair of the Scientific Evaluation Committee of the Anesthesia Patient Safety Foundation (APSF). From 1970–1973 he was Editor in Chief of the journal *Anesthesiology*. He was also a member of the FDA’s Respiratory and Anesthetic Drug Advisory Committee.

Jeffrey Cooper (1946-) was born and received his early schooling in Philadelphia, Pennsylvania. He received his BS in Chemical Engineering (1968), and an MS in Biomedical Engineering (1970) from Drexel University, and a PhD in Chemical Engineering at the University of Missouri (1972). He is a Professor of Anesthesiology at Harvard Medical School, and is the father of incident reporting in anaesthesia – indeed, in medicine. He received several honours for his work in patient safety, including the 2003 John M. Eisenberg Award for Lifetime Achievement in Patient Safety from the National Quality Forum and the Joint Commission and the 2004 Lifetime Achievement Award from the American Academy of Clinical Engineering. He has a particular talent for supporting and mentoring others, and both authors have cause for considerable gratitude in this respect.

Ellison (Jeep) Pierce (1929–2011) was President of the American Society of Anesthesiologists, founder of the APSF, and an elected Fellow of the Royal College of Anaesthetists. He received awards and citations from the Food and Drug Administration, the American Medical Association, the Royal Society of Medicine and the Russian Society of Anesthesiology. To quote from his obituary in the APSF Newsletter “*when the specialty was faced with a malpractice crisis at the start of the 1980s, Jeep thought about protecting*

patients first and doctors second. That was a risky political move, but he didn't hesitate. He just did the right thing."

Frederick Cheney (1935-) completed his specialist training in 1964 and joined the Faculty at the University of Washington where, 30 years on, he became Chairman. As Chair of the American Society of Anesthesiology Committee on Professional Liability, he organised the Closed Claims Study. From 1989, he concentrated his research activities on the ASA Closed Claims Project. In 2007, he created an endowed Chair of Anesthesia Patient Safety in the name of his mother, Laura Cheney.

John Eichhorn (1947-) was born in Cleveland, Ohio, attended Princeton University, and graduated from Harvard Medical School in 1973. He was the creator and original Editor of the newsletter of the APSF. He was a member of the WHO Safe Anesthesia Working Group, and the Safe Surgery Saves Lives global initiative. In recognition of his seminal contributions he was awarded the 2010 John Eisenberg Award for Individual Achievement in Healthcare Quality and Safety from the Joint Commission of the National Quality Forum in the USA.

JS (Nik) Gravenstein (1925–2009) was born in Berlin. He graduated from the University of Bonn Medical School in 1951 and from Harvard Medical School in 1958. He contributed to the safety of anaesthesia as head of several departments of anaesthesia, as Editor of the International Journal of Clinical Monitoring, as author of a book "Clinical Monitoring Practice", and as a pioneer in high fidelity simulation. A founder of the APSF, he was a Board Member for ten years. He led a team at the University of Florida which developed the "Gainesville Anesthesia Simulator". He was a "calm and collected" mentor, and a gracious and generous host and teacher (to W.B.R. amongst many). On Gravenstein's retirement, Jeep Pierce stated "I have not met a greater gentleman who has contributed more to the specialty of anesthesia than Nik Gravenstein".

Dan Raemer (1950-) graduated in Electrical Engineering from the University of Massachusetts in 1972. He then studied BioMedical Engineering and received a Master of Science in 1975, gaining a PhD in Bioengineering from the University of Utah. In Vermont, he and others started a program providing clinical engineering services to hospitals throughout the State (this program continues today). In 1993 he joined the nascent Boston Anesthesia Simulation Program begun by Jeff Cooper. He streamlined the pilot courses that had been introduced into coherent curricular entities that could be applied to large cohorts of anesthesia trainees. He expanded simulation and crisis resource management into other fields such as emergency medicine, intensive care, medicine (codes), and air rescue and turned them into ongoing programs. His vision was responsible for the creation and success of the Society for Simulation in Healthcare.

Angela Enright (1947-) was born and raised in Ireland, graduating from University College Dublin. She interned at St Vincent's Hospital, Dublin, then moved to Canada, training in anaesthesia at the University of Calgary, Alberta. She was President of the Canadian Anesthesiologists Society in 1994–95, and chaired the Organizing Committee for the 12th World Congress of Anesthesiologists held in Montreal in 2000. She is known for her promotion of education around the world, particularly in low income areas, in many ways following in the footsteps of Kester Brown but adding her own mix of excellence, charm and inspiration. As the immediate past President of the World Federation of Societies of Anaesthesiologists she coordinated and largely undertook the development of extensive educational material – translated into several languages. She is a Founding Director of the Lifebox Foundation. She was awarded the Order of Canada in 2011.

T.C.K. (Kester) Brown (1935-) was born in Kenya. He became the Director of Anaesthesia at the Royal Children's Hospital in Melbourne, and developed a worldwide reputation for himself and his Department. He became a member of the WFSA Education Committee in 1984, and President of WFSA in 2000. He was dedicated to helping those with limited resources and opportunities. He encouraged others to share in this passion, and mentored both of the authors. He advanced patient safety through his teaching, advocacy and personal example.

Atul Gawande (1965-) was born in Brooklyn, New York. His parents, both doctors, were immigrants from India. He grew up in Athens, Ohio. He graduated from Stanford, and he majored in Philosophy, Politics and Economics at Balliol College, Oxford as a Rhodes Scholar. It may seem unusual to include a surgeon in a chapter on the history of the patient safety movement in anaesthesia, but Atul Gawande is no ordinary surgeon: his contribution to patient safety in anaesthesia has been exceptional and has not ended. He joined Al Gore's presidential campaign in 1988, worked closely with Bill Clinton during his 1992 campaign, and went on to become a senior advisor in the Department of Health and Human Services. He returned to school (Harvard), in 1993 completing his medical training and specialising in surgery. He has a Master of Public Health (from the Harvard School of Public Health). In 2007, he became director of the WHO Safe Surgery initiative, which has a strong emphasis on the importance of anaesthesia to the safety of patients worldwide.

Olaitan Soyannwo (1945-) was born at Ilisan-Remo, Ogun State, Nigeria. She went to Mayflower school, Ikenne and Queen's College, Yaba, Lagos and then the University of Ibadan Medical school, qualifying in 1971. She trained in anaesthesia in England and has been a Consultant in Anaesthesia and Intensive Care at the University College Hospital, Ibadan since 1981, serving as Professor and Head of Depart-

ment of Anaesthesia and Dean of the Faculty of Clinical Sciences. She was a key member of the Anaesthesia Safety Group of the Safe Surgery Saves Lives Campaign, and her advocacy (in the face of external scepticism about the relevance of “expensive technology” to low income areas of the world) facilitated the decision to include pulse oximetry on the WHO Safe Surgery Checklist. She was a major contributor to the revision of the International Standards for a Safe Practice of Anaesthesia.

Iain Wilson (1936-) was born in the UK and graduated from Glasgow University. While training in anaesthesia he worked in the Royal Air Force (1979–85) and as a Lecturer at the University of Zambia (1986–8), where he co-authored the first perioperative outcome study in the region. He is internationally known for his contribution to training, and chairs the Publications Committee of the WFSA where he established Update in Anaesthesia, and Anaesthesia Tutorial of the Week, as freely available training and CPD resources. He is a co-editor of the Oxford Handbook of Anaesthesia. He was a member of the Anaesthesia Safety Group of the Safe Surgery Saves Lives Campaign and led the WFSA Global Oximetry project in Uganda (79). He was elected President of the Association of Anaesthetists of Great Britain and Ireland in September 2010, bringing the influence and resources of this organisation to the support of the Life-box initiative.

Where and How Does the Anesthetic Process Help or Hurt Patients Independent of Producing Anesthesia?

Harriet W. Hopf

Summary

This chapter provides exemplars of good and bad outcomes that can result from anesthesia and anesthetists. In the 1850s, Snow determined that chloroform could kill by “cardiac syncope.” In the 1930s, Lundy guided the banking and administration of blood, and Lundy and Rovenstine established pain clinics. In the 1970s, Bonica established pain as a subspecialty.

Ibsen’s response to the terrible 1952 Copenhagen polio epidemic, manual support of breathing, led to intensive care units, ventilator development, and the creation of modern blood-gas analysis by Astrup and Severinghaus. In 1953, Apgar devised her “score”, a number describing the neonate’s condition. In 1956, Lassen showed the lethality of prolonged nitrous oxide administration. Later investigators suggested health hazards to occupational exposure to nitrous oxide.

Beecher advocated the use of informed consent in volunteers and patients in 1959. In the 1960s, he argued for establishment of Institutional Review Boards to govern human experimentation, and he helped define brain death.

In the 1960s, surgeon Hunt demonstrated that surgical wounds often have low tissue oxygen levels that predisposed to infection and impaired healing. Hopf showed that surgical site infections correlated with low wound oxygen levels. In the 1970s, Huch, Lubbers and Severinghaus developed transcutaneous oximetry, later adding transcutaneous carbon dioxide measurements.

Studies in the 1980s showed that exposure to inhaled anesthetics protected the heart from subsequent ischemia. Also, in the 1980s, Cahalan led in the evaluation and application of transesophageal echocardiography.

In the 1980s and early 1990s, Hunt’s group and Hartmann found that generous fluid administration benefited wound healing. In 1996, Kurz et al. reported that maintaining normal core temperature reduced wound infection rates, and Schmied et al. found that mild hypothermia increased intra- and postoperative blood loss. In the late 1990s, Weiskopf found that a hemoglobin of less than 7 g/dL impaired cerebral function in resting fit volunteers.

In 1985 and 1995, psychiatrist Langer and anesthesia colleagues demonstrated that deep anesthesia with isoflurane decreased patient suffering from mental depression. In the 2000s, Olney’s group suggested that anesthetics could impair the developing brain of rats. This concern resulted in a presently ongoing multidisciplinary effort to determine whether similar effects occur in humans, particularly very young patients.

In the 1990s and 2000s, inhaled anesthetics were found to deplete the ozone layer (especially halothane) or act as greenhouse gases (especially desflurane). In the 2000s, the prolonged use of large tidal volumes was found to injure the lungs.

Introduction

Anesthesia offers amnesia and immobility, transporting patients painlessly through surgery and providing optimum conditions for surgeons. From the discovery of anesthesia to the present, anesthetists have accepted diverse challenges unre-

lated or only tangentially related to rendering patients unconscious and/or insensitive to the surgeon’s knife. Some actions of anesthetists/anesthetics caused harm to patients (e.g., hepatitis, renal injury) or society (e.g., environmental pollution) while others had salutary effects (e.g., diminishing mental depression, increasing myocardial tolerance to ischemic injury).

We begin with a definition of outcomes research. Taking the two words at face value, any investigation defining good and bad outcomes might be considered outcomes research. But respected investigators may take a different view. Daniel Sessler (personal communication, 16 Sept 12) doubts that

e-mail: harriet.hopf@hsc.utah.edu

we “should extend the term to include all important game-changing research. There are lots of small studies that are critically important, but aren’t what most people consider to be outcomes research.” Sessler would “reserve the term for large-scale clinical trials evaluating outcomes that are meaningful to patients.”

Others, such as the editors of this book argue that large-scale outcomes trials are at one end of outcomes research—research that tells us about clinical outcomes, good and bad. The definition of large-scale itself is ambiguous. Such trials have to be large enough to reveal significant changes in outcome (if they exist), but the size needed depends on the incidence and consistency of the outcome. It might range from a few hundred to millions of subjects. Why should we not call the studies requiring only tens to a hundred or two hundred subjects to define a good or bad clinical outcome, outcomes research? Where one draws the line is arbitrary.

For the purposes of this book, we will take both views, assigning the stories of large-scale clinical trials to Chapter 43 written by the editors, with the invaluable assistance of Arthur Wallace, and usually assigning smaller trials to the present chapter. We draw a line at roughly two hundred subjects, and the present chapter will look at the history of studies of less than this “number” and Chapter 43 will look primarily at studies of more than this number, particularly (but not limited to) those involving cardiovascular studies. Using chronologies within themes, both chapters provide exemplars of good and untoward outcomes. Many contributions are covered in detail elsewhere in this history, and some will be dealt with but briefly in both chapters. Anesthetists and anesthesia contributed greatly to these advances and retreats, often leading these stories. Many others also contributed to what has been a collaborative effort shared with colleagues outside of anesthesia, all focusing on issues relevant to patients in the perioperative period. Finally, we acknowledge that there is insufficient space to tell all the fine stories that might be told.

1846–1860: William Morton and the Discovery of Anesthesia

Most would not think of Morton’s grand discovery as outcomes research, unless one uses the broad definition suggested above. Morton’s observations in patients repeatedly confirmed an outcome, the production of insensitivity to surgical pain—despite Morton barely knowing what he was doing. Morton did not need fancy statistics or large numbers to produce “anesthesia outcomes research” because his goal, “anesthesia”, always occurred; anesthesia was produced 100% of the time. If an outcome occurs 100% of the time, small studies can readily document an end-point, an outcome.

1848–1854: John Snow Connects Chloroform and Cardiac Syncope

Unlike Morton, Snow knew what he was doing. He wrote books about anesthesia and recorded summaries of each of the thousands of anesthetics he administered [1, 2]. From observation, he defined the characteristics pertaining to increasing depth of anesthesia (called by Snow, degrees of anesthesia). An appreciation of these characteristics enabled Snow and others to deliver anesthesia safely, at least most of the time.

When the issue of death from chloroform arose, Snow referred to his case records and to experiments he had conducted in cats and frogs. Against this background, he provided a detailed, case-by-case examination of 50 published reports of deaths between 1848 and 1854, associated with chloroform administration throughout Europe, the US, and Jamaica [1]. Hannah Greener was the first of these deaths, and Snow opined “From the lips becoming suddenly blanched in the above case, there is every reason to conclude that the heart was suddenly paralysed.” Snow considered several possible causes of death, concluding that

“In all the cases in which the symptoms which occurred at the time of death are reported, there is every reason to conclude... that death took place by cardiac syncope, or arrest of the action of the heart. In forty of these cases, the symptoms of danger appeared to arise entirely from cardiac syncope and were not complicated by the over-action of the chloroform on the brain. It was only in four cases that the breathing appeared to be embarrassed....”

Thus Snow, applying his patient and research experiences (a large database) to bear on diverse reports, cleverly concluded that death resulted from sudden stoppage of the heart. We would add that the stoppage probably resulted from arrhythmias or excessive depression secondary to anesthetic overdose, something Snow had devised methods to avoid.

1850s: Treatment of the Spasms Induced by Tetanus

An arsenal of potent drugs may be given to patients with benefit in mind, but little understanding of the disease being treated or the mechanistic basis of the drugs’ action. Let us smile, beware, for our ignorance is greater than we can imagine. So in the 1850s, physicians thought to diminish the spasms from tetanus by administering curare. The patients died (e.g., see Sayres) [3]. Not until 1954, was curare applied to the management of tetanus in a more rational and beneficial manner when Lassen et al. [4] and Honey et al. [5] not only gave curare, but also ventilated the lungs of their patients, who then happily survived.

1930s–Present: Blood Banking/Transfusion Medicine

At the Mayo Clinic in 1933, surgeon Charlie Mayo set anesthesiologist John Lundy with the task of improving blood transfusion [6]. The expertise of anesthesiologists in obtaining venous access for transfusions made an anesthesiologist the logical choice for this role. By 1935, Lundy's successes indicated a need for a more dependable blood supply than donors giving blood directly to the patient. In 1935, he demonstrated that blood could safely be stored in an icebox for up to 14 days, thus establishing "the first blood bank in North America."

By the 1960s, transfusion of banked refrigerated blood had become routine, but administration of large volumes to hemorrhaging patients was noted to lead to cardiac arrest from hypothermia. Anesthesiologists Boyan and Howland devised a system to warm the blood by passing the intravenous tubing through a warm water bath before infusion into the patient [7]. By this means, they could increase the rate of blood administration while decreasing the incidence of cardiac arrest in massive transfusion from 21 of 36 patients, to 1 of 45 patients.

In the late 1960s, anesthesiologist Ron Miller was stationed at the US Naval Support Activity Hospital in Da Nang during the Vietnam War, giving him extensive experience with massive transfusion (defined by Miller as greater than 20 units of blood) [8]. Using his experiences he described the effects of massive transfusion on coagulation and acid-base balance. His observations helped define the best combination of blood products for managing the effects of massive hemorrhage on coagulation function.

Perioperative blood transfusion increases the risk of complications such as surgical site infection (SSI). Studies in the 2000s indicated that preoperative anemia predicted postoperative complications [9, 10]. Several studies focused on the acceptability of using 'old' (nearing the end of storage expiration date) blood for transfusions in surgical patients. Old blood may be a hazard in cardiac surgery and pediatric patients, but Weiskopf et al. did not find that it was a problem when only 1 or 2 units were transfused [11].

1930s–Present: Pain Management

Because they manage the pain otherwise associated with surgery, anesthetists are natural leaders in the management of pain outside the operating room. In the 1930s, anesthesiologists John Lundy at the Mayo Clinic and Emory Rovenstine at Bellevue Hospital, established regional block clinics in an attempt to manage pain [12]. Anesthesiologist John Bonica published his classic textbook "The Management of Pain" in

1953, and became Chair of Anesthesiology at the University of Washington in 1960, where he immediately created a multidisciplinary chronic pain program. Bonica helped demonstrate the key role that anesthesiologists play in the treatment of chronic pain [13]. In 1973, Bonica organized a meeting which resulted in founding of the International Association of the Study of Pain with its associated journal, *Pain* [14]. Anesthesiologists subsequently joined with other members of the medical community to collegially develop the field of pain management and pain clinics, but it began with Lundy, Rovenstine, and, most of all, with Bonica.

1940s–1960s: Beecher's Contributions to Ethics

Anesthesiologist, Henry Beecher, observed that the wounded at Anzio in 1944 had a remarkably decreased need for morphine to relieve pain [15]. Their wounds provided the means to exit from the horrors of war. This led Beecher to the thought that the mind could control perception, something plausibly explained by physiologists Melzak and Wall with their 1965 spinal gate theory [16]. Beecher emphasized how effective placebos were, making their inclusion in a blinded manner mandatory to provide a controlled experiment [17]. Beecher then questioned whether ethical practice demanded the application of informed consent. A series of publications by Beecher followed his first in 1959 on "Experimentation in man" [18]. These ultimately led to the present demand for informed consent and the authority of Institutional Review Boards to govern human research in all of medicine [19].

Beecher assisted in the birthing of transplantation which made use of organs harvested from the dead. But when were the dead really dead? Specifically, when was the patient's brain really dead? In 1968, Beecher led in the definition of brain death [20].

1950s: Status Asthmaticus and Status Epilepticus

Because volatile anesthetics relax bronchial smooth muscle, they (and even rectal ether) were used to treat patients with status asthmaticus in the 1950s and earlier [21]. This was effective during administration of the anesthetics but did nothing to treat the underlying problem, and required intensive monitoring and often hemodynamic support. Thus, this treatment of status asthmaticus was never widely adopted. Similarly, anesthesiologists and colleagues used volatile anesthetics as a last resort to treat status epilepticus [22] because of anesthesia's effect on electroencephalographic activity. Again, because the underlying disorder (rather than the

EEG) was not treated and hemodynamic support was usually required to achieve the degree of suppression required, the treatment never became routine.

1950s–Present: Training of Others in Resuscitation

Anesthesiologists have played a major role in treating and training others to treat victims of trauma and accident. This has extended to on-site management during major disasters and improved planning for such rare and catastrophic events.

Anesthesiologists pioneered instruction of members of the general public in emergency CPR in many countries. Peter Safar was one of these in the US. In Australia, the combination of readily accessible beaches and warm weather led to an alarming number of drownings, prompting Tess Cramond to begin teaching CPR in the early 1950s, in conjunction with Surf Life Saving Australia. She later taught CPR to the Ambulance Training School and other organizations, encouraging colleagues throughout the country to follow her example. She founded the Australian Resuscitation Council in 1976.

In the early 1990s, several anaesthesiologists were engaged in teaching primary resuscitation and anesthesia care in third world countries. In 1995, the WHO asked Douglas Wilkinson from Oxford, UK to write a review of trauma management for developing countries. Together with anesthesiologists Haydn Perndt, Marcus Skinner (both from Australia) and Michael Dobson of Oxford, he developed a Primary Trauma Care (PTC) course. Following several courses in Africa and the South Pacific, it became clear that there was a need for expansion of the courses, instruction programs, and educational materials.

With the assistance of the World Federation of Societies of Anaesthesiologists, the number of courses and the countries involved multiplied. Instructor courses took place first in Oxford, then expanding to countries around the world. In 2003, the PTC manual became a WHO official publication. By 2010, the manual had been translated into 14 languages and courses had been run in over 60 countries.

1950s–Present: The Anesthesiologist Goes to the Patient

In most parts of the world, the patient who suffers some disaster is transported to the nearest hospital for urgent care. But wartime experiences suggested that a more immediate application of therapy might provide a better outcome. In France, anesthesiologists acted to make this a reality. In the 1950s, French health authorities asked anesthesiologists to organize emergency medicine and prehospital care to deal

with the 13,000 yearly deaths on French roads. In the 1960s, the first mobile medical emergency response units (Service mobile d'urgence et de réanimation, SMUR) were developed. French anesthesiologists Maurice Cara (Paris), Pierre Huguenard (Créteil), Louis Lareng (Toulouse) and Louis Serre (Montpellier) expanded this into the prehospital emergency system known as SAMU (Service d'Aide Médicale Urgente). Medical teams (often including an anesthesiologist) went from hospitals in specially equipped ambulances, helicopters, or fixed wing planes to care for patients with life-threatening emergencies. A 1986 French law [23] specified that SAMU should act as a dispatch and reception center for all medical emergency calls, 24 hours a day. In 2006, this service conducted 1,890,439 missions, having received 15 million calls.

1952: Polio Leads to Artificial Ventilation, Monitoring and Intensive Care

Of the polio epidemics that moved through the world in the 1940s and 1950s, the one striking Copenhagen in 1952 was among the worst, with hundreds of patients requiring ventilatory support and driving development of intensive care medicine and the intensive care unit (ICU) [13]. Anesthesiologist Bjørn Ibsen, had spent a year as an assistant anesthesiologist at the Massachusetts General Hospital in 1949–50, becoming familiar with the use of intermittent positive pressure ventilation (IPPV). Despite Ibsen's youth, he convinced Lassen, the director of Blegdams Infectious Diseases Hospital in Copenhagen, to allow him to introduce IPPV via a tracheostomy to keep patients with respiratory failure alive (see Fig. 55.7) [24]. Hundreds of volunteer anesthetists and other medical personnel, including medical and dental students supplied the IPPV by manually ventilating the lungs of each patient. Their contribution was essential, since the supply of ventilators was virtually non-existent. Equally important was concentrating these terribly sick patients in one location where support, supplies and personnel could be focused. Polio had forced the development of the basic ingredients of ICU medicine.

An immediate need in this crisis was to assess the adequacy of ventilation by what IPPV did to individual patient blood gases. But the blood/gas machine had not been invented and the then known laboratory procedures were too cumbersome. Clinical chemist Poul Astrup took the first step towards modern carbon dioxide monitoring in blood [25], by supplying Ibsen's rag-tag team with much needed information about how well they were doing. The need for something more automated and more controllable to supply IPPV, also prompted the development of ventilators. And finally, the lessons Ibsen learned in the 1952 polio epidemic of 1) ventilatory support (including blood analysis) and 2)

concentrating resources/personnel led him to organize the first ICU in 1953 [26].

1953: The Apgar Score

Anesthesiologist Virginia Apgar (1909–1974) was the first woman appointed as a full professor at the Columbia University College of Physicians and Surgeons (see Fig. 16.6). She sought to provide better care to newborns suffering from ‘fetal anoxia’ and requiring resuscitation. In 1950, she reported that oxygen levels in newborn blood might vary greatly immediately after delivery [27]. To assist in determining which newborns required a higher level of care, she developed the Apgar Score, a number between 0 (bad) and 10 (good) describing the neonate’s condition. She published a description of the score in 1953 [28]. She later demonstrated that low Apgar scores correlated with low blood oxygen levels and pH. The “Apgar” remains as a cornerstone of newborn evaluation today.

1954–1958: Evolution of Blood-Gas Electrodes

Astrup had gone part way towards the rapid analysis of respiratory gases in the blood. Physical chemist Richard Stow introduced the carbon dioxide electrode at the 1954 meeting of the American Physiological Society [29]. His findings influenced anesthesiologist John Severinghaus, who tested and improved on Stow’s ideas [30]. Leland Clark (similarly not an anesthesiologist, but who also influenced Severinghaus and other anesthesiologists interested in measuring blood gases) introduced the self-contained polarographic oxygen electrode in 1956 [31]. Severinghaus set to work adapting it to measure oxygen in the blood. In 1957, he combined a Stow-Severinghaus carbon dioxide electrode and a Clark electrode with a heated cuvette that stirred the blood sample, thus creating the first blood gas analysis system [32]. A year later, he added a pH electrode, creating the first blood gas machine, a device routinely used today (see Fig. 55.15) [33].

1956: Nitrous Oxide May Not Be Innocuous

In 1956, Lassen et al. administered nitrous oxide to diminish the pain from spasms produced by tetanus. The pain diminished, but after a few days of therapy with nitrous oxide, the patients developed severe bone marrow depression, and some died [34]. This is the same Lassen who appealed to Bjørn Ibsen to do something to save the Copenhagen patients suffering from polio in 1952.

Decades later, anesthesiologists and other investigators showed that this untoward effect probably resulted from the

capacity of nitrous oxide to inactivate methionine synthase [35, 36], a vital enzyme responsible for synthesizing the essential amino acid, methionine, and producing folate, needed for formation of DNA.

Exposure to nitrous oxide as a patient or as a member of the operative team who may breathe the gas released from the anesthetic machine, may result in subtle or less than subtle injury because we are not created with an equal amount of methionine synthase. Even if we were, the production of methionine synthase requires absorption of vitamin B12. So the patient who is a vegetarian (with less access to B12) or is an alcoholic or is just old (with a decreased production of intrinsic factor—needed to absorb B12) may be more vulnerable to inactivation of methionine synthase and its consequences. Anesthesiologists and others showed that fatal consequences can result in patients with a rare deficiency in the capacity to manufacture methionine synthase, who breathe nitrous oxide even briefly (1–2 hours) [37].

1960s–1980s: Tissue Oxygen Levels, Infection, and Wound Healing

In the 1960s, surgeon Thomas Hunt demonstrated that surgical wounds commonly have tissue oxygen levels low enough to impair resistance to infection and healing capacity [38]. Hunt quickly recognized the value of collaborating with anesthesiologists, eventually spurring the creation of a major current area of investigation within anesthesia, specifically outcomes research related to wound healing.

In the 1970s and 1980s, Hunt and his collaborators developed minimally invasive methods, based on the Clark electrode, to continuously measure oxygen partial pressures in surgical wounds. They demonstrated that decreased PO_2 in wounds can impair white cell function. By the mid-1990s, anesthesiologist Harriet Hopf under Hunt’s tutelage showed that surgical site infections (SSIs) correlated with low wound oxygen levels [39]. In that study, PO_2 in most surgical wounds was less than normal, often low enough to impair white cell function. In volunteer studies, infusion of epinephrine [a model of sympathetic nervous system (SNS) activation] decreased wound PO_2 levels substantially—as did hypovolemia. Hunt predicted that preventing perioperative cold exposure/hypothermia, hypovolemia, pain, and stress would lessen SNS activation, thus preventing peripheral vasoconstriction and maintaining wound oxygen levels close to normal. This would improve healing and resistance to infection. He also understood that anesthesiologists held the key to the SNS. Then a surgery resident working in his lab, I (HH) decided to switch to anesthesiology. This started a 25-year collaboration and provided a mechanism for recruiting other anesthesiologists to study wound outcomes, including Dan Sessler (Fig. 42.1), Andrea Kurz, Kate Leslie,

Fig. 42.1 Daniel Sessler. (From www.nlm.nih.gov/medlineplus/magazine/issues/summer07/articles/...)

Ozan Akca, Barbara Kabon, Elizabeth Fleischmann, and Paul Myles.

1970s–1980s: Transcutaneous Oxygen and Carbon Dioxide Measurement

The blood gas monitoring systems devised in the 1950s, could not be used to continuously monitor respiratory gases in the body. In the 1970s, Huch, Lubbers and Severinghaus developed transcutaneous oximetry to provide a nearly-continuous monitor of arterial oxygen [40–42]. In the late 1970s and early 1980s, Beran et al. and Severinghaus added transcutaneous analysis of carbon dioxide [43, 44]. The device heated the skin under the electrode, increasing cutaneous blood flow, thereby arterializing cutaneous gases and minimizing diffusion distances of oxygen and carbon dioxide to the electrode surface. Monitoring of both gases was found to accurately reflect arterial blood gas values in infants, and

transcutaneous oximetry continues to be used for this purpose in neonatal ICUs. In older children and adults, measurement of transcutaneous oxygen partial pressures is less accurate, particularly at high PO_2 values. Transcutaneous oximetry did find new life, however, in the 1980s, when surgeons Hauser and Shoemaker demonstrated that transcutaneous oximetry could be used to quantify skin oxygen levels in ischemic limbs [45]. Transcutaneous oximetry is now used routinely in wound clinics to determine a patient's capacity to heal. Anesthesiologists have contributed to this field [46, 47].

1970s–Present: Anesthesiologists and Disasters

The involvement of anesthesiologists in on-site management of victims of major disasters came to the fore in the Moorgate Tube Train accident, in London in 1975. 43 people died and 72 required treatment in hospital. Prior planning, good communication, and the need for mobile medical teams to have emergency management experience, were all identified as key factors in the successful management of disaster victims. Anesthesiologists around the world subsequently became core members of local and national disaster planning processes.

In 1977, The Association of Anaesthetists of Great Britain and Ireland established the Pask Certificate of Honour. Named after Edgar Pask, anaesthetist and experimental physiologist in the Royal Air Force, the award honors the gallantry of a registrar anaesthetist in the Moorgate disaster. In 2010, the award was made to 113 anaesthetists who had served in the Armed Forces in Iraq from 2003 to 2009.

Successful completion of Fellowship training of anesthesiologists in Australia and New Zealand now requires accreditation in one of the following courses: Emergency Management of Severe Trauma (EMST), Advanced Trauma Life Support (ATLS) or Effective Management of Anaesthetic Crises (EMAC).

1976: Volatile Anesthetics Can Predispose to Arrhythmias

Small studies are of limited or no use if they do not uncover a significant effect (they may be too small to reveal a significant difference). They are only useful if they reveal significant differences. For example, in 1976, Johnston et al. reported on the arrhythmias in 48 patients having transphenoidal removal of pituitary tumors after receiving submuscular injections of epinephrine in saline to minimize bleeding [48]. Of patients anesthetized with halothane, 50% developed three or more premature ventricular contractions at a dose of 2.1 mg/kg epinephrine, a dose significantly less than the 6.7 mg/kg dose of epinephrine required to produce the

same rate of PVCs during anesthesia with isoflurane. This small study in humans showed that the alkane, halothane, predisposed to ventricular arrhythmias far more than did the ether, isoflurane.

1980s: Potent Anesthetics May Decrease Myocardial Injury

In the 1980s, inhaled anesthetics were shown to have preconditioning effects mimicking ischemic preconditioning (a brief period of myocardial ischemia preceding a more prolonged period will protect the human heart from subsequent periods of ischemia [49] thereby reducing the impact of myocardial ischemia [50].) The protection was found to be long lasting (days) [51, 52], a change persisting in the absence of anesthesia, indicating that volatile anesthetics (all of them) can up-regulate and down-regulate genes. Perhaps this explains other phenomena such as the long-term remedy supplied by anesthesia to treat severe mental depression (see below).

1980s: The introduction of Trans-Esophageal Echocardiography

Studies examining survival of the heart in the face of stresses such as hypoxia make use of a now-ubiquitous device, transesophageal echocardiography. This noninvasive approach to evaluating the heart broke onto the scene in the early 1980s. Anesthesiologist Michael Cahalan was a leader of the evaluation and use of this device. His 1987 review article noted that echocardiography could be used to support the clinician (including the surgeon) and to further research [53].

1980s–2000s: Hypovolemia Increases Wound Infection

In the 1980s and early 1990s, Hunt's group examined the effect of hypovolemia on wounds, and found evidence for the benefit of generous fluid administration. Michael Hartmann, an anesthesiologist in Malmo, Sweden, demonstrated in 1992, that giving more fluid in response to low wound oxygen levels increased healing capacity (collagen deposition) in colon surgery patients [54]. This area of investigation was challenging. First, patients in the 1980s and 1990s were generally hypothermic. Hypothermia induced peripheral vasoconstriction and diuresis, thereby decreasing total blood volume by about 20% and limiting venous acceptance of additional fluid. A cold hypovolemic patient who received a fluid bolus might develop pulmonary edema, despite a low total blood volume. Second, heart rate, blood pressure, and

urine output frequently remained normal despite up to a 20% volume loss.

Optimum fluid volume management to prevent complications remains controversial [55]. Brandstrup's group in Copenhagen, demonstrated that giving about 2700 ml of colloid (large molecule) containing fluids improved wound outcomes more than giving 5000 ml of crystalloid (salt water). But Kabon and colleagues showed that giving high volumes of crystalloid intraoperatively led to higher wound oxygen levels than giving standard volumes (near the Brandstrup crystalloid value). Anesthesiologists, including TJ Gan, Markus Rehm, and Matthias Jacob, in addition to those already mentioned, continue this debate over fluid management. Current research is focused on so-called goal-directed therapy, in which transesophageal echocardiography, non-invasive cardiac output monitors, and other approaches are used to guide fluid therapy. Goal-directed therapy is promising, although formulation of guidelines must await completion of the large randomized trials that will provide the evidence.

In 2000 [56], anesthesiologists Greif and colleagues demonstrated that patients having colon surgery had less SSI (and an increase in wound oxygen) when given 80% oxygen during surgery. Several subsequent studies found similar results, but two found no benefit, leaving us with uncertainty about the value of high-inspired oxygen. Most agree that breathing high concentrations of oxygen for a few hours in the perioperative period is safe. A 2012 report by Meyhoff and colleagues found that mortality is not decreased by greater concentrations of oxygen for a subset of patients (those with cancer), and post-hoc analysis suggested the need to evaluate potential adverse effects of increased concentrations in patients undergoing surgery for cancer [57]. Ensuring the adequacy of perfusion by preventing activation of the SNS, appears to be a major determinant of success.

1985: Potent Anesthetics May Cure Mental Depression

Could volatile anesthetics be used to treat mental depression? Electro-convulsive therapy (ECT) (administered along with short acting hypnotics) is frequently and successfully used to treat major depression, but it is associated with prolonged memory loss. In 1985, psychiatrist Langer and anesthesia colleagues in Vienna reasoned that perhaps the therapeutic benefit of the convulsions might be associated with the electrical silence that follows seizures rather than the convulsion, itself. If so, perhaps the use of inhaled anesthetics to achieve electrical silence in such patients might be advantageous because there would not be a prolonged effect on memory. They demonstrated that deep anesthesia with isoflurane, inducing a period of 'electrocerebral silence,'

reduced depression in 9 of 11 subjects [58]. These results were confirmed in 1995 [59].

In 1993, a separate group from Wurzburg also demonstrated that burst-suppression associated with a deep level of isoflurane anesthesia was as effective as ECT [60]. They noted that anesthesia required more time and monitoring than ECT, and therefore suggested it as a second level intervention. Use of isoflurane did not become routine, probably because psychiatrists make treatment decisions and the support for treatment with isoflurane came from small studies, only some of which were randomized and controlled.

Scott Tadler from the Dept. of Anesthesiology at the University of Utah revived the idea of treating depression in patients with concentrations of isoflurane sufficient to briefly cause burst suppression. First, using animal models of learned helplessness, he and colleagues demonstrated that isoflurane has an antidepressant-like effect (SC Tadler, A Light, R Hughen. (2009). Isoflurane Demonstrates Antidepressant-like Activity in a Mouse Model of Depression [Abstract]. *Anesthesia and Analgesia*, 108(S), 212.). The effect was comparable to that of desipramine, using the forced swim test in mice. Paul Shepard, a psychiatrist at the University of Maryland, picked up on these results and demonstrated an antidepressant like effect in rats for isoflurane, but not for halothane. These results imply antidepressant effects unique to isoflurane and perhaps a result of medication-induced cerebral isoelectricity (achieved by isoflurane but not halothane) These data suggest the need to explore the effects of other medications that cause isoelectricity. Next, in an open label pilot study, Tadler, Weeks and colleagues found that isoflurane effectively treated depression and caused less memory loss than traditional electroconvulsive therapy [61, 62]. Finally, preliminary results from a 2011 study indicate that ketamine acutely diminished depression in patients not responsive to ECT [63]. Whether this positive result would be sustained for more than a few hours is unknown but worth pursuing.

1990s: Post-Operative Cognitive Dysfunction

Anesthesia profoundly affects the central nervous system, but we assume that the alterations are transient, disappearing when anesthetic administration ceases. After all, the patient does awaken. Or are there persistent subtle effects that vex—or help—us? In the 1990s, Olney's group found that halothane could prevent MK-801 (a drug with properties similar to ketamine) from inducing neurotoxicity [64], later adding isoflurane and propofol [65]. However, in 2003, Olney's group suggested that midazolam, nitrous oxide and isoflurane given to the developing brain of rats caused cere-

bral apoptotic degeneration [66]. Injury to neurons in adult rat brains might be produced by nitrous oxide, with isoflurane acting to protect the brain [67].

Could similar effects produce postoperative cognitive dysfunction (POCD) in humans? In 1998, anesthesiologists Moller et al reported that patients older than 60 years were more likely to have POCD than unoperated peers, with operated patients still differing from controls 3 months after surgery [68]. But is this a consequence of the surgery, the anesthetic, being in a strange (hospital) environment or all of the above? In 2003, anesthesiologists Rasmussen et al. found that, yes, POCD occurred after surgery in patients aged 60 or greater, but that the extent of dysfunction after 3 months did not differ between patients given general versus regional anesthesia [69].

Finally, are children, particularly younger children, at risk of POCD? Considerable laboratory and epidemiological data have been gathered, with inconclusive evidence prompting concern. In 2011, this concern resulted in a presently ongoing multidisciplinary effort to determine whether such effects exist [70].

1990s: What Is Acceptable Anemia?

Renal transplantation and the AIDS epidemic transformed transfusion medicine, leading anesthesiologists to re-evaluate the management of anemia, blood loss, and transfusion. LT Goodnough championed approaches to reduce blood transfusion, acceptance of a lower transfusion threshold (7 g/dL hemoglobin rather than 10), and investigated the potential value of pre-donation of autologous blood and use of erythropoietin to increase red cell mass in patients scheduled for surgery potentially producing large blood loss. In the late 1990s, anesthesiologist Richard Weiskopf and his colleagues at UCSF, defined the physiologic responses to acute severe anemia in unanesthetized fit volunteers. Their findings supported the concept of a transfusion target of 7 g/dL [71].

1990s: Hypothermia, Oxygenation, and Infection

Sessler, at UCSF, defined how anesthesia leads routinely to hypothermia. In 1988, he and his colleagues found that anesthesia broadens the threshold to the body's response to hypothermia [72]. In the mid-1980s, Scott Augustine (a Navy anesthesiologist in San Diego) developed the forced air warmer (Bair Hugger), the first effective means of maintaining normal core temperature during anesthesia (aside from keeping the operating room too warm for the surgeons) [73]. Thus,

by 1990, anesthesiologists were poised to examine whether preventing SNS activation by keeping patients warm during surgery would reduce SSI.

Based on Hunt and colleagues' demonstration that SNS-induced peripheral vasoconstriction caused wound hypoxia; on Sessler and his colleagues' demonstration of the mechanisms of anesthesia-induced hypothermia; and on Augustine's development of a successful method for preventing anesthesia-induced hypothermia (the forced air warming blanket), maintenance of intraoperative normothermia was investigated as a means of improving wound outcomes. The outcome trial that resulted was published in 1996 [74]. It demonstrated that maintaining normal core temperature (36.6°C) while aggressively providing fluids and pain control reduced SSI by 67% in colon surgery patients, compared with a control group allowed to cool to 34.7°C (the routine in clinical practice at the time). Schmied et al. in Sessler's group added further to the importance of maintaining normothermia [75]. They found that mild hypothermia (only a 1.6°C decrease) increased intra- and postoperative blood loss.

The effect of these studies on practice was rapid and widespread. By 1999, Center for Disease Control (CDC) infection control guidelines incorporated maintenance of normal core temperature for patients undergoing colon surgery. Numerous devices are presently marketed to safely prevent and treat anesthesia-related hypothermia, including forced air warmers, resistive warmers, and conductive warmers. Of note, pre-warming the patient prevents much intraoperative hypothermia and should be considered for most patients [76].

1990s: Prevention of Deep Venous Thrombosis (DVT)

Venous thrombo-embolism significantly increases morbidity and mortality in patients undergoing surgery, and anesthesiologists have, along with surgeons, played a major role in instituting preventive measures. Pulmonary embolism is the third most common cause of preventable hospital related death, and commonly follows DVT in the lower limbs [77, 78]. Surgical patients are at significant risk of developing DVT, due to intraoperative venous stasis and changes in fibrinolytic activity, as well as low postoperative mobility. The simple technique of ensuring that occlusion of calf blood vessels is avoided during surgery, is the responsibility of the anesthesia care team. Additional measures have included intermittent calf compression with sequential compression devices, and the intra-operative use of low molecular weight dextrans [79]. Rapid post-operative mobilization is also a feature of modern surgery, and anesthesiologists have played a role by adopting drugs that are rapidly eliminated.

1990s–2000s: Inhaled Anesthetics Affect the Environment

Inhaled anesthetics can affect the environment in two ways. One is by depletion of the ozone layer. As proposed by chemists Frank Rowland and Mario Molina in 1973, breakdown of anesthetics containing bromine (halothane) or chlorine (chloroform, halothane, enflurane, isoflurane), releases the atomic halogen which, in turn, breaks down ozone [80]. Since ozone absorbs ultraviolet light, its loss would permit more ultraviolet light to reach the surface of the earth with potentially devastating effects. Rowland and Molina won the 1995 Nobel Prize for their work. The Montreal Protocol on Substances That Deplete the Ozone Layer was an international agreement limiting the release of such halogenated compounds into the environment and came into effect in the late 1980s [80], with subsequent improvement in the ozone layer. Release of inhaled anesthetics appears not to have been included in the Protocol. The anesthetics desflurane and sevoflurane in the 1990s, displaced the earlier chlorine- and bromine-containing anesthetics, and neither desflurane nor sevoflurane contain these halogens, being halogenated solely with fluorine (harmless to the ozone layer) [81].

However, inhaled anesthetics can affect the environment in a second way. All absorb infrared light. In 1937, Luft made use of this in his design of the infrared analyzer [82]. In 1991, Norwegian anesthesiologists noted the ability of nitrous oxide to act as a greenhouse gas and suggested use of lower inflow rates to minimize release into the atmosphere [83]. In 2010, anesthesiologist Susan Ryan, working with basic scientists, demonstrated that inhaled anesthetics are greenhouse gases, opening a new avenue for arguing about optimal anesthetic technique [84]. Not all anesthetics provided equal concern, desflurane having a several-fold greater potential environmental impact. However, "the overall contribution of inhalation anesthetics to greenhouse gas emission is miniscule..." [85] "approximately 0.01% of that of the CO₂ released from global fossil fuel combustion." [86] Even so, the anesthesia department at the University of Utah saved the equivalent greenhouse gas potential of driving 5.4 million miles over one year, by converting much of their anesthetic vapor use at their hospitals from desflurane to isoflurane. Ryan and Jodi Sherman from Yale addressed the wide range of environmental issues in anesthesia: [87] supply chain waste and contamination; disposal of unused drugs; entry of metabolized drugs into the water supply; greenhouse gas production; and disposable waste generation. The Stockholm County Council (<http://www.janusinfo.se/In-English/>) has compiled data that allows comparison of the environmental impact of various drugs based on persistence, bioaccumulation, toxicity, and expected concentration in the environment. Few anesthetic drugs have been

classified in this way, but such data may ultimately guide anesthesiologists interested in providing the best anesthetic care with the lowest ecological footprint. For now, regional anesthesia appears to have the smallest footprint.

2000s: Prolonged Use of High Tidal Volumes May Cause Pulmonary Injury

A 2003 meta-analysis by anesthesiologists Petrucci and Iacovelli, found that using smaller tidal volumes in patients suffering from acute respiratory distress syndrome (ARDS) or acute lung injury (ALI) might decrease mortality [88]. In 2007, anesthesiologists Mascia et al. found that large tidal volumes per se produced lung injury in patients with severe brain injury [89]. In 2008, internists Meade et al. disputed the survival value of smaller tidal volumes in patients with ARDS or ALI [90]. However, Lellouche et al. reported in 2012 that large tidal volumes lead to organ failure and prolonged ICU stay in cardiac surgical patients [91].

2009–2012: Ethical Violations in Anesthesia

From 2009 to 2012, three anesthesiologists (Scott Reuben, Joachim Boldt, and Yoshitaka Fujii) and a cardiologist (Don Poldermans) engaged in anesthesia related research, admitted to research misconduct, ranging from ethics violations to fabrication of data. This worldwide misconduct, from the US to Europe to Japan, led to retraction of more than 100 articles, with at least 200 more in jeopardy. All four individuals were publishing research germane to the topic of this chapter; that is, in areas independent of producing anesthesia.

Does working outside the mainstream of traditional anesthesia related research make it easier to commit fraud? Is this a reflection of the degree to which anesthesia related research has come to be increasingly focused on topics outside of producing anesthesia? Are journals just getting better at identifying misconduct? Regardless, this is a concerning development!

2012: Uncertain Ethical Behavior in Anesthesia

Should anesthetists participate in the intravenous delivery of drugs deliberately intended to kill those sentenced to death? In 2012, the American Board of Anesthesiologists said no, indicating that they would revoke the certification of any anesthesiologist participating in such lethal injection, defending their action by pointing to the Hippocratic injunction that physicians do no harm. Those supporting lethal injection argued that anesthesiologists are best equipped to supply such injections humanely.

Reflections

The practice of anesthesiology touches patients managed by every surgical subspecialty and many medical ones, including radiology, cardiology, gastroenterology, and emergency medicine, prompting, as this chapter suggests, an awareness of the challenges within many disciplines and a collaboration with a broad range of colleagues. Thus it is appropriate that anesthesiologists have contributed to increased knowledge and improved practice in such disparate areas as blood banking, cardiac protection, infection prevention, critical care, pain management, patient safety, and patient comfort. They are likely to continue these contributions.

Summary

Anesthesia outcomes research as large-scale clinical trials, began at anesthesia's inception. Ether caused postoperative nausea and vomiting (PONV). By mid-twentieth century, many drugs were shown to decrease PONV. In 2004, Apfel reported that combining antiemetics with different actions enhanced efficacy.

Beecher and Todd's 1952 article on outcomes in 600,000 patients indicated that anesthesia killed 1 in 2000 patients, and that curare given without proper reversal increased the incidence 6-fold. The 1966 National Halothane Study of 856,515 patients, reported no increased mortality with halothane anesthesia but found rare cases of massive hepatic necrosis. Also in 1966, a 200-patient study connected methoxyflurane and renal injury, and in 1973 this was shown to be dose-related.

Notwithstanding the absence of quantitative numerators and denominators, 1980s-2000s' reviews of closed-claims data identified egregious anesthetic errors and prompted remedial measures. Similarly, in 1991, Rigler and Drasner found a cauda equina syndrome in 4 patients given 5% lidocaine through a new spinal catheter that localized the injected lidocaine. This led to a 1998 study that found a more subtle injury from intrathecal lidocaine in 1,863 patients.

Slogoff and Keats' 1980s studies of patients having coronary artery bypass operations (CABG) showed that a greater heart rate correlated with postoperative myocardial infarction, independent of anesthetic choice. In 1989, Mangano, Leung and others initiated Studies of Perioperative Ischemia (SPI) which morphed into the Multicentered Study of Perioperative Ischemia (McSPI). These richly productive, prospective, expensive, outcomes researches in the 1990s-2000s showed: that surrogate evidence of ischemia (e.g., that obtained with TEE) predicted adverse clinical outcomes (e.g., myocardial infarction); that several drugs (e.g., acadesine, beta adrenergic blocking drugs, aspirin) might protect surgical patients at risk of myocardial injury from ischemia; and that aprotinin caused clotting of grafts and increased mortality. However, in 2012, critical re-analysis of earlier outcome studies supplied new information suggesting that perhaps aprotinin is useful after all. Wallace's inexpensive 2010 retrospective study of 38,779 electronic medical records of operations confirmed that perioperative beta blockade reduced perioperative mortality.

In the late 2000s, Pronovost led efforts to apply checklists to markedly decrease untoward consequences such as infection. Similarly, Loftus and Koff and colleagues at Dartmouth decreased hospital acquired infections by promoting hand hygiene by anesthesia providers in the operating room.

In conclusion, anesthesia outcomes research has led to evidence based outcomes, improved anesthesia care, and decreased perioperative risk.

Introduction

Assembling this history of outcomes research in anesthesia demanded decisions concerning what to include and exclude. By this apology, we note that we omitted important developments. The present essay follows the suggestion by Sessler (personal communication, 16 Sept 12) that outcomes research is "the term for large-scale clinical trials that evaluate outcomes that are meaningful to patients". A broader view might define outcomes research as research that tells us

about clinical outcomes, good and bad, and includes small-scale as well as large-scale clinical trials. For the purposes of this book, Harriet Hopf provides (Chapter 42) a history of outcomes research in small-scale clinical trials, trials including as many as approximately 200 subjects (but we are liberal in our interpretation). The present chapter will focus on the large-scale trials with a particular emphasis on those investigating cardiovascular issues.

1846 to the 2000s and Apfel's Low Cost Study of Nausea and Vomiting

Starting with Morton's demonstration, postoperative nausea and vomiting (PONV) has been a problem of interest to anesthetists and patients. A 1936 survey of about 10,000 patients found that 40.6% vomited in the postoperative period [1]. The common anesthetics of the day—nitrous oxide, cyclopropane, and ether—are highly emetogenic, so the observation was not surprising.

Researchers sought drugs that might treat or prevent nausea and vomiting. Anti-histamine and anti-cholinergic drugs were introduced in the 1940s to prevent motion sickness, and made the first lasting impact on PONV. It seemed logical that drugs which worked against motion sickness might prevent PONV. In the early 1950s, two groups [2, 3] found that dimenhydrinate (Dramamine), introduced after World War II to decrease motion sickness, reduced PONV when given before induction of anesthesia. In 1955, anesthesiologists Dent, Ramachandra, and Stephen [4] showed that the antihistamine cyclizine (Marezine) given prophylactically, decreased PONV. This study of 3000 patients in the Post Anesthesia Care Unit also found that regional anesthesia produced less PONV than ether or cyclopropane. Sodium thiopental also produced less PONV than ether, but more than regional anesthesia. Head and neck surgeries had a higher rate of PONV than abdominal surgeries, although that may have been related to differences in anesthetic management. Interestingly, the group missed what is now recognized as one of the strongest predictors: female gender.

In 1960, anesthesiologists Bellville, Bross and Howland showed that phenothiazines protected against PONV [5, 6]. In this study of 3794 patients, they also found that 28% of females vomited vs. 9.3% of males. Larger total doses of anesthesia and intraoperative hypotension both predicted higher rates of PONV. Paul Janssen synthesized droperidol in 1961, and it was used in combination with fentanyl by the mid-1960s. It was one of a group of dopamine receptor antagonists useful for decreasing PONV. Developed by Glaxo in 1984, ondansetron, a 5-HT-3 (serotonin) antagonist, was released for use in the late 1980s and was quickly found to be effective against PONV [7]. In 1986, Doze et al. demonstrated that propofol was more effective than methohexital

in decreasing PONV [8]. In 1994, McKenzie et al. found that adding dexamethasone to ondansetron further decreased PONV [9].

In 1961, Eger et al. reported that premedication could vastly influence PONV in children anesthetized with ether [10]. Premedication with the GABAergic drug pentobarbital, resulted in an incidence of vomiting of 18% in children. Omission of the barbiturate doubled the incidence of vomiting, while substitution of the opioids meperidine or morphine for pentobarbital, quadrupled the incidence compared with those receiving only an anticholinergic.

During the half century leading up to 2000, anesthesiologists applied diverse antiemetic drugs, including antihistaminics, anticholinergics, barbiturates, phenothiazines, dopamine receptor antagonists, serotonin receptor antagonists, dexamethasone, and propofol to minimize PONV. Each had merit but none was perfect. Each affected a different receptor, a clue that led to the next development. In 2004, Apfel reported an outcomes study in 5,199 patients at high risk for postoperative nausea and vomiting, in a randomized, controlled trial of factorial design to evaluate interactions among as many as three antiemetic interventions [11]. The primary outcome (nausea and vomiting within 24 hours after surgery), was evaluated blindly. The study found that combining antiemetic drugs, blocking different emesis-mediating receptors, decreased postoperative nausea and vomiting. The greater the number of different receptors blocked, the greater the prophylaxis. This 5,199 patient study was performed for \$500,000 (\$96/patient) by using a clever business model. German medical students needing to do research as part of their medical education, were recruited as study coordinators with the promise of being able to write manuscripts using the study database, and receiving credit toward their degree requirements. This special educational requirement allowed a large, inexpensive, outcomes study.

Understanding the Risks of Anesthesia

Anesthesia is inherently dangerous. Modern examples come to mind. In 2002, the Russian military conducted an unintended outcomes study involving 850 attendees held hostage by terrorists at the Moscow Opera House. It is speculated that both terrorists and attendees were anesthetized with an aerosolized version of fentanyl without benefit of anesthesia personnel: 129 (15%) died. "Studies" of the famous provide similar outcomes: John Bellucci, Chris Farley, Jimi Hendricks, Michael Jackson, Janice Joplin, Marilyn Monroe, Elvis Presley, Anna Nicole Smith, and Amy Winehouse to name a few. And we in anesthesia know of colleagues who, unattended, self-administered anesthesia with lethal results. Safe anesthesia demands the presence of the trained and vigilant anesthetist.

Many advances including improved equipment, education, better medications, and new or improved monitors, decreased anesthetic-induced mortality from the 15% rate with no anesthetic care (the Moscow Opera House), to the miniscule rate associated with modern anesthesia. However, safety also resulted from the results of outcomes research, from large and small clinical trials.

1920s–1930s: Study Commissions to Improve Anesthesia Care

Anesthetic study commissions, supported by the American Medical Association (AMA), developed registries of case reports of anesthesia-associated deaths in the 1920s and 1930s. In April 1938, an editorial in the *British Journal of Anaesthesia* opined [12]:

“If fault is to be found in the development of anesthetic practice, as it is seen today, that fault lies in our failure notably not to reduce the fatalities of anaesthesia. It should not be beyond the wit and skill of anaesthetists to secure safety without abandoning modern progress. The number of deaths on the table is not negligible, even when the patient is ordinarily fit and the operation not a grave one. The cure of this type of fatality is education and more education, for these fatalities do not occur, with the expert.”

1946: Bishop Assembles Data

In a 1946 report, Harold Bishop considered the basis for “6 deaths which have occurred in the operating rooms of two hospitals with which we have been associated during the past four years. A total of 20,021 anesthetics have been administered during that time. Four of these patients had received an anesthetic; one patient died during the course of operation without anesthesia; one patient died during a therapeutic sympathetic nerve block [13].” Six deaths in 20,021 anesthetics indicated a mortality of 1:3,337. But anesthesia was not responsible for all of these (e.g., one patient died from a “fatal pulmonary embolism during manipulation of the hip under anesthesia” (embolism confirmed at autopsy), and thus the incidence was still less. On the other hand, Bishop’s data did not include deaths from anesthesia that resulted after the conclusion of surgery, and thus his report probably underestimated mortality.

Bishop also discussed data for anesthetic-associated mortality from other reports, noting that in New York City for the years 1928 to 1936 there were 758 deaths in the operating room, and of this number, 412 were attributed to anesthesia. However, this collection of statistics lacked two dimensions: a complete numerator (the sum of all anesthetic-caused deaths, intraoperative and postoperative); and a denominator (the total population of anesthetized patients from which

Fig. 43.1 From Bishop’s report [13], we know that the total deaths, and deaths with tonsillectomy and adenoidectomy associated with anesthesia in the US, remained constant for a decade. We don’t know how many anesthetics were given in each of these years, so we cannot tell whether matters were worse, better, or unchanged with time. (Data from Bishop [13])

these patients were drawn). Bishop also presented the number of deaths in the US associated with anesthesia, stating that “These figures would indicate that up until 1936, deaths under anesthesia were not decreasing”. This conclusion can’t really be made without an estimate of the number of operations per year. Bishop noted that one operation, tonsillectomy, supplied a substantial fraction (15%) of the total deaths (Fig. 43.1), but failed to indicate what fraction of total surgery this procedure represented. Finally, Bishop cited the work of Gillespie for studies in the US, England, Australia and Canada for roughly the 1920s and 1930s, studies giving the deaths during anesthesia as 1 in 804 patients from a total number of cases of 227,546. Again, we didn’t have a complete numerator (i.e., deaths after surgery were not considered). It was a beginning, but more was needed.

1949: Gregory also Wants a Commission

John Gregory’s 1949 article, “The pathology of sudden and unexpected death under anesthesia” [14], reviewed the accepted causes of anesthesia-related mortality, criticized their lack of pathologic basis or validation, and called for a commission to:

Define detailed criteria for the study of sudden death under anesthesia.

- Be comprised of at least two physiologists, two pathologists, two pharmacologists, and two surgeons (but no anesthesiologist)
- Receive and study exhaustive data on all sudden deaths.

- Ensure that a postmortem examination was accomplished before a case could be considered for statistical purposes.

Gregory raised several important issues. Many reasons given for death had little pathophysiologic basis, and supplied no explanation (e.g., status lymphaticus). Several diagnoses were indistinguishable without an autopsy (e.g., acute coronary thrombosis and pulmonary embolism). Many blamed “the agent used or the ineptitude of the anesthesiologist.” There also seemed to be a tension between blame assigned to the anesthesiologist and the surgeon. Gregory thought that the basis for

“preventing deaths under anesthesia are the proper selection of agent and its mode of administration, and the management of the patient before and during anesthesia. The necessary knowledge of the normal and pathologic physiology and pharmacology of anesthesia is exceedingly large and complex. Not one surgeon in ten has been given such training or has the time or energy to acquire it. Thus, it is perfectly clear to me that the average surgeon should have little to do with anesthesiologic control. If an accident occurs the anesthesiologist is held accountable, either overtly or covertly. It is his duty to the patient and to medical science to demand the authority commensurate with his responsibility.”

Gregory also noted an “apparent peculiar liability of the Negro to sudden death under anesthesia...The central commission should instigate, encourage and even direct these and other pertinent investigations [14].” Gregory identified socioeconomic differences and access to health care as causes of poor outcomes and the need for remediation of socioeconomic disparities in medical care. Aspects of this commission paralleled those of the American Society of Anesthesiology closed claims database that identified many issues essential to the improvement of anesthesia care [15–18].

1948–1952: The Beecher and Todd Study

At mid-century, Henry Beecher and Donald Todd took a giant step forward in anesthesia outcomes research [19]. They sought to determine the rate and etiologies of deaths attributable to anesthesia, and whether deaths were caused by the agent, technique, or misapplication. Finally, they attempted to assess the responsibility of the anesthetist. They believed that anesthesia caused an unnecessarily high death rate, that knowledge of what was dangerous was inadequate, and that directing attention to these issues would improve outcomes. Prospectively, they collected data on all deaths in 600,000 patients undergoing anesthesia at 10 major university hospitals, over a five-year period. A surgeon and the chief anesthetist of each institution, examined the record of every deceased patient and reported on anesthetic agents, techniques, type of surgical procedure, and causes and

classification of all deaths. Deaths were divided according to whether they resulted from patient disease, error in diagnosis, error in surgical judgment, error in surgical technique, or anesthesia. Residents, nurses, surgeons, anesthesia specialists, medical students, interns, and occasional physicians gave inhalation, intravenous, local, spinal, topical, regional, rectal, and caudal anesthetics. Although curare and curare-like drugs (“curares”) were used in 44,100 cases, only 13,200 (4.3%) of all cases received controlled ventilation and 600 (0.2%) received assisted respiration. Deaths related to anesthesia when curares were not given (266) were 1:2,100, but were 1:370 (118) when curares were used. No discussion considered the possibility that the use of curares without supporting ventilation caused the 6-fold increased mortality, or that the lungs of patients receiving curares should be artificially ventilated, or that the residual effects of the curares should be reversed. They also identified increased mortality with thiopental, and with the use of tracheal tubes with inflatable cuffs—but just 2 cases: “one cuff got inflated with nasal oxygen, with fatal rupture, and the other broke during lobectomy for abscess and allowed the dependent lung to be suddenly flooded with detritus.”

The discussion of the increased risk included power calculations, adjustments for case risk type, possible interactions with other agents, timing of deaths, surgical type, anesthetist experience, gender differences, gross misuse, and dose. Despite such sophisticated analyses, Beecher and Todd concluded that there must be some inherent toxicity of curare, and that the deaths were from circulatory collapse. Notwithstanding the failure to recognize partial paralysis from not reversing the effects of the curare as the probable cause of the curare-related deaths, this 600,000 patient study was a landmark in anesthesia outcomes research. An interview with Cecil Gray in 1996 [20] focused on the reason for the failure to reverse the residual effect of curare:

“The Americans were frightened of prostigmine because of its effect on the heart. You give enough and the heart just stops. But atropine blocked that action but didn’t block the action on the muscles, the reversal of the tubocurarine.”

1966: A National Study Finds no Increased Risk with Halothane

Anesthetic molecules may be degraded by the alkali (bases) used to remove carbon dioxide, or may be metabolized by the patient’s liver or kidney. The resulting degradation products may be injurious, sometimes highly injurious. In the late 1800s, deaths from hepatic injury were found to occur with chloroform use. Scholler showed in rats, that this noxious effect was due to the metabolism of chloroform to a noxious metabolite [21]. It was hoped that halothane, released for clinical use in 1957, would not share the hepatotoxicity

possessed by chloroform. At first, as we all held our breaths, this seemed to be the case. But in the 1960s, rare cases of hepatic injury appeared, cases with a peculiar “syndrome” that had components suggesting that injury was based on an allergic mechanism [22]. The concern regarding halothane hepatotoxicity was intense. Halothane had largely replaced the older anesthetics, ether and cyclopropane. Few anesthetic converts to halothane wanted to return to the days of yesteryear, and again “drop” the flammable and irritating ether. But if ether were safer, well, then.... In December 1961, the Committee on Anesthesia of the National Academy of Sciences-National Research Council appointed a study group to report periodically on halothane anesthesia, with special attention to evidence of association with fatal postoperative hepatic necrosis. They found insufficient evidence to either establish or refute a causal relationship. Postoperative mortality at the time was 2%, and death attributable to massive hepatic necrosis appeared to be rare, perhaps one death in 10,000 operations. But in May 1963, the manufacturer issued a drug warning based on 12 cases of fatal hepatic necrosis following the use of halothane.

In response to the concern regarding hepatotoxicity, the National Halothane Study was initiated in June 1963, with funds provided by the National Institute of General Medical Sciences. It was appreciated that such a study would be large, difficult and costly, but the perceived great value of halothane justified the expense. Before the subcommittee completed its plans for a cooperative, randomized, prospective trial, several additional cases of hepatic necrosis were reported and several institutions severely restricted the use of halothane. Sensing some urgency, and after considering the feasibility, and cost of a prospective, randomized, clinical trial with sufficient power to identify a 1:10,000 risk, the subcommittee decided to survey the incidence of hepatotoxicity for the years before the issue of hepatotoxicity had been raised. Initially, 54 medical centers volunteered to participate in this collaborative retrospective study, but ultimately only 34 contributed data for the four-year study period from 1959 to 1962. This 37% drop-out of participants illustrates a difficulty of large-scale outcomes research.

The subcommittee sought to identify 0.1% differences in mortality rates, mandating a study of approximately one million patients. For all deaths thought to represent massive hepatic necrosis, a photocopy of the complete chart and sections of hepatic tissue were reviewed by a panel of six pathologists with a special interest in hepatic disorders. For the final 856,515 patients, 29.8% received halothane, 25.5% nitrous oxide-barbiturate, 17.2% cyclopropane, 11.9% ether, and 15.6% “other” agents [23, 24]. Massive hepatic necrosis per 10,000 patients was not increased for halothane (1.02), versus nitrous oxide-barbiturate (0.69), cyclopropane (1.7), ether (0.49), or other agents (0.82). Although mortality varied among the five anesthetic practices, mortality following

halothane (1.87%), was slightly less than the average for all anesthetics (1.93%). The study concluded that fatal postoperative hepatic necrosis was rare, and was usually associated with circulatory shock, sepsis, or previous hepatic disease. However, the possibility of halothane-induced hepatic necrosis following single or multiple administrations could not be excluded. There were unexpected large differences in postoperative mortality rates among participating institutions (halothane range 0.54 to 5.59%, nitrous oxide-barbiturate 0.17 to 6.55%, cyclopropane 0 to 21%, ether 0 to 13%, other 0.66 to 17.2%). Variations in measured criteria could not explain these differences.

The National Halothane Study resolved an important question using retrospective epidemiologic analysis. As such, it represented an important milestone in anesthesia outcomes research.

In the 1970s and 1980s, it was found that, as with halothane, the new inhaled anesthetics, enflurane and isoflurane, could produce hepatic injury. However, consistent with the lesser metabolism of enflurane and isoflurane, the incidence of hepatic injury with these anesthetics was much less. In the 1990s, desflurane and sevoflurane were released. It appeared that these anesthetics were still less injurious to the liver in that so few cases were reported after tens or hundreds of anesthetics have been given. For example, only a few cases of severe hepatic injury have been reported after desflurane anesthesia. One did appear to represent an allergic response to desflurane metabolism to an acetyl radical [25]. Another had nothing to do with the anesthesia, instead the hepatic injury resulted from a herpes virus infection coincident to anesthesia [26]. The minimal hepatotoxicity found with desflurane and sevoflurane in part may have resulted because neither contained chlorine, and in part because of low metabolism (especially desflurane)

1966: Nephrotoxicity Associated with Methoxyflurane Anesthesia

In the same year that the National Halothane Study determined halothane to be safe, Crandall, Papas, and Macdonald identified 16 cases (17% of patients) of high output renal failure after anesthesia with methoxyflurane, a significantly greater incidence than found in a comparison group of 100 patients given a different anesthetic [27]. They identified the pathology of the high output renal failure by fluid challenges, and the inability of ADH (Pitressin) injections to increase urine osmolality. Methoxyflurane was almost certainly the causal agent. But an editorial by Leroy Vandam concluded that more information was required before methoxyflurane could be indicted as a harmful drug, recommending its continued use until multiple, prospective, randomized, clinical trials were conducted [28].

Seven years passed until in 1973, Michael Cousins and Richard Mazze reported that subclinical toxicity occurred at 2.5–3 MAC-hours (i.e., administration of 1 MAC methoxyflurane for 2.5 to 3 hours) [29]. All patients exhibited clinical toxicity at dosages exceeding 5 MAC-hours. Cousins and Mazze cautiously suggested that methoxyflurane be used where it offered specific advantages, and where dosages of less than 2.5 MAC hours could be assured.

1978: Large, Prospective, Cardiology Outcomes Research

Modern perioperative cardiac outcomes research began with the 1978 publication “*Cardiac risk factors and complications in non-cardiac surgery*” by Lee Goldman et al. [30]. Using multivariate regression analysis, these cardiologists demonstrated that postoperative cardiac death correlated significantly with (a) myocardial infarction in the previous 6 months; (b) third heart sound or jugular venous distention immediately preoperatively; (c) more than five premature ventricular contractions per minute, documented at any time preoperatively; (d) rhythm other than sinus, or premature atrial contractions on the preoperative electrocardiogram; (e) age over 70 years; (f) significant valvular aortic stenosis; (g) emergency operation; or (h) a 33% or greater decrease in systolic blood pressure for more than 10 min intraoperatively.

1980s–1990s: Prospective Anesthesiology Cardiac Outcome Research

Slogoff and Keats began the contribution by anesthesiologists to the modern era of cardiac outcomes, with their 1985 publication “*Does perioperative myocardial ischemia lead to postoperative myocardial infarction [31]?*” This study of 1,023 patients undergoing elective coronary artery bypass operations (CABG), found that postoperative myocardial infarction was unrelated to preoperative patient characteristics such as ejection fraction and left main coronary artery disease. Tachycardia, rather than patient selection, determined the frequency of infarction. This prospective study was sufficiently large to reasonably examine outcomes for both myocardial ischemia (a surrogate outcome), and postoperative myocardial infarction, showing a difference in infarction between those who had myocardial ischemia (6.9%), and those who did not (2.5%).

Slogoff and Keats extended this work in 1989 [32]. They prospectively randomized 1,012 patients to receive enflurane, halothane, isoflurane, or sufentanil. New ST segment depression (a surrogate outcome) appeared in 310 patients (30%), while the incidence of postoperative myocardial

infarction was 3.6–4.7%, and death was 1.2–2.4% (definitive clinical outcomes). The study demonstrated that preoperative myocardial ischemia was the strongest predictor of intraoperative ischemia. The authors concluded that approximately 90% of new myocardial ischemia observed during anesthesia reflected unrecognized preoperative ischemia, and only 10% arose from anesthetic management. They also concluded that, despite differences in the hemodynamic consequences of the study anesthetics, the choice of anesthetic did not influence outcome, and that the crucial role of the anesthesiologist is control of heart rate. Slogoff and Keats anticipated future cardiac risk reduction efforts when they stated “In the clinical situation studied here, the major role of the anesthesiologist in preventing PMI (perioperative myocardial infarction) remains limited to control of heart rate, primarily by beta-adrenergic blocking drugs [32].” A perhaps not surprising additional finding from their earlier study [31] was that the individual anesthesiologist could influence outcome: Their “anesthesiologist 7 had the highest incidence of intraoperative tachycardia, myocardial ischemia, and postoperative myocardial infarction.”

1988: Use of Closed Legal Cases to Identify Risk

In the 1980s a new form of outcomes research began with the development of the American Society of Anesthesiologist’s (ASA) closed claims database. Although providing important data, the limitation of this database was the lack of a denominator. Furthermore, the numerator was also limited since these cases represent only “closed” claims and not all such incidents. The ASA closed claims database has been used for analyses of cases wherein causation of complications and many factors including regional anesthesia [33], obstetric care [33], respiratory events [18], eye injuries [34], risk management issues [35], burns [36], awareness [37], difficult airway [38], pulse oximeters [39], capnography [39], pediatric anesthesia [40], regional anesthesia [41], drug errors [42], spinal cord injury [43], and chronic pain [44] might be inferred.

In 1988, anesthesiologist Robert Caplan and colleagues reported on the associations with unexpected cardiac arrest during spinal anesthesia in 14 patients, finding that ventilatory depression and sympathetic blockade with bradycardia played major roles [16]. One of the editors of this book (LJS) remembers a personal experience with such an event (fortunately not resulting in a significant adverse outcome or leading to legal action). He had given a spinal anesthetic to a surgical colleague and they were chatting as the operation, a urological procedure, began. Sudden profound bradycardia, cardiac arrest, and loss of consciousness ensued. The event was immediately noted and cardiopulmonary resuscitation (from the head of the OR table) initiated with rapid return

of normal circulation. The patient opened his eyes, and upon seeing his shaken colleague said “Larry, you look terrible!”

In 1990, Caplan reported on adverse respiratory events occurring in 522 patients, finding that inadequate ventilation and intubation of the esophagus accounted for over half of the cases and much more than half of the settlement costs [15]. The “cure”, in part, was an ASA-mandated use of capnography, a nearly perfect method of detecting when the tracheal tube was in the wrong place. Herein was an example of the value of this closed claims analysis in that establishing a standard (capnography) was associated with decreased liability insurance costs.

Closed claims analysis for detecting problems caused by anesthesia or anesthetists, and, sometimes, the cure of such problems continues to the present. These studies paralleled the earlier characterization of critical incidents in anesthesia [45, 46], incidents which led or *could have led* to patient injury. This process has in large part driven the developments in safe practice in anesthesia, including the promulgation of minimum monitoring standards, and crisis management algorithms. Other countries have taken up this approach to improving care, and the principles have been applied across a broad spectrum of health care practices, including other medical specialties and nurses [47, 48].

1989: Dennis Mangano, Jacqueline Leung, SPI and McSPI

In 1989, Mangano (Fig. 43.2) assembled a group of investigators to form the Study of Perioperative Ischemia (SPI) that ultimately became The Multicenter Study of Perioperative Ischemia (McSPI). In 1989, Jackie Leung published the “*Prognostic importance of post-bypass regional wall-motion abnormalities in patients undergoing coronary artery bypass graft surgery. SPI Research Group*” [49]. This small study of 50 patients undergoing elective CABG surgery, used surrogate variables [continuous transesophageal echocardiography (TEE), electrocardiography (ECG, recorded with a Holter monitor), and hemodynamic measurements] during the prebypass, postbypass, and early postoperative intensive care unit (ICU) periods to define outcome. TEE and ECG evidence of ischemia were related to adverse clinical outcomes (postoperative myocardial infarction, ventricular failure, and cardiac death). The association of surrogate markers with hard clinical outcomes was a crucial advance. This pioneering work was a collaborative one between anesthesiology (Leung, O’Kelly, Mangano), medicine (Tubau, Browner), epidemiology (Browner), and cardiology (Hollenberg).

Further analyses of the story of SPI and McSPI, illustrate the opportunities and difficulties inherent in outcomes research. Mangano, the founder of McSPI, has published 147

Fig. 43.2 Dennis Mangano. (Courtesy of CBS)

manuscripts as of 2012, the results of which have fundamentally changed the perioperative care of patients with cardiac disease undergoing surgery. After obtaining a doctorate in physics and mathematics, Mangano worked at Bell Laboratories. He then shifted to medicine and anesthesiology. His medical research began with animal studies, small studies of human physiology, and case reports. In 1989, he undertook a larger trial (94 patients) a study of pentastarch that taught him several important lessons [50]. “There were no significant between-group differences, ... indicat(ing) that pentastarch is as safe and effective as 5% albumin for plasma volume expansion after cardiac operations with no apparent adverse effects on coagulation. If commercially available at a lower cost than albumin, it would appear to be a reasonable first choice for colloid therapy in this setting.” While this small commercial study did not affect clinical practice, it provided seed money and the concepts needed to begin epidemiologic studies that would fundamentally change anesthetic care of these patients.

SPI, the predecessor to McSPI, started as a collaboration between anesthesiology, cardiology, internal medicine, epidemiology, and surgery, and began with a small prospective study, of the incidence of myocardial ischemia in 50 patients awaiting CABG [51]. The next study evaluated wall motion abnormalities in 50 patients undergoing CABG [49]. These small studies had inadequate power to show a change in either death or myocardial infarction, forcing study design based on either surrogate outcome variables (myocardial ischemia) and/ or composite end points (death and myocardial infarction and congestive heart failure and arrhythmia), rather than a more definitive end point such as death.

1990: Multiple Groups Conduct Outcomes Research

By 1990, multiple groups were conducting outcomes research in anesthesia. Forrest performed a prospective, multi-centered (15 hospitals in the US and Canada) clinical trial in 17,201 patients, randomized to receive enflurane, fentanyl, halothane, or isoflurane anesthesia [52, 53]. This study showed that pooling of data across institutions was possible, and that differences among the four anesthetics could be found for minor clinical outcomes. Nineteen patients died (0.11%), with the anesthetic possibly contributing in seven of these (0.04%). The rates of death, myocardial infarction, and stroke in the study population were too small (less than 0.15%) to allow conclusions regarding the relative rates of these outcomes among the four anesthetic agents. While the rates of 16 of 66 types of adverse outcomes in the study population differed significantly among the four study agents, these outcomes were minor in degree or clinical importance. Ventricular arrhythmias were more common with halothane. Hypertension and bronchospasm were more common with fentanyl, and tachycardia was more common with isoflurane. Recovery from anesthesia during the first 30 min was slowest in patients given halothane. In addition, patients given fentanyl experienced less pain during the first hour in the recovery room.

This study allowed several conclusions. Anesthesiologists could conduct large (17,201 patient), multi-centered, international, randomized clinical trials. Anesthesia had become so safe that there were few major definitive (infarction or death) outcomes (0.11% mortality) in these mostly healthy patients. The study confirmed what everyone already knew: that halothane was associated with arrhythmias, fentanyl slowed the heart rate and relieved pain, and halothane delayed emergence. To reveal clinically significant differences in major outcome variables would require extremely large sample sizes, or extremely high-risk patients undergoing major surgery, or extremely bad care. Outcome studies

in patients undergoing minor surgery, or outpatient surgery, have such low event rates for mortality that enormous sample sizes are required to have adequate statistical power to show a significant result.

1992: A randomized, Prospective Clinical Trial with Desflurane

Early in its history, the SPI group investigated the effects of isoflurane on coronary steal, finding that isoflurane was safe and did not lead to steal [54]. James Helman and the SPI group next examined the new anesthetic desflurane, finding that at high concentrations (10%) it caused transient pulmonary hypertension, tachycardia, myocardial ischemia, and bronchospasm [55]. The desflurane study again showed that a relatively small (200 patients) outcome study, could demonstrate significant effects if the study used a high risk population (patients with coronary artery disease), undergoing a major operation (CABG), if the anesthetic were given at an excessive dose (inhaled induction), and if surrogate outcome variables (Holter ECG, pulmonary artery pressure, TEE) rather than more definitive outcome measures were used. Indeed, the study compared the incidence of myocardial infarction and death after desflurane, with those in a control group given sufentanil, finding differences in transient myocardial ischemia and pulmonary hypertension, but not in death or myocardial infarction.

1990–1992: Mangano's NIH Non-cardiac Surgery Epidemiologic Study

By linking a surrogate outcome variable (Holter ECG derived myocardial ischemia) to two-year mortality, the study of 474 patients provided the basis for the development of therapies to reduce perioperative risk. This study identified a dynamic risk factor, myocardial ischemia, which could be used in small randomized trials to test possible therapies. Most risk factors, such as age, history of some chronic disease (such as hypertension, diabetes, coronary artery disease, peripheral vascular disease), or some chronic health risk factor (like smoking) are fixed. Fixed risk factors cannot be acutely modified to reduce risk. Myocardial ischemia is different; it can be minimized or abolished immediately via therapies. A clinically validated surrogate outcome variable, allowing design of a small clinical trial to test a therapy, cuts the size and therefore the cost and duration of outcome trials. A validated surrogate outcome variable associated with a definitive outcome such as death, allows the design of smaller, less expensive studies, thus speeding the development of therapies.

The next major development in anesthesia outcomes research from SPI, was the long term follow-up study. The Framingham study had shown the value of longitudinal studies of patients, but this was a new concept in anesthesia outcomes research. Patients in the 474 patient NIH study, the atenolol study, the clonidine study [56], and the EPI-2 study, were followed for at least 5 years and some for as long as 10 years. This long-term follow-up increased the power of these studies to identify differences in more definitive outcomes such as death. If intraoperative death is the only “outcome”, short-term studies have to be extremely large, because the event rates are small, even in high-risk cases. Even studies from 1925 to 1945 quoted intra-operative death rates of 0.1%, an incidence mandating tens to hundreds of thousands of patients in order to detect significant changes. However, if the event rate is 3 to 8% per year (common in high risk populations), differences in long-term mortality can be seen in 200 high-risk patients studied for 5–10 years—perhaps even less.

The NIH funded the original 474 patient SPI epidemiologic study, and the research produced more than 30 highly cited manuscripts. Two follow-up NIH grants were submitted. One proposed investigating medical therapies for preventing myocardial ischemia in patients undergoing non-cardiac surgery (atenolol and clonidine). This grant scored extremely well but was not funded. Reviewers were concerned that the study population did not include equal numbers of women and men, a problem as the study location (a Veterans Administration Hospital) had only 5% female patients. This deficiency was corrected by collaborating with the San Francisco Kaiser Hospital, but the revised grant was still not funded after again receiving an excellent score.

The members of SPI met to decide what to do. A schism occurred. Jackie Leung wanted to regroup, downsize the studies, and resubmit. Mangano wanted to pursue commercial funding from drug company studies, using the excess funds generated to do the unfunded clinical studies. Acting on his belief, Mangano took the small organization, the Study of Perioperative Ischemia (SPI) Research Group, and expanded it to the Multi-Centered Study of Perioperative Ischemia (McSPI).

Outcomes research takes many forms. It can be a prospective, randomized, clinical trial to test for specific effects of medications. It can be an epidemiologic study of standard care. A simple and relatively inexpensive way to pursue epidemiological studies is to obtain a database collected for some other purpose, such as the Medicare database, or census data, or computerized medical records. McSPI took a different, vastly more expensive approach. Rather than performing an inexpensive retrospective analysis of available databases, providing records for tens of thousands or

millions of patients, McSPI collected detailed, prospective epidemiologic data in a limited number of patients with surrogate outcome variables such as Holter ECG to detect myocardial ischemia. Although cost and work-load were great, and sample sizes were small, the depth of information was extensive. McSPI started small and learned to think big from experiences in a study of 156 patients [57]. The next study included 200 high-risk patients undergoing non-cardiac surgery or coronary artery bypass graft (CABG) surgery [58]. Sample size and risk increased in the subsequent 1990 study, to 474 men with coronary artery disease (243) or at high risk for it (231), all undergoing elective non-cardiac surgery [59]. Sample size would ultimately increase 10-fold. The 474 patient study linked the surrogate outcome variable, myocardial ischemia detected by a Holter ECG monitor, to a composite end point, combining cardiac death, myocardial infarction, unstable angina, congestive heart failure, or ventricular tachycardia. The surrogate outcome variable, Holter ECG, detected myocardial ischemia, which predicted a single long-term outcome, 2-year mortality [60].

1996–2004: Risk Reduction Accomplished with Drugs

McSPI began large, commercially funded studies that applied definitive outcomes. These studies included acadesine in 116 patients [61], 566 patients [62], 2,698 patients [63], and finally a meta-analysis in 4,043 patients [64]. The meta-analysis found that acadesine reduced the risk of perioperative cardiac death, myocardial infarction, and combined adverse cardiovascular outcomes. The 2,698 patient study also showed a decreased long term mortality.

The McSPI system then began trials of atenolol [65, 66], clonidine [56], aspirin, coumadin, epidural versus PCA (patient controlled analgesia), mivazerol [67], dexmedetomidine [68], draflazine, propofol [69], RSR-13, C5B-Inhibitor, and COX-2 inhibitors [70]. Mangano and colleagues also performed multicenter observational studies on thousands of patients undergoing coronary artery surgery, the EPI-1 [71] and EPI-2 [72] studies, investigations that provided data for several researches, including the effects of aprotinin on outcomes (see below). McSPI's studies led to the development of perioperative beta blockade [73, 74] and perioperative clonidine [56] to decrease perioperative cardiac risk. The requirement of definitive end points (myocardial infarction or death) necessitated the need for enormous studies. For example, mivazerol was studied in three phases, a 24 patient, then a 300 patient [73], and finally a 2,854 [67] patient study. The plan to study dexmedetomidine was similar, with a 24 patient, then a 300 patient, and finally a 3000 patient study.

2006: Aprotinin and Outcome

The history of aprotinin shows not only the importance of outcomes research, but highlights the critical importance of meticulous evaluation. Aprotinin is the bovine version of the small protein basic pancreatic trypsin inhibitor, or BPTI, which inhibits trypsin and related proteolytic enzymes. It was originally investigated in the 1960s for the treatment of pancreatitis [75]. Aprotinin's ability to reduce acute fibrinolysis associated with extracorporeal circulatory support, was recognized in 1961 [76]. Clinical observation identified its effects on hemorrhage [77], and it was used to reduce hemorrhage [78]. Fibrinolysis leads to the lysis of clots. Aprotinin inhibits such lysis and thereby should decrease hemorrhage and the need for transfusions. Aprotinin competed with two other antifibrinolytics, the lysine analogues, tranexamic acid and epsilon aminocaproic acid. It became a standard in cardiac anesthesia in Europe, particularly in Germany. FDA approval for US use eventually came in 1993. By then, more than 30 studies had evaluated aprotinin use in cardiac surgery. Design problems, including non-randomization, lack of a control group, historical controls, and/or small sample size compromised these studies, but the consensus was that aprotinin reduced the severity of hemorrhage and the need for transfusion with cardiac surgery. Aprotinin was thought to be safe although there were instances of anaphylaxis. Study results also suggested that it might increase [79, 80] graft thrombosis, but the small size of many studies hindered the likelihood of identifying this adverse event [80].

The FDA required three US prospective, randomized studies before approval, 2 of which showed efficacy for a reduction in perioperative blood utilization and loss [79, 81, 82]. Bayer began selling aprotinin in the US, and the \$1,000 per dose medication was extensively marketed. After approval, Bayer supported an international study addressing the issue of graft patency after cardiac surgery in 796 patients [83]. Aprotinin reduced thoracic drainage volume by 43%, and the requirement for red blood cell administration by 49%, but graft occlusions occurred in 15.4% of aprotinin-treated patients and 10.9% of patients receiving a placebo ($P=0.03$). The increased risk of graft occlusion was more apparent in European centers. The authors divided the study results by country: "At United States sites, patients had characteristics more favorable for graft patency, and occlusions occurred in 9.4% of the aprotinin group and 9.5% of the placebo group ($P=0.72$). At Danish and Israeli sites, where patients had more adverse co-morbidities, occlusions occurred in 23.0% of aprotinin- and 12.4% of placebo-treated patients ($P=0.01$). Aprotinin did not affect the occurrence of myocardial infarction (aprotinin: 2.9%; placebo: 3.8%) or mortality (aprotinin: 1.4%; placebo: 1.6%)." This division of the study by country reduced the statistically significant effects,

decreased the concern regarding risk, and allowed marketing of the drug to continue.

However, if an outcomes study shows an adverse event, dividing the study into sub-studies, reduces the power to show the effect. How were McSPI investigators to deal with this concern? Bayer might be reluctant to fund a study revealing an adverse effect. McSPI investigators collected data in the EPI-2 study that allowed the analysis of the effects of aprotinin versus tranexamic acid, and epsilon-aminocaproic acid, on morbidity and mortality [84]. Elizabeth Ott compared medical care in the US, Canada, UK, and Germany, identifying a surprising result [85]. In-hospital mortality was 1.5% (9/619) in the UK, 2.0% (9/444) in Canada, 2.7% (34/1283) in the US, and 3.8% (32/834) in Germany ($P=0.03$). Composite outcomes (morbidity and mortality) were 12% in the UK, 16% in Canada, 18% in the US, and 24% in Germany ($P<0.001$) [85]. Regarding the increased mortality in Germany, Ott found that "the practices associated with adverse outcomes were the intraoperative use of aprotinin, intraoperative transfusion of fresh-frozen plasma or platelets, lack of use of early postoperative aspirin, and use of postoperative heparin." Aprotinin was used in 15% of US cases and 85% of German cases. The effects of aprotinin on renal failure, and morbidity and mortality, were rapidly published [84, 86]. Multinational outcomes research with sufficient power to identify definitive but rare outcomes had found that aprotinin increased the risk of death by a factor of 2.5. The German physicians could not identify the more than doubling of risk with the use of aprotinin because almost every patient having cardiac surgery in Germany (85%) was given aprotinin.

International, or multi-centered studies may be essential to identify practices that increase small risks by 2 to 3 fold. Individual physicians are unlikely to discern such effects. Bayer conducted a 60,000 patient retrospective epidemiologic analysis and found results similar to those of McSPI [81], but publication was delayed [87]. The delay deferred FDA action, and allowed aprotinin to remain on the market for another two years. Ultimately the BART trial (Blood conservation using Antifibrinolytics in a Randomized Trial) [88], a multicenter, blinded trial, randomly assigned 2,331 high-risk cardiac surgical patients to one of three groups: 781 received aprotinin, 770 received tranexamic acid, and 780 received aminocaproic acid. The relative risk of death in the aprotinin group was 1.53 (95% CI, 1.06 to 2.22). The BART trial concluded that "Despite the possibility of a modest reduction in the risk of massive bleeding, the strong and consistent negative mortality trend associated with aprotinin, as compared with the lysine analogues, precludes its use in high-risk cardiac surgery." Aprotinin was removed from the US market. Outcomes research using epidemiologic techniques and a randomized trial had been used to delineate the risks.

But did they? Some researchers began to question the results [89]. The reliability of Mangano's 2006 conclusions were disputed on the basis that the non-randomized, non-blinded observational trial was subject to bias in the choice of aprotinin in some patients [90]. In addition, Mangano's analysis did not include the impact of bypass time, the number of vessels grafted, or whether the procedure was done "off pump."

The more influential BART study has also attracted criticism. Although it was a randomized controlled trial, 137 patients were excluded from analysis for unknown reasons, and the trend in the mortality for these patients was opposite to that for the included patients [91]. A large number of primary outcomes (excessive bleeding) were reclassified from the originally reported data, favoring the lysine analogues [91]. It has also been noted that both the method and control of anticoagulation was inconsistent [92].

Meta-analyses that include the BART data have been published as recently as 2011. However it is now apparent that the weight of the BART study may have inadvertently swayed the conclusions [93–95].

These concerns prompted Health Canada to review the BART study. The conclusion was that the BART study was not a reliable assessment of the safety of aprotinin, and further, that the benefits of the drug in coronary artery bypass surgery outweigh the risks [89, 91]. The Commission on Human Medicines (CHM) has also reviewed the previous studies and arrived at a similar conclusion, leading to the lifting of the suspension of aprotinin in Europe in 2012 [92].

2008: Lessons Learned from POISE

The Peri-Operative Ischemic Evaluation (POISE) [95, 96] study was conducted by PJ Devereaux, who wished to re-evaluate the capacity of perioperative beta blockade to prevent myocardial ischemia. He first conducted a meta-analysis of studies of perioperative beta blockade, which showed that beta-blockade was effective [97]. He then reduced the number of studies included in the meta-analysis until the analysis showed that beta-blockade wasn't effective [97]. The Canadian government and AstraZeneca, the manufacturer of metoprolol XL used in the study, underwrote (\$3,000,000) the POISE trial, a 10,000 patient randomized, clinical trial with death, stroke, MI, as well as hypotension, bradycardia, and atrial fibrillation as the primary outcomes [95]. The POISE trial obtained its results from 190 hospitals in 23 countries including Cuba, Iran, China, and India, but not the US. During the study design, investigators reasoned that if the study failed to show an effect, it would be criticized for inadequate drug dose. Accordingly, they chose a dose that

could not be criticized as too low. But every medication has a correct dose and a therapeutic index. Patients in the POISE study received multiple doses of metoprolol XL, apparently 400 mg on the day of surgery, and then 200 mg each day for a month. The 400 mg starting dose exceeded the recommended starting dose for metoprolol XL: 25 mg for hypertension, 100 mg for coronary artery disease, and 12.5 mg for congestive heart failure. A second problem arose. Because of limited funding (\$300 per patient), site monitoring was only performed at 6% of centers. This incomplete monitoring revealed that 10% of data were fraudulent, defined as non-existent (no patient actually existed), and the "data" for these "patients" were excluded from analysis.

From the 10,000 planned patients, data from 8,351 patients were included in analyses. Metoprolol decreased the risk of myocardial infarction but increased the risk of hypotension, bradycardia, stroke, and death. Publication of the results from this enormous study initially generated considerable attention, but the limitations noted above curtailed continued interest.

2006–2009: Clean Hands Decreased Infection

The interest among anesthesiologists in surgical site infections, expanded to include research on how anesthesiologists might help prevent all types of Healthcare Associated Infections (HAI). Studies in the 1990s found that central venous catheters, placed by anesthesiologists in the operating room, were more likely to be infected than those placed elsewhere in the hospital, and that careful attention to sterile technique and wide draping substantially reduced the infection rate. Anesthesiologist Peter Pronovost, at Johns Hopkins (named by TIME magazine in 2008 as one of the most influential persons of the year), partnered with a statewide safety initiative in Michigan, to show that implementation of a checklist-based intervention to increase adherence to evidence-based practices, markedly decreased the incidence of catheter-related bloodstream infections [98].

Anesthesiologists Loftus and Koff, and colleagues at Dartmouth, contributed to HAI prevention by evaluating the impact of hand hygiene by anesthesia providers in the operating room [99]. At baseline, anesthesia providers performed hand hygiene (soap and water or alcohol based gel) less than once per hour in the operating room. The anesthesia work area and the patients' intravenous catheters commonly became contaminated with bacteria within a few minutes of the start of a case. Providing a clip-on device that dispensed alcohol gel and provided periodic reminders for hand hygiene, increased the rate of hand hygiene to about 7 times per hour, reduced workspace and intravenous catheter contamination, and reduced HAI.

2006-Present: Does Anesthetic Choice Affect Cancer Recurrence?

In 2006, Exadaktylos et al. reported results from a retrospective study, showing that patients having mastectomy for breast cancer had a greater chance of recurrence if a general as opposed to a regional anesthetic were used [100]. This and other evidence supported the notion that anesthetic management, and particularly choice of drugs and choice of regional vs. general anesthesia, might increase the risk of recurrence in patients with cancer [101], but other studies did not [102]. Some opioids and other anesthetic agents might inhibit host defenses, specifically natural killer cell function. But as of 2012, anesthesiologists Kavanagh and Buggy, found the present evidence for a connection between the effects of anesthetic technique and cancer recurrence to be equivocal [103]. A multicenter trial will examine this premise [104].

2010: Arthur Wallace Performs Inexpensive, Retrospective, Epidemiologic Studies Using Analysis of Electronic Medical Records

Outcomes research may be undertaken with retrospective analysis of computerized medical records. Wallace conducted a study in 5,000 patients using McSPI EPI-2 data entitled “*The association of the pattern of use of anti-ischemic agents on morbidity and mortality after coronary artery bypass surgery*” [105]. This study investigated the effects of perioperative beta blockade and other anti-ischemic agents on morbidity and mortality. He repeated the study using VA computerized medical records for 38,779 operations performed between 1996 and 2008 at a cost less than 0.3% of the cost of the EPI-2 study and found parallel results [106]. The ability to study 7.5 times the number of operations for 0.3% of the cost, shows the advantages of retrospective epidemiologic analysis of computerized medical records. The EPI-2 study had collected robust data over 5 years, from 70 centers in 17 countries in 5,065 patients, prospectively studied undergoing coronary bypass surgery. The study cost \$38,000,000. The advantages of this prospective design included the ability to randomize and collect in depth data, but the cost and human effort disadvantages were enormous. The EPI-2 data set quickly became outdated as the last patient was operated on in June of 2000. The study enrolled patients who had coronary artery bypass surgery using extracorporeal support, excluding the then common “off-pump” CABG, thereby precluding conclusions about relative risks and benefits. Outcomes research based on retrospective analysis of computerized medical records can reduce the cost and difficulty of outcomes studies, and increase the richness of their findings.

Some Reflections

Cardiologists developed large, randomized, prospective, clinical outcomes studies with definitive but rare end points, techniques subsequently adopted by anesthesiologists. The development of pharmacologic techniques to reduce perioperative cardiac risk with beta blockers [74], statins [107], clonidine [56], and aspirin [72], directly flowed from this research. However, such outcome studies were expensive and difficult—and could provide positive results, negative results, and sometimes results with negligible benefit. For example, \$11,000,000 and a decade were spent studying the effects of hypothermia on neurologic outcome with cerebral aneurysm surgery, finding that hypothermia did not improve outcome, a negative result that had the salutary effect of sparing future patients from the side effects of hypothermia [108]. The POISE study of more than 8,000 patients consumed \$3,000,000, to indicate that although beta sympathetic blockade may decrease myocardial infarction it may increase other untoward effects such as stroke and death. Another interpretation suggested that the POISE study showed only that all drugs have a therapeutic index, and that dose matters, and that the increased incidence of stroke and death resulted from the excessive use of beta blockade. After two decades of work and \$45 million, the EPI-1 and EPI-2 studies demonstrated the benefits of aspirin for cardiac surgery, the risks of aprotinin, and clarified the risks of neurologic outcomes with cardiac surgery. Despite the expense and difficulty, outcomes research is essential for the improvement of anesthesia care and the reduction in perioperative risk. Anesthesia outcomes research leads and has led to evidence based medicine that improved anesthetic and medical care.

Acknowledgment We gratefully acknowledge the stories and advice given us by Arthur Wallace, particularly concerning the outcome studies that examined factors affecting the safety of anesthesia in patients at risk of cardiovascular disease. His knowledge of SPI and McSPI was invaluable. Where the telling of these stories adds error, it is error that we have introduced.

Summary

Medical genetics began with the twentieth century rediscovery of Gregor Mendel's nineteenth century work on plant genetics [1]. In the early 1900s, British scientist Archibald Garrod made the first major advance in human genetics by identifying inborn errors of metabolism as a recessive trait [2], leading to George Beadle and Edward Tatum's 1941 promulgation of the 'one gene, one enzyme' theory [3]. In a landmark 1949 paper [4], Linus Pauling's group linked sickle cell anemia to a specific protein derangement, the first proof that genetic changes could produce human disease. This set the stage for the birth of pharmacogenetics, described by Arno Motulsky in 1957 [5], named by Friedrich Vogel in 1959 [6], and established by Werner Kalow's monograph in 1962 [7]. The next sections of this history provide exemplars of pharmacogenetic discoveries having major implications in anesthesia.

Introduction

Approximately 50 years ago, pharmacogenetics (defined as how genetic makeup may influence response to a drug) began to be applied to explain drug action in humans, increasingly revealing that genetic variation present in deoxyribonucleic acid (DNA) ultimately determines drug metabolism and effectiveness via encoded proteins, providing hope that individually tailored medical therapy might improve outcome and safety, the essence of personalized medicine. We begin with the birth of pharmacogenetics and continue by describing events surrounding clinical observations on 3 genetic pathologies important in anesthesiology: prolonged apnea with

succinylcholine, malignant hyperthermia, and hepatic drug metabolism by a cytochrome P450 (CYP) enzyme CYP2D6 (Fig. 44.1). Next, we highlight some pharmacogenetic studies, particularly genetic variation in adrenergic and opioid receptor genes, followed by reflections on how modern genome science methods may provide insights that underlie aspects of perioperative patient care. We conclude by discussing future directions.

Prolonged Apnea After Succinylcholine

The depolarizing muscle relaxant succinylcholine entered clinical practice in 1951. Paralysis from succinylcholine peaks in approximately 45 seconds and usually lasts for 2 to 6 minutes, convenient for facilitating tracheal intubation. In 1952, anesthesiologists reported rare cases of prolonged paralysis after its use. Biochemical studies revealed why. Plasma butyrylcholinesterase (BChE, also called pseudocholinesterase) hydrolyzes succinylcholine to inactive components. Succinylcholine acts quickly and briefly in individuals with normal BChE activity, but abnormal BChE activity in 1:2500 (0.04%) of Caucasians [8, 9] prolongs succinylcholine activity—and paralysis—by 5 to 10-fold. In 1952, Bourne *et al.* [10] reported that “those patients who recover slowly from succinylcholine had significantly lower pseudocholinesterase levels than did patients recovering at the normal speed.” Lehmann and Evans, and Kalow independently established the mechanism. Lehmann's group detected decreased levels of BChE in patients with prolonged paralysis [11], leading to their suggestion that a genetic cause, rather than chronic disease or chemical

poisoning, altered BChE activity. In their 1956 landmark publication, Lehmann and Evans investigated families of 5 unrelated patients having prolonged responses to succinylcholine [12], finding otherwise healthy family members with low BChE activity without any reason for such levels. These findings provided a genetic link to prolonged paralysis after succinylcholine.

In 1951, Werner Kalow (Fig. 44.2) proved that procaine-esterase was actually BChE. He provided a more efficient method to measure esterase activity. Serendipitously, he contacted Donald Gunn, a physician using low-dose succinylcholine to dampen muscular contractions during electric shock therapy. Gunn noted that a few patients remained relaxed for almost an hour rather than 2 to 6 minutes. Kalow discovered that BChE enzymes from 2 of these patients behaved differently from normal BChE, and inferred that a genetic change caused a structural difference in the enzyme. In the families of these two patients, Kalow found differential inhibition of BChE by a local anesthetic called dibucaine (also known as cinchocaine or nupercaine). Dibucaine inhibited 79% of normal BChE activity. In both parents of the two patients, inhibition was only 62%, and minimal inhibition (16%) occurred in patients having a prolonged effect of succinylcholine. Such patients had two abnormal genes for BChE (homozygous trait); the parents were heterozygous with one normal and one abnormal gene, and the average person had two normal genes. Succinylcholine was one of the first drugs whose metabolism was shown to be affected by genes displaying simple Mendelian patterns of inheritance [13].

Fig. 44.2 Werner Kalow (1917–2008) joined the University of Toronto, Canada, in 1951, and remained active in academics as a pharmacologist until the year of his death. (From Kalow W: Atypical plasma cholinesterase. A personal discovery story: a tale of three cities. *Can J Anaesth* 2004; 51: 206–11, with permission.)

Kalow and his co-workers then demonstrated that individuals having a prolonged response to succinylcholine had abnormally functioning BChE rather than a low quantity of enzyme. They had a genetically determined defect in BChE—a so-called dibucaine resistant enzyme, or atypical enzyme—causing the abnormal reaction to succinylcholine. Kalow's use of dibucaine inhibition percentage remains the standard for classifying heterozygous, homozygous, and wild-type phenotypes of BChE. His findings and his study of other examples of varied responses to drugs, motivated him to write his 1962 book “Pharmacogenetics: Heredity and the Response to Drugs” [7] establishing pharmacogenetics as a new scientific discipline. Subsequently, over 40 polymorphisms associated with BChE deficiency were described, the most common being the A and the K enzyme variants. The A (for “atypical”) variant has an altered activity while the K variant (after Kalow) results in a lesser production of enzyme. Although prolonged paralysis following succinylcholine is now a rare but easily managed clinical problem, the finding of prolonged muscle relaxation with succinylcholine in specific individuals provided the first evidence for serious clinical effects from genetic variation, and highlighted anesthesiology as a discipline wherein genetics had immediate clinical implications.

Malignant Hyperthermia

Succinylcholine contributed to another anesthesia-related pharmacogenetic discovery. Malignant hyperthermia (MH) is an uncommon adverse pharmacogenetic syndrome associated with administration of succinylcholine and/or inhaled volatile anesthetics [14]. The mechanism triggering this reaction remains unknown (severe stress alone can trigger MH). When triggered, MH increases cytosolic Ca^{2+} in skeletal muscle cells, and this increase can produce hyperthermia, hypermetabolism, muscle rigidity, breakdown of muscle tissue, and death [15].

Here is the story of the discovery of MH. On 8 April 1960, a car hit a 21 year old student, fracturing his right tibia and fibula [16]. Upon arrival at the casualty department of the Royal Melbourne Hospital, in Victoria, Australia, he and his mother expressed more concern about the anesthesia than his leg. Ten family members (3 cousins and 7 aunts and uncles), out of 38, had died during or shortly after receiving ether anesthesia. This family history caused the student's mother to request a local anesthetic when the boy had an appendectomy at age 12. The consultant anesthesiologist on 8 April was James Villiers. Having heard the story, he and the surgeon learned that the patient's cousin had recently been safely anesthetized with a "modern anesthetic" at the nearby children's hospital. After excluding porphyria, the only condition known at the time to affect anesthesia, Villiers believed that the deaths must have been due to "ether convulsions" and recommended using a new, possibly safer anesthetic, halothane—plus vigilant monitoring. Ten minutes into anesthesia, hypotension, tachycardia, cyanosis, and hyperventilation occurred, and the soda lime canister became very hot. The fractures were quickly set, and anesthesia administration discontinued. The patient remained cyanotic and unresponsive and became hot and sweaty. He was immediately packed in ice from a nearby cardiac theater, and within an hour, he was awake and alert. His subsequent course was uneventful. He was the first recorded patient to have had—and survive—MH [17].

Villiers referred the patient to Richard Lovell, who, in turn asked his research assistant, Michael Denborough (Fig. 44.3), to see the patient. Denborough had an interest in genetics, and the familial history led him to suspect a previously unrecognized inborn error of metabolism. When the student again required anesthesia for an impacted renal calculus in 1961, John Forster of the Royal Melbourne Hospital gave him an uneventful spinal anesthetic [16].

In 1964, deaths were noted to have occurred during anesthesia in a large Wisconsin (USA) family. One child had died in Toronto, Canada, and Beverly Britt, the anesthesiologist, along with Kalow and RA Gordon, a professor of anesthesia, organized inquiries throughout Canada. This led to presentation of 13 cases of MH at a 1966 symposium in Toronto [18].

These patients had evinced two common features: muscle rigidity and high temperature. The first description in the American literature of a patient with MH, with reported blood gas data, was similar to that of Villiers in that the patient survived after being packed in ice [19]. When this case was presented at the annual American Medical Association meeting, several in the audience reported caring for similar patients who had received halothane and succinylcholine.

In November 1969, a patient at the Royal Melbourne Hospital received halothane and succinylcholine and died from MH [20]. This patient's right arm had become rigid, prompting a test of plasma creatine kinase activity, an enzyme involved in energy production in muscle fibers. Creatine kinase activity was increased, indicating muscle breakdown. The original student who had broken his leg in 1960, and some of his relatives also were found to have increased serum creatine kinase activity—evidence of a generalized muscular disease [21]. In 1970, in Johannesburg South Africa, H Isaacs and M Barlow independently observed increased serum creatine kinase levels in relatives of MH patients [22]. Impressed by the muscle rigidity, Kalow and Britt tested their muscle samples for contractile force *in vitro*. Muscle from patients with MH exhibited abnormally strong contractions in the presence of caffeine. Caffeine was used because it induces *in vitro* skeletal muscle contraction. This resulted in the first clinically useful test for detection of a predisposition to MH in 1970 [23]. In 1971, F Ellis and colleagues showed that halothane augments muscle contraction in patients who are susceptible to MH [24].

In the early 2000s, molecular genetic testing for MH susceptibility was introduced in Europe [25] and North America [14]. The genetic assessments were based on DNA sequence variations in the skeletal muscle type ryanodine receptor (*RYR1*) gene, which encodes a protein involved in the excitation-contraction process of muscle cells. In 1990, MacLennan *et al.* had identified the *RYR1* gene as a candi-

date gene that might mediate MH [26]. More than 180 *RYR1* variants have since been documented, with 29 considered mutations predisposing to MH [27, 28]. In 2001, the European Malignant Hyperthermia Group published criteria for proof of causation, and agreed on guidelines for molecular genetic detection for susceptibility to MH. These guidelines are the first to describe genetic screening for testing in anesthesiology [25, 29, 30].

CYP2D6 Enzyme Variation

The next pharmacogenetic discovery relevant to anesthesia came in the late 1960s, in association with a description of an enzyme, now called CYP2D6. CYP2D6 affects metabolism of 25% of the drugs used in medicine, including anesthesiology [31]. CYP2D6 is part of a family of cytochrome P450 (CYP) drug metabolizing enzymes, enzymes involved in metabolism of morphine derivatives, β -blockers, antiarrhythmics, antipsychotics, and antiemetic drugs [31]. Polymorphisms (specific variations in protein structure and function) in *CYP2D6* can affect drug efficacy, side effects, and toxicity. Beginning in 1967, 3 laboratories independently discovered polymorphic CYP2D6.

Folk Sjöqvists' group in Sweden found that metabolism of two CYP2D6 substrates showed considerable inter-individual variation in metabolite plasma levels. Two phenotypes were identified in 1967 [32]. Studies in 19 identical (monozygotic) and 20 fraternal (dizygotic) sets of twins in 1969, suggested the difference was gene-based [33].

At St. Mary's Medical School in London in 1975, Robert Smith studied debrisoquine, a new agent for treating hypertension. Several healthy volunteers, including Smith, received 40 mg of debrisoquine. Everyone but Smith seemed unfazed by the injection, but Smith became severely hypotensive and collapsed. He recovered fully, but his startling reaction prompted further investigation, revealing that his debrisoquine hydroxylase, the enzyme that metabolizes debrisoquine, eliminated only 10% of the drug. The normal enzyme eliminates 80%. Smith then identified 2 medical students with deficient debrisoquine hydroxylase, traced the family histories, and found that the trait was inherited. His team then tested hundreds of volunteers, discovering that 1 in 10 developed hypotension after debrisoquine. Although 10% of the population were homozygous carriers, 45% were heterozygote carriers of the deficient gene and could transmit it to their children. Smith's observations had uncovered a mechanism explaining numerous adverse drug reactions [34].

Finally, Michel Eichelbaum's group in Bonn, Germany, studied the antiarrhythmic effects of sparteine [35]. Two subjects complained of double vision, blurred vision, dizziness, and headache after receiving the drug. Both had 4–5

times higher sparteine plasma levels than other individuals, demonstrating a defect in the capacity to oxidize some drugs, a defect inherited as an autosomal recessive trait. In 1980, Bertilsson *et al.* in Sweden showed that subjects having an impaired metabolism of debrisoquine, also had an impaired metabolism of sparteine [36]. Also in 1980, Kalow found that students of European *versus* Chinese descent differed in their capacity to metabolize debrisoquine and sparteine [37], the first observation of inter-ethnic differences in drug metabolism. Debrisoquine and sparteine metabolism were suspected to be genetically linked [38]. A search then began for the gene underlying their variable pharmacokinetics.

In 1985, Distlerath *et al.* purified the protein—CYP2D6—responsible for the altered metabolism from human liver microsomes [39]. In 1987, Eichelbaum *et al.* localized the gene encoding CYP2D6 to chromosome 22 [40]. CYP2D6 was the first polymorphic P450 to be characterized at a molecular level, initially identified as a gene responsible for altered metabolism of debrisoquine, sparteine, and other drugs [41]. Further study revealed that CYP2D6 is the only non-inducible enzyme of the P450 family of enzymes. Non-inducible means that it is constantly expressed rather than being turned on or off. As a result, a mutation of the enzyme may cause sustained inter-individual variation in enzyme activity [31]. Genotyping for CYP2D6 activity is drug specific, and the need for typing an individual is limited. If genotyping is needed, patients are assigned to one of four categories based on their ability to metabolize CYP2D6 substrates: ultrarapid metabolizers (UM), extensive metabolizers (EM), intermediate metabolizers (IM), and poor metabolizers (PM) [42]. PMs (two non-functional gene alleles) metabolize CYP2D6 substrates less well than their counterparts (IMs, EMs, UMs). UMs possess multiple functional copies of the same normal CYP2D6 gene, and an increase in the number of functional copies in an individual increases the rate of metabolism of CYP2D6 substrates (Fig. 44.4).

CYP2D6 genetic variations have other clinical implications. In 2006, Koren *et al.* [43] described a neonatal death leading to the suggestion that breastfeeding mothers taking codeine for postpartum pain should be genotyped for CYP2D6 activity. CYP2D6 O-demethylates codeine to morphine. Mothers and neonates that are CYP2D6 UMs or EMs may produce toxic blood levels of morphine or its active metabolite morphine-6-glucuronide (M6G). The infant in this case report was a CYP2D6 EM, and had a blood concentration of 70 ng/ml morphine; neonates breastfed by mothers receiving codeine normally have concentrations of 0–2.2 ng/ml [43]. The mother was a CYP2D6 UM, and her breast milk had 87 ng/ml morphine—the normal range being 1.9–20.5 ng/ml at doses of 60 mg codeine every 6 hours [43]. Thus the infant had 2 reasons for increased morphine levels. These findings and those from case-control studies [44] indi-

Fig. 44.4 CYP2D6 activity predicts ability to metabolize a wide range of drugs (see text for details). Clinical doses of nortriptyline (a tricyclic antidepressant) to be used in different genotypes are indicated. (From Meyer UA: Pharmacogenetics—five decades of therapeutic lessons from genetic diversity. *Nat Rev Genet* 2004; 5: 669–76 with permission.)

cate that codeine should be avoided in breastfeeding mothers with CYP2D6 EM and UM genotypes.

Genetics and Pharmacodynamic Variation

Pharmacokinetics (what the body does to a drug) and pharmacodynamics (what a drug does to the body) can influence the effectiveness and metabolism of medicines given to produce anesthesia. The previous section concentrated on pharmacokinetics, identifying genetic alterations in drug metabolizing enzymes that change circulating drug levels. The next section explores pharmacodynamic effects, specifically genetic variations in receptor proteins that may alter activation of signaling pathways, despite the presence of constant drug concentration. We present 3 clinically relevant examples.

β -Adrenergic Receptors and Altered Physiologic Responsiveness

β -adrenergic receptors (β ARs) influence cardiac contractility, heart rate, and vessel dilation. Anesthesiologists use β AR agonists and antagonists to ensure intraoperative hemodynamic stability and improve perioperative outcome

[45]. β_2 AR genetic variants, generally single nucleotide polymorphisms (SNPs), were initially identified in 1993 and 1994, and clinically relevant β_1 AR SNPs were identified in 1999 and 2000 [46]. β_1 AR and β_2 AR antagonist therapy after acute myocardial infarction (MI) decreases *aggregate* patient mortality, a fact known for decades [47]. In 2005 Lanfear *et al.* [48] asked whether specific sub-groups of individuals benefited more than others, from β AR antagonist therapy. Examining four common β_1 and β_2 AR SNPs, Lanfear found *increased* mortality with β AR blocker therapy in individuals with genetic variants in the gene encoding the β_2 AR (*ADRB2*) (about 25% of the acute MI population), whereas the remaining patients benefited. Such findings suggest that β_2 AR DNA testing might indicate which patients should receive β AR antagonists after MI. If these findings are reproduced, such genetic testing would routinely precede the use of β AR antagonists after MI.

Airway hyper-reactivity associated with asthma is a concern to anesthesiologists. Bronchodilators prescribed to prevent or to treat airway hyper-reactivity interact with β_2 ARs. In 1999, Lima *et al.* [49] reported that asthmatic subjects who were homozygous for the Arg16 wild-type (normal) allele in *ADRB2* (i.e., they had 2 copies of the normal gene), initially demonstrated enhanced responsiveness to β_2 -agonist bronchodilators, compared to patients homozygous for the

Gly16 variant. However, this acute protective effect of Arg16 differed from results in studies assessing prolonged β -agonist therapy. In 2004, Israel *et al.* [50] showed that mildly asthmatic patients who were homozygous for Gly16, improved with long-term albuterol therapy, a result subsequently confirmed [51]. Our current understanding is that in Arg16 homozygous patients, long-acting β -agonist therapy may increase severe asthma exacerbations. Alternative treatment strategies may better help this subgroup of individuals [52]. This provides another example of how pharmacogenetics may help guide and/or facilitate alternative treatment strategies [53].

μ -Opioid Receptor Variation and Pain Medicine Effectiveness

Opium has been harvested from poppies and smoked to relieve pain and alter mentation for centuries. Morphine, codeine, and non-narcotic alkaloids come from this folk remedy. Opium is also the precursor for recreational drugs such as heroin. Morphine and other clinically relevant opioid analgesics primarily target the μ -opioid receptor (μ OR), a receptor whose gene, *OPRM1*, varies extensively. In May of 1998, Wendel and Hoehe described the μ OR gene (*OPRM1*) [54]. Three months later, Bond and her colleagues discovered a SNP at position 118 in 10% of their study population, and suggested that this A118G polymorphism (in which guanine substitutes for adenine at position 118 in the receptor protein) alters the extracellular binding site of the μ OR, thereby changing the binding affinity of β -endorphins (the natural endogenous biochemical for the opioid receptors) as well as exogenous opioids [55]. Two reports of the functional consequence of the A118G genetic variant came in 2002. Wand *et al.* [56] found that healthy volunteers carrying the G118 variant, had increased cortisol responses when given the opioid-antagonist, naloxone. Days later, Lötsch *et al.* [57, 58] suggested that the A118G polymorphism protects against morphine-6-glucuronide toxicity.

Variants of the μ OR gene may explain inter-individual responses to opioid analgesia [59]. An approach to examining the heritable component of pain perception and response to opioids has historically involved twin studies [60]. Other clinical studies relevant to anesthesia have examined the potential pharmacogenetic effect of the common A118G polymorphism, on the response to various opioids after surgery, or when given to women for labor pain during epidural analgesia. Importantly, the dose of intravenous morphine required by post-surgical patients has been shown to vary, based on an individual's μ OR genotype [61]. Defining μ OR genetic variants is needed to understand complex pain pathways, stratify pain phenotypes into their individual components, and create novel predictive genetic tests for use in pain medicine [62].

Sodium Channel Genetic Variants and Channelopathies

A rare, fascinating, and deadly condition preventing the perception of pain has enhanced our understanding of sodium channels' role in pain perception. It has also entered popular culture (see "The Girl Who Played with Fire" by Stieg Larsson). Survival and protection of the body demands the perception of pain (e.g., to remove one's fingers from a hot object). In 2006, Cox *et al.* [63] described the genetic basis of a congenital inability to experience pain. In unrelated consanguineous Pakistani families, Cox and colleagues identified 3 loss-of-function mutations of *SCN9A*, a gene encoding for the alpha subunit of the voltage-gated $\text{Na}_v1.7$ sodium channel, which, along with other voltage-gated sodium channels, subserves the generation and conduction of action potentials that mediate pain. Isolated patients and families subsequently demonstrated similar mutations [64–66]. Presently 15 loss-of-function recessive trait mutations of the channelopathy-associated insensitivity to pain phenotype are known [66].

Genetic and Genomic Methods, Tools, and Their Impact

Variation in response to disease onset and severity, or to drug treatments, may result from augmenting/dampening of cascades of genes. Animal models have facilitated examination of the effect of genetic variability in the context of a whole organism. We now review some of the most common of these non-human models to see how they have advanced the field.

Classic Non-Human Models

The study of genetics began with Mendel's observations of pea plants. Animal models—rats, cats, dogs, and monkeys—have also been used. The most commonly used models today include the nematode *Caenorhabditis elegans* (*C. elegans*), the fruitfly *Drosophila melanogaster* (*D. melanogaster*), and genetically engineered mice (knock-out and transgenic mice). These models reflect key discoveries in medicine, as acknowledged by several Nobel Prizes. Below we summarize advances related to the understanding of genetics and anesthetic mechanisms for each of these classic genetic models.

C. elegans is a transparent roundworm approximately 1 mm long. It reproduces rapidly allowing generations to be studied quickly. This simple organism was the first multicellular organism with a nervous system to have its genome completely sequenced. Under normal conditions *C. elegans* is almost constantly moving. When exposed to a volatile

anesthetic, after an initial phase of increased locomotion, uncoordinated motion progresses to immobility. When *C. elegans* is removed from the anesthetic, motion returns quickly. Phil Morgan and Helmut Cascorbi first described this model as a tool to study the mechanism of action of volatile anesthetics in 1985 [67]. Over the last two decades, Mike Crowder, Phil Morgan, and Marge Sedensky applied this model to study those mechanisms [68]. The two most common endpoints used to measure anesthetic effects in *C. elegans* have been uncoordination (or change in motion caused by anesthetic exposure), and immobility. The mechanisms of the two anesthetic actions are distinct and most likely reflect different aspects of the complex behavioral effects.

Mutations in neuronal proteins (called syntaxin) of *C. elegans* significantly alter the sensitivity to volatile anesthetics (a 33-fold range of sensitivity for isoflurane), suggesting that syntaxin is a possible target of volatile anesthetics. Overall, genetic studies suggest that a vast group of molecular targets or pathways determine anesthetic sensitivity. More recent studies have identified additional sites of action of volatile anesthetics, including ion channels and mitochondrial proteins. The implication that mitochondria were involved in anesthetic sensitivity was highlighted by the observation that children anesthetized with sevoflurane to perform muscle biopsies for the diagnosis of suspected mitochondrial defects, had different anesthetic responses as a function of their mitochondrial function. Modification of genes have been used to create anesthesia sensitive and resistant worms, facilitating exploration of mechanisms of anesthetic action [68], such as identifying most recently that complex I of the electron transport chains (ETC) is a possible target of volatile anesthetics [69].

Physical characteristics of *D. melanogaster* such as eye bristles, wing patterns, antenna, and patterns on the head and thorax have been used as phenotypic markers for alterations in specific genes. As with *C. elegans*, the entire genome and several variants of *D. melanogaster* have been sequenced in the last decade. Howard Nash at the NIH, discovered strains of *D. melanogaster* that were either sensitive or resistant to inhaled anesthetics [70]. Genes that regulate states of arousal, gene copy number, and unusual ion channels that serve as a depolarizing leak may underlie resistance and sensitivity. The *D. melanogaster* nervous system stays active during anesthesia and in this, and overall conservation of genes and their function, provides parallels with the human nervous system.

Some of the yet unresolved questions about the mechanism of action of anesthesia are related to the fact that (1) the numerous endpoints associated with the anesthetic state are probably the result of effects at different sites of anesthetic action, (2) 'immobility' as observed in nematodes doesn't reflect the state of 'loss of consciousness and perception of pain' that is the goal of anesthesia, and (3)

genetic studies do not explore all the pathways involved in mechanism of action, such as regulation that occurs downstream.

Mario Capecchi, Martin Evans and Oliver Smithies received the Nobel Prize in Medicine for their 1989 creation of the first knockout mouse, a mouse lacking a specific gene. By inactivating a specific gene, and observing the consequent differences in physiologic expression and phenotype, the function of the gene can be inferred. These models have been used to further our understanding of human biology, including mechanisms of anesthetic action [71]. Such genetic manipulation allows a controlled change heretofore only available as natural variations as described above (e.g., consider the natural variations in the opioid receptor). Knockout mice have been used to assess the relevance of numerous ligand- and voltage-gated channels to mediate the effects of inhaled anesthetics, particularly their capacity to produce immobility in the face of noxious stimulation. However, despite high hopes, a review by Sonner in 2003 [72] and a follow-up review by Eger in 2008 [73] do not suggest that the hopes have been realized. Why? Knockout of a gene affects but one ion channel, and then only one member of what may be a large family. What if anesthesia results from actions on multiple channels? And the body may compensate for the loss of function produced by a knockout, obscuring the consequences of the knockout.

A potential solution to the issue of compensation lies in the use of knockin mice. In contrast to knockout mice, the targeted gene allows the production of an altered channel that responds normally (it is hoped!) to its ligand (e.g., glycine or GABA) but not to, say, an anesthetic. In the early 1990s, several investigators, notably Gregg Homanics, Neil Harrison and Adron Harris produced such mutations and engineered knockin mice from them. In 1997, John Mihic from Harris' laboratory described such a mutation for glycine and GABA_A [74]. A GABA_A1 knockin mouse was made from this mutation. However, a 2007 report on the resulting mouse did not reveal that it was resistant to the immobilizing effect of isoflurane [75]. Results from this mouse suggested that it was resistant to the amnestic effects of isoflurane. One step at a time!

In contrast to the slow progress with inhaled anesthetics, a knockin mouse allowed a dramatic insight into the mechanism underlying one aspect of the actions of etomidate and propofol. In 1999, Uwe Rudolph suggested that the actions of benzodiazepines might lie in specific parts of the GABA_A receptor [76]. Building on this, in a 2003 landmark report, Rachel Jurd from Rudolph's laboratory found that the immobilizing action of etomidate and propofol were virtually eliminated in a knockin mouse in which the response to GABA was "normal", but the capacity of etomidate and propofol to enhance the response of the GABA_A receptor was abolished [77].

Human Genetic Studies

Human genetic studies “associate” specific genetic variants and the ensuing altered biologic pathways, with endpoints such as occurrence of disease, altered response to drugs, or death. Three prerequisites must be satisfied to yield meaningful findings: (1) robust clinical phenotyping (e.g., quantifiable physiologic parameters such as blood pressure or heart rate change, pharmacological responses; and/or long term clinical outcomes), (2) expert biostatistical analysis including statistical genetics, and, (3) high quality genetic analysis (i.e. genotyping, sequencing, and genome wide association studies).

Clinical Phenotyping

Specific measures, including vital signs, pain scores, blood chemistries and plasma drug concentrations, can define clinical phenotypes. To be valid, such measures must be reproducible within a given individual. Since many genetic effects are small and additive, “crisp” detailed clinical phenotypes are essential for a valid clinical genetics study. However, “mined” DNA databases combined with vaguely measured phenotypes have had limited power. Well designed genetic association studies that examined cardiovascular outcomes from medication choice usually result in clinically useful findings [48], but reliable and applicable findings have been elusive in studies of genetic influences on pain perception and response to analgesics [78]. Conflicting outcomes in pain studies examining the effect of the A118G polymorphism may relate to the use of subjective visual analog scores rather than measurable outcomes such as blood pressure. In addition to this inter-person variability, there is also complexity underlying the pain phenotype (multifactorial, highly subjective, various pain modalities—experimental pain, labor pain, acute post-operative pain, ischemic pain, inflammatory pain and of course chronic pain).

Integration of Animal and Human Genetic Studies

One method connecting animal models to human disease first identifies relevant genes and proteins in humans, then studies their mechanistic effects in animal models, and finally translates such information back to the clinic to improve outcomes. Jeffrey Mogil, at McGill University proposed such a paradigm for pain research [79]. His work largely focuses on the second step of this paradigm and the human association studies required for translation into the clinic. Mogil *et al.*'s 2003 publication [80] presented a translation of genetic findings from rodent models examining several genetic variants to humans. Women with two variant alleles of the *MC1R* (melanocortin-1 receptor) gene, which deter-

mine fair skin, and red hair [81], and immunomodulation [82], had increased sensitivity to a κ -opioid drug. But drugs acting at the μ -opioid receptor, not the κ -opioid receptor, represent the mainstay of clinical treatment of moderate to severe pain. So Mogil performed an analogous study in 2005 [83] with the μ -opioid receptor morphine metabolite, morphine-6-glucuronide (M6G). Human redheads inheriting two or more inactivating variants of the *MC1R* gene had increased analgesic responsiveness to M6G. In the same year, Liem and colleagues [84] observed that lidocaine was less effective in preventing pain in redheaded women. Also in 2003, Mogil observed that drugs from diverse neurochemical classes (e.g., μ -opioid, κ -opioid, cannabinoid, nicotinic, and α_2 -adrenergic) had high genetic correlations: mouse strains were either sensitive or resistant to analgesia, regardless of the drug used. This suggests that analgesic pathways may interact to confer sensitivity across drug classes [79].

The next step was high throughput discovery of the involved genes. In 2007, Mogil created the *PainGenes Database* [85], an open-to-all interactive online database cataloging genes whose null mutant has a published pain related phenotype. Each gene and phenotype is derived from knockout mice studies reporting changes in either nociceptive or analgesic sensitivity. It remains to be seen whether the *PainGenes Database* will facilitate translation of pharmacogenetic studies into clinical trials and clinical care.

Exercise to Exhaustion

Are the patterns of the stress response to major surgery in humans unique to surgery or seen with all extremes of human physiology? This is one of multiple questions raised by anesthesiologists and scientists interested in the parallels that can be drawn between the peri-operative period as a model of acute stress, and other ‘stressors’ that individuals may experience in their life. Studies in the 2000s of exercise to exhaustion, suggest commonalities with perioperative stress. Half-marathon runners have been examined before a race, immediately after the race, and 24 hours later for inflammatory markers. Peripheral blood mononuclear cells (PMBCs) have been examined using a microarray approach, showing upregulation of mitogen-activated protein kinase-activated protein kinase-2 (MAPKAP-K2), L-selectin, IL-1 receptor antagonist (IL-1ra), and thioredoxin (which may play a role in oxidant defense), as well as downregulation of CD81 (which promotes B and T cell activation and T cell maturation) [86]. Others have found increases in cortisol and adrenaline [87, 88], increased cytokines in plasma or urine (levels which decrease by the following day) [89–95], and generation of reactive oxygen/nitrogen species [96]. Acute endurance exercise also affects gene expression of metabolic

transcriptional co-activators and transcription factors [97]. Such effects on the immune system and inflammation suggest that exhaustive exercise produces findings similar to those from perioperative stresses.

Sepsis

Similarly, in the 2000s, it was found that severe sepsis provides another challenge to human physiology, paralleling perioperative stresses. The inflammatory response to sepsis was studied by administering bacterial endotoxin IV over 24h to healthy volunteers with measurements of the resulting acute-phase cytokines in serum [98]. And a network-based approach was used to define biologic targets from 200,000 published articles [99]. In general [99], 2–4 hours post endotoxin, secreted proinflammatory cytokines and chemokines increased, consistent with early activation of innate immunity. The 4 to 6h post endotoxin time was critical, with increased expression of transcription factors, both those that initiated and those that limited immune response. In summary, although sepsis provides an initial activation of innate immunity, the resultant whole body response to the stress of infection is remarkably similar to that found in cardiac surgery or exhaustive exercise models. This suggests that, independent of the insult, the human stress response triggers identical changes in genes, proteins, and metabolites.

Gene Expression Studies of Myocardial Preconditioning

In 1986, Murry and co-workers reported that exposure of the heart to a short episode of ischemia/reperfusion affords protection against a subsequent more prolonged period of ischemia. In 1997, Cason's group showed that cardioprotection from "ischemic preconditioning" can also be achieved by administration of isoflurane [100]. In the next few years, other potent inhaled anesthetics were also shown to produce this phenomenon [101]. Indeed, hundreds of reports have appeared showing prolonged protection by diverse inhaled anesthetics. The prolonged nature of protection implies a genetic up or down regulation. Regulation of potassium channels and a recently emerging understanding of the important role of mitochondrial homeostasis, in dampening oxygen free-radical cascades leading to cell apoptosis and death, underlie the protection. Microarrays have been applied to evaluate organ-specific responses to surgical stress, and CPB with cardioplegic arrest [102]. These studies have identified different transcriptional programs activated in ischemic *versus* anesthetic preconditioning, the differential activation resulting in distinct cardioprotective phenotypes [103]. Similarly, characteristic gene expression patterns have been

described in chronic ischemia that differ from those found in experimental induced ischemic preconditioning [104, 105].

Conclusion

Genetics and genomic medicine can be important to anesthesia-related clinical care. Genetic studies have revealed mechanisms underlying malignant hyperthermia, have given us the dibucaine number for testing for the presence of an impairment in succinylcholine degradation, and have aided our understanding of mechanisms of anesthesia action and/or effectiveness of drugs used to induce the anesthetic state. Genetic studies can explain outliers and the "bell-shaped curve" of clinical responses. Our application of genetics to anesthetic delivery will advance in tandem with technical advances such as rapid and relatively inexpensive sequencing of individual genomes. Genetic diagnostics and pharmacogenetic predictions will increasingly define anesthetic practice.

Acknowledgements The authors thank Arno Motulsky for his critical reading of the manuscript and for granting a personal interview where he provided insights into the history and future of pharmacogenetics. We are grateful for his historic contributions to genomic science, and we are honored to have him contribute to this manuscript. The authors also thank Gary Peltz for granting a personal interview and allowing a close examination of his research.

Nicholas P. Franks

Summary

Soon after Morton's 1846 demonstration of ether anesthesia, von Bibra and Harless proposed that ether acted by extracting brain lipids. In 1901, Overton noted that this theory did not explain the rapid reversibility of narcosis and proposed that anesthetics acted by dissolving in the lipids, not *vice versa*. In support of this theory, Meyer and Overton showed that anesthetic potency correlated with partitioning between water and lipid. In the next half century, not all agreed with their theory. Harris' 1951 book, for example, suggested that anesthetics might act by impeding diffusion through membranes, or by diminishing metabolism, or by asphyxiation.

In the early 1900s, women in labor might receive morphine and scopolamine to produce "twilight sleep". They might thrash and scream, but not recall pain, an early example of different mechanisms mediating different components of anesthesia.

In 1961, Pauling and Miller proposed that anesthetics acted by forming hydrates of water at membrane surfaces... but many inhaled anesthetics did not produce hydrates. In 1963, Merkel and Eger described "MAC", a measure of inhaled anesthetic equipotency. MAC gave the partial pressure at the site governing a crucial anesthetic endpoint, immobility, in the process also producing amnesia. Further undermining the hydrate theory, Eger et al. found a poor correlation between MAC and the anesthetic partial pressure required to form hydrates.

Investigators in the 1970s embraced the Meyer and Overton hypothesis, offering four "lipid theories". Anesthetics might change bilayer dimensions (volume or thickness), increase bilayer fluidity, induce phase transitions in bilayer lipids, or alter bilayer permeability. Mullins suggested that anesthetics acted by expanding the membrane, a beguiling theory that might explain the remarkable ability of high pressures (e.g., a hundred atmospheres) to antagonize anesthesia. But in the early 1970s, Lieb and I tested how anesthetics altered membrane bilayers, by 1978 finding they didn't. We turned our attention to protein sites of action. By 1982, the evidence against lipid theories was convincing, while evidence for protein theories was thin. But in 1984, we showed that anesthetics inhibited a protein, firefly luciferase, at anesthetizing concentrations—a Meyer-Overton correlation, except that no lipids were involved. Our studies of stereoselectivity in the 1990s were also consistent with a protein site of anesthetic action.

The debate became "which protein?" By the early 1990s, studies showed that propofol and etomidate potentiated GABA_A receptor responses, and that specific receptor amino acids influenced effects of inhaled anesthetics and etomidate. In 1993, both Antognini and Rampil found that the spinal cord mediated immobility caused by inhaled anesthetics. In 2005, Jinks showed that central pattern generators in the ventral horn were the specific targets. By the 2000s, most investigators agreed that specific molecular targets for inhaled anesthetics must exist, but did not agree as to which targets mediated particular endpoints.

The Greatest Challenge

Understanding how general anesthetics reversibly remove consciousness and sensibility to pain has been one of the great challenges in pharmacology and neuroscience. The extraordinary diversity of anesthetics (ranging from noble

gases to complex steroids), together with the intangible nature of human consciousness, makes this a particularly difficult problem to solve. Until relatively recently, most research into how general anesthetics act has been directed at the molecular level, [1–6] and this will be a primary focus of this chapter¹.

¹Readers looking for scholarly accounts of anesthetic mechanisms should read the reviews I have cited in the text. What they will find here is a personal account of how the field has changed during the past 35 years from my own, inevitably biased, perspective.

Within one year of the public demonstration in Boston of the use of ether as an anesthetic, Ernst von Bibra and Emil Harless proposed the first mechanism of anesthetic action, suggesting that ether extracted fatty components of brain cells, and these fatty components then accumulated in the liver [7]. Moreover, they argued that other compounds with this property would be anesthetic—the first physicochemical theory. This work influenced the thinking of both Hans Horst Meyer and Charles Ernest Overton who independently proposed a new, and highly influential, theory of anesthetic action that was also based on an interaction between anesthetics and lipids [8, 9].

The Meyer-Overton Hypothesis

Overton recognized two major difficulties with the notion that anesthetics extracted brain lipids. First, this could not easily account for the rapid reversibility of narcosis upon removal of the anesthetic. Second, lipids would in fact be insoluble in dilute aqueous solutions of ether. Overton turned the idea on its head and proposed that anesthetics dissolved in the lipids, and not *vice versa*. This changed the physical state of brain cell lipids, thereby producing narcosis. Overton clearly regarded this as the critical causal step in the induction of anesthesia. In support of this idea, both Meyer and Overton showed that the potency of an anesthetic in animals closely correlated with its partitioning between water and lipid (using olive oil, a complex mixture of triglycerides, as a convenient model lipid).

Importantly, the correlation between anesthetic potency and lipid partitioning had a slope of unity, meaning that at the point of anesthesia, the concentration in the lipid would be the same for all anesthetics (Fig. 45.1). Hence was born the influential lipid theory of anesthesia (refined and made more quantitative by Meyer's son, Kurt Meyer). Kurt Meyer summarized the theory [10]: "Narcosis commences when any chemically indifferent substance has attained a certain molar concentration in the lipoids of the cell". However, Kurt Meyer cautiously avoided describing this as a mechanistic theory—"it is not really a theory which explains the mechanism of narcosis but rather the expression of an experimentally observed regularity, a rule of which every theory must take account". The simplest interpretation of this observation is that whatever determines the solubility of anesthetics in olive oil, also determines their solubility at their sites of action in the brain. The most parsimonious idea, of course, as originally stated by Overton, was that these sites in the brain *were* membrane lipids and that something must be happening to these lipids which caused anesthesia. This idea has two fundamental problems. The first is that the data on which it was based were incomplete. The second is that it is wrong. More to that point in a moment.

Fig. 45.1 The Meyer-Overton correlation between anesthetic potency in animals and partitioning between water and lipid bilayers

Twilight Sleep

In the early 1900s, women in labor might receive a combination of morphine and scopolamine to produce something called "twilight sleep" (see Chapter 48. A History of Pain Relief during Childbirth). Delivery might occur with thrashing and screaming, but afterwards the mother would recall nothing, believing that she had experienced a pain-free delivery. This supplied an early modern example of the possibility that different mechanisms might mediate the components of anesthesia. In this case, scopolamine blocked remembrance (produced amnesia), but neither scopolamine nor morphine sufficiently blocked the perception of, and motor/movement response to, noxious stimulation.

The Variable Impact of Meyer and Overton (And Hermann)

In the next half century, Meyer and Overton's hypothesis appears to have received a mixed reception. In 1930, Henderson [11] suggested it was important and pointed to the site of anesthetic action, but a 768-page book by TAB Harris entitled *The Mode of Action of Anaesthetics* [12] published in 1951 suggested otherwise. Eger says that this book was the most exciting text he read in his residency (1956–1958) because it was full of ideas on how things acted. No matter that the ideas usually were, in retrospect, incorrect. Harris noted that an LR Hermann had thought of the Meyer-Overton Hypothesis in 1866.

More importantly, in his single page (p 51) devoted to the Hypothesis, Harris concluded that Meyer and Overton were wrong: “This generalization does not bear criticism, for there are drugs—such as many of the benzol derivatives—which have a high oil/water partition coefficient, but do not produce narcosis”, a thought anticipating the cut-off for large alcohols and the non-immobilizers as contradictions to the Hypothesis.

Harris focused on many other things in his text, considering in detail the importance of kinetics to achievement of an anesthetic effect. He noted suggestions that anesthetics might act by impeding diffusion through membranes, a recurring theme in theories of narcosis. He focused on the capacity of anesthetics to diminish metabolism, and argued (p 103) that “it is impossible to escape the suggestion that the state of narcosis must be attributed to the diminution of cell energy which results from the inhibition of the oxidation of glucose, lactate and pyruvate.” He gave credence to the notion that some (not all) anesthetics “act...as a simple asphyxiant gas(es).” (p 164)

Two Inventions in the Early 1960s

In 1963, Giles Merkel and Eger published [13] a description of “a method for determining equipotency”, a method using dogs that was applied two years later to humans [14]. They called the standard “MAC” (the minimum alveolar concentration that abolished movement in response to noxious stimulation in 50% of subjects).

This invention had several implications for mechanisms of anesthetic action. First, it dealt with kinetics and metabolism as confounding factors in measures of potency. The alveolar concentration (really the partial pressure) was assumed to be in equilibrium with the partial pressure in arterial blood, and given sufficient time for equilibrium, the partial pressure at the site of anesthetic action. That is, with those caveats, MAC gave the partial pressure at the site of anesthetic action, wherever that might be.

Second, the endpoint chosen, absence of movement in response to noxious stimulation, was a crucial clinical endpoint, one required for any operation. It also exceeded the concentration required to abolish memory, thus providing a two-for-one: production of immobility virtually guaranteed production of amnesia.

Third, it forced a consideration of what constituted anesthesia.

Fourth, MAC and the technique that underlay it, spawned similar measures of other clinically meaningful endpoints such as MAC-awake, the alveolar concentration eliminating appropriate response to command in 50% of subjects—a measure of consciousness.

Finally, the data producing MAC imposed another requirement for theories of narcosis. They had to explain the

extraordinarily steep dose-response relationship associated with the production of immobility: at a concentration 10% less than MAC, 90% of subjects might move; but at a concentration 10% greater than MAC, 90% would not move. MAC was not a theory of narcosis, but it provided a powerful tool to investigate theories. (For experimental studies with animals, many used and continue to use the loss of righting reflex, an easily measured endpoint of central nervous system depression by anesthetics which correlates well with loss of consciousness in humans [6], but is not of such direct relevance clinically.)

Linus Pauling [15] and, independently, Stanley Miller [16] supplied a second invention in 1961, this one a theory of narcosis, an alternative to the lipid-based theories. They proposed that anesthetics formed microcrystals of water, or “icebergs” as Miller put it, hydrates perhaps stabilized by protein side chains, which disrupted membrane or enzyme function, possibly by effectively thickening membranes. In support of their theory they noted that the partial pressure required to produce anesthesia by several gaseous anesthetics correlated with the partial pressure required to produce the hydrate. Eger remembers a 1961 meeting of the Association of University Anesthetists (later Anesthesiologists) at which Pauling presented his hypothesis. A great showman, he pulled models of his icebergs (he called them clathrates), molecules connected with springs, from a small sports bag he had carried to the podium. “With a snap, each iceberg grew before our eyes. There it was! Visual proof of the theory!”

But the iceberg theory never took hold and remained largely forgotten as one of many ingenious, but unsupported, theories. Well, not just unsupported; there was evidence against it [17, 18]. Many inhaled anesthetics failed to produce the requisite icebergs.

Biophysical Table-Talk

Many investigators were less inclined than TAB Harris to dismiss the correlation found by Meyer and Overton. They sought to give the correlation a mechanistic basis. In 1982, my colleague Bill Lieb and I summarized what we thought were the shortcomings of such lipid theories [2]. An unimpressed reviewer² of the submitted manuscript described our analysis as “biophysical table-talk”. This marvelous phrase has lived with me ever since and I happily use it here to describe the lipid theories based on the central observations of Meyer and Overton.

²This reviewer was not the only person who was unimpressed by our review. We received a letter from Linus Pauling telling us that, in fact, he had solved the problem of how anesthetic acted many years previously (see above).

Lipid theories fell broadly into four different camps. Anesthetics were said to change the dimensions of the bilayer (volume or thickness), increase the fluidity of the hydrocarbon chains, induce phase transitions in the bilayer lipids, or alter bilayer permeability. Lorin Mullins made an early and long-lasting suggestion that anesthesia occurred when anesthetics had expanded the membrane by a critical amount. This Critical Volume Hypothesis, refined and extended by Keith Miller and Brian Smith in the 1970s [19], became one of the best-known concepts. It was particularly beguiling because it might explain the remarkable ability of high pressures (e.g., a hundred atmospheres pressure) to antagonize general anesthesia—the so-called Pressure Reversal of Anesthesia.

Also in the 1970s, the concept of lipid fluidity was all the rage. Theories proposed that altered bilayer fluidity underlay anesthesia. It was suggested that anesthetics induced chain-melting phase-transitions in membrane lipids, similar to those known to occur in pure, artificial lipid bilayers. Jim Trudell proposed the most sophisticated version of this [20], suggesting that anesthetics disrupted the lateral phase separation of lipids. Finally, there were theories arguing that anesthetics compromised permeability of the lipid bilayer portion of nerve membranes [21].

It is impossible to do justice to the hundreds of papers written in support of various lipid theories. The array of possible explanations for anesthesia were bewildering, but when I became interested in the problem while pursuing my PhD with Maurice Wilkins in the early 1970s, I had little doubt that one of these lipid theories must be correct. I had been using and developing the techniques of X-ray and neutron scattering to study lecithin-cholesterol lipid bilayers, and we had the highest resolution structural description available [22, 23].

My first project (and, as it turned out, the direction of my subsequent career) began with an argument with Bill Lieb over coffee. Lieb³, an expert on membrane permeability working in the lab as a postdoctoral Fellow, explained that anesthetics would thicken lipid bilayers because the anesthetics would tend to accumulate in the center of the bilayer where the packing density was lowest. I argued the opposite—the increased fluidity of the lipids would reduce the effective hydrocarbon chain-length, and the bilayer would get thinner. We decided to do the experiment. We started work in January 1975 (and worked together for 30 years until his death in 2005).

³Lieb was a native of Chicago and had a novel, an effective, way of avoiding jet-lag. He simply stayed on Chicago time all his life. He therefore arrived in the lab at around 2 in the afternoon and we would work together until the evening. He would then continue until the early hours when he would write me a letter telling me what he had been up to. This modus operandi persisted for the 30 years that we worked together.

Our results were a shock. I vividly remember looking at the first diffraction pattern, expecting to see an obvious change in the pattern of intensities, but it looked exactly the same as the control. A detailed analysis showed no detectable changes in bilayer structure at clinically relevant concentrations. Neither of us had considered that *both* of our predictions might be wrong. It took a long time and more experiments to convince us that this result was correct. We used both X-ray and neutron diffraction, tried various anesthetics, and explored all artifacts we could think of. Three years later, we sent a paper describing our work to *Nature* [24], which had just published a paper by Denis Haydon, claiming that anesthetics caused membrane thickening [25].

We were not alone in questioning the validity of lipid bilayer theories. In 1976, Boggs et al. [26] showed that fluidity changes caused by anesthetics were extremely small and that they did not correlate with the size of the reduction in fluidity produced by pressures reversing anesthesia in animals. Nonetheless, the tide took a long time to turn.

There were both quantitative and qualitative problems with lipid theories. First, the concentrations of anesthetics causing anesthesia in animals produced either undetectable or extremely small effects in lipid bilayers. So small, in fact, that a slight rise in temperature could usually mimic the effect. Some proponents of lipid theories argued that the effects of temperature and anesthetics can never be exactly equated. True, but for simple biophysical theories claiming that bilayer properties such as volume or fluidity were critical, it was difficult to ignore their predictions regarding the effects of temperature. More importantly, the decrease in anesthetic potency found with increasing temperature [27, 28] was a major qualitative problem because almost all lipid theories predicted the opposite.

Second, the exceptions to the Meyer-Overton correlation were usually ignored. The most notable at the time were the long-chain alcohols, compounds that were highly soluble in olive oil and lipid bilayers, but were not anesthetics. As Miller and Smith wrote in 1973, this was “a feature that defies explanation in terms of the lipid solubility model” [29]. The fact that some fluorinated compounds also lack anesthetic activity, despite their lipid solubility, was exploited in the 1990s by Eger to investigate anesthetic mechanisms [30–32].

Third, lipid theories have difficulty explaining why anesthetic enantiomers (mirror-image isomers) may have different potencies in animals. This was known for barbiturates [33] in the 1970s, but interpretation of the data was not straightforward because of the potentially confounding effect of differential rates of metabolism.

Perhaps the most unsatisfactory aspect of almost all the lipid theories was that they provided no plausible mechanistic explanation of how the postulated changes in bilayer properties affected the functioning of membrane proteins

which (almost) everyone believed to be the ultimate target. The explanations were usually along the lines of "... and then a miracle happens". Miller put it more soberly in an editorial [34] in 1977: "... although we can be quite precise about the lipid perturbations, we know comparatively little about the protein's involvement."

Why were lipid theories so popular? Probably because they grew naturally out of the Meyer-Overton correlation which, as Kurt Meyer pointed out [10], has to be accounted for by any successful theory. There was another reason—lipid theories possibly explained the remarkable observation that high pressures (of the order of 100 atm) could antagonize the actions of general anesthetics. During the 1970s and 1980s, anesthetic action and pressure reversal went hand in hand; explain one and you must explain the other. However, the concentration-response curves for general anesthesia are extremely steep, as mentioned above. Consequently, a small change in potency can cause a dramatic "reversal" (i.e., a big change in anesthetic effect), but the shift in the anesthetic dose-response relationship may be small. For mice, for example, the shift for a range of simple gases is only about 30% [2].

Does pressure cause a true pharmacological antagonism, directly reversing the molecular effects of anesthetics, or is the effect physiological, with pressure causing incidental changes in the animal (for example, by increasing the general level of excitability), and thereby decreasing anesthetic potency? The possibility that it is caused by a physiological antagonism is, I now believe, the most plausible explanation. I recall Brian Smith, at a meeting in Calgary in 1984, conceding that an anesthetized mouse restored to "normality" by pressure "didn't look like it would be too good at mental arithmetic". In the absence of anesthetics, pressure causes an increased excitability called the "High Pressure Nervous Syndrome." A generalized increase in excitable tone would explain why pressure can reverse the actions of not just simple gases, but also highly selective intravenous agents [35] which bind to specific receptors with minimal changes in system volume, where a pharmacological antagonism is most difficult to imagine.

Model Proteins

Although by 1982 the evidence against lipid theories was convincing, at least for Bill Lieb and me, evidence favoring the alternative—that anesthetics bound directly to protein targets—was thin. This was not an original notion, but had not taken off, partly because of the pre-eminence of the Meyer-Overton hypothesis, and partly because the diversity of chemicals causing anesthesia seemed inconsistent with the specificity of enzyme and protein action. In our 1982 review [2] we highlighted one class of proteins, the luciferase enzymes,

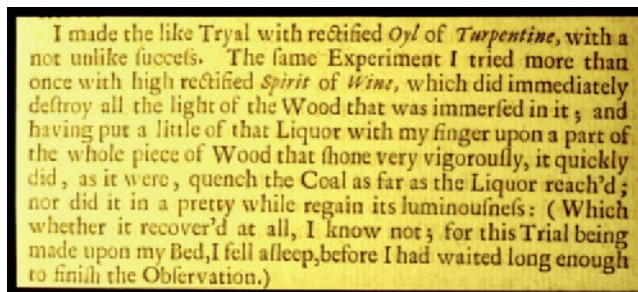

Fig. 45.2 The first anesthetic experiment on a luciferase enzyme as described by Robert Boyle [36]. Boyle was contrasting the light emitted by burning coals and that emitted by wood that had been infected by a bioluminescent fungus ("shining wood") and tried the effects of ethanol ("high rectified spirit of wine"). (From Boyle R: Observations and trials about the resemblances and differences between burning coal and shining wood. *Phil Trans.* 1667;2:605–612, with permission.)

that looked to be sensitive to anesthetics, and we decided to work on these. We met with skepticism from local and more distant colleagues. Keith Miller, who represented mainstream thinking, wrote to us in January 1983 "I don't share your optimism about finding a protein site that behaves like a lipid bilayer!... if you present me with a new example that works, then so be it." Nothing could have stimulated us more.

Work from Princeton by Frank Johnson, Woody Hastings, Henry Eyring, WD McElroy, and their colleagues from the 1940s, furthered our enthusiasm to work on luciferase enzymes. They had studied various luciferase enzymes, in intact organisms and in crude cell-free extracts. Indeed, centuries earlier, Robert Boyle had reported [36] that ethanol inhibited bioluminescence (Fig. 45.2). Eyring, had developed absolute rate theory for enzyme reactions in the 1930s and had also helped develop a curious way of looking at the inhibition of enzymes which centered around the involvement of a thermally-denatured form of the protein that was said to co-exist with the native form [37]. We pointed out that anesthetic binding directly to the native form provided a more plausible explanation for their data [2] and gave more plausible values for binding entropy and enthalpy. This analysis was a turning point in our thinking and pointed the way forward for our research.

We chose to work on the enzyme from the firefly, because Issaku Ueda in Salt Lake City had shown [38] that the bioluminescence from crude extracts of firefly tails was as anesthetic-sensitive as that in bacterial enzymes, and because pure crystalline protein could be prepared using simple affinity chromatography [39]. We purchased lots of firefly tails, purified the luciferase enzyme, and built the apparatus necessary to rapidly mix the enzyme with its substrates and record the resulting flash of light with a photomultiplier. The results were spectacular. Every simple anesthetic compound we picked off the shelf inhibited the enzyme at its anesthetic concentration in animals (Fig. 45.3). We had our

Fig. 45.3 The correlation between anesthetic potency in animals and the inhibition of the soluble enzyme, firefly luciferase

own Meyer-Overton correlation, except that this time, no lipids were involved. The fact that inhibition of the enzyme was purely competitive in nature (the anesthetics simply competing for the binding of the endogenous ligand, luciferin) made this result immediately generalizable. If the architecture of a protein pocket on luciferase could account for anesthetic potency, then surely a similar site could exist amongst the thousands of proteins in the central nervous system.

We sent our results to *Nature* including, in our excitement (hubris?), a suggestion for the cover. The paper was immediately rejected without review. On appeal it went out for review and eventual publication [40]. The results were first presented at the Third International Conference on Molecular and Cellular Mechanisms of Anesthesia, held at Calgary in 1984, and a commentary [41] on the meeting described our results as “an interesting departure from the mainstream” and concluded, rather grudgingly we thought, that “it appears, in principle, that protein sites cannot be ruled out”.

We went on to study the long-chain alcohols and found that, unlike lipid bilayer solubility [42], firefly luciferase displayed cutoffs in anesthetic potency for both alkanes and alcohols mimicking those seen in animals [43]. Our later work using X-ray crystallography also showed the anesthetic binding sites on the enzyme [44], and that the enzyme had a similar temperature dependence of anesthetic potency to animals [45], although it did not show pressure reversal.

The keystone for a new paradigm was in place, but further building blocks and at least another decade of work were required, before the idea that anesthetics acted by binding directly to proteins became the mainstream view. One argument

Fig. 45.4 This photograph of Bill Lieb (*right*) and myself was taken at Imperial College in 1992 to accompany an article about our work [48]. The caption to the photograph described us as “Lipid Theory Skeptics”. Photograph taken by Nick Jackson. (From Matthews R: A low-fat theory of anesthesia. *Science*. 1992;255:156–157 with permission.)

involved the stereoselectivity of action of those anesthetics that were “chiral”, or in other words existed as two mirror-image forms (enantiomers). If anesthetics bound to sites on proteins, then one might expect that the two mirror-image enantiomers would act differently. As mentioned earlier, it had been appreciated since the 1970s that the enantiomers of various barbiturates differed in their anesthetic potencies, but this could have been explained by differential binding to their target sites, or by different rates of metabolism. To avoid metabolism (or kinetics) as a confounding problem, in 1989 we studied the difference in potencies of the enantiomers of isoflurane. Don Halpern, of Anaquest, part of the BOC Group, based in Murray Hill, New Jersey, synthesized the enantiomers of isoflurane. After the purified enantiomers arrived in London, they remained unopened for several months in a refrigerator while we screwed up courage to test whether they differentially affected ion channels, as a protein binding site would predict. Our first experiment in August 1989 revealed (to our great relief) that the S(+) enantiomer of isoflurane was about twice as potent as the R(−) enantiomer in opening an anesthetic-activated potassium channel and in inhibiting nicotinic acetylcholine receptors. Because the enantiomers affected lipid bilayers equally, this seemed to us good evidence that, even for the less potent inhaled agents, general anesthetics bound directly to protein targets. Work in 1998 reinforced this point using the intravenous anesthetic etomidate [46].

A few months after our 1991 paper [47] was published, an article [48] appeared in the same journal about our work. Bill Lieb and I were pictured (Fig. 45.4) with the caption “Lipid theory skeptics”. This editorial gave a fair reflection of the mood at that time. For Keith Miller, it was “still too early to write off the lipid theory”. “None of the experiments are absolute proof” said a skeptical Adron Harris. But by now,

we had no doubts and turned our attention to characterizing anesthetic binding sites on proteins using X-ray crystallography [49] and, more importantly, tried to develop strategies for identifying which were the relevant protein targets in the central nervous system [3].

Which Proteins in the Central Nervous System Are Relevant Targets?

In the 1990s, the emphasis shifted from the “lipid vs. protein” debate to the question of “which proteins?” For some, this had always been the focus. A decade earlier, Roger Nicoll, Jeff Barker, Bob Macdonald and Richard Olsen had argued that anesthetic-potential of the inhibitory GABA_A receptor was a possible mechanism underlying neuronal inhibition [50]. In 1982, Nicoll and Madison suggested that an unidentified anesthetic-activated potassium channel was a plausible target for inhaled anesthetics [51].

Over the past two-to-three decades, numerous studies examined the effects of diverse anesthetics on putative targets. In 1994, Bill Lieb and I wrote another review, but this time focused on which protein targets were or were not relevant to anesthesia [3]. We concluded that “General anaesthetics are much more selective than is usually appreciated and may act by binding to a small number of targets in the central nervous system.” We highlighted the importance of a few targets including GABA_A receptors, glycine receptors, NMDA receptors and anesthetic-activated potassium channels. Since then, two themes emerged from studies on putative targets. One came from investigations focused on intravenous anesthetics, concluding that these highly selective drugs may act on only a single target. Another theme emerged from (some) investigations of inhaled anesthetics, one that emphasized non-selectivity. It is convenient to tell these two stories separately.

Targets for Intravenous Anesthetics

Definitive work has been done with propofol and etomidate. Electrophysiological studies in the late 1980s, and early 1990s showed that both drugs potently potentiated responses of the GABA_A receptor to GABA [52, 53]. Concurrently, heterologous expression systems such as the *Xenopus* oocyte and the HEK cell line enabled expression and characterization of neuronal ion channels and the effects of general anesthetics. Adron Harris, Neil Harrison and Jerry Lambert vigorously applied this technique, studying receptors with defined subunit compositions *in vitro*. This lovely approach allowed testing of the effect of site-specific mutations of amino acids on anesthetic sensitivity. Two 1997 papers proved most influential. By using chimeric ion channels

composed of sensitive and insensitive forms, followed by site-directed mutagenesis, Adron Harris and Neil Harrison demonstrated that specific amino acids influenced the effects of inhaled anesthetics acting on GABA_A and glycine receptors [54]. The second study by Paul Whiting, Jerry Lambert and colleagues came to the same conclusion for etomidate [55].

For etomidate, the first step was the demonstration that the β subunit plays a critical role [56]. Etomidate has a roughly ten-fold greater effect on GABA_A receptors containing $\beta 2$ or $\beta 3$ subunits versus $\beta 1$ subunits. This 1997 discovery [56] was followed by the discovery [55] that mutation of a single amino acid in the $\beta 3$ subunit (Asn289) to its $\beta 1$ equivalent (Ser) markedly decreased the actions of etomidate. While the sensitivity of GABA_A receptors to etomidate greatly depended upon the type of beta subunit, propofol showed little subunit dependence. Nonetheless, the same mutations in $\beta 2$ or $\beta 3$ subunits affected both anesthetics [57]. This finding led, in 2003, to the production of “knock-in” mice [58, 59] containing mutations in either $\beta 2$ or $\beta 3$ subunits that were expected to render the animals insensitive to etomidate and/or propofol but “normally” sensitive to GABA. The resulting $\beta 3(N265M)$ mice were dramatically resistant to both etomidate and propofol for the anesthetic endpoint of withdrawal from a painful stimulus, but retained their normal sensitivity to alphaxalone. These data reflected the *in vitro* data for sensitivity, and showed that a single target is responsible for this endpoint for etomidate and propofol. But other endpoints (e.g., the duration of loss of righting reflex) were less affected or not affected at all, suggesting that etomidate and propofol had additional targets.

These results demonstrated that $\beta 3$ -containing GABA_A receptors are crucial targets for etomidate and propofol for the loss of response to a painful stimulus and that both $\beta 2$ - and $\beta 3$ -containing GABA_A receptors mediate the loss of righting reflex caused by etomidate. I believe that these fundamental conclusions are sound, although I suspect that the presumed “silence” of the mutations is an oversimplification. Our understanding of how propofol and etomidate act at the molecular level is more advanced than that for any other anesthetic (with the possible exception of dexmedetomidine, which is a highly selective α_2 -adrenergic agonist with anesthetic properties [60]), but our understanding of which targets are important for inhaled agents is much less complete.

Targets for Inhaled Anesthetics

In 1993, Joseph Antognini and Ira Rampil independently made one of the great advances in defining the gross anatomic target of inhaled anesthetics, finding that the spinal cord and not the brain mediated immobility produced by inhaled

anesthetics [61, 62]. A dozen years later, Steve Jinks showed that central pattern generators within the ventral horn of the spinal core were the specific targets [63].

LJS, one of the editors of this book recalls that similar to the initial rejection by *Nature* of Franks and Lieb's paper [40]. The paper by Rampil was also initially rejected for publication by LJS—the then Editor of *Anesthesiology* who responded to the compelling argument by the authors to solicit an additional review, resulting in its publication.

But identification of the definitive molecular targets for inhaled anesthetics has progressed slowly. Since the late 1990s, most of us have assumed that, as with intravenous agents, specific targets must exist. What is not agreed, however, is what these targets are and which ones significantly contribute to particular anesthetic endpoints. While opinions currently differ about how many targets are relevant for inhaled anesthetics, certain ion channels and receptors appear more likely to play a role than others [1, 3, 5, 6].

The 1997 work of Harris and Harrison [54] mentioned above, laid the foundations for a continuing theme of work. They found that specific mutations in GABA_A and glycine receptors could ablate their potentiation by inhaled anesthetics and alcohols. What emerged from a large body of work was a bewildering complexity serving to emphasize how difficult it is to interpret the effects of “simple” alterations to allosteric proteins. Nonetheless, a plausible case emerged for a specific binding site of the GABA_A and glycine receptor for inhaled anesthetics [64]. This work did not directly bear on whether or not these receptors contributed to anesthesia in whole animals. However, because potentiation of GABA_A receptors containing $\beta 2$ and $\beta 3$ subunits was sufficient at least for etomidate and propofol, and because many inhaled anesthetics (e.g. halothane, isoflurane and sevoflurane) potentiated exactly the same receptors (see, e.g. ref. [65]), it seemed reasonable to postulate that this would contribute to the anesthesia caused by these inhaled anesthetics. Because the potentiation caused by volatile anesthetics is usually smaller (typically half) than that observed with etomidate and propofol (at equi-anesthetic concentrations) then GABA_A receptors containing $\beta 2$ and $\beta 3$ subunits cannot be the only target.

Perhaps not surprisingly in view of the low potencies of volatile agents, stereoselectivity has provided less guidance as to which targets are most likely. Nonetheless, stereoselectivity has been observed in animals with isoflurane [66–69] (although this might depend upon the endpoint), and a similar degree of stereoselectivity is found in potentiating the GABA_A receptor [70].

Volatile anesthetics show no absolute requirement for particular GABA_A subunits for their potentiating effects, and generally show little subunit dependence. This may explain why the successful knock-in approach with etomidate (see above) has not proven to be so straightforward for inhaled

agents. Nonetheless, the $\beta 3$ (N265M) mice discussed above show a significant increase in MAC for halothane, enflurane and isoflurane, although no changes in their loss of righting reflex [71]. These data support the idea that GABA_A receptors play some role in the actions of volatile agents although others disagree [72].

While during the last fifteen years, GABA_A receptors have taken center stage, other potential targets have also been investigated. For example, glycine receptors, which are often co-localized with GABA_A receptors, and of particular importance in lower brain centers and the spinal cord, are a plausible target for inhaled agents [73–75]. Glycine receptors can exist as $\alpha\beta$ heteromers or α homomers. Their plausibility as a target is particularly strong for the loss of response to a painful stimulus which appears to be determined predominantly by actions in the spinal cord [5]. In both expression systems [75] and neurons [73, 74], low concentrations for all of the volatile agents potentiated the action of glycine on glycine receptors, but there was no evidence of stereoselectivity [73]. Definitive data, genetic or otherwise, proving the role of glycine receptors in general anesthesia, have yet to be published.

The so-called two-pore-domain potassium channels regulate membrane excitability and thereby provide another plausible target for inhaled general anesthetics. In 1982, Nicol and Madison suggested that inhaled anesthetics might work by activating potassium channels [51] and in 1988, we provided further supporting evidence in identified neurons of the pond snail *Lymnaea stagnalis* [76]. Among the 15 mammalian subunits so far identified, volatile and gaseous anesthetics activated TREK, TASK and TRESK channels, although the activation was anesthetic specific [77, 78].

Data from a knock-out mouse from Michel Lazdunski's laboratory [79] published in 2004 supported a role for TREK-1. This work culminated from a series of studies by Eric Honoré and Amanda Patel and their colleagues [78, 80] showing that TREK-1 was sensitive to diverse inhaled anesthetics. Knock-out increased MAC by less than 10% to nearly 50% and minimally affected the loss of righting reflex. However, the increases in MAC did not correlate with the effect on *in vitro* current in wild-type receptors.

In the past few years, we found that mice lacking TASK channels were significantly less sensitive to anesthetic-induced loss of righting reflex and response to a painful stimulus [81, 82]. Furthermore, selective ablation of TASK channels from cholinergic neurons (including the cholinergic motor neurons of the spinal cord), changed MAC by essentially the same amount as did whole-animal knock-out [81].

As with all knock-out data, one has to be cautious in interpretation because compensatory changes can occur. Data on knock-in animals or on conditional knock-outs where TREK-1 or TASK expression is eliminated only in certain anatomical sites will be required before the data on

knock-out animals can be considered to be the final word on the role of this channel in general anesthesia.

How Many Targets Are Relevant for Inhaled Anesthetics?

During the last fifteen years, two views emerged regarding the number of plausible targets for inhaled anesthetics: one believed that only a few targets were important (Eger and I are in this camp [3, 83]) and the other believed that anesthesia resulted from small effects at many targets [84].

The use of inappropriately high concentrations for *in vitro* experiments has long been a problem in this field. Many experimenters have used aqueous concentrations of anesthetics without translating them to gas phase concentrations reflecting activity. This is surprising, given the widespread acceptance of MAC as a precise measure of anesthetic potency for inhaled anesthetics [85]. An added complication has been that many *in vitro* experiments were conducted at room temperature whereas anesthetic potencies were usually established (for mammals) at 37°C. Because MAC decreases with decreasing temperature [27, 28], this means that these gas-phase concentrations were excessive for room-temperature experiments, leading to the perception that more targets were “sensitive”, and therefore relevant, than is probably the case.

Another argument invoked by Eger in particular, has been that one should be able to test the importance of any given target by testing how anesthetic potency changes when that target has been perturbed in some way (modified by a knock-in or inhibited by another drug, for example). This systematic approach over the last several decades has tended to conclude that no single target is particularly important. The results with this approach may be particularly convincing where a receptor has been removed or blocked without affecting MAC (i.e., a negative result). Two examples: In 1978, Marilyn Harper with Eger showed that a wide range of opioid antagonist doses have no effect on MAC, indicating that opioid receptors do not mediate the immobility produced by inhaled anesthetics [86]. Similar studies using blockers in 2002 indicated that acetylcholine receptors were irrelevant to inhaled anesthetic-induced immobility [87]. This last study illustrates the importance of the anesthetic endpoint to the issue of mechanisms. Acetylcholine receptors do not mediate the immobility produced by inhaled anesthetics but may have a great deal to do with the mediation of the amnesia produced by inhaled anesthetics. Inhaled anesthetics potentially block transmission at acetylcholine receptors at sub-MAC concentrations [88, 89]. Overall, these results were consistent with the more profound clinical effect of inhaled anesthetics on memory than on immobility.

But what about studies that might not produce a definitively negative result? The problem is that, if more than three or four targets are involved, then perturbing only one of them by, say, knockout may cause too small a change in potency to be measured against a control animal whose baseline

excitability has, almost inevitably, been disrupted. Eger might respond by arguing that at least for MAC, differences of 10% can be defined with relatively few animals, as few as five to ten, arguing further that changes in baseline activity can be dealt with by assuring that the control and knockout animals only differ in the specific receptor knocked out.

The question of the exact number of targets for inhaled anesthetics remains an open one although I retain my prejudice, based in part on Occam’s Razor, that a small number of targets is most likely. (Although I hear the warning of Bill Paton—“God does not shave with Occam’s Razor”.)

And what if...?

Over the past three decades, mainstream thinking has shifted from lipid to protein theories of narcosis, from membrane bilayers to protein receptors and channels. For some injected anesthetics (etomidate and propofol and opioids and dexmedetomidine), the proof that a single protein can explain most of the narcotic effect seems overwhelming. Less clear is whether a few or many proteins mediate particular inhaled anesthetic endpoints. A few voices in the wilderness would have us return to the days of yesteryear, to a lipid theory of narcosis. In 2003, Robert Cantor argued that in addition to binding to and activating their receptors, neurotransmitters modulate their receptors by an action on the adjacent membrane [90]. He postulated that anesthetics might act by mimicking the membrane-based non-specific effect of neurotransmitters. In 2007, Jim Sonner’s group provided results consistent with Cantor’s notion [91]. The group found that applying GABA to glycine receptors at GABA concentrations that had little or no direct effect on the glycine receptors, nonetheless potentiated the effect of glycine by over 100%. The reverse also was true: glycine potentiated the effect of GABA on GABA_A receptors. And finally, background acetylcholine concentrations that did not affect NMDA receptor currents decreased the current produced by glutamate (plus glycine) application by up to 50%. Others have argued [92], however, that the actions of GABA on glycine receptors is simply accounted for by GABA binding directly to the glycine receptor and acting as a weak agonist. No doubt future work will establish exactly how one neurotransmitter can affect the actions of another and hence determine whether or not these observations have any relevance to anesthetic mechanisms.

Combatants and Collaborators

Before making some final remarks, I want to mention some important drivers of the research into anesthetic mechanisms, at least during the time that I have been involved. I believe that the polarization of a field into two opposing

camps (such as lipid vs. protein) can be highly productive. Notwithstanding its potential dangers, Bill Lieb and I have had great fun sparring with Keith Miller and many others. It was usually good natured and respectful. In contrast to this combative spirit which I have tended to adopt, others have taken a more collaborative approach (and the one does not exclude the other). A notable example has been the series of Anesthetic Mechanisms conferences started by Raymond Fink and which grew into the international conferences that continue to this day. Ray was a remarkable individual who single-handedly organized the first few meetings before they were taken on by others, particularly Sheldon Roth and Keith Miller. I recall Ray telling me towards the end of his long life, with tears in his eyes, how the death of a young patient of his in South Africa during World War II, was the catalyst for him to understand the scientific basis of his practice as well as he could. The “Fink Meetings” as I think of them, are one of his many legacies. Other examples of the collaborative approach were the large Program Project Grants on anesthetic mechanisms funded by the US National Institutes of Health. The Programs of Miller, Evers, Eckenhoff, Lynch and Eger have been collaborative enterprises that have had a major impact on our understanding of how anesthetics act. Collectively these brought together some of the best workers in the field and spawned countless novel approaches and collaborations. I was fortunate to be an occasional visitor to the meetings of Principal Investigators on the Program, organized by Eger, which was aimed at understanding inhalational anesthesia. This group was an eclectic mix of scientists including mainstream neuroscientists as well as chemists and physical chemists, some of whom still held the torch for lipid-based theories. Eger was there as the ringmaster to challenge and cajole.

Final Remarks

In this chapter I have focused on molecular mechanisms of anesthesia, mainly because this aspect of anesthesia has fascinated me most, but also because it has been the main focus of the field during the last 50 years. Many questions remain to be answered at the molecular level: which targets are *really* important for inhaled anesthetics, where are the molecular binding sites on the relevant receptors, and how does binding translate into changed channel function, to name but three. The long-awaited publication [93] of a crystal structure of general anesthetics (sevoflurane and propofol) binding to a transmembrane receptor was, at least for me, a crucial landmark along the road towards understanding anesthetic action at a molecular level. While this work at the molecular level will take its course, attention in the field of anesthetic mechanisms is beginning to shift once again. If anesthetics act at a limited number of protein targets, then it is reasonable to

ask whether this specificity extends to the level of neuronal networks. This will, I'm sure, be a main focus of research in the next decade and beyond, with the ultimate goal of identifying the neuronal networks in the brain and spinal cord that mediate anesthetic endpoints ranging from amnesia, to unconsciousness, to immobility.

Acknowledgement Although this chapter only bears my name, I want to acknowledge the many contributions and suggestions made by the Editors (particularly Ted Eger).

Ron Jones

Summary

Valerius Cordus synthesized diethyl ether in 1540 and shortly thereafter Theophrastus Bombastus von Hohenheim (Paracelsus) noted that it could diminish pain. Priestley synthesized nitrous oxide in 1774, and in 1800, Davy found that it decreased pain and suggested its use for surgery. In the 1820s, Hickman advanced the notion of anesthesia, but Davy quashed Hickman's idea. Von Liebig synthesized chloroform in 1831.

The recreational use of diethyl ether and nitrous oxide and a desire to eliminate the pain of surgery, initially led to unsuccessful (nitrous oxide) demonstrations or unreported use in patients undergoing surgery. Long's experience with ether in 1842 is as famous as his failure to publicize the discovery. Anesthesia was born on 16 Oct 1846 (Ether Day) with Morton's public demonstration of ether anesthesia. Simpson's 1847 discovery of the anesthetic effects of chloroform followed. Nitrous oxide (restored to favor in the 1860s) and ether combined with oxygen provided anesthesia for a century, with modest competition in the 1930s to 1950s from divinyl ether, cyclopropane and trichloroethylene.

World War II advances in fluorine chemistry enabled development of compounds halogenated with fluorine to eliminate flammability. The major advance was Suckling's synthesis of halothane in the early 1950s. Released for clinical use in the mid-1950s, halothane swept away its pungent, toxic, flammable predecessors, dominating anesthesia for more than a decade. Its use in newly developed vaporizers (Copper Kettle and Fluotec) allowed the precise control of anesthetic concentrations, contributing to its safety and popularity.

World War II also gave birth to methods, particularly the infrared analyzer, to continuously analyze inhaled anesthetics. This facilitated the measurement of the Minimum Alveolar Concentration (MAC) required to eliminate movement in response to noxious stimulation in 50% of subjects, an anesthetic EC50.

Halothane was less than perfect. It caused a rare, immunologically-based and potentially fatal hepatic injury. This spurred the synthesis of progressively less metabolized, less toxic, and less soluble (faster recovery) anesthetics. Enflurane came first, and displaced halothane in the US in the 1970s. However, enflurane could cause convulsions and in the 1980s, isoflurane, a compound less soluble and without convulsant properties, replaced enflurane. The rise of ambulatory, day case surgery in the 1980s increased the demand for more rapid awakening from anesthesia, and the 1990s saw the release of the poorly soluble anesthetics, sevoflurane and desflurane.

Two decades have passed since the clinical release of a new inhaled anesthetic. What we have is very good, but it seems wrong to stop just short of perfect.

The Foundations Are Laid: Why Ether?

Ether Day, 16 Oct 1846, introduced anesthesia to the world. It had to be ether—and nitrous oxide and chloroform—all inhaled anesthetics, because no useful alternative existed. Drugs that might produce anesthesia by intravenous delivery either did not exist or were too dangerous in their actions. Furthermore, the hypodermic syringe had yet to be invented. What about swallowed drugs? Ingestion of opium could de-

crease pain, but ingestion sufficient to minimize the pain of surgery would stop breathing. Alcohol also could produce insensibility, but control over its dosing was too crude. The patient ingesting too little might have an exaggerated response to stimulation (surgery), and the patient ingesting too much might die. And once inebriation set in, one could not add more or subtract from what had been given. No, inhaled anesthetics, especially ether or chloroform were the only possibility. Their application required no complicated device; a handkerchief would do. And their effect could be controlled. The anesthetist could give more to produce a greater effect, or stop administration and the patient would eliminate the anesthetic by breathing. As long as the anesthetic hadn't stopped the patient from breathing, the anesthetic would float away.

The Age of Enlightenment

But why 16 Oct 1846? Part of the answer may lie in the social, theological, and scientific circumstances of the late eighteenth and early nineteenth centuries—the Age of Enlightenment. The Age of Enlightenment was the name given to the eighteenth century philosophical movement that placed greater emphasis on reason and observation than on tradition and theological dogma. This movement profoundly influenced later eighteenth and early nineteenth century science. No idea, no belief was exempt from scrutiny, making Western Civilization the tolerant, science and idea based society it is today.

The humanist philosophers of the Enlightenment such as Jeremy Bentham, David Hume, and Voltaire questioned the moral basis of many accepted practices including religion, slavery, and cruelty. Bentham (1748–1832) helped found London University and University College, London. After his death, his clothed skeleton was fitted with a wax model of his head and kept in a glass fronted cabinet at University College, his natural but shrunken head being placed at his feet. To this day, during meetings of the College Council, the cabinet's door is opened so that his spirit can be present. Bentham stated: “*The greatest happiness of the greatest number is the foundation of morals and legislation.*” And “*Nature has placed mankind under the governance of two sovereign masters, pain and pleasure*” [1].

At the end of the eighteenth century, few accepted the notion that sensation could be abolished without endangering life. From a scientific perspective, pain was viewed as an essential aspect of physiology and necessary to healing. And in Christian theology pain entered the world after Eve's disobedience in the Garden of Eden. Thus, the philosophical advances of the Enlightenment conflicted with scientific and theological paradigms. Enlightenment philosophers abhorred pain and suffering whereas scientific and religious thinking accepted pain as a necessary part of life. The late Emanuel (Manny) Papper, of the University of Miami, summed up this crucial change in social attitudes in this way. “*The discovery of anesthesia required the flowering of the view that the individual was important and deserved to have happiness. If only the group was important, the suffering of individuals was not and anesthesia was not something to be sought*” [2].

Studies of the anatomy and physiology of the nervous system, at the beginning of the nineteenth century, engendered a change in the attitude of science. Charles Bell and Francois Magendie established that specific parts of the brain controlled specific functions, that different nerves conducted sensation versus movement, and that vital functions (e.g., of the heart and lungs) were governed independently. If pain was a process independent from vital functions, then pain might be abolished without affecting vital functions, a belief required to make a search for anesthesia reasonable.

The Birmingham Lunar Society

At this time of changing scientific, moral and social attitudes toward pain and suffering, three individuals laid the foundations needed for the subsequent development of inhaled anesthetics; the scientist Joseph Priestley, the physician Thomas Beddoes and the philosopher and social reformer Jeremy Bentham, noted above. All were members of the Birmingham Lunar Society, so named because meetings were held at the time of the full moon, so that afterwards its members could better navigate their way home. Its diverse membership included James Watt (the steam engine), Josiah Wedgewood (pottery), Samuel Taylor Coleridge (poet) and Erasmus Darwin, grandfather of Charles.

The Birmingham Lunar Society financially supported Joseph Priestley (1733–1804), famed for his 1770s discoveries of oxygen and nitrous oxide. Priestley termed what the French chemist Lavoisier later called oxygen, ‘dephlogisticated air’. Lavoisier was guillotined in 1797, after the French Revolution. The politically radical Priestley vigorously supported the Revolution. His attitude later forced him to flee his hometown and eventually, his country. Thus, the French revolution significantly altered the lives of both these pioneers of chemistry, pioneers linked by oxygen.

Joseph Priestley, from the English county of Yorkshire, was a scientist and radical political thinker (his application to join Captain James Cook's 1772 Antarctic expedition was rejected because of his political and religious views). He influenced, and in turn was influenced by Bentham. Priestley produced nitrous oxide—or ‘gaseous oxyd of azote’—in 1772, by exposing nitric oxide to a mixture of iron filings, sulfur and water. He noted that nitrous oxide delayed decay of animal tissues (perhaps by excluding oxygen), a potentially useful finding in an age of no refrigeration. He also suggested that “*...considerable use might be made of it in medicine...*” [3]. Later he became a correspondent and friend of Benjamin Franklin. On the second anniversary of the fall of the Bastille, his political sympathies led a Royalist mob to ransack his home, library and scientific apparatus, and he fled to London. Ostracized by his scientific colleagues, he left Britain in 1794 to join his sons in Northumberland, Pennsylvania and took up farming. Hilaire Belloc, the poet and historian, was a great-grandson.

Beddoes, Davy, and the Pneumatic Institution

Like Priestley, Thomas Beddoes (1760–1808) had radical political and social views and supported the French Revolution. He was of short stature, short temper and large girth. In the latter part of the eighteenth century, pneumatic medicine came into vogue. Various gases were given by various routes, including as enemas, in the hope of some therapeutic action.

Beddoes' radical views were not well received in conservative Oxford where he lectured in chemistry, so he moved to Bristol which had a reputation for tolerance. With the financial support of the Lunar Society, he founded the Pneumatic Medical Institution intent on investigating the medicinal effects of gases, including nitrous oxide, particularly on tuberculosis. In 1798, Beddoes recruited as his assistant, a young apothecary's apprentice from Cornwall, *Humphrey Davy*, who at age 20 started to experiment on himself with nitrous oxide.

By 1800, Beddoes and Davy had demonstrated both euphoric and analgesic effects of nitrous oxide. Members of the Lunar Society, including the poet, Samuel Coleridge, and Peter Roget, famous for his *Thesaurus*, visited the Institute to breathe nitrous oxide. Coleridge, known for his supernatural poems, '*The Rime of the Ancient Mariner*' and '*Kubla Khan*' inhaled nitrous oxide at the Pneumatic Institute and observed: "*I had recollections of such unmingled pleasure than I ever had before experienced*". This observation probably relates to the lack of hangover effects associated with nitrous oxide compared with opium—to which he was addicted.

Davy (1778–1829) found that nitrous oxide could relieve the pain of toothache and stated: "*As nitrous oxide in its extensive operation appears capable of destroying physical pain, it may probably be used with advantage during surgical operations in which no great effusion of blood takes place* [4]." Davy was a hands-on scientist who studied the effects of nitrous oxide on himself. In one experiment he was put into a box-like chamber whilst an assistant added aliquots of nitrous oxide. His lively description of the effects of the gas need to be interpreted in the light of the fact that oxygen was not co-administered [5]. Thus everything was in place in 1800 for the emergence of anesthesia. Yet nearly 50 years passed before Davy's prediction became reality. Why? In 1960, writing about the first 100 years of anesthesia, WS Sykes commented: "*What is surprising is that (Davy's) suggestion was ignored by the very people whom it should have interested most: that surgeons should have continued for nearly fifty years longer to operate on screaming, struggling patients in full consciousness. Surely a lasting testimonial to their thickheadedness*" [6].

Davy left the Pneumatic Institute in 1801. He was politically conventional and became a respected part of the British scientific establishment. He subsequently made a negative contribution to the development of inhaled anesthetics, by his unenthusiastic reception of a communication sent to the Royal Society, of whom he was a sometime President, a communication from a Shropshire doctor, Henry Hill Hickman.

The Sorry Story of Henry Hickman

While in Shifnal, Shropshire, Beddoes birthplace, Hickman (1800–1830) became interested in Pneumatic Medicine. He

was thus aware of the work of Beddoes and Davy (who later contributed to his undoing). Driven by a desire to relieve pain during surgery, Hickman experimented on the '*torpid state*' or suspended animation caused by inhalation of carbon dioxide. Despite some success in relieving pain during surgery in animals under the '*torpid state*', the largely London based scientific and medical establishments of the day did not accept his views. In 1824, he wrote to the Royal Society: "*...something has not been thought of whereby the fears (of the patient) may not be tranquilized and suffering relieved*" [7]. The snub given by Humphrey Davy and others may be explained in parochial terms. Shropshire is a rural county, which many Englishmen would be hard pressed to place. Undeterred, Hickman took his claims of pain free surgery to the French '*Academie Royale de Medicine*', France, having at the time a reputation for medical innovation. But he fared no better with that medical establishment. Rejected and depressed, Hickman committed suicide in 1830, at age 31. Whether his studies were relevant remains unclear (administration of carbon dioxide can cause anesthesia, but the concentrations needed could compromise oxygen delivery). His importance lay in his view of pain-free surgery as an achievable goal.

Everything Comes Together: The 1840s in the United States

Coleridge's dependence on opium was not unusual for his time. In Europe and America, the recreational use of drugs was relatively common. Recall the parties at the Bristol Pneumatic Institution where nitrous oxide was inhaled for its euphoric effects. So popular was nitrous oxide that in some circles it replaced champagne. One visitor at such a party, skeptical of the effects of the gas breathed '*quite a sufficiency*' and: "*...he began to dance and devastate the adjoining flower-bed in his ecstasy* [8]." And there is a parallel in diethyl ether ("*ether*"), synthesized in 1540 by Valerius Cordus. Ether was sold by chemists as '*sweet (oil of) vitriol*' and used, like nitrous oxide, as a recreational drug ('*ether frolics*'). Now to Crawford Long in rural Georgia, in a small town called Jefferson.

Crawford Long and Ether-Sniffing in Jefferson, Georgia, 1842

Crawford Long (1815–1878), a native of Jefferson Georgia, studied medicine at the University of Pennsylvania. He attended ether frolics as a student and in the early 1840s introduced such frolics to the citizens of Jefferson, including his friend and patient, James Venable. Long purchased ether from a pharmacist in Athens, Georgia, Robert Goodman, and

anecdotally, Long told Goodman in November 1841, that pain free surgery might be possible after inhaling ether [9].

Venable complained of a large cyst on his neck, wanting it removed but fearful of the pain that removal would cause. Long, appreciating the analgesic effects of ether, reportedly advised: “*Breathe ether then I’ll cut off the cyst*” [10]. Familiarity with ether sniffing made Venable receptive to the suggestion. Thus, on 30 March 1842, the date usually taken as that of the first successful general anesthetic in a human, Long removed Venable’s cyst without pain. Long remembered:

“When giving it to Venable, with one hand I held the towel over his mouth and nose permitting him to breathe a little air as he inhaled the drug; my other hand I kept on his pulse. When he became insensible to the prick of a pin I operated. As an inducement to Venable to allow himself to be the subject of the experiment, my charge for the operation was nominal, \$2.00 Ether; 25 cents” [9].

Although the date, 30 March 1842, is generally acknowledged to be that of the first successful use of ether in surgery, there is a report that in January of that year William Clarke, a medical student from Rochester, New York, and a regular ether sniffer, used ether during a dental extraction, the patient being Miss Hobbie and the dentist, Elijah Pope [11].

Although Long used ether several times in ensuing years he did not publicize his achievements. By the time (1849) he told the world, Boston had seen successful public demonstrations of general anesthesia. Long comes off well in this history. Modestly, he never claimed to be the one who should have been given credit for the discovery of anesthesia. He died a happy man.

Colton, Wells, and the Grand Exhibition at Union Hall, Hartford, 10 Dec 1844

Gardner Colton, a medical student at Columbia University, sought to subsidize his medical career with exhibitions of the inebriating effects of nitrous oxide, one such in Hartford Connecticut in December 1844. A local dentist, Horace Wells (1815–1848), attended the exhibition, as did a Samuel Cooley, who, under the influence of nitrous oxide, ran against a bench and cut his leg. Wells noticed that Cooley did not appear to feel any pain from his collision with the bench, and Cooley confirmed Wells’ observation.

Wells wished to enlarge his practice by providing pain-free dentistry. Wells had an abscessed tooth and persuaded Colton to bring a bag of nitrous oxide to Wells’ office the next day. Wells breathed the nitrous oxide, and while under its influence, a colleague, John Riggs, painlessly (according to Wells) extracted the abscessed tooth. Wells subsequently experimented with the manufacture and use of nitrous oxide in his dental practice with uneven success. Undaunted, he ar-

anged to demonstrate the anesthetic effects of nitrous oxide before the faculty and students of Harvard University, including the surgeon in chief of the Massachusetts General Hospital, John Collins Warren. A student agreed to have a tooth extracted, but the demonstration was less than successful. According to Wells, he removed the mask too soon. The student groaned toward the end of the extraction and this was taken as a failure by an audience all too ready to label the experiment unsuccessful. Wells “*heard the word ‘Humbug’ called out over and over again*” [12].” He later wrote that “*...several expressed their opinion that it was a humbug affair (which in fact was all the thanks I got for this gratuitous service)...*” [12]. Wells never recovered from this failure and died, a suicide in January 1848.

Wells’ failure demonstrates a fundamental problem of nitrous oxide anesthesia; limited potency. By itself, it is a weak anesthetic or in modern parlance, the minimum alveolar concentration needed for anesthesia is 105%—more than can be obtained at sea level [13]. Thus, used alone it is at the limits of its ability to produce anesthesia, as Wells in front of his skeptical audience, found to his cost. And, when given at 100% of an atmosphere (the greatest partial pressure possible at sea level), part of the effect is not anesthesia but lack of oxygen. Indeed, a pupil of Claude Bernard’s in Paris, Paul Bert, understood that 100% nitrous oxide could not be administered without causing hypoxia and undertook animal studies conducted in a hyperbaric chamber, a technique that was then used in patients, but was too cumbersome for routine use [14].

Morton, Jackson, and Anesthesia. Who Made the discovery?

William GT Morton (1819–1868) had been a student and then partner of Wells. In their partnership they used a solder invented by Riggs (the dentist who extracted Wells’ tooth on 11 December 1844) in the manufacture of an improved denture. The solder used by Wells, Morton and Riggs was endorsed by a well known Boston physician, Charles Jackson (1805–1880), with whom Morton was destined to disagree over who should be acknowledged as the discoverer of anesthesia.

Morton was present at Wells’ failed attempt to demonstrate nitrous oxide anesthesia in 1844, and was convinced that the principle was sound. Greed prompted him to continue pursuit of pain free dental surgery. Advances in dental techniques had introduced far superior artificial teeth but fitting them necessitated the removal of not only the stumps and remnants of the originals but also their roots. Many patients could not bear the pain and fled before completion of the surgery. Morton knew about Wells’ work with nitrous oxide and had heard first hand, accounts of its efficacy from

his patients. So Morton discussed the matter further with his colleague Charles Jackson. Jackson suggested to Morton that ether could produce some numbing effect if applied around a tooth to be extracted, not realizing that inhalation of the vaporized ether would be the cause of the “numbing”. Morton experimented with the use of ether in animals and on himself, and extracted the tooth of Eben Frost in his Boston office on 30 September 1846. Morton subsequently undertook several extractions successfully with ether, and like Wells, sought to demonstrate his finding publicly [15].

Henry Bigelow, a surgeon at the Massachusetts General Hospital, had read about Morton’s activities and had witnessed extractions under ether. He arranged with Warren (who had witnessed Wells’ failed attempt to demonstrate anesthesia with nitrous oxide) a parallel attempt using ether on 16 October 1846, Ether Day. Warren was one time Dean of Harvard Medical School and founder, with others, of the Massachusetts General Hospital in 1821. He initiated the Boston Medical and Surgical Journal which became the New England Journal of Medicine.

The patient, Gilbert Abbott had an arterio-venous malformation in his neck. But Morton’s apparatus for administering ether was not quite ready and Morton was tardy. Warren was losing patience when Morton arrived with his apparatus, a glass flask with two necks and a sponge contained within the flask. The sponge ensured the saturation of the air breathed by Abbott with ether vapor, and prevented the aspiration of liquid ether. Warren testily remarked: “Your patient is ready, sir!” Morton had Abbott breathe the ether for a few minutes, and then returned Warren’s comment, word for word. The operation began, initially with no response from Abbott. As with the attempted demonstration of anesthesia with nitrous oxide, toward the end of surgery Abbott moved and vocalized but when asked afterwards, he confirmed that he had felt no pain. Warren then supposedly provided the most famous quotation in anesthesia: “*Gentlemen, this is no humbug*”. Abbott stayed in hospital nearly two months after the surgery. A century and a half later he would have left that day.

Superficially, Morton’s demonstration was no more successful than that of Wells two years earlier. But Morton was a greater extrovert, he was not as rushed, and he used an agent that was more potent and had a longer lasting effect—being 25 times more soluble in blood than nitrous oxide [16, 17]. He supplied anesthesia for a longer procedure. And in Henry Bigelow, he had the backing of a member of the Boston medical establishment. A second demonstration on the following day, using a slightly modified apparatus, was also successful and the world, or at least the Boston medical world, was convinced of Morton’s discovery. From November onwards, ether was used extensively in Boston and environs.

Morton and Jackson disputed who discovered anesthesia. The details are complex and do not appreciably add to this

narrative. The underlying motivations appear to have been Morton’s longing for a fortune (greed) and Jackson’s enormous ego. Clever Charles Jackson graduated with honors from Harvard University in 1829. He became a prominent geologist, hard working and ambitious. Ambition led him to pursue imaginative, perhaps inappropriate, methods to enhance his reputation. An example: Traveling by ship from France to America in 1832, Jackson met Samuel Morse, an American portrait painter who was also interested in the electric telegraph. Morse devised a code to be transmitted by electromagnetic relays. The American Congress gave Morse financial support. In 1843, a line was constructed from Washington DC to Baltimore. The famous message: “*What hath God Wrought*” was sent on 24 May 1844 using his system of dots and dashes. Imagine Morse’s surprise to find in a Boston paper: “...*that the electro-magnetic telegraph which SFB Morse of New York claims to have made, was really made by our fellow citizen Charles T Jackson*”. It took several years for Morse to correct the situation just as it took several years for Morton to be recognized as the discoverer of *etherization* for pain free surgery. After Morton’s death, Jackson became possessed with what he saw as his just and rightful recognition. But the momentum of history, and probably justice, conspired against him. Jackson ended his days in an institution for the mentally insane, perhaps brooding on the injustices heaped upon him by Morse, Morton, and the world in general.

Although Morton is generally credited with the discovery, he never made the fortune he had hoped might be his. He tried to publicize his cause in 1847, by administering ether to American soldiers fighting Mexicans off the port of Vera Cruz, and to soldiers at the battles of Fredericksburg (December 1862) and Wilderness (May 1864), just a few years before his death in 1868. He hoped to receive a \$100,000 award from the US Congress, but Congress happily did nothing, finding that several citizens (Wells, Jackson, and Morton) had made conflicting claims. In addition, the US Civil War preoccupied Congress much of the time.

Oliver Wendell Holmes Coins “Anaesthesia”

And what of the word “Anesthesia”? The professor of Anatomy and one time Dean of Harvard Medical School was Oliver Wendell Holmes, better known today as an essayist. From the Greek for sensation, *aesthesia*, he christened this new phenomenon ‘*anaesthesia*’, or lack of sensation. The first Academic Department in our specialty in the UK was at Oxford University. The then University Registrar, Sir Douglas Beale, told the Chair, Robert Macintosh, that the Department would be named ‘*Anaesthetics*’ to be consistent with *politics* and *economics*. The linguistic authority, Peter Cuff, Vice Regent of Pembroke College Oxford, noted that

the word ‘Anaesthesia’ meant loss of feeling. He added...“*I cannot see how it would be right to have a professor of that state, any more than a Professor of Amnesia.*” He went on to review alternatives: “*Anaesthesiology: the subject and practice of Anaesthesia and Anaesthetics. The word first occurs in Steadman’s Medical Dictionary 1914*”. Cuff continued to state that the term ‘Anaesthesiology’ was too clumsy and recent for Oxford.

News Travels to Liverpool

News of Morton’s discovery traveled fast. A wooden paddle steamer of the Cunard Line, the ‘*Acadia*’, arrived with the news in Liverpool on December 16, providing the basis for an account of Morton’s use of ether that was reported in the Liverpool Mercury. The ship’s surgeon, William Fraser, went home to Dumfries where his news prompted the use of ether for setting a leg fracture on 19 December. On that day, the American physician Francis Boott, living in London, received a letter from Henry Bigelow, describing Morton’s ‘discovery’, carried aboard the *Acadia*. He convinced a dentist, James Robinson, to give ether to his niece, a Miss Lonsdale, for a molar extraction. After Robinson’s successful painless extraction, Boott persuaded the Professor of Surgery at University College Hospital, Robert Liston, to operate using ether. On 21 December, a medical student, William Squire, provided ether anesthesia to Frederick Churchill while Liston uneventfully amputated Churchill’s leg. Liston commented that: “*This Yankee Dodge, gentlemen, beats mesmerism hollow*”. The operation provoked considerable publicity and ether’s role in the UK was assured.

It is noteworthy that Liston immediately compared ether anesthesia with mesmerism. Mesmeric anesthesia was practiced widely in Europe and the US in the nineteenth century, and its followers did not take well to the introduction of etherization. Introduced by Austrian, Franz Anton Mesmer (described as stubborn, secretive, an opportunist and plagiarist) [18], mesmerism was a mystical ‘science’ in which the practitioner placed himself between energizing heavenly ‘fluidism’ and human disease. John Elliotson was a proponent of mesmeric anesthesia and editor of ‘*Zoist*’ *A Journal of Cerebral Physiology and Mesmerism and Their Applications to Human Welfare*. *Zoist* was published until 1855. Mesmeric anesthesia had a strong following in the Southern US. That popularity may have contributed to Long’s reluctance to advertise his activities.

The use of ether anesthesia spread well beyond the US and the UK. Here is an example concerning the first anesthetic given in Singapore in August 1847.

“On Monday last Kling (Indian) boatman was brought to Mr Little, Surgeon, with a large splinter of wood run in his hand, and suffering much pain. Mr Little tried to extract the splinter

by several means during which poor Kling suffered much pain. So Little resolved to try ether as this appeared a good case to test its powers. The man’s own hubble-bubble was then brought, into which a few ounces of Ether were poured. Mr Little then closed Kling’s nostrils by means of a flat letter clip and asked the patient to inhale the ether from his hubble-bubble. After extensive surgery, during which Mr Kling was quite insensible the paper clip was removed from the patient’s nose and water thrown in his face. Kling declared he had felt no pain and was much struck with the sight of his bandaged hand” [19].

Ether had limitations however. Being highly soluble in blood and pungent, it produced a slow onset of anesthesia, often marred by excitement. Therefore, some skill was needed in its successful administration, a skill that many surgeons lacked, and presumably such individuals may have abandoned its use. However, John Snow (1813–1858), the first specialist anesthetist, reported that he did not have a single failure administering ether anesthesia. Snow’s safe use of ether doubtless stems from his scientific background in chemistry and physiology as well as being one of the first to recognize the importance of the use of an inhaler for its quantitative delivery, as opposed to the ‘rag and bottle’ approach which delivered an unknown concentration. Still, the quest for a less pungent agent continued. Here we leave America, with the principal protagonists in bitter dispute about priority, committing suicide or going mad, and travel back across the Atlantic to the sober capital of Scotland, Edinburgh.

Simpson, Snow, and Chloroform

In 1831, von Liebig in Germany described a new compound called ‘perchloride of formyl’. Dumas termed it chloroform in 1834. Chloroform (CHCl₃) was used, like nitrous oxide and ether, as a recreational drug. Horace Wells’ addiction to chloroform played a part in his suicide. However, social uses played no part in its discovery as an anesthetic. James Simpson (1811–1870), nicknamed ‘Young’ because of his youthful appearance, was Professor of Midwifery in Edinburgh. He used ether on 17 January 1847, at the Edinburgh Infirmary, to relieve the pain of labor. Because of its slow onset of action, ether seemed less than optimum to Simpson—who began a search for a less pungent alternative.

Simpson sequestered a variety of liquid compounds in an oak dresser in his morning room at 52 Queen Street, Edinburgh. Among these was chloroform, which his colleague, James Waldie, had recently synthesized in Liverpool. From June 1847, Simpson and his associates, including James Duncan, would breathe the vapors from the bottles in the oak dresser. On 4 November, Duncan was at the bottles and reported to his sister that he: “...*found himself awakening slowly and pleasantly from an unconscious sleep, which the timepiece showed must have lasted about quarter of an hour*

[20].” That night Simpson, Duncan and another colleague, Thomas Keith, filled their glasses with the pleasant smelling liquid and after a brief period of disinhibition and excitement, narcosis intervened. Simpson awoke to exclaim: “*This is far stronger and better than ether*”. The next day Simpson used this stronger and better agent successfully to relieve pain during labor. By 10 November, he had compiled sufficient successful cases to report to the Edinburgh Medical and Chirurgical Society, and on 15 November he published a paper; ‘*On a new anaesthetic agent, more efficient than sulphuric ether*’, which sold 4,000 copies.

The Duchess of Sutherland sent one copy to Queen Victoria, and Snow soon started using chloroform. Snow presciently observed: “*It certainly has greater advantages for patients but greater care is necessary in its use to avoid accidents* [21].” Victoria requested chloroform for the birth of two of her children.

It is a myth that the Church had staunchly opposed chloroform’s use during childbirth on theological grounds [e.g., “*In sorrow thou shalt bring forth children*” (Genesis iii, 16)] until Victoria’s use in childbirth subdued the opposition. Derek Farr, a student of Colin Russell of the Open University in England, searched for documents indicating that the Church objected to pain free labor. He found little supporting evidence. Explanations for the myth were presented at the 8th Priestley Conference at the Royal Society of Chemistry in London, on 22–24 April 1997 [22]. Opposition to anesthesia for laboring woman came from the medical community, often disguised in religious terms. Reasons for opposition may have varied from honestly held physiological objections—pain is necessary for effective labor—to less charitable interpretations. No objector was a woman.

By Christmas of 1847, chloroform featured in children’s pantomimes, and in 1849, the first of several chloroform muggings were reported by ‘HN’ in the Times (of London) newspaper. With respect to an elderly relative of his: “*Coming round after an agreeable dream, he hazily recollected three men. His purse, keys, spectacles, and gold eye glass were gone and his pockets ransacked*” [23].

Chloroform Kills

We know now that chloroform has potent cardiovascular effects, can cause the heart to beat erratically, and may lethally damage the liver and kidney. In October 1847, 15 year old Hannah Greener had a toenail removed under ether anesthesia. Illegitimate and abused, Hannah led a hard life and had long suffered from painful feet. On 28 January 1848, she had another toenail removed, but this time chloroform was used. Within moments of breathing chloroform, Hannah was dead. The Times reported her death, the first of many associ-

ated with chloroform anesthesia [24]. After a post-mortem enquiry, the jury concluded that: “*Hannah Greener died of congestion of the lungs produced by the direct effects of chloroform*.” The true cause of death cannot be known, but it is likely that she died from the tendency of chloroform to cause cardiac arrhythmias. Vomiting and aspiration of vomit offer another possibility.

The ease of use by the non-trained, the ‘*rag and bottle*’ method, whereby chloroform was dropped onto a simple face mask or a handkerchief, made chloroform popular. (My father, not a specialist anesthetist, used chloroform frequently by this method aboard the World War II cruiser HMS Belfast, now moored near Tower Bridge on the river Thames. It is worth a visit as the old ‘sick bay’, complete with operating theatre and anesthetic equipment is well preserved.)

Simpson and Snow disagreed on why patients died during or after chloroform, citing either its respiratory or cardiac effects. And they disagreed on how to give it. Simpson argued that: “*Inhaling instruments frighten patients, whilst the handkerchief does not* [25].” Snow advocated inhalers as safer because of the control offered over delivered chloroform concentrations. Although Snow was correct, their disagreements outlasted both of them.

The greatest protagonist for the safety of chloroform given by simple means was Lieutenant-Colonel Edward Lawrie (1846–1915). As the senior medical officer and driving force for sixteen years, at the medical school in Hyderabad, he followed unfailingly, the teachings of his hero and former chief, Professor James Syme (1799–1870). While most of the profession concerned about the deaths from chloroform argued that the cause was cardiac, Lawrie maintained that the cause was asphyxia or overdose. The findings of the first (1888) and second Hyderabad commissions (1890) reinforced Lawrie’s view. However, the commissions were financed by Lawrie’s benefactor, the Nizam of Hyderabad, and chaired by Lawrie himself. The science was dubious. Lawrie, who claimed to have safely given 40,000 to 50,000 administrations, engaged in prolific correspondence to the British Medical Journal and the Lancet [26]. An example of his single-mindedness may be seen in his reply to comments in The Lancet in 1889: “I have no wish to say anything to give offence to those who hold the same view as the writer of the annotation, but I hold that those views are wrong, and that there is no such thing as chloroform syncope [27].”

Augustus Waller (1856–1922), lecturer in physiology at St Mary’s Medical School in West London, advocated administration of chloroform in concentrations between 1% and 2% [28]. Others advocated safe use of concentrations up to 3%, and a variety of inhalers were developed to achieve its accurate administration. In 1901, Waller joined the Chloroform Commission convened by the British Medical Association (BMA). The commission did not issue its final report until 1910, by which time Edward Embley (1861–1924) had

published the results of his extensive research in Melbourne, Australia [29–31]. In the 25 pages devoted to his research, he pointed out defects in Lawrie's case. He proved conclusively that sudden death during chloroform administration was due to the effect of chloroform on the heart, not the respiration. This paved the way for A Goodman Levy (1866–1954), whose research established that ventricular fibrillation was the actual cause [32]. Lawrie remained unconvinced to his death.

Remember that chloroform was the “British” anesthetic and ether the “American” anesthetic. Perhaps it is not surprising that a decade later, the Committee on Anesthesia of the American Medical Association (AMA) concluded that: “*The use of chloroform as an anesthetic could no longer be justified.*” Despite Embley, Levy, the BMA, and the AMA, chloroform continued to be used for another half-century in the US. Eger remembers being asked if he wanted to use it in his residency in 1957. He declined. With the introduction of the safer halothane, chloroform and ether both disappeared as anesthetics in the US.

However, ether remained in use in other parts of the world (often for economic reasons), well into the 1980s. One reason for its continued use, well past its “sell by date” in the UK, was a technique of rapid induction of anesthesia with ether as taught by Harry Churchill-Davidson of St Thomas's Hospital (situated opposite the Houses of Parliament in London). Harry C-D, as he was known, was a larger than life, English gentleman. He had the patient breathe 10% carbon dioxide in oxygen for 5 min, ensuring profound hyperventilation. The ether dial was then turned to maximum over the next 10 breaths and the energetic breathing ensured a rapid induction with the added benefit that the tracheal tube was sucked into place by the patient. Ether was still used in the UK in the mid 1980s; I'm told that an enthusiast (perhaps John Snow's ghost) gave ether at St. Bartholomew's Hospital in London as late as 1985.

Before we leave the year 1847 one further topic deserves mention. In this year the first theory of the neuro-physiological basis of anesthesia was proposed. Mike Halsey, who had worked with Eger and John Nunn on the molecular basis of anesthetic action, noted that, von Bibra, Harless, and von Herman suggested that the dissolution of fat within neurons caused the state of anesthesia [33]. The theory did not explain how recovery from anesthesia occurred.

Inhaled Anesthetic Developments in the Second Half of the Nineteenth Century

Ether and chloroform continued as mainstays of anesthetic delivery for a century after their introduction. Nitrous oxide temporarily fell from favor after Wells' failed demonstration, but Gardner Colton re-introduced it in 1862, and it has

Fig. 46.1 Edmund Andrews. (Photograph of portrait, Feinberg School of Medicine Library, courtesy of the EIE collection)

remained in use ever since. The surgeon, Edmund Andrews (Fig. 46.1), suggested that the concurrent addition of oxygen would enhance the safety and usefulness of nitrous oxide [34]. The effective use of this suggestion required the development of compressed gases, containers that withstood high pressures, and a means for the controlled delivery of the gases, toward the end of the nineteenth century. The non-pungent nitrous oxide was then used to smooth and hasten the induction of anesthesia with the more pungent ether. In most developed countries, ether gained in popularity as skill in its administration increased and its greater safety was recognized. The lesser safety of chloroform probably prompted differences in the skills of US versus Commonwealth anesthetists. Its dangers mandated that medically knowledgeable persons, particularly physicians, give chloroform, but in the US, anyone could and did give ether. In the US, the safest anesthesia was probably given by nurse anesthetists trained in the art (see Chapter 22). And so, for a time, anesthesia advanced more rapidly in the UK than in the land of its discovery.

The First Half of the Twentieth Century

The first half of the twentieth century saw the discovery of several new inhaled anesthetics, most being but marginal improvements on ether. Consider ethylene, or ethene, the first member of the alkene series (C_2H_4), the polymer being polyethylene. In 1908, growers noted that carnations failed

to flower in greenhouses where there had been a leak of ethylene, used for illumination. The expression ‘*go to sleep*’ was used to describe the condition of the ethylene contaminated carnations. This chance finding that ethylene induced ‘sleep’ in carnations prompted Arno Luckhardt to trial its use as an anesthetic. Ethylene entered clinical practice around 1923 [35]. As it was more potent than nitrous oxide, and thus could be administered with greater oxygen concentrations, it transiently became popular in the US. However, ethylene is highly flammable and by the early 1930s, several explosions had occurred. This, along with the introduction of the more potent cyclopropane, caused its use to wane. However, Eger remembers with awe, a presence of history while giving ethylene at Chicago’s Presbyterian Hospital in the early 1950s for emergency surgery. The Presbyterian Hospital was the site of the first use of ethylene in patients.

Cyclopropane’s introduction as a general anesthetic was also initiated by a chance finding. Cyclopropane was synthesized in 1882. George Lucas and Velyien Henderson in Toronto thought that a contaminant of a cylinder of propylene might have resulted in toxic reactions. Two kittens put in a jar with the contaminant, cyclopropane, were anesthetized and recovered uneventfully [36]. Henderson was the first human subject anesthetized with the gas. Cyclopropane had several advantages. It was potent, having a MAC of approximately 10% [37]. Because of its potency, poor blood solubility, and lack of irritant properties, it induced anesthesia quickly. It did not depress the heart; in fact it increased blood pressure. However, it could explode, it caused the heart to sometimes beat irregularly, and it depressed breathing. Indeed, as early as 1956, the Ministry of Health in the UK set up a working party to investigate fires and explosions associated with anesthesia and reported a total of 36 explosions and three deaths between 1947 and 1954. These limitations and the advent of the nonflammable halothane eventually led to the abandonment of cyclopropane. However, as late as the 1980s, it continued to be used, especially in children, and in patients who needed support of their blood pressure. Eger remembers in the 1960s, promising volunteers that if they would breathe 10 breaths of 50% cyclopropane they would fall asleep by the tenth breath. He lied. They all fell asleep by the third breath.

Vinethene (Vinesthine, Vinydan), the commercial name for divinyl ether ($\text{CH}_2\text{CH-O-CHCH}_2$), was the first inhaled anesthetic developed with some notion of a relationship of structure to activity (a precedent sometimes, erroneously in my opinion, accorded halothane). Leake and Chen deliberately combined the advantageous properties of ether (high potency) and ethylene (absent pungency and low solubility), substituting two ethylene moieties for the two ethane moieties in ether to produce divinyl ether [38]. Its primary advantage was that it was one-quarter as soluble in blood as ether [39]. It was used for approximately 40 years, particu-

larly to smooth the induction of anesthesia with ether. Larry Saidman remembers that it was still in use for this purpose in the early 1960s. He recalls that some skill was needed to hold both the divinyl ether bottle and the ether can in the right hand and maintain the airway with the left hand all the time using an open drop ether mask!

In the late 1930s, the degreasing and dry cleaning agent, trichloroethylene (CCl_2CHCl) or Trilene, was introduced as an anesthetic by the London anesthetist Langton Hower, finding favor mostly in the UK [40]. It had been sniffed illicitly by thrill seekers and had found a place in medicine as a treatment for trigeminal neuralgia. Trilene possessed innate analgesic properties, and was inexpensive and easy to administer. Perhaps most attractive, it was non-explosive, a particular advantage because of the increasing use of electrocautery by surgeons to stop bleeding. But Trilene produced a high incidence of postoperative nausea and vomiting and had the potential to be hepatotoxic. It had to be used in an open (high-flow) system because it reacted with carbon dioxide absorbents to produce the nerve gas phosgene. Nevertheless, Trilene continued to be used by cost conscious anesthesiologists for many years after the introduction of halothane.

Changes in society in the early part of the twentieth century drove the search for improved inhaled anesthetics. Doctors wanted to improve the patient experience during and after surgery, and patients expected more. Anesthetics used before World War II were toxic (especially chloroform and Trilene), associated with postoperative nausea and vomiting (all anesthetics), or explosive (ether, ethylene, cyclopropane, Vinethene), or had a combination of these unwanted effects. Nitrous oxide caused nausea and vomiting, had a subtle toxicity, and lacked sufficient potency to produce surgical anesthesia. Chloroform use provided an example of how prevailing societal attitudes influenced anesthetic use. Although chloroform was easy to use, produced a pleasanter induction than ether, and was non-explosive, death from cardiovascular side effects or liver or renal injury were relatively common. As the twentieth century advanced, ‘patient safety’ became a concern of doctors and of society in general. Litigation motivated some of the changes. Chloroform continued to be used commonly in the UK and the Southern US, as opposed to the Northern US where litigation was increasingly an issue. Indeed, I’m unaware of any British anesthetist being sued following a chloroform-induced death even though the jury at Hannah Greener’s inquest clearly believed that chloroform caused her demise.

Even before World War II, we knew where to search for a better inhaled anesthetic. In a prophetic introduction to their studies on fluorine derivatives of chloroform in 1932, Harold Booth and E May Bixby of Western Reserve University in Cleveland stated: “*A survey of the properties of 166 known gases suggests that the best possibility of finding a new non-combustible anesthetic gas lay in the field of organic fluoride*

compounds. Fluorine substitution for other halogens lowers the boiling point, increases stability and generally decreases toxicity [41].” Every time I read this, especially the last sentence, I marvel at Booth and Bixby’s perspicacity. We knew what should be done, but the great electronegativity and reactivity of fluorine made it difficult to study, and we lacked sufficient expertise in its control in the 1930s. Then war broke out, and we found the expertise.

Advances in Fluorine Chemistry During World War II

Scheele identified fluorine in 1771, but it was not isolated until 1886 because fluorine is the most electronegative of all elements, and is very reactive. Like all halogens (five non-metallic elements which form simple salts like sodium chloride or table salt—the word ‘halogen’ derives from the Greek ‘salt producing’) fluorine is not found in the free state in nature. Chemists in the 1930s could synthesize but few fluorine-containing compounds that might have anesthetic activity.

Two military goals greatly advanced fluorine chemistry, and led to the synthesis of the first fluorinated anesthetic, methoxyflurane. First, the huge increase in demand for high octane aviation fuel necessitated production of a catalyst—hydrogen fluoride. Second, in 1942, the best chemists available in the US were recruited to the Manhattan Project to develop the atomic bomb containing the fissile U[235] isotope of uranium. U[235] had to be separated from its natural, non-fissile isotope, U[238]. To do this required making the uranium volatile—a gas! And that could be done by combining uranium with fluorine to make uranium hexafluoride (UF₆). The rest was simple: just use a jillion centrifuges to separate U[235] F₆ from U[238] F₆ and then remove the fluorine. The atomic bomb detonated 300m above Hiroshima on 6 August 1945, contained U[235]. Thus, great advances in fluorine chemistry occurred, advances enabling the synthesis of diverse, potentially anesthetic compounds. The aphorism ‘*Every evil hath its good, every sweet its sour*’ was never more apposite (attributed to Oliver Wendell Holmes Jr. whose father, as previously noted, coined the term ‘anaesthesia’).

Two developments linked the Manhattan Project and fluorinated anesthetics. The first led to methoxyflurane (CH₃-O-CF₂-CHCl₂). As part of the Manhattan Project, William Miller, Edward Fager, and Paul Griswold synthesized several fluorinated methyl ethyl ethers [42]. Methoxyflurane was synthesized in 1944 but went unnoticed. Miller and his colleagues were working for the Manhattan Project at SAM Laboratories, Columbia University, under contract number W-7405-Eng-50 and at SAM Laboratories Carbide and Carbon Chemicals Corporation, New York City under contract number W-7405-Eng-26, Supplement No 4. The details of methoxyflurane’s synthesis were published in Volume 1 of Division VII of the Manhattan Project Technical Series. I in-

clude the contract numbers to demonstrate that fluorinated anesthetics directly resulted from nuclear weapons research. I’m unaware that this has previously been noted in the anesthetic literature. Miller submitted the details of his synthesis to the Journal of the American Chemical Society, when I was six days old (submitted to JACS 30 April 1947). Ten years were to pass before its rediscovery as an anesthetic. Miller, later of Cornell University, thereby became the first to synthesize a fluorinated inhaled anesthetic. But he did not realize or pursue its anesthetic possibilities; he was pre-occupied in developing weapons of mass destruction.

Second, in a search for a better anesthetic, Earl McBee (who worked on U[235]) synthesized 46 fluorine-containing ethanes, propanes, butanes, and an ether for the Mallinckrodt Chemical Works. Mallinckrodt gave these compounds to Benjamin Robbins, the first Chairman of Anesthesia at Vanderbilt University and a member of the Pharmacology Department, to test for anesthetic activity. The Pharmacology Department at Vanderbilt had historical close links with the Mallinckrodt Chemical Works which is why Robbins was involved with their assessment. The Mallinckrodt Chemical Works manufactured ether and cyclopropane, and thus had an interest in anesthesia. The founder, Edward Mallinckrodt Jr., went to school with Paul Lamson, who became Chairman of Pharmacology at Vanderbilt. He gave his old school friend a grant of \$25,000 a year, to fund research related to anesthesia.

In 1946, Robbins published his preliminary report [43]. Although no compound was a useful anesthetic, three compound structures differed but slightly from halothane. In two, a single chlorine substitution for either hydrogen or bromine would have produced halothane—as would the addition of a single fluorine and alteration of the position of chlorine in the third. The race was still on.

Julius Shukys synthesized the first fluorinated anesthetic to enter practice, an ethyl vinyl ether (CF₃-CH₂-O-CHCH₂) named fluroxene (Vinamar, Fluoromar). John Krantz in Maryland studied it in the late 1940s [44], and it entered practice in 1953. However, it was not ideal, producing rapid breathing and heart rate, it was flammable, and it could injure the liver. Indeed, although toxicity in primates was small, it was lethal to many other species [45]! Larry Saidman also remembers its propensity to cause nausea and vomiting, hence its alternative names ‘Vomomar’ and ‘Fluorobarf’. Had fluroxene been subjected to today’s standards, it never would have been tested in humans. The search for a better agent crossed the Atlantic back to Britain.

Chance and Science Come Together: The Story of Halothane

Imperial Chemical Industries (ICI), in Cheshire in the North of England, founded a pharmaceutical division in 1944, having previously synthesized fluorine containing compounds

in the 1930s for use as refrigerants. Chance again played a crucial role. In the 1930s, John Ferguson, later to become ICI's Research Director of the General Chemical Division, tested agrochemical agents that might be used to fumigate grain silos to rid them of weevils and beetles. Some of the agents stunned but did not kill the weevils. Remembering this in 1951, he prompted a young fluorine chemist working at ICI, Charles Suckling (with whom I have discussed the subject) to explore fluorinated compounds as anesthetics. Suckling set about searching for an anesthetic, combining the multi-perspectives of patient, surgeon, anesthetist, and manufacturer. Although Suckling synthesized and selected the compounds for testing, recognize that Ferguson's earlier chance observations set Suckling on the road leading to the synthesis of the halogenated alkane ($\text{CF}_3\text{-CHClBr}$) called halothane. Suckling succeeded surprisingly quickly, halothane being the ninth of twelve compounds tested for anesthetic activity [46]. Suckling then asked the pharmacologist, James Raventos, to determine the relevant pharmacology. Suckling described Raventos as: "*Wise with an impish sense of humour and an infectious chuckle, cautious until sure of his facts*". Raventos found in animals that the new hydrocarbon had desirable properties; non-flammability, absent pungency, high potency (close to that of chloroform), no obvious toxicity, and could produce a rapid induction of and recovery from anesthesia [47]. Although halothane had significant cardiovascular effects (it could predispose to irregular beating of the heart and could depress the heart), its dangers were far less than those of the other eleven 'highly cardiotoxic' compounds synthesized by Suckling.

The laboratories of ICI are in Widnes, Cheshire, close to the Manchester Royal Infirmary where an anesthetist, Michael Johnstone, worked. Johnstone had witnessed the limitations of 'rag and bottle' chloroform anesthesia and this experience determined his career choice, believing that as an anesthetist he could improve the lot of the patient. On January 20, 1956, Suckling received a telephone call from Raventos, who was in the operating theater with Johnstone to witness the first use of halothane in a patient. Ethical approval was not sought, and preclinical investigation had not been undertaken as was standard practice for the time. Raventos related that everything had gone satisfactorily, and in turn, Suckling relayed the message to Ferguson. Unknown at that moment, chance had played yet another role in the successful development of halothane. The first patient scheduled for operation, the one that would have received halothane, had awakened unwell, and her surgery was postponed. The second patient received halothane in her stead. The next morning the first scheduled patient developed jaundice! Had the patient received halothane, surely the halothane would have been blamed, ending halothane's use forever. To paraphrase Lefty Gomez, an American baseball player, "it is better to be lucky than good".

Johnstone continued the early trials [48], and by September of 1956, over 500 patients had received halothane. The trials were widened before its release in the UK in 1957, and the US in 1958. In the initial trials, halothane was given by the open drop method, but a calibrated vaporizer, the Fluotec, was soon developed by a small engineering firm, Cyprane, and this vaporizer facilitated the commercial success of halothane. In the US, fortuitously, another vaporizer, the Copper Kettle had already been developed [49]. Both of these vaporizers allowed anesthetists to control the depth of anesthesia, quickly and predictably. Due to the combination of high vapor pressure, lower blood solubility, and high potency, precise control was essential to the safe delivery of this new potent inhaled anesthetic.

The advantages of the new alkane rapidly placed it as the anesthetic of choice world wide. But within four years of its release, cases of unexplained postoperative liver failure emerged. Bunker and Blumenfeld reported that a 16 year old school girl had died in the Sutter Community Hospital in Sacramento, of liver failure, 13 days after being exposed to halothane for a minor surgery [50]. Gerald Brody (pathologist) and Robert Sweet (anesthesiologist) reported four cases of severe hepatic injury after halothane anesthesia [51]. Such observations prompted Bunker to propose that the National Academy of Sciences in Washington organize a study of the safety of halothane, a study that would define the risk imposed on our patients by this extraordinarily useful anesthetic. One thing seemed clear: although halothane might cause severe injury to the liver, the incidence appeared to be less than that seen with chloroform. But how much less? A large epidemiological study would be needed to sort out the incidence and the characteristics, the phenotype, associated with "halothane hepatitis". A large scale retrospective analysis was undertaken and the results published in 1966 [52], with more detailed results published in 1969 [53]. Only 3 patients out of 367,000 given halothane gave clear evidence of a direct cause and effect relationship. The anesthesia community breathed a sigh of relief.

Mounting evidence indicated that halothane-induced liver damage took two forms [54]. One was mild, transient and sub-clinical, measurable only by changes in liver function tests. The rare second form resulted in fulminant injury to the liver and a high mortality. Between 1978 and 1985, the UK Committee on Safety of Medicines (CSM) received 84 reports of liver injury after halothane with adequate histories in 62 patients. Of the 62, 41 had been exposed to halothane more than once. The mortality rate was 29% in patients given but one anesthetic with halothane; 41% after two exposures; and 56% in those given more than two. Not only did mortality increase with repeated exposures, the time to the appearance of injury shortened. These relationships suggested an immune-mediated, allergic-type reaction, with the

following sequence mediating injury [55]. The liver metabolizes halothane to a reactive form of trifluoroacetyl ($\text{CF}_3\text{-COO-}$) which by virtue of its reactivity can combine with liver proteins (liver proteins because they are nearby). The addition of the trifluoroacetyl group to the protein changes the immune character of the protein which is no longer recognized as “self” or normal, but as “foreign”. The body’s immune system produces antibodies that attack the “foreign” proteins and, thereby, injure the liver. A greater immune response is mounted with repeated exposures to halothane, as would occur with repeated vaccinations. The precise sequence of events is complicated. Although the incidence of fatal halothane-induced hepatitis was small, it enormously impacted on the use of halothane. Halothane is now available in the UK only to special order. Use of halothane continues in developing countries where costs trump the rare risk of severe injury of the liver.

ICI did not attempt to produce a better inhaled anesthetic to follow up on their success with halothane. However, in 1983 they introduced an alternative to thiopental, propofol (isopropylphenol) for intravenous induction and maintenance of anesthesia. Thus, the early 1980s saw the end of a nearly 150 year era, in which inhaled agents were the invariable foundations of general anesthesia and total intravenous anesthesia became a viable alternative.

The introduction of halothane also marked a new era in anesthetic pharmacology. Twenty years earlier, Booth and Bixby had predicted part of halothane’s beneficial and detrimental effects: fluorine substitution produced an anesthetic that was non-explosive and less toxic than chloroform. The rare association with hepatic failure initiated epidemiological surveys (outcome studies, studies required for our present goal of evidence-based medicine) and extensive studies into the immunological basis of unpredicted side effects.

Methoxyflurane

Although Miller (later at Cornell) and colleagues synthesized methoxyflurane under a Manhattan Project contract in 1944, only in 1960 did Joseph Artusio and Alan Van Poznac, also at Cornell publish their results of studies of methoxyflurane in humans [56]. Methoxyflurane was non-explosive, extremely potent with a MAC of 0.16%, and purportedly a good analgesic. This latter property gave it a place in obstetric analgesia (licensed for use in obstetrics in 1970 in the UK). But problems with methoxyflurane limited its use. It was too soluble in blood to allow a rapid induction and recovery [57]. The liver metabolized more than 50%, perhaps even 75% of the methoxyflurane taken into the body [58], with metabolites excreted in the urine for up to 12 days post-operatively. Prolonged use—3 MAC-hours or longer—could cause high output kidney failure [59]. The French had a nice term for this ‘*Diabetes Insipidus Fluorique*’. Methoxyflu-

Fig. 46.2 A young Ross Terrell, probably in the 1960s. (Courtesy of Airco files)

rane never gained widespread acceptance in the US, and its use slowly withered away. Licenses for its use have lapsed in the UK and North America. However, in Australia, paramedical personnel, the military, and emergency departments still use it regularly for analgesia. Self-administered by means of a disposable device allowing a maximum dose of 6 ml over 50 to 55 min, it remains registered for use in Australia, New Zealand and the Middle East. The only manufacturing facility is now in Australia [60].

The next fluorinated anesthetic to be introduced came from the efforts of the chemist Ross Terrell (Fig. 46.2), from a sustained project, underwritten by the Ohio Chemical Corporation, dedicated to the development of a better inhaled anesthetic [61]. But first we need to review the topic of depth of anesthesia and how to measure it. The discovery of the measurement was concurrent with and partially driven by the rise of halothane as the predominant anesthetic of the day.

Defining Anesthetic Depth: The Minimum Alveolar Concentration or MAC

In 1847, by dint of painstaking observation, John Snow defined depth as a succession of five degrees, the fourth being the degree commonly used to facilitate the progress of surgery. During World War I, Arthur Guedel refined Snow’s

concepts, arriving at a scheme of four stages, the third being that used for surgery [62]. The introduction of premedication, the use of opioids and then muscle relaxants provoked a debate concerning what the term ‘anesthesia’ meant—what did it encompass and could depth be scientifically measured? Cedric Prys-Roberts observed that anesthesia is the state in which, as a result of drug induced unconsciousness, the patient neither perceives nor recalls noxious stimuli [63]. The motor response to noxious stimuli is essentially an all or none one with motor activity resulting from stimulation of the inadequately anesthetized patient. Snow observed that his third degree permitted such movement but the fourth degree did not [64].

Eger, Saidman and Brandstater used this motor reflex as an end point in defining the minimum alveolar concentration (MAC) of anesthetic needed to inhibit movement in 50% of subjects [65]. This concentration is greater than that required to produce unconsciousness. The concept of MAC, developed by Eger and his colleagues in San Francisco, was an important contribution to the anesthetist’s ability to conceptualize and thus modify depth of anesthesia and use different inhaled agents safely. It enabled quantitative comparisons of the effects of inhaled anesthetics and the ability to define factors affecting the depth of anesthesia.

A Search for Metabolically Stable Ethers

Like his predecessors searching for a better anesthetic, Ross Terrell synthesized several series of fluorinated compounds including alkanes, alcohols and various ethers. A potentially useful compound would produce a “smooth” anesthetic state, preferably without also producing convulsions. A useful compound would be stable, would resist degradation by the liver or by carbon dioxide absorbents, and would not be toxic. He quickly discarded alkanes because they predisposed to irregular beating of the heart, and focused (because they did not so predispose) on ethers, particularly methyl ethyl ethers. Terrell worked with dogged persistence—remember halothane was Suckling’s 9th compound. In 1963 Terrell synthesized a methyl ethyl ether ($\text{CHF}_2\text{-O-CF}_2\text{-CHFCl}$) that had the code name Investigational Compound Number 347 or I-347 because it was the 347[th]structure he synthesized. A first report of its anesthetic characteristics appeared in 1966 [66], and it was given the generic name ‘enflurane’.

Enflurane

Compared with halothane, enflurane had two immediately apparent, indeed predictable advantages, and other disadvantages that became clearer with time. First, it was a fluo-

rinated methyl ethyl ether, and ethers, unlike alkanes, tend not to cause cardiac arrhythmias. Second, only 2–3% of the enflurane taken up was metabolized, and thus it was less likely to cause injury from potentially toxic metabolites. That is, the relatively low metabolism meant that defluorination was small, far smaller than with methoxyflurane, and cases of postoperative renal insufficiency did not appear. So enflurane provided a potentially safer alternative to either halothane or methoxyflurane. Not predicted, was the early finding of an association of enflurane anesthesia with tonic and clonic muscular activity [67]. Indeed, EEG epileptiform activity was common, although frank seizure activity was uncommon.

By the mid 1970s, enflurane supplanted halothane in much of the developed world except that halothane continued to be used for anesthesia in children because of halothane’s absence of pungency. Methoxyflurane and Trilene had hardly any followers and a few stalwarts refused to give up ether. The non-flammable, minimally toxic, potent characteristics of enflurane increasingly made it the leader.

At this juncture two trends increasingly influenced anesthetic practice, trends ensuring a persistent search for alternatives to halothane and enflurane. First, advances in anesthetic and surgical techniques, coupled with economic considerations, increased the demand for and scope of day case (patients being both admitted and discharged the day of surgery) surgery. By the 1980s, surgery was increasingly being performed on a day case basis, and in the US, by the 1990s, this increased to a majority. Second, obesity rates in prosperous nations steadily increased. In 1980, I left the UK to work at the University of Michigan Medical Center in Ann Arbor. I remember being stunned at the high proportion of obese patients. Eventually, the rest of the world caught up with this epidemic of obesity. The increasing use of day case surgery and increasing girth of the population dictated a need for anesthetics that were eliminated rapidly to speed the rate of recovery. Those were not the only goals of the ideal anesthetic. Additionally, it should be non-flammable, lack toxicity (for both patient and operating room personnel), and have minimal cardiorespiratory effects. Also, it should be inexpensive. Both enflurane and halothane fell short of the ideal.

A Search for Less Soluble Anesthetics

Terrell’s team synthesized more than 700 compounds in the 1950s and 60s, in pursuit of a better inhaled anesthetic. They synthesized the 469[th]compound in 1965, two years after having synthesized the structural isomer enflurane. I-469 ($\text{CHF}_2\text{-O-CHCl-CF}_3$) was given the generic name, isoflurane (from the term ‘isomer’).

Table 46.1 Year introduced, solubility, and metabolism

Year	Anesthetic	Blood solubility ^a	Percent metabolized ^b
1844	Nitrous Oxide	0.47	0.00
1846	Diethyl Ether (“Ether”)	12	
1847	Chloroform	8.4	
1950s	Halothane	2.4	20–40
1960s	Methoxyflurane	12	75
1970s	Enflurane	1.8	3
1980s	Isoflurane	1.4	0.2
1990s	Sevoflurane	0.65	3
1990s	Desflurane	0.45	0.02

^a Defined as the blood/gas partition coefficient: the concentration of anesthetic in blood divided by the concentration in the overlying gas when the anesthetic is in equilibrium between the two phases (gas and blood)

^b The percent metabolized indicates the percent of the anesthetic taken up that is metabolized. With occasional aberrations (e.g., methoxyflurane), the trend has been to develop progressively less soluble and less metabolized inhaled anesthetics

Isoflurane

Isoflurane continued the trend towards a lower solubility and a greater resistance to metabolism (Table 46.1). In animals, it had a good “anesthetic syndrome” without evidence of the convulsive activity seen with enflurane. It was stable to UV light and alkali, including soda lime. It thus looked promising. However, the manufacturing process required purification by distillation, and the isomers of I-469 have boiling points close together. Thus a large number of distillations were initially needed to obtain the pure compound, and the expense of such distillations nearly led to the abandonment of isoflurane.

However, these problems were overcome, and Eger and colleagues in San Francisco reported on the first clinical trials in 1971 [68]. They confirmed the attractive characteristics of isoflurane. There was no innate convulsant activity, and more rapid elimination ensured faster recovery than with enflurane. Being a structural isomer of enflurane, isoflurane was predicted to have a similar MAC, but this was not so. The lesser potency of enflurane compared with isoflurane possibly resulted from enflurane’s capacity to stimulate the brain—to cause convulsions. Only an ethereal odor marred isoflurane’s clinical profile and gaseous induction of anesthesia remained smoother with halothane, especially in less experienced hands.

Isoflurane was scheduled for release to the anesthesia community in the mid-1970s. And then disaster struck. Eger got a phone call from Thomas Corbett at the University of Michigan. Corbett had studied the potential carcinogenicity of isoflurane, believing he had found evidence for such a terrible possibility [69]. Corbett’s study was flawed in several respects. For example, there were insufficient control animals, an absence of blinding of the investigators to experimental versus control animals, failure to use peer animals as controls, inadequate statistical analysis, and absence of a comparator anesthetic. And if isoflurane caused cancer, was this an effect of all anesthetics or was it—as Corbett thought—most dangerous with isoflurane? One could not tell from Corbett’s study whether isoflurane presented a problem of carcinoge-

nicity, but in the absence of certainty, the release of isoflurane was cancelled.

Wendell Stevens and Eger, with Corbett’s help, set out to repeat Corbett’s study, correcting the errors of that study. Using Corbett’s general methodology but expanding control comparisons and adding studies of all the then used inhaled anesthetics, they studied the carcinogenicity of anesthetics in thousands of mice. Corbett participated in the analysis, examining each specimen for evidence of the development of cancer. But in this case, Corbett was blinded to the origin of the animal (i.e., whether the animal had been exposed to an anesthetic or not). The experiment took two years to complete, and the findings exonerated all anesthetics except, possibly, methoxyflurane [70].

Exonerated, isoflurane was released for clinical use in 1980/1. Although more expensive than enflurane, its superior properties caused it to displace enflurane. Halothane still had a place, chiefly for inhalation induction of anesthesia in children. But its use in children worried many anesthetists as it was argued, perhaps fancifully, that anyone should only be anesthetized once with halothane, and it was best not to use up this opportunity(!) Inhalation induction apart, the only property of concern with isoflurane was that it decreased arterial pressure by opening up blood vessels—as opposed to halothane which decreased pressure by depressing the heart. This vascular dilation included the coronary vessels, which sounds beneficial, but a report suggested that in patients with pre-existing coronary narrowing, isoflurane could cause ‘stealing’ of coronary blood away from those areas less able to dilate [71]. A debate about coronary steal commenced which was lively at the time, but subsequent studies did not support the original report. Coronary steal seems not to overly concern contemporary anesthetists.

More than 30 years after its introduction, isoflurane continues to be popular, a testament to the excellence of the compound Terrell synthesized in 1965. But it was not the ideal inhaled anesthetic. Even lesser solubility could be an advantage in longer-duration day case surgery, and in the

Fig. 46.3 Prof. Kazuyuki Ikeda administering the first sevoflurane anesthetic to a patient. (Prof Ikeda to EIE)

obese patient. Less metabolism would bring with it theoretical, and possibly, clinical advantages as would absence of pungency—important to an inhaled induction of anesthesia, particularly in children. Each of the next two inhaled anesthetics to be used clinically, sevoflurane and desflurane, supplied some of these desirable characteristics.

Sevoflurane

Although synthesized after desflurane, the fluorinated methyl propyl ether sevoflurane [$\text{CH}_2\text{F}-\text{O}-\text{CH}(\text{CF}_3)_2$] was evaluated earlier and so appears first in our chronological review. At Travenol Laboratories, Richard Wallin and Bernard (Barney) Regan (a skilled synthetic organic chemist with a profound interest in anesthesia and understanding of anesthetic literature) synthesized sevoflurane. Terrell had also synthesized sevoflurane, but had set it aside because it was not stable in soda lime. Wallin and Martha Napoli, pharmacologists with Travenol Laboratories Inc at Morton Grove in Illinois, described its pharmacology in abstract form in 1971, and in 1975, a full report followed [72].

This comprehensive evaluation reported that sevoflurane's cardiorespiratory effects were unremarkable but drew attention to two problems. Sevoflurane is not stable in bases such as soda lime. And the fluorine atom on the methyl group is vulnerable to cleavage. Although less metabolized than methoxyflurane, the cleavage raised the possibility of kidney injury. Indeed, in 1976 Russell Van Dyke of the Mayo Clinic, commented [73] on a paper from Dick Mazze and his colleagues in Palo Alto [74] comparing the renal effects and me-

tabolism of sevoflurane and methoxyflurane in rats: “Unfortunately, the study of sevoflurane may be rendered academic, since the compound appears to be unstable in base, a characteristic shared by several halogenated hydrocarbons.”

Nevertheless, sevoflurane continued into volunteer studies which found that induction was rapid and smooth [75]. Several subjects volunteered that a sense of the odor of the anesthetic preceded loss of consciousness, all before the fifth breath. However, subsequent clinical trials in the US were halted. The decision was influenced by experiences with methoxyflurane and to some extent halothane, drugs significantly metabolized and toxic to liver, kidney or both. Beyond metabolism of sevoflurane to fluoride ions, base-containing carbon dioxide absorbents like soda lime degraded sevoflurane to two vinyl ethers, termed Compounds A and B, and these compounds were thought to have toxic potential. And it didn't help that about this time, a study showing that if rats were given phenobarbital and then anesthetized with sevoflurane, they died or had severe injury to their livers and kidneys [76].

So sevoflurane went away (See Chapter 31)—to Japan. Maruishi, a small pharmaceutical company, continued the development of sevoflurane (Fig. 46.3). Drug registration in Japan nearly 30 years ago differed from that in the US or Europe. The opinion of a small number of influential individuals could determine the receipt of a license for clinical use. Soon after application was made, sevoflurane appeared for clinical use in Japan, and by the later 1980s was probably the most widely used inhaled anesthetic in that country. The predicted postoperative renal problems did not materialize. Eventually sevoflurane would re-emerge on the world stage (reviewed later), but meantime developments were taking place in the US.

Desflurane

Two issues prompted US based pharmaceutical companies to continue to search for a new inhaled anesthetic. First, was a perceived need for an agent less soluble than isoflurane and maybe sevoflurane (see Table 46.1). It would also be desirable if the anesthetic were stable in soda lime, insignificantly metabolized, and non-pungent. Second, patent protection of isoflurane was coming to an end, and commercial interests suggested that a better replacement for isoflurane would be of economic as well as clinical value. So in the mid 1980s, Terrell and Eger re-examined Terrell's 700 compounds with these criteria in mind. They focused on a later compound in the series, the 653[rd], synthesized in 1966. It was difficult and dangerous to synthesize (synthesis involved the use of elemental fluorine, an explosive atom) and had a vapor pressure close to one atmosphere, precluding its use in the then standard variable-bypass vaporizer. However, this compound was halogenated entirely with fluorine and was predicted to have the desired low solubility and to have great stability.

A digression. I was returning one evening with Ross Terrell to our downtown hotel in San Francisco, in a cab driven by a morbidly obese taxi driver. Hearing our conversation he was keen to tell us about his recent stomach stapling operation, and stopped the cab to talk. For reasons not immediately relevant to this essay, our conversation turned to philosophy, specifically to that of the Austrian philosopher, Ludwig Wittgenstein who in 1941, had worked as a porter in the pharmacy of Guy's Hospital in London (where the first volunteer studies of desflurane were to take place). I was at Guy's in the 1980s and not only had I read Wittgenstein's opaque *Tractatus Logico Philosophicus* but so had the taxi driver. We instantly bonded. Both of us having only a layman's knowledge of twentieth century philosophy, the conversation eventually waned, and he wanted to know why we were in town. Ross explained that we were reviewing inhaled anesthetics and had been discussing future developments. Not only did our new friend appreciate twentieth century philosophy, but when, at his request, Ross drew the isoflurane molecule, it was clear that he was also a gifted amateur chemist. He pronounced the molecule 'ugly' in view of the presence of the chlorine atom on the alpha ethyl carbon and suggested that were it to be replaced by a fluorine atom, then it would be better looking, and with fluorine having a lower atomic weight than chlorine, it would have a lower molecular weight, which he appeared to appreciate was an advantage. Ross mentioned that he had already synthesized this molecule and had discussed it with Eger at the University of San Francisco. It is comforting to think, that perhaps for one last time, chance (remember Lefty Gomez: "I'd rather be lucky than good!") in the guise of the coming together of a morbidly obese taxi driver, the spirit of philosopher Lud-

Fig. 46.4 Ron Jones poses as Napoleon while Jeremy Cashman breathes desflurane. Cashman was the first human subject anesthetized with desflurane (late 1980s). (Courtesy of the author)

wig Wittgenstein, an anesthetist from Guy's Hospital, and a skilled fluorine chemist, had a place in the development of $\text{CF}_3\text{-CHF-O-CHF}_2$, Investigational Compound Number 653, desflurane.

The first reports on the pharmacology of desflurane appeared in 1987 [77, 78], and the initial volunteer studies were performed at Guy's Hospital in 1988 [79]. The first volunteer, Jeremy Cashman (Fig. 46.4), then Lecturer in Anaesthetics at Guy's Hospital, was studied on 10 October 1988. It became apparent over the next few years that desflurane approached the ideal in many, but not all, characteristics. Its blood:gas partition coefficient of 0.42–0.48 was less than that of sevoflurane, enabling the most rapid recovery achievable with a potent inhaled anesthetic. And the molecule seemed indestructible. Thus there was virtually no metabolism, and in clear distinction from sevoflurane, the molecule was stable in bases such as soda lime. The MAC value was around 6% and so was compatible with high concentrations of oxygen, unlike nitrous oxide.

However, it was not an ideal anesthetic. Concentrations of desflurane exceeding MAC could irritate the respiratory tract making it unsuitable for a rapid inhaled induction. And a rapid increase in concentration beyond MAC could provoke considerable, albeit usually transient, increases in blood pressure and heart rate. In adults, the popularity of desflurane was second only to that of sevoflurane in the

US. It found a particular place in surgery in obese patients because of the fast recovery associated with its use. It also had an advantage in prolonged anesthesia, again because of the low solubility and rapid recovery. One last disadvantage was that desiccated carbon dioxide absorbents, particularly an absorbent called Baralyme[®], could degrade desflurane to carbon monoxide. Baralyme[®] has since been removed from clinical practice, and so, apparently, has the problem.

The Return of Sevoflurane

After nearly a decade of apparently safe use in Japan, sevoflurane was again re-evaluated in the US and the UK. Burnell Brown, at the University of Arizona, led the re-evaluation of sevoflurane. He emphasized two issues that needed examination. After prolonged anesthesia what range of concentrations of inorganic fluoride ions might be anticipated? And was sevoflurane's use in soda lime or any alternative base such as Baralyme contraindicated because of breakdown to the vinyl ethers, Compounds A and B? Essentially, the answer seemed to be that despite all the theoretical issues involved, there did not appear to be a clinically important incidence of postoperative renal complications following even prolonged sevoflurane anesthesia [80]. Indeed the authoritative 2009 British National Formulary has this statement: "*However in spite of extensive use, no cases of sevoflurane-induced permanent renal injury have been reported*". It is an unhappy coincidence that two of the most crucial personalities in the development of sevoflurane, the synthesizing chemist Barney Regan and the lead clinician in its re-evaluation, Burnell Brown, died before their retirement, and before the agent became established as a popular choice the world over.

I fondly remember Burnell Brown. He had a particular love of nineteenth century romantic music and was an accomplished pianist. In Brussels one day, we were looking around an old music shop, and he found an early manuscript of a chamber piece by the Russian composer, Alexander Borodin. Burnell was especially pleased as Borodin was a chemist and founder of a medical school in Moscow.

Other Developments of the Second Half of the Twentieth Century

Aliflurane [CH₃-O-c(CFCCIFCF₂)] was an ether, like enflurane and isoflurane, halogenated with chlorine as well as fluorine. The compound progressed as far as volunteer assessment by Holaday et al. around 1978 [81]. It had properties not dissimilar from isoflurane, but it was more soluble

than isoflurane in blood, and it was flammable in oxygen at 3 to 4%. Its development did not progress further.

Xenon was shown to have anesthetic properties in mice in 1946 [82], and Stuart Cullen and Erwin Gross anesthetized two patients with it in 1950 [83]. It had a low solubility in blood (blood:gas solubility coefficient 0.11) and a potency that produced anesthesia, without depriving the patient of oxygen [84]. As a noble gas, it was invulnerable to degradation and was unlikely to injure any tissue. High cost and limited availability restricted its application. Nonetheless, it has attracted attention as a potential niche anesthetic for patients at risk of inadequate blood flow to certain vital organs. It may protect the brain against transient lack of oxygen [85], or trauma to the brain [86]. Unlike some anesthetics, it seems to have no untoward effects on the developing brain [87].

However, it appears to have a particular drawback, the capacity to produce considerable postanesthetic nausea and vomiting [88]. The British Oxygen Company asked me and my colleagues to undertake a volunteer trial using xenon alone for induction and maintenance of anesthesia. All our volunteers either felt sick or had prolonged nausea and vomiting after exposure to xenon alone, and after discussion and observation by the ethical committee, we abandoned the trial. Whether xenon will find a clinical place in anesthesia remains unclear.

Inhaled Anesthetics and the Environment

And what of the environmental impact of the inhaled anesthetics that we release into the atmosphere? Two issues need to be considered. First, there is the global warming potential which is calculated for 1kg of agent in the gaseous phase over a time period relative to carbon dioxide. Using this ratio the global warming potential of nitrous oxide is 300, isoflurane 1100, sevoflurane 1600 and desflurane 1900. The relative potency of the different agents adds complexity to the situation. Thus, although nitrous oxide has a low global warming potential, the sheer volume of its use compared with other agents more than compensates for this and in absolute terms it is the most damaging of all. However, the vast majority of nitrous oxide release is from agricultural and industrial processes. Second, we need to consider ozone depletion in the upper atmosphere, which is related to chlorine atoms. Hence, desflurane and sevoflurane have no effect, whereas isoflurane has some ozone depleting potential. Were it still in use, Trilene or chloroform would have the most ozone depleting activity, as the molecules contain three chlorine atoms.

Previous discussions have considered the negative influence of inhaled agents on the environment, but intravenous

agents also may have an effect. No one knows how much carbon dioxide is produced in the production of propofol, but it is not negligible. Although the step in its manufacture from phenol is simple, manufacture of the lipid medium used to dissolve propofol must generate appreciable amounts of carbon dioxide. Policies prompting a move to total intravenous anesthesia (with propofol) to decrease carbon production may do the reverse, and thus aggravate rather than alleviate climate change. When assessing the overall effect of the processes of anesthesia, simple calculations and assumptions may result in a green paradox.

Concluding Thoughts

At the beginning of the second decade of the twenty-first millennium, the three inhaled agents having clear roles in contemporary anesthetic practice are: isoflurane, the most cost effective for routine procedures; sevoflurane, particularly useful in pediatric anesthesia and when inhaled anesthetic induction is indicated; and desflurane which has a place in prolonged surgery, or surgery for the obese patient, in low flow anesthetic systems, or when rapid emergence from anesthesia is of paramount importance. These three agents taken together possess the characteristics wanted in an ideal inhaled anesthetic, but none alone possesses all the wished for traits. The anesthetic market is not a large one compared with others such as those for chemotherapeutic agents or antibiotics. The commercial rewards are not there, and thus it is difficult to envisage much time and effort being invested in an attempt to bring together the useful characteristics of these three agents in one ideal agent. What a pity.

Paul F. White

Summary

Wren began intravenous (IV) anesthesia in 1656, using a goose quill and a bladder to inject wine and ale into a dog's vein. Invention of the hollow needle in 1843 and the hypodermic syringe in 1853 allowed IV administration of drugs. By the 1900s, diverse drugs, including ether, had been given IV for sedation.

Redonnet made the first IV barbiturate, Somnifen, in 1920. Weese and Scharpff synthesized the short-acting hexobarbital in 1932, but the introduction of thiopental by Lundy and Tovell in 1934 provided the greater advance, dominating induction of anesthesia for the next half century. Price suggested in 1960 that thiopental redistribution from brain to muscle, rather than to fat, explained the rapid awakening from thiopental. This work underlay many subsequent pharmacokinetic and pharmacodynamic concepts. Thiopental decreased cerebral metabolism and cerebral blood flow, leading to its use in the 1970s to protect the brain from hypoxic insult. Methohexital, a shorter-acting barbiturate with central nervous system-stimulating properties, was introduced in 1956 and remains a popular anesthetic for electroconvulsive therapy (ECT).

Etomidate was synthesized in 1964. It had desirable cardiovascular properties, but untoward corticosteroid effects limited its use. Introduced in 1965, ketamine maintained blood pressure in hypovolemic patients, but psychomimetic side effects restricted its use. Benzodiazepines underwent trials in the 1960s and 1970s. In the 1970s, steroid anesthetics enjoyed restricted interest. None of these drugs displaced thiopental.

Glen and colleagues at ICI synthesized propofol in 1973. It took another decade to solubilize it safely. Introduced in 1983 in a phospholipid formulation, propofol displaced thiopental because of its favorable early recovery profile and low incidence of postoperative side effects. Its rapid degradation enabled the use of continuous infusions to maintain sedation or anesthesia without unduly prolonging recovery. Propofol infusions became popular for maintenance of general anesthesia as part of "balanced" and total IV anesthesia (TIVA) techniques. As sedation practices continued to expand, propofol became used for most minor surgical and diagnostic procedures performed outside the operating room, and for ventilator-dependent patients in intensive care units.

In the 1980, Schwilden and others introduced computer-assisted titration of intravenous anesthesia and the first "target controlled infusion" (TCI) system. From the late 1980s, sedation and TIVA techniques increasingly utilized pharmacokinetic-based computer controlled devices for administering IV anesthesia—except in the US.

Current research is focused on propofol-like IV anesthetics that are devoid of pain on injection or cardiovascular depression. Closed-loop TCI systems are also being developed using non-invasive cerebral function monitoring devices.

Introduction

Sedative-hypnotic drugs are the 'foundation' of intravenous (IV) anesthesia. They are used for induction and maintenance of general anesthesia as part of 'balanced' or total IV anesthesia (TIVA) techniques, or for IV sedation during local and regional anesthesia. Sedative-hypnotics are frequently combined with other drugs including volatile agents, opioid

and non-opioid analgesics, muscle relaxants, cardiovascular drugs and local anesthetics. This essay focuses on the historical development of sedative-hypnotic drugs in anesthesiology.

Modern hypnotic drugs produce dose-related sedation, progressing to loss of consciousness or hypnosis (i.e., artificially-induced sleep), after the Greek god of sleep, *Hypnos*. As with inhaled anesthetics, some hypnotics can provide immobility and muscle relaxation, and directly or indirectly affect other major organ systems as a result of their cardiovascular and/or metabolic effects. As with inhaled anesthetics, steep dose-response curves characterize most IV anesthetic effects, allowing clinicians to precisely achieve the desired sedative or hypnotic (unconscious) state. Despite

many similarities among IV anesthetics, there are clinically important differences which this chapter will review from a historical perspective.

Before 1900

Intravenous (IV) anesthesia and analgesia began in 1656 with the English architect and founder of the Royal Society, Christopher Wren (1632–1723). Wren used a syringe consisting of a dog's bladder and a needle formed from a goose quill, while Robert Boyle (1627–1691; of gas law fame) from Oxford provided a large dog and assistants to restrain it [1]. Wren wrote “I have injected wine and ale in a living dog into the mass of blood by a veine, in good quantities, till I have made him extremely drunk, but soon after he pisseth it out.” The dog survived the experiment! Wren and Robert Major were the first to conceive of injecting centrally-active compounds intravenously [2]. Wren later injected opium intravenously [1, 3]. However, he was not the first to administer opium intravenously to humans, a distinction belonging to Sigismund Elsholtz (1623–1686) from Brandenburg, Germany, in 1665 [3].

Facilitating administration of IV drugs were Irish surgeon Francis Rynd's (1801–61) invention of the hollow needle in 1844, and French surgeon Charles Pravaz's (1791–1853) invention of the syringe in 1853. Concurrently, Scottish physician Alexander Wood (1817–1884) developed the first true hypodermic syringe and used it to inject morphine into painful joints [4]. Notwithstanding Wren's demonstration, IV anesthesia *per se* did not begin until the second half of the 19th century. In 1864, Adolf von Baeyer (1835–1917) synthesized malonylurea by condensing urea (an animal waste product) with diethyl malonate (an ester derivative of the acid of apples). Von Baeyer and his German colleagues celebrated their discovery in a local tavern commemorating the feast of Saint Barbara, prompting their decision to name their new compound ‘Barbituric acid’ (by amalgamating Barbara + urea). Although barbituric acid itself did not affect the central nervous system (CNS), it led scientists working at the Bayer Company (no relation to von Baeyer) to subsequently develop many different barbiturate compounds with sedative and hypnotic properties.

In 1869, Oskar Liebreich (1839–1908), a German physician and pharmacologist, reported that chloral hydrate (which when combined with alcohol later became known as a ‘Mickey Finn’) could be used as an IV anesthetic [5]. In 1872, Pierre-Cyprien Oré described IV anesthesia using chloral hydrate at the Société Chirurgicale de Paris [6]. Despite Oré's enthusiasm, the high mortality rate associated with IV chloral hydrate limited its popularity for IV anesthesia until the next century.

Fig. 47.1 This apparatus was designed by the Kny-Scheerer Co. for use with any type of IV anesthetic drug. As described in a report on Intravenous Anesthesia by two New York surgeons, William Honan and J Wyllis Hassler, read at the American Association of Anaesthetists meeting in June, 1913: “the narrow tube by the side of the reservoir was for the introduction of hedonal or isopral preliminary to the employment of a solution of ether.”

1900–1940

In an essay read before the American Association of Anaesthetists in June, 1913 (Published in a supplement to the *Ann Surg* 1913:58, 900–16), New York surgeons William Honan and J. Wyllis Hassler described ether as an “anaesthetic veneer”, noting that with “the usual methods of inhalation anaesthesia, a robust patient may go to an operating room for an operation of an hour's duration only to emerge beaten, broken and shattered, and in such condition that months (or even years) may intervene before he recovers his normal status of health.” In their lengthy essay, they described in detail the technical approach to administering IV anesthesia, including early IV delivery systems (Fig. 47.1).

Hedonal, Ether, Paraldehyde, Magnesium, and Alcohol

In 1909, Russian pharmacologist Nicholas Krawkow (1865–1924) demonstrated the anesthetic properties of hedonal in St. Petersburg. Hedonal was a urethane derivative used primarily to treat insomnia. It was the first agent given intravenously that produced surgical anesthesia with “a moderate degree of safety” [7]. Unfortunately, hedonal

dissolved minimally in water, had a slow onset, and a long duration of hypnotic action. In 1909, Ludwig Burkhardt in Wurzburg, Germany, described IV administration of ether and chloroform for surgical anesthesia [8]. Subsequently, in 1911, Felix Rood in England gave a 5% solution of ether in saline intravenously to 18 patients [9], reporting that it enabled great flexibility of anesthetic depth, and was accompanied by minimal postoperative vomiting or pulmonary irritation. In 1913, HLC Noel and HS Souttar described the anesthetic effects of IV paraldehyde (Paral) [10], and shortly after, CH Peck and SJ Meltzer described the anesthetic effects of magnesium sulfate given by continuous IV infusion [11]. K Naragawa used ethyl alcohol for IV anesthesia in 1921 [12], as did H Cardot and H Laugier in 1922 [13]. However, none of these anesthetics became popular in clinical practice.

The First Effective Barbiturates

In 1903, Nobel laureate Emil Fischer (1852–1919) and Joseph von Mering (1849–1908), two German chemists working at Bayer, synthesized the first derivative of barbituric acid (diethyl-barbituric acid) possessing sedative and hypnotic properties, an oral sedative named “Veronal”, named after Mt Verona where Fischer had recently spent a holiday [14]. In 1921, the French anesthesiologist, Daniel Bardet reported the first clinical use of an IV barbiturate, Somnifen, a mixture of diethyl-barbituric acid (Veronal) and diallyl-barbituric acid (Dial), for induction of anesthesia [15]. However, low solubility in water and a long duration of hypnotic action limited the clinical use of Somnifen. In 1929, JH Fjelde reported his use of a smaller dose of Somnifen for ‘induction’ before ethylene anesthesia [16].

“The patient is put to sleep right in his room, a distinct advantage which further relieves him of further thoughts of the coming operation. When awakening they are back in their own bed and have no recollection of having been to the operating room at all. A wonderful feature (of the drug)!”

Introduced in 1927, a more water-soluble barbituric acid derivative called Pernoston (originally Pernocton), gained acceptance for induction of general anesthesia—as part of the increasing acceptance of intravenous induction of anesthesia [17]. H Weese and W Scharpff synthesized the first rapid and short-acting barbiturate, hexobarbital (Evipan, Evipal) in 1932 [18]. Despite producing prominent excitatory side effects, hexobarbital was widely used in Europe. LG Zerfas described the intravenous use of soluble sodium amytal (amobarbital) in 1930 [19]. Although Zerfas cautioned users regarding the prominent cardiorespiratory depressant properties of amobarbital, it became the most popular intravenous anesthetic in North America until the introduction of thiopental.

Thiopental and Methohexital

Fischer and von Mering described the sulfur-containing barbiturates in 1903 [17]. They administered a single dose to a dog which promptly died, leading them to conclude that sulfur made the compound toxic. They immediately discontinued this avenue of research. In the early 1930s, Ernest Volwiler and Donalee Tabern, working at Abbott Laboratories, resumed studies on the sulfur-containing barbiturates. After trials in animals, two compounds were presented to the American anesthesiologist John Lundy (1894–1973) to investigate at the Mayo Clinic, namely sodium allyl-sec-butyl-thiobarbiturate (also known as thiosebutal), and sodium ethyl (1-methyl-butyl)-thiobarbiturate, a sulfur derivative of pentobarbital (Nembutal), which was called thionembutal or “Hypnotic 8064”. In 1934, Lundy and Ralph Tovell reported their initial clinical experience with thionembutal in 2207 patients [20]. They observed that rapid injection of thionembutal led to respiratory depression which was monitored by taping a fluffy piece of cotton to the patient’s upper lip and using the movement of the cotton to measure the respiratory rate. This monitoring technique was subsequently referred to as “Lundy’s butterfly”. Two years later, Ralph Waters’ group in Madison, Wisconsin published results of their study of thionembutal [21], subsequently renamed sodium thiopental or thiopentone [Pentothal]). Thiopental rapidly replaced other barbiturates for intravenous induction of anesthesia, particularly in the Americas.

1940–1960

Thiopental

Anesthesia folklore suggested that after the Japanese attack on Pearl Harbor in 1941, “more USA servicemen died from thiopental than war-related injuries”, but no direct evidence supports that assertion. It is true that large doses of thiopental administered to hypovolemic but otherwise healthy traumatized patients could produce profound hypotension. When administered as the sole anesthetic during World War II, the cardiorespiratory depressant effects led to deaths, and FJ Halford, a surgeon, suggested that IV anesthesia with thiopental was “an ideal method for euthanasia” [22]. He also wrote “While intravenous anesthesia would seem ideal for war injuries because of its compactness, ease of preparation, and non-explosive characteristics, it should clearly be recognized that under war conditions, anesthetics cannot always be given by highly skilled anesthesiologists, but have to be given by doctors, nurses and even orderlies, for whom the art is strange....” What a wonderfully perceptive statement! But an analysis by FE Bennetts [23] suggested that the number killed, missing or fatally injured as a result

of the attack on Pearl Harbor was 2403 and despite shortages of oxygen and transfusion supplies, thiopental caused few deaths.

The German pharmacologist Helmut Weese (1897–1954), the director of research at the Bayer Co., introduced another thiobarbiturate, known as Baytenal or buthalitone, with a ‘brief’ recovery time. In Britain, it was marketed as Transithal or Ulbreval. As with hexobarbital, a high incidence of involuntary muscle movement led to its abandonment. In Germany, ethyl-sebutyl-thiobarbiturate, known as Inaktin, produced actions similar to thiopental and was briefly popular in the 1950s. Pharmacologists Zima, von Werder and Hotovy attempted to accelerate the breakdown of the barbiturate molecule by substituting a methyl thioethyl group at position five [24]. The resulting drug, called Nercval in the US and Thiogental in Germany, was very short-acting but less effective than thiopental as an induction agent.

The rapid onset of hexobarbital’s action was considered to be due to the methyl group on the molecule. This stimulated further research into methylated barbiturates, and researchers at Eli Lilly Laboratories developed Lilly 22,451 in 1956. The drug showed greater potency and faster recovery than thiopental, but also possessed convulsive properties. Further modification led to Lilly 25,398, known as methohexital (Brevital). Methohexital continues as a popular IV anesthetic for dental and short procedures, in particular where less suppression of CNS electrical activity is desirable (e.g., surgery for seizure disorders and electroconvulsive therapy). Although methohexital allowed a more rapid recovery of consciousness than thiopental (or its chemical analog, thiamylal, also known as Surital), the occurrence of excitatory side effects made methohexital less attractive for short-lasting surgical procedures following the discovery of propofol. Despite its well-known cardiovascular and respiratory depressant side effects, thiopental dominated IV anesthesia from the mid-1930s until the introduction of propofol in the mid-1980s. In 1982, Dundee and McIlroy wrote “Thiopentone.....will be hard to replace by non-barbiturate agents... methohexitone still holds a place for brief procedures, but this agent may be replaced by a shorter-acting non-barbiturate” [14]. They did not mention propofol.

Steroid Anesthetics

In the early 1940s, Hans Selye (1907–82) discovered that glucocorticoid steroids such as progesterone could produce sleep in rodents [25]. Selye found anesthetic properties required the presence of an oxygen atom at either end of the steroid molecule. While pregnanedione was the most potent of the steroids tested, it was poorly soluble in water

and irritated veins—and never reached clinical practice. Hydroxydione (marketed as Viadril and Presuren), a water-soluble steroid, came into clinical practice in the mid-1950s. However, its slow onset (3–5 min), high incidence of thrombophlebitis, and prolonged recovery times limited acceptance.

1960–1980

IV Inhaled Anesthetics

As Burkhardt, Rood, Honan and Hassler reported in the early 1900s [8–10], inhaled (volatile) anesthetics such as diethyl ether and chloroform could be given intravenously. A half century later, the modern ‘Godfather’ of inhalation anesthesia, Edmond (“Ted”) Eger from UCSF, confirmed these observations [26]. Although this route of administration avoided airway irritation, the anesthetic state it produced was no better than that produced by inhalation of ether, and required fluid volumes occasionally producing pulmonary edema. Although interest in IV infusion of volatile anesthetics recently returned [27], it is unlikely to gain widespread clinical acceptance in the future.

Thiopental

Henry Price (1922–2002) pioneered the effort to connect the pharmacokinetic (PK) effects of IV anesthetics to their pharmacodynamic (PD) effects. In 1960, he suggested that redistribution of thiopental from vessel-rich tissues (e.g., brain) to less well-perfused tissues (especially muscle)—rather than elimination of the drug from the body or uptake by fat—governed the initial rapid awakening from thiopental [28]. Cedric Prys-Roberts and Chris Hull in England, and Don Stanski in the US, used these pharmacokinetic-dynamic concepts to expand our understanding of the clinical properties of newer IV drugs (see Chapter 40).

Thiopental was used to induce a deep coma-like state in patients with traumatic head injuries (or strokes), the rationale being that thiopental possessed ‘brain protecting effects’ because of its ability to decrease cerebral metabolism and intra-cranial pressure. In 1962, Ellison (“Jeep”) Pierce and colleagues at the University of Pennsylvania demonstrated that thiopental proportionally decreased cerebral metabolic rate and cerebral blood flow, and increased cerebral vascular resistance [29]. In 1973, Jack Michenfelder (1931–2004) and Richard Theye (1923–1977) at the Mayo Clinic, showed that thiopental diminished cerebral energy requirements by reducing metabolic activity, thereby affording some degree of protection of the functioning brain

(i.e., the brain in which thiopental could decrease metabolic rate) [30]. Unfortunately, in the absence of brain function (i.e., in the case of severe [global] hypoxic brain injury), thiopental provided no improvement in clinical outcome. Nevertheless, thiopental-induced coma remains a common treatment for acutely head-injured and post-cardiac arrest patients.

Etomidate

The cardio-respiratory depressant effects of thiopental prompted a search for a more 'ideal' IV anesthetic, one having thiopental's good characteristics but not its limitations. In 1964, Paul Janssen (1926–2003) and colleagues reported their synthesis of etomidate, a new IV anesthetic, with a chemical structure unrelated to that of any other IV anesthetic. Alfred Doenicke described early clinical studies with etomidate in 1974 [31]. An aqueous solution of etomidate (Amidate) was unstable at physiologic pH, and etomidate was formulated as a 0.2% solution with 35% propylene glycol at a pH of 6.9, a combination producing pain on injection. In 2006, a lipid emulsion formulation (Etomidate-Lipuro) was introduced in Europe which produced less pain on injection [32]. Etomidate advocates pointed to a major advantage compared to thiopental: minimal cardio-respiratory depression even in patients with clinically-significant cardiovascular disease [33]. Many anesthesiologists considered it to be the induction agent of choice for high-risk patients who would benefit from preservation of a normal blood pressure during induction of anesthesia (i.e., patients with clinically-significant cardiac and cerebrovascular disease), from so called 'stress-free' anesthesia. My research group at Stanford University subsequently demonstrated that etomidate's ability to maintain a 'stress-free' state was not due to its central effect, but rather to a peripheral action, namely inhibition of adrenal steroidogenesis.

Propanidid

A chance observation that eugenol, a centrally-active compound derived from the oil of cloves and cinnamon exhibited anesthetic properties, led Jean Thuillier and Robert Domencio to use a congener of eugenol for IV anesthesia [34]. Propanidid [Epontol, Fabontal], a phenoxyacetic acid derivative of eugenol, was introduced into clinical practice in Europe in the 1960s as the first non-barbiturate IV anesthetic. This so-called ultra short-acting anesthetic became popular for brief day-surgery (ambulatory) procedures. Unfortunately, this poorly water-soluble compound was formulated in a Cremophor EL solution causing hypersensitivity reactions that led to the withdrawal of propanidid from clinical practice.

Steroid Anesthetics

In the early 1970s, Glaxo Research examined many pregnanedione derivatives, eventually leading to the development of CT-1341, a mixture of two steroids, alphaxalone and alphadolone in a Cremophor EL solution, and eventually marketed in 1973 as Althesin (also Alfathesin) [35]. Alphaxalone provided the anesthetic activity, and alphadolone enhanced the solubility of alphaxalone. Althesin became a popular anesthetic in Europe and elsewhere for short day-surgery procedures, but was never marketed in the US. Its brief duration of action facilitated control over the hypnotic state when administered as a continuous infusion for maintenance of anesthesia [36]. Unfortunately, as with propanidid, the Cremophor EL solubilizing agent produced rare but dangerous hypersensitivity reactions, resulting in Althesin's withdrawal from the market in 1984.

Minoxalone, a water-soluble, rapid-acting steroid was developed in 1979. However, excitatory reactions and more prolonged recovery times limited its use. Most recently, the steroid anesthetic pregnanolone (eltanolone), a naturally occurring metabolite of progesterone, solubilized in the lipid emulsion used to dissolve propofol, was tested for its anesthetic properties. Although it rapidly induced an hypnotic state [37], etanolone produced longer recovery times than propofol, and it was never approved for clinical use.

Phencyclidine (PCP) and Ketamine

PCP was synthesized in 1928. Investigations into the clinical use of cyclohexylamines began in 1958, with two compounds produced by the Parke-Davis Company, CI 395 and CI 400. Both drugs produced disorientation, agitation and hallucinations. According to Vincent Collins, CI 400 produced "reverberation" (i.e., selecting a phrase that would then be repeated rapidly, sometimes for the entire duration of the procedure) [38]. Although rejected for use in humans because it produced hallucinations, mania, delirium and disorientation, CI 395 (Sernyl, [the name it was given prior to clinical testing is said to be derived from 'serenity']) was approved for use in veterinary medicine in 1962 [39].

Calvin Stevens, working at Parke Davis Laboratories, synthesized the 'sister' drug of Sernyl known as CI 581, later called ketamine (Ketalar or Ketaject). After relocating to the US and entering the practice of anesthesia, Guenter Corssen (1916–1990) became an active investigator and passionate advocate of new IV anesthetic drugs and delivery systems. In 1965, he and Ed Domino (father of Karen Domino (author of chapter 18 in this book) at the University of Michigan first used ketamine clinically [40]. They noted that "CI 581 appears to produce a state resembling cataplexy where patients felt as though they were in outer space, or had no arms and

legs.” They proposed the term “dissociative anesthesia” to describe an unconscious state with profound analgesia but devoid of the cardio-respiratory depressant effects associated with the commonly used barbiturate compounds [41].

In the early 1970s, as a graduate student in pharmacology at the University of California, San Francisco, I became interested in IV anesthesia, initially investigating the pharmacologic properties of ketamine and its interactions with the volatile anesthetics [42]. Ketamine was a racemic mixture of two optical isomers and in a preliminary clinical trial we performed at UCSF in the late 1970s, it was found that the S(+) isomer possessed more potent hypnotic and analgesic properties than the R(−) isomer [43]. The S(+) enantiomer also produced less prominent psychomimetic properties and allowed a faster recovery of cognitive functioning [44].

Subanesthetic doses of ketamine produced profound analgesia and amnesia without suppressing consciousness and protective reflexes, useful properties in patients having emergency surgery. Analogous to PCP, anesthetic doses of ketamine could produce untoward psychomimetic side effects. A surgical colleague asked a young Eger to anesthetize an elderly VIP with diabetes and significant vascular disease, for debridement of a gangrenous big toe. Eger suggested to the patient that a spinal anesthetic might be just what was needed, but the patient demurred, observing that the surgeon had suggested this new anesthetic, called ketamine. Prompted by youth, arrogance, and an absence of any experience with ketamine, Eger agreed, supplying what generously might be called an “uneven” anesthetic. Nonetheless, he and the patient survived. A month later, his surgical colleague called on Eger to again anesthetize this patient. Eger had barely entered the room for his preoperative visit when the patient pointed his finger at him and said “Don’t you give me that stuff again. I wasn’t right in my head for two days.”

Luis Vasconez (a prominent plastic surgeon at UCSF) and I, developed a ketamine-based sedation-analgesic technique for patients having cosmetic surgery procedures [45]. The technique consisted of an intravenous benzodiazepine followed by sub-hypnotic doses of IV ketamine in combination with local analgesia. With this technique, patients breathed spontaneously and maintained good oxygenation without requiring ventilatory assistance or supplemental oxygen. Many patients reported vivid dreams (e.g., one elderly San Francisco matriarch commented in a beautifully composed ‘Thank You’ card [that had a flock of multi-colored birds flying through the sky on the cover] that she felt she was flying above the operating table throughout the procedure). Although some patients reported dreams akin to “near death” experiences (e.g., descending down a dark tunnel with a bright light at the end), most patients found the dreams interesting and many reported pleasant experiences.

In 1999, Manzo Suzuki and colleagues described the opioid-sparing effects of low-doses of IV ketamine

(50–100 µg/kg) given to supplement opioid analgesics [46]. More recently, several investigative groups have described the use of 100–200 µg/kg to minimize or replace opioids as part of an IV anesthetic technique, thereby decreasing respiratory depression [47]. These small doses of ketamine produce analgesia without the untoward psychological sequelae associated with ‘anesthetic’ doses.

Benzodiazepines

In 1961, Sternbach and Reeder at Hoffman-La Roche Laboratories synthesized the first IV benzodiazepine—diazepam (Valium). Released for clinical use in 1963, psychiatrists used it to relieve chronic anxiety, neurologists to control seizure disorders, and anesthesiologists to relieve acute situational anxiety prior to surgery. In 1965, Stovner and Endresen in Oslo reported on its use IV as an induction agent [48]. However, diazepam’s solubilizing agent, propylene glycol, produced pain on injection and venous irritation (i.e., thrombophlebitis). These properties and a prolonged recovery after short surgical procedures limited its popularity.

In 1971, lorazepam (Ativan, Temesta) was developed at Wyeth Laboratories and introduced into anesthesia practice for use as a premedication, but this benzodiazepine produced prolonged postoperative amnesia and fell into disfavor when elective surgery shifted from a hospital-based to an ambulatory setting. As with diazepam, lorazepam produced significant pain and venous irritation following IV administration.

In 1976, Rodney Freyer and Armin Walser at Hoffman-LaRoche Laboratories synthesized midazolam (Versed or Dormicum), a water-soluble IV benzodiazepine. Jerry Reves and his associates at the University of Alabama conducted the first trials in 1978, concluding that “Ro 21-3981 is a promising intravenous anesthetic agent. It appears superior to the closely related benzodiazepine, diazepam, in that it is more potent, less irritating, and shorter-acting” [49]. However, induction of anesthesia with midazolam produced a more prolonged recovery than did thiopental (or ketamine) [50], and it never became popular for that purpose. Nevertheless, it quickly became widely used as a sedative-hypnotic agent for premedication and IV sedation.

At a meeting held on Hilton Head Island immediately before the launch of midazolam, Roche’s anesthesia advisory board warned the company that the availability of the higher concentration (5 mg/ml) of midazolam used for induction of anesthesia might lead to excessive dosing of the drug when given for IV sedation. The company ignored these warnings, and the FDA almost withdrew approval of this valuable drug following reports of multiple deaths due to ventilatory depression after IV administration (at doses similar to those used with diazepam) for sedation by non-anesthesiologists. These clinicians were unaware of the more rapid onset,

greater potency, ‘steeper’ dose-response curve, and more profound respiratory depressant effects of midazolam compared to diazepam [45].

1980–Present

Propofol

Iain Glen and colleagues at Imperial Chemical Industries (ICI) Laboratories in Macclesfield, England synthesized ICI 35-868, or propofol (2,6-diisopropylphenol) in 1973. The poor solubility in water prompted its initial solution in Cremophor EL and ethyl alcohol (the alcohol was soon removed). Preliminary studies in humans by Brian Kay and George Rolly in 1977 confirmed the excellence of propofol for induction of anesthesia, offering a rapid onset and short duration of action [51]. Pain on injection and possible anaphylactic reactions led these investigators to suggest that “Should further work in man confirm that ICI 35-868 has a desirable anaesthetic profile, it is hoped that an alternative formulation can be developed....” In 1983, propofol was reformulated in an Intralipid solution and subsequently marketed as Diprivan. Kay in the UK and Bob Fragen in the US performed the initial studies of the new formulation for induction of anesthesia [52, 53]. The major limitation seemed to be pain on injection, especially when injected into small veins.

A more serious problem appeared shortly after its introduction into clinical practice in 1986. Severe systemic infections associated with bacterial contamination of the injected propofol solution occurred when anesthetists attempted to ‘avoid wasting’ this expensive new anesthetic [54]. An anesthesiologist in New Zealand had saved the unused propofol from his cases on a Friday, and administered it to patients on the following Monday. Seven patients developed systemic infections with the same organism. Similar findings were reported in Canada. In the US, the Center for Disease Control reported post-surgical infections from contaminated propofol in Michigan, Maine, Illinois and California. Awareness of the problem led to an immediate solution—discarding all unused propofol at the end of the day. The manufacturers of commercial propofol took additional measures, namely adding excipients to retard bacterial growth (e.g., EDTA or bisulfite).

As a young academician at Stanford University, I met one of the international leaders in IV anesthesia, Professor John Dundee from Belfast, Ireland at an international meeting in Vienna in the early 1980s. We discussed our mutual interests in the barbiturates, ketamine, midazolam and propofol (even though propofol was not available for clinical investigation in the US at that time). Dundee strongly encouraged me to conduct clinical studies with this novel IV anesthetic for

day-surgery cases. When I returned to Stanford University, I contacted the medical director at Stuart Pharmaceuticals (the company which was responsible for developing propofol [Diprivan] for clinical use in the US) to discuss a research proposal to compare propofol with methohexital for induction and maintenance of anesthesia for short ambulatory surgical procedures. After obtaining IRB approval, I initiated the randomized, prospective study at Stanford.

Approximately one week after initiating the study, the US representative for ICI in the UK contacted me and advised against pursuing this study because the company had serious concerns about using the drug for maintenance of anesthesia. They felt that propofol might adhere to the volumetric drip chamber and IV tubing, and a negative outcome from this study might delay its approval by the US Food & Drug Administration for induction of anesthesia. The company’s primary interest at that time was to introduce propofol [Diprivan] in the US as an alternative to thiopental for routine induction of anesthesia. Fortunately, I convinced them to allow me to continue my study by arguing that the maintenance period for brief ambulatory procedures was so short that the maintenance infusion could also be considered as a ‘slow bolus injection’ (over 15–20 min). As it turned out, their fears were groundless and subsequent clinical studies confirmed the safety and efficacy of propofol infusions for maintenance of general anesthesia as part of balanced and total intravenous anesthetic techniques.

In the 1980s, outpatient (ambulatory) surgery became increasingly popular for elective surgical procedures. In this context, propofol offered clinically significant advantages over both inhaled and other IV anesthetics [55, 56]. Propofol produced less residual postoperative sedation and less nausea and vomiting (PONV), side effects that were known to delay discharge after ambulatory surgical procedures. Post-anesthesia care unit (PACU) nurses commented that patients given propofol were more alert and clear-headed (i.e., less drowsy) and not infrequently displayed behavior consistent with a mood elevation (‘euphoria’). Rapid awakening and absent PONV were important because efficiency and economy assume greater importance in the ambulatory setting and compensated for the initial greater expense of proprietary propofol (Diprivan).

The early awakening after a single (induction) dose of propofol might equal that after a similar induction dose of thiopental because initial recovery (i.e., awakening or emergence) resulted from re-distribution of drug from brain to muscle and subsequently to fat, as described earlier for thiopental by Price [28]. Although redistribution occurred almost as rapidly with thiopental as with propofol, later recovery events were more dependent on drug metabolism and elimination (i.e., hepatic and renal clearance). Hepatic clearance of propofol was approximately 10 times greater than that of thiopental [56]. This latter factor increasingly influenced

recovery from its sedative-hypnotic effects as the duration of administration increased (as with a prolonged propofol infusion for sedation of ventilator-dependent patients in the intensive care unit (ICU)).

In 1980, Cedric Prys-Roberts from Bristol, England, introduced the concept of continuous intravenous anesthesia and the need for an index comparable to the minimum alveolar concentration (MAC) for volatile anesthetics [57]. He emphasized the importance of knowing the pharmacokinetics of an intravenous anesthetic in optimizing the continuous infusion technique. In 1985, Jerry Reves and his colleagues at the University of Alabama developed one of the first computer-assisted continuous infusion (CACI) devices [58]. In 1990, Gavin Kenny and his colleagues in the UK introduced the concept of target-controlled infusion (TCI) to facilitate administration of a propofol infusion for maintenance of general anesthesia [59]. In order to develop a computerized delivery system for propofol, information regarding the plasma (blood) propofol concentration, and the theoretical ‘target’ concentration in the brain or the “effect site” to produce the desired anesthetic state, was needed. One of the early studies describing propofol’s pharmacokinetic-dynamic profile was performed by my research group at Stanford University [60].

Although the availability of TCI systems facilitated the use of IV anesthesia throughout the world, no pharmacokinetic-based drug delivery system has been approved for clinical use by the US FDA. One FDA concern was that these systems are based on theoretical models derived from groups rather than actual measured concentrations of the drug in the blood and/or brain of the individual patient. A monitor measuring hypnotic effect (e.g., bispectral index [BIS] monitor) could potentially provide a surrogate endpoint for monitoring propofol’s effect on the brain. Using this EEG-based cerebral function monitor to assess propofol’s cerebral effects during balanced and TIVA anesthesia, a colleague of mine from Japan created a closed-loop delivery system providing for a prompt emergence from anesthesia even after prolonged administration of a large dose of propofol [61]. Other clinical studies have demonstrated that the use of BIS monitoring may reduce the average infusion rate of propofol during the maintenance period, thereby facilitating a faster emergence from general anesthesia [62].

I obtained an investigator-sponsored IND from the FDA in 1986, to study propofol for IV sedation during local and regional anesthesia, as part of a monitored anesthesia care technique [63]. Propofol provided for a more rapid recovery of cognitive function than midazolam, even when flumazenil was administered after midazolam [64]. Steve Shafer utilized data from our original propofol sedation study [63] to develop the dosing guidelines in the Diprivan package insert. The use of propofol for IV sedation progressively expanded worldwide, and in 2013, over 70% of propofol is administered for IV sedation in the operating room, and for diagnos-

tic and therapeutic procedures in locations remote from the OR (including the ICU).

With prolonged administration of propofol to critically ill neonates and adult patients in the ICU, cases of fatal lactic acidosis and hyperlipidemia were reported. This led to efforts to develop a lower lipid formulation of propofol (e.g., Ampofol [Amphastar Pharmaceuticals]). Unfortunately, this formulation was associated with increased pain on IV injection [65].

Etomidate

Untoward effects (e.g., nausea and vomiting) limited the clinical acceptance of etomidate for induction of anesthesia and IV sedation [66]. More importantly and unexpectedly, in 1984, an increased mortality was reported in critically-ill patients sedated with etomidate infusions in the ICU [67]. This finding was surprising in light of etomidate’s favorable hemodynamic profile and its alleged ability to produce a ‘stress free’ anesthetic state associated with low levels of cortisol and circulating catecholamines. Subsequent research at Stanford University demonstrated that etomidate inhibits 11- β -hydroxylase, an enzyme in the adrenal cortex responsible for the synthesis of cortisol, aldosterone, 17-hydroxyprogesterone, and corticosterone [68]. Etomidate suppressed adrenocortical function, and suppression persisted for 5–8 hr after even a single induction dose of etomidate [69]. Nevertheless, there may be hope for a “new” etomidate derivative. Cotton and colleagues reported that an analog of etomidate, methoxycarbonyl-etomidate, retains etomidate’s favorable pharmacologic properties but is so rapidly metabolized that it does not produce prolonged adrenocortical suppression after a single bolus injection [70].

S (+) Ketamine

Doenicke and his German colleagues [71] ‘re-discovered’ S(+)-ketamine more than a decade after our initial clinical study [43]. S(+)-ketamine was approved for clinical use in Europe in the late 1990s and is currently under clinical investigation in the US. However, the racemic mixture remains the most commonly used formulation of ketamine in most parts of the world [72].

Flumazenil

Unique among IV sedative-hypnotic drugs, the benzodiazepines possess a receptor specific antagonist, flumazenil (Romazicon, Anexate). Flumazenil was developed by scientists at Roche Laboratories and was introduced into clinical

practice in 1987 for reversal of residual midazolam-induced sedation and benzodiazepine overdose. Unfortunately, due to its rapid elimination relative to the benzodiazepine agonist, flumazenil therapy is associated with frequent ‘re-sedation,’ [73], and it is rarely used clinically except as an antidote for treating massive benzodiazepine overdose in the emergency department and to treat iatrogenic overdoses in diagnostic suites.

Total IV Anesthesia (TIVA)

In Chapter 40 by Fisher and Shafer entitled “Pharmacokinetic and Pharmacodynamic Modeling in Anesthesia”, these authors describe the ‘key players’ responsible for describing the PK-PD concepts that led to the development of modern TIVA. The clinical application of these PK-PD models improved the ability of clinicians to administer IV anesthesia and led to its growing acceptance throughout the world.

During the French–Indo-Chinese war in the late 1940s, two French anesthesiologists, Laborit and Huguenard developed a “lytic cocktail” to prevent circulatory shock in the wounded [74]. The so-called state of “artificial hibernation” (or “neuroplegia”) was induced by the simultaneous injection of a barbiturate; an analgesic, meperidine; and the tranquilizer chlorpromazine (L’Argactil), and was described as “a state of stress-free suspended animation”. The concept was characterized as “neurolept-analgesia,” a term Oliver Wendell Holmes had considered in 1846, before suggesting the term ‘anaesthesia’ to describe the newly demonstrated phenomenon. George DeCastro and associates in Belgium replaced chlorpromazine with the butyrophenone, haloperidol, and meperidine was replaced by the potent opioid analgesic fentanyl to produce another variant of neurolept analgesia [75]. Paul Janssen (1926–2003) and his colleagues at Janssen Pharmaceutica mixed another butyrophenone, droperidol, with fentanyl to produce the neurolept-anesthetic drug combination marketed as Innovar [76]. Although the FDA subsequently placed a ‘Black Box Warning’ on droperidol because of its ability to produce dose-related QT prolongation, there has not been a single case report describing ‘torsade de pointes’ or cardiac arrhythmias in the operating room even when large doses of droperidol were administered as part of a neurolept anesthetic technique [77]. A common observation was that patients given large doses of Innovar would lie quietly, awake and perfectly still, the picture of tranquility. When later asked how they felt, many would reply that it seemed as if they were in a ‘chemical straight-jacket’. Eger remembers patients given Innovar who commented that they believed that they were “going to die!” Because of the untoward psychotropic effects associated with droperidol (and other butyrophenones), many anesthesia practitioners abandoned neurolept-anesthesia. However,

small doses of droperidol (0.625–1.25 mg IV) remain in use for the prevention of PONV [77].

A feared complication of TIVA is the occurrence of awareness (recall) during the operation. Historical data suggests that awareness occurs more frequently during IV anesthesia than during general anesthesia with inhaled (volatile) anesthetics, in particular when patients receive neuromuscular blocking drugs [78]. Recent large scale clinical studies have reported that cerebral monitoring with the BIS device can reduce the incidence of intraoperative recall [79, 80]. However, a recent study by Avidan and colleagues found that use of a BIS monitor offered no significant advantage when end-tidal anesthetic gas monitoring was utilized during volatile anesthesia [80].

In addition to general anesthesia with TIVA, the use of lower dosages of IV sedative-analgesic drug infusions (e.g., propofol-remifentanyl or propofol-ketamine), in combination with local or regional analgesic techniques, represents an increasingly popular form of IV sedation, commonly referred to as monitored anesthesia care [81]. However, if the infusion rates of these sedative-analgesic drugs are too high or the patient is unusually sensitive to the CNS depressant effects of these compounds, the patient can rapidly progress from a state of ‘deep’ sedation to unconsciousness and the technique becomes yet another form of TIVA.

To facilitate a better understanding of IV anesthesia techniques, an international group of anesthesiologists, led by Elmer Zsigmond from Chicago, formed the Society for Neurolept Anesthesia (SONLA) in the 1980s. Recognizing the growing importance of other forms of IV anesthesia (e.g., TIVA and monitored anesthesia care), we changed the name of the society to the Society for Intravenous Anesthesia (SIVA), and it later became the International Society for Anesthetic Pharmacology (ISAP) [82]. The latter name change indicated the attempt to bring together experts in both IV and volatile anesthetic drugs in an attempt to improve anesthesia by combining the strengths of both techniques. At a scientific meeting in Cadiz, Spain in 1995, Steve Shafer described the advantages and disadvantages of inhalation versus intravenous anesthesia in a fictitious debate between Professor EI Eger II (‘Edmundo Eger Segundo’) and myself (‘Pablo Blanco’), a former graduate/medical student at UCSF who worked with Eger’s research group in the 1970s [83]. Neither anesthetic technique nor their proponents survived unscathed.

Reprise

Intravenous anesthesia, specifically TIVA, evolved from a technique used to induce anesthesia, to one providing ongoing unconsciousness and amnesia for surgical procedures performed under local, regional, and general anesthesia [84].

The use of propofol for induction and maintenance of anesthesia has grown remarkably during the last three decades, and in some parts of the world is now the standard for both sedation and general anesthesia [85]. However, the use of combined IV and inhaled (volatile), so-called 'balanced' anesthetic techniques, remains the most popular approach for general anesthesia in the US and other countries where computer-based IV drug delivery systems are not routinely available. Finally, the search continues for a more ideal IV anesthetic than propofol (e.g., a 'painless' propofol-type drug possessing analgesic properties but without cardio-respiratory depression).

Theodore H. Stanley

Summary

“Opioids” relieved pain for 6,000 years. In 1805, Serturmer isolated morphine from opium. In the last half of the nineteenth century, morphine pre-anesthetic medication shortened induction and decreased anesthetic requirement.

Several new opioids were synthesized between World Wars I and II. In 1942, the opioid antagonist nalorphine was synthesized. Using meperidine as a template, Janssen produced fentanyl in 1960 adding sufentanil and carfentanil in 1974 and alfentanil in 1976. In the late 1980s, Glaxo synthesized remifentanyl.

In the mid twentieth century, opioids were combined with sedatives, tranquilizers, and other drugs to produce “neuroleptanalgesia”, “neuroleptanesthesia”, and “artificial hibernation”. One form of this theme combined small doses of morphine and then fentanyl with halothane-nitrous oxide anesthesia in the 1950s and 1960s.

High-dose morphine “anesthesia” appeared early in the 1960s, becoming popular in patients having valvular heart surgery despite incomplete amnesia, histamine release with marked venodilation, and postoperative respiratory depression. Substitution of fentanyl for morphine produced less histamine release and less hypotension. Fentanyl doses up to 50 µg/kg minimized perioperative cardiovascular and stress hormonal changes.

The terms “effect site” and “context-sensitive half-time” arose in the early 1990s, displacing concepts such as half-life as guidelines for administering opioids and other anesthetics. The introduction of remifentanyl in the mid 1990s decreased the reliance on degradation and redistribution to terminate opioid effect. Rapid metabolic clearance terminated remifentanyl’s presence, providing a short duration of effect irrespective of the duration of infusion.

The introduction of short onset, short duration, intravenous anesthetics (particularly propofol and remifentanyl) led to the development of total intravenous anesthesia (TIVA). Quantification of the pharmacokinetics of these compounds, invention of “anesthetic depth” monitors, and availability of “smart” infusion pumps enabled Schwilden and others to show that kinetic models can predict effect-site concentrations for populations.

Until the 1970s, little research focused on perioperative pain management, particularly during the postoperative period. Postoperative analgesia consisted of fixed modest intramuscular doses of opioid given at set intervals, often resulting in inadequate analgesia. The 1970s discovery of spinal opioid receptors opened a new path to pain management. The 1970s also saw the invention of patient controlled analgesia. In the 1980s, transdermal patches and transmucosal delivery systems expanded the means of opioid delivery and improved pain control.

Early History

“Opioids” constitute the oldest class of compounds still routinely used to relieve pain [1–4]. For 6,000 or more years, patients swallowed or inhaled opium obtained from the poppy plant, *Papaver somniferum* [1–4]. Ancient Egyptians used it to ease pain and induce sleep [1, 2]. Avicenna (Ibn Sīnā, 980–1037), an 11th century CE Persian physician, philosopher, and scientist, described opium as the most powerful of stupor producing substances [1]. For centuries, the dried

milky juice of the poppy’s seed pod, mixed with brandy or wine or the juices of mandragora, hemlock, hemp, or henbane [1–4], might be swallowed to minimize the agony of surgery. Few patients drinking these confections however, had event-free, reliable anesthesia [1–4]. These inadequacies led some countries (France) to condemn (for witchcraft) physicians attempting to create anesthesia with potions, later declaring the practice illegal [1, 2].

To make a “sleeping sponge” in the Middle Ages, a sea sponge was soaked with the juices of opium, mandragora, henbane root and more [1]. Patients were told to breathe through the sponge and swallow any juices leaking from it. Despite some popularity, “sleeping sponges” were minimally successful. If unconsciousness did supervene (perhaps from ingesting opium and alcohol), application of a vinegar-

e-mail: Theodore.Stanley@hsc.utah.edu

soaked sponge to the face supposedly revived the patient [1–4].

In 1656, Christopher Wren gave solutions of opium (and other compounds) intravenously via a quill inserted into a dog's vein. He caused unconsciousness in some dogs but killed others. Anesthetic and surgical practice did not change as a result [2]. In the 18th century, tincture of raw opium (laudanum or paregoric elixir) was injected to produce analgesia. A Dutch chemist named Le Mort formulated the first of these preparations in 1715 [5].

Opioids in the Nineteenth and Early Twentieth Centuries

Advancing the controlled administration of opioids, Serturner isolated morphine from opium in 1803 [1–4, 6], Francis Rynd introduced the hollow needle in 1844, and Charles Pravaz made the piston syringe in 1853 [1–4, 7]. Using the needle and syringe, Alexander Wood initiated intramuscular delivery of medications, injecting morphine in measured amounts to treat neuralgias [8].

Codeine (o-methyl morphine) is one of 20 pharmacologically active opioids in opium. It is found in concentrations of 0.9–3.0% in raw opium and was first isolated in 1832 in France by Pierre Robiquet. Morphine, the most common alkaloid, represents 4–23% of opium [9]. Codeine was originally used for its anti-tussive and anti-diarrheal actions, and is currently one of the most widely used opioids in the world. Its popularity reflects a wide margin of safety; the ability to be used alone or in combination with non-opioid analgesics (acetaminophen, Tylenol, aspirin); and efficacy as a peri-operative analgesic (for mild to moderate pain), cough suppressant and anti-diarrheal agent.

By the mid 1850s, ether and chloroform anesthesia were used world-wide [1] with often slow and sometimes stormy anesthetic inductions. Intramuscular injection of 10–15 mg of morphine made anesthetic induction faster and smoother [1–3, 10–12]. The addition of atropine or scopolamine intramuscularly further smoothed induction by reducing airway secretions. Preanesthetic injection of the combination became routine in the late 1800s. Morphine was the first premedicant used before general anesthesia [10, 11]—unless one considers the occasional fortifying slug of alcohol.

Alder Wright, an English chemist working in St. Mary's Hospital Medical School in London synthesized heroin (diamorphine or diacetyl morphine) in 1874 [13]. It was not introduced clinically until resynthesized 23 years later by Felix Hoffman, working for the German pharmaceutical company today called Bayer. Diacetyl morphine is 1.5–2.0 times as potent as morphine. Bayer marketed the compound

as a non-addictive morphine substitute and cough suppressant from 1898 to 1910, under the trademark “Heroin”. The Bayer Company also marketed Heroin as a cure for morphine addiction until it was discovered that it is rapidly metabolized into morphine and is essentially a more rapid acting form of morphine. The Heroin story became a historic blunder for Bayer [14]. Because of its popularity as a recreational drug, heroin is now only legally available for use as a peri-operative intravenous analgesic in the UK and a few European countries.

Between 1895 and 1905, some clinicians in Europe and the US noticed that increasing the dose of morphine premedication shortened the time for induction and decreased the amount of inhaled anesthetic needed [11, 12]. Extrapolating from these observations led to a morphine-scopolamine anesthesia or “twilight sleep” [11, 12, 15, 16]. Large doses of morphine (sometimes as much as 1–2 mg/kg) plus scopolamine (0.01–0.04 mg/kg) injected in divided doses provided complete anesthesia for surgical procedures and obstetric deliveries. This approach to anesthesia was initially popular [11, 12, 15, 16], a remarkable outcome given the profound respiratory depression caused by these doses of morphine and the concurrent absence of assisted or controlled ventilation. The technique was abandoned after 1915 because of associated operative morbidity and mortality. From 1915 to 1947, intraoperative opioid use virtually disappeared in the US [2–4, 10–12, 15, 16]. When hydromorphone (Dilaudid) and hydrocodone (Dicodid) were introduced in 1926 and 1943 respectively, they were used almost exclusively before or after surgery [2–4]. Introduction of the short-acting barbiturates and especially thiopental in 1935 [1, 10, 17, 18], and the popularization of “balanced anesthesia” ultimately renewed enthusiasm for the intraoperative use of opioids in the late 1940s [19, 20].

Balanced Anesthesia and the Introduction of Meperidine

The concept of “Balanced Anesthesia” originated with George Crile's 1910 theory of “Anoci-association” [18]. Crile believed that light general anesthesia blocked the psychic stimuli associated with surgery while local anesthetic agents injected around or dripped onto nerves blocked painful stimuli.

John Lundy introduced the term “balanced anesthesia” in 1926 [19] to describe the balance of agents and techniques needed to produce the different components of anesthesia (analgesia, amnesia, muscle relaxation and blockade of autonomic reflexes). Of course in the 1920s and 1930s, neuromuscular blocking agents had yet to be introduced, and surgeons' resistance to the intra-operative

Table 48.1 Opioids synthesized in Germany from 1914 to 1937

use of morphine (because of the problems of morphine-scopolamine anesthesia) meant that opioids rarely (except as part of premedication) supplied the analgesic component of balanced anesthesia. Nitrous oxide, diethyl ether or a local anesthetic supplied analgesia [4, 10]. This changed with the introduction of meperidine in the US after World War II [20].

Preparing for World War II in the 1930s, the German government sought a synthetic opioid that could replace morphine. Morphine had proven useful in managing pain from battle injuries, but was only available (at that time) from outside Germany. Blockade could impede access to morphine. In 1932, while searching for a synthetic anticholinergic drug, the German chemical industry made a synthetic opioid, meperidine (called pethidine in Europe) [21, 22]. In 1946, meperidine became available in America. In 1947, William Neff in California reported that meperidine provided the analgesia needed in N₂O-O₂ techniques [20]. Two years later, English anesthetists Mushin and Rendell-Baker described the use of meperidine as an analgesic supplement during N₂O-O₂ anesthesia [22].

Initially in the US and UK, opioids were used with N₂O-O₂ after induction with thiopental [4, 10, 20, 23, 24]. Later, in the 1950s and 1960s, small amounts of morphine and then fentanyl were used to supply analgesia during halothane–nitrous oxide anesthesia [4, 10, 20, 25]. Greater amounts of opioids were given with enflurane (1970s) and isoflurane (1980s) to supply analgesia and decrease the amount of inhaled agent required. In addition, their action on the central vagal nucleus in the brain minimized tachycardia [26, 27]. These approaches continued with sevoflurane and desflurane (1990s to present) [10, 28]. Some form of balanced anesthesia that includes administration of an opioid is perhaps the most common anesthesia technique used today in adult patients in the US and elsewhere. Its popularity is based on evidence that combinations of opioids and inhaled anesthetics allow the use of lower doses and/or concentrations of each [10]. Less depression of the cardiovascular and other systems, a more rapid recovery, and possibly less post-operative side effects may result.

Germany and World Events Impact Anesthesia, Science, Thinking and Commercial Development in the US, UK, and Europe

As noted above, the failure of heroin to be “the new and superior morphine of the future” embarrassed Bayer in the 1910–1914 period. The beginning of World War I in June of 1914, and the political events leading to World War II, stimulated German universities and pharmaceutical companies to synthesize new opioid analogues or opioid like compounds with strong analgesic activity. Most chemists of the period chose either morphine, thebaine or codeine (all components of opium) for their starting point, hoping to produce semi-synthetic compounds having less addictive properties, fewer side effects, and as much or more analgesic, anti-tussive and anti-diarrheal activities. New semi-synthetic opioids (oxymorphone, oxycodone, hydrocodone, and hydromorphone) and opioid-like compounds (meperidine and methadone) all resulted between 1914 and 1937 (Table 48.1). A few of these made it to the US before the end of World War II (hydromorphone [Dilaudid], late 1920s; oxycodone, 1939; hydrocodone, 1943), and fewer made it to the UK, but most remained unavailable in these two countries until after the war (Personal communication with Dr. Paul Janssen and Dr. Jorge de Castro).

After the war, the Allies confiscated German patents, trademarks and research records. Some research records were slowly released over the next two decades, slowing the post-war introduction of these opioids into the UK, and North and South America. In contrast, the availability, use, and experience of clinicians in Continental Europe with the German opioids before, during and after World War II, allowed physicians in these countries to become familiar with intravenous opioids and opioid-like analgesics as analgesic supplements. This accelerated European acceptance of the Janssen opioids introduced in the late 1950s–1980s. First came dextromoramide (Palfrum), followed by phenoperidine and then fentanyl, alfentanil and sufentanil, some mixed with new intravenous hypnotics, tranquilizers, sedatives, and amnestics as early forms of balanced anesthesia. The successes of German companies with the new opioids, and the popularity of ultra short acting barbiturates stimulated many European pharmaceutical companies to pursue

the development of similar compounds from the late 1940s through to the 1960s.

During this period, the situation in the US and the UK differed significantly from that in Europe. The German opioids synthesized between 1914 and 1937 were either not available or had limited impact on anesthesia practice (perhaps partly due to surgeons' resistance to the use of intra-operative opioids as mentioned previously) in these countries. In addition, most companies in the US and UK anesthesia related business (British Oxygen Company, Ohio Medical, von Foregger, Heidbrink, McKesson and others) sold anesthetic machines which delivered anesthetic gases contained in tanks (also sold by the companies) or volatile liquids delivered from vaporizers on their machines. Inhalation anesthesia was a US and UK invention, and to an extent is still a more important part of anesthetic practice in the US and UK than intravenous anesthesia, the reverse being true in Europe (see section on total intravenous anesthesia). Finally, the capital cost of the machines required to deliver an inhaled anesthetic exceeded that required to deliver an intravenous anesthetic, a significant factor for Europe, recovering from an economically disastrous war. Thus in the first two decades after World War II, European but not North American companies vigorously pursued development of new intravenous opioid and non-opioid anesthetic compounds.

Neurolept Analgesia—Anesthesia

In the late 1940s and early 1950s, European investigators re-examined inhalation anesthesia [4, 29–33], believing they might create a better state of general anesthesia with less organ system depression by substituting or adding intravenous compounds. The success of the barbiturates in the 1930s and early 1940s stimulated several European companies to look at other “intravenous anesthetics” as potential alternatives to inhalation agents. These approaches sought a “better anesthetic state,” one that provided analgesia (and thus was more effective at blocking the “stresses of surgery”), anxiolysis, sedation and hopefully amnesia without disturbing (or minimally altering) cardiovascular, respiratory, and other vital organ functions [4, 29, 30].

In 1954 in France, Laborit and Huygenard introduced the idea of artificial hibernation [29]. They attempted to inhibit cellular, autonomic, and endocrine mechanisms that are normally activated in response to stress. They developed a “lytic cocktail” containing an analgesic (meperidine), two tranquilizers (chlorpromazine and promethazine), and atropine [29, 30]. The resultant “artificial hibernation” (also called ganglioplegia or neuroplegia) often produced circulatory depression and delayed awakening, and did not achieve widespread popularity [4]. Another approach called “ataralgesia” nominally provided tranquility and freedom from pain by

combining an analgesic (meperidine), a tranquilizer (mepazine), and an analeptic (aminophenazole). A related cocktail called “narco-ataralgesia” used diazepam, phenoperidine, and droperidol. Neither was widely accepted for reasons similar to those described above [4].

Janssen synthesized haloperidol, the first member of a new series of tranquilizer compounds called butyrophenones in the late 1950s. It induced a syndrome called “neuroleptosis” [4, 32] consisting of inhibition of psychic, vegetative, and motor functions (patients became cataleptic) and suppression of apomorphine-induced vomiting. In 1959, de Castro and Mundeleer combined haloperidol with the new narcotic analgesic, phenoperidine in the first demonstration of neurolept analgesia (NLA)—a detached, pain-free state without marked circulatory depression [33]. In the 1960s, NLA with haloperidol and phenoperidine achieved significant popularity in Europe as an alternative to anesthesia using potent inhaled agents [4, 31, 34]. Janssen and colleagues then produced even more potent drugs, the butyrophenone droperidol, and the opioid fentanyl [4]. In 1963, de Castro and Mundeleer found the fentanyl–droperidol combination superior to haloperidol and phenoperidine for NLA, with more rapid onset of analgesia, less respiratory depression and fewer extrapyramidal side-effects [4, 31, 34]. Use of NLA with fentanyl and droperidol became widespread throughout Europe in the 1970s and early 1980s. When N₂O was added to the mixture in the early 1960s (to improve analgesia and amnesia), the technique was called neurolept anesthesia (NLAN).

Besides droperidol and haloperidol, a phenothiazine (usually chlorpromazine and promethazine) or sometimes diazepam were used with fentanyl for neurolept analgesia in Europe during the 1960s–1980s. Some historians believe the numerous variations in NLA techniques developed during this interval deterred further popularization of the technique. Reasons cited include confusion about the choice, timing, and dosage of drugs to be administered, and the unclear indications for and contraindications to NLA [4]. It is also possible that NLA and NLAN are inferior approaches to anesthesia. That might explain the numerous variants developed in a search for something better. As a result, many European clinicians lost confidence in the efficacy of NLA and NLAN. In the US, neither NLA nor NLAN became popular because of the aforementioned concerns, the lack of experience, and the unavailability of many of the compounds [4, 10].

Opioid Antagonists and Agonist-Antagonists

Pohl synthesized the first opioid antagonist, N-allylnorcodeine in 1914 while attempting to improve the analgesic properties of codeine [4, 10]. The discovery that this compound mildly antagonized the respiratory depression produced by morphine went unnoticed for 26 years, until

McCawley and co-workers (in 1940) in search of a strong analgesic with “built in” antagonistic action, attempted to prepare N-allylnormorphine (nalorphine) [4, 10]. Weyland and Erickson successfully synthesized nalorphine in 1942, and then found that the drug blocked all actions of morphine [4, 10]. In 1950, Schnider and Hellerback, found that nalorphine possessed strong analgesic properties in humans [4, 10, 35], but the doses needed to provide analgesia also yielded severe psychotomimetic effects, rendering it clinically unsuitable as an analgesic.

In 1960, naloxone was synthesized and found to be a more potent and less toxic opioid antagonist than nalorphine [4, 10, 36]. Naloxone produced no dysphoria at any dose but had a short duration of action [35]. By the 1970s, it had largely replaced nalorphine in the peri-operative period [4, 10]. In the 1980s, a longer lasting pure opioid antagonist called nalmefene was introduced for clinicians needing prolonged opioid antagonistic activity [10].

The discovery of nalorphine stimulated a search for other agonist-antagonist drugs in the 1950s. Most chemists focused on replacing the methyl (CH₃) group attached to the N of the piperidine structure in morphine (Fig. 48.1) or oxymorphone. Pentazocine (also known as Fortral or Talwin) was the first successful agonist-antagonist produced [4, 10, 37]. Synthesized by the Sterling-Winthrop Research Institute of the Sterling Drug Company of Rensselaer, New York in 1958, it was approved by the FDA in 1967 and released in mid-1967 in the US, England, Mexico, and Argentina. The hope was that pentazocine (which acts principally at κ rather than at μ receptors) would provide analgesia with less respiratory depression than morphine, and less liability for abuse. Although the potential for abuse is less and a ceiling for respiratory depression does occur at doses of 30–70 mg, the compound is only one-half to one-fourth as potent as morphine, resulting in maximal analgesia at a dose similar to that causing respiratory depression. It can also cause dysphoric side effects similar to those of nalorphine. None of the other agonist-antagonists found clinical or commercial success.

Re-introduction of High-Dose Opioid Anesthesia

Morbidity and mortality, likely from inadequate ventilation, caused the abandonment of twilight sleep by 1915. By the 1960s, assisting and controlling ventilation had become commonplace, enabling the re-introduction of high dose opioid administration. In the early 1960s, the cardiac anesthesia group at the Massachusetts General Hospital (MGH) in Boston, and de Castro in Brussels independently experimented with high-dose “opioid anesthesia” [38–41]. The Boston group used morphine and de Castro used fentanyl. Both used opioids to produce anesthesia without compromising cardiovascular stability. Their patient populations differed

Fig. 48.1 Morphine and meperidine shared characteristics that made them analgesics and provided clues in the search for a better opioid analgesic

however: the sickly Boston patients had surgery for end stage cardiac valvular disease while De Castro’s had routine surgical procedures such as cholecystectomy or bowel resection.

The cardiac anesthesia group at MGH contended with end stage rheumatic aortic and/or mitral valvular heart disease, low cardiac indices, and pulmonary dysfunction [38, 39]. The then standard induction of anesthesia, carefully performed with thiopental and succinylcholine, followed by N₂O, halothane and curare, frequently produced hypotension and arrhythmias, and cardiac arrest was not uncommon. Death during or soon after surgery was distressingly frequent. All patients required mechanical ventilation in the Respiratory Care Unit and most received morphine to enable them to tolerate their tracheal tubes. The anesthesiologists caring for these patients made a surprising observation: tens of milligrams of morphine were

usually required for tracheal tube tolerance in the post operative period, but these huge doses had minimal circulatory effects, and often resulted in unconsciousness [38, 39].

From this observation, Myron Laver, one of the cardiac team, reasoned that morphine might substitute for barbiturates and inhalation anesthetics for induction of anesthesia, and the team moved from small to large doses of morphine, first with additional inhalation anesthetics and then with only oxygen plus a neuromuscular blocking agent and scopolamine. Few of the patients anesthetized with the new technique reported awareness or pain. The high-dose morphine technique changed induction of anesthesia from an anxiety filled period to a calm controlled one that also set the stage for an orderly transition to postoperative mechanical ventilation.

After using the technique in 1,000 patients, the MGH cardiac anesthesia team formally studied 15 patients (7 with aortic-valve disease and 8 without major heart or lung disease) [39]. Published in December of 1969, the report confirmed the benign nature of a large dose of morphine in severely compromised patients. The 15 patients breathed 100% oxygen while 1 mg/kg of morphine was slowly infused [39]. The anesthetist had to shout at the patient to prompt continued breathing. Hemodynamics, measured frequently, remained stable, and additional morphine, sometimes up to 3.0 mg/kg was given. As the patients became unresponsive, they were paralyzed and the trachea intubated. Results of the study were “startling and pleasing” [38, 39]. The control patients (no heart or lung disease) had no consistent hemodynamic response; those with aortic valve disease experienced increased cardiac output and decreased systemic vascular resistance. The report changed the practice of anesthesia for patients with severe cardiac disease. Within months, clinicians throughout the US experimented with high-dose morphine-oxygen anesthesia in patients having cardiac surgery, and similar patients having major non-cardiac procedures, and reported positive results. Lowenstein’s classic article was rejected for presentation at the annual meeting of the American Society of Anesthesiologists.

Meanwhile in Brussels in the early 1960s, de Castro looked for ways to provide anesthesia that minimally altered cardiovascular dynamics and also blocked the “stress hormonal” responses to major surgery [40, 41]. He was not a cardiac anesthesiologist but did provide anesthesia for patients undergoing most kinds of surgery. He used large doses of the newly-introduced fentanyl (up to 50 $\mu\text{g}/\text{kg}$) plus oxygen to produce what he called analgesic anesthesia [40, 41]. He gave analgesic anesthesia to patients having cholecystectomy, gastric resection, bowel surgery, and similar operations, finding minimal cardiovascular and stress hormonal changes during and after surgery. He suggested that analgesic anesthesia had advantages beyond minimal cardiovascular and stress hormonal changes; simplicity (no need for hypnotics);

lack of side effects (no histamine release which can occur after morphine) and a high therapeutic index (safety margin 400 vs. 70 for morphine). His patients did not report awareness but their lungs often required mechanical ventilation for up to 3 hours after surgery, before tracheal extubation could be accomplished. He reported his results at the World Congress of Anesthesiology in Mexico City in 1976 [40]. He was unable to publish his results in a major anesthesia journal but did publish them in a regional European journal [41]. Because his work remained unknown to most anesthesiologists, it had little impact on the world anesthesia community.

Between December 1969 and 1975, numerous reports extolled the virtues of morphine-oxygen anesthesia in severely ill patients [42–47]. Stanley studied the effects of high (1–3 mg/kg) and ultra-high (8–11 mg/kg) doses of morphine in patients undergoing cardiac surgery, finding advantages and disadvantages [43, 44]. The ultra-high doses decreased the need for non-opioid pharmaceutical supplementation and ensured that patients were “unaware”, but produced increased veno-vasodilation, requiring markedly greater crystalloid and or/colloid fluid replacement to maintain stable intra and postoperative hemodynamics and adequate urinary output. The greater infusion of fluids increased tissue edema. High dose morphine anesthesia became particularly popular in sick patients having valvular heart surgery [4, 10, 42–49]. However, nothing’s perfect! Problems with incomplete amnesia, histamine release, prolonged postoperative respiratory depression, increased blood volume requirements secondary to marked venodilation, and hypotension and hypertension limited the popularity of morphine as a sole anesthetic [4, 10, 42–49].

The problems with high-dose morphine prompted studies of high-dose fentanyl anesthesia in animals [50–53], and then in patients having first valvular and later coronary artery surgery [54–56]. Clinical success in the late 1970s and early 1980s dramatically increased fentanyl usage. Sales in the US increased 10-fold during the first year the drug was off-patent (1981) [34]. Why? Before the reports of high-dose fentanyl anesthesia, fentanyl was infrequently used in a dose exceeding 50 μg for an entire operation. However, after the reports, fentanyl doses used in cardiac operations increased to 50–100 $\mu\text{g}/\text{kg}$ [34, 42]. High-dose fentanyl anesthesia rapidly replaced high-dose morphine for both cardiac patients having valvular heart surgery and patients undergoing the new coronary artery bypass operations in the 1980s [10, 42]. Fentanyl’s advantages over morphine were its greater potency and ease of use (it could be safely administered rapidly in a minute or less), its shorter onset and duration of action, and an absence of histamine release and venodilation. As a result, induction of anesthesia was faster. There was less hypo and hypertension, blood and crystalloid volume requirements were not increased, and tracheal extubation and post-operative recovery occurred sooner [10, 42].

The marked increase in fentanyl usage throughout the world in the early 1980s spurred the Janssen Company to develop sufentanil and alfentanil [4, 10, 34, 42, 57–61]. Glaxo experimented with new opioids, resulting in remifentanyl [62], and Anaquest of the British Oxygen Company developed its own series of opioids that are on the brink of being introduced for wild life immobilization [63]. Alza and Anesta (young drug delivery companies in the mid 1980s) began experiments with fentanyl in transdermal patches and oral mucosal lozenges [64–68].

Paul Janssen and the Fentanyl Family of Analgesics

Janssen (“Dr. Paul” to friends and colleagues) was born (1926), raised, and educated in Belgium. After graduating from medical school, he gained a PhD while working with Nobel Prize winner Corneille Heymans at the University of Ghent [34]. His father, Conrad Janssen, much influenced Dr. Paul. His father started his professional life as a family doctor, later selling pharmaceutical products [34], mostly tonics, stimulants, vitamin preparations and organic extracts. During college, Dr. Paul, perhaps because of exposure to his father’s business, saw the importance of chemistry to medicine, what he called “medicinal chemistry.” He realized that selling only generic medicines limited the future of the company, and this heightened his interest in new drugs. He also understood that chemical structure determined action. In 1953, after visiting several US and European pharmaceutical companies and pharmacologists, Dr. Paul started Janssen Pharmaceutica. An early interest was the pain produced by muscle spasms. In 1955, he introduced the fifth of his newly synthesized compounds, ambucetamide (Neomeritine), a uterine antispasmodic still marketed for the relief of menstrual pain.

In 1953, morphine (Fig. 48.1) was the standard analgesic. Dr. Paul knew about the synthetic alternative, the less potent meperidine (see above). Both meperidine and morphine contain a piperidine ring (Fig. 48.1), and Dr. Paul conjectured that this was important to the production of analgesia. Working with meperidine as the lead molecule (because it was less complex and easier to manipulate than morphine), they began a search for molecules that were more powerful and specific analgesics, molecules with fewer unwanted side effects [34].

In 1956, the Janssen team thought that meperidine was one-tenth as potent as morphine because it poorly penetrated the blood-brain barrier.¹ To overcome this limitation, they believed a more fat soluble derivative was needed, leading

¹ In retrospect, we know that they got it backwards. Morphine penetrates more slowly than meperidine. But the rationale doesn’t matter to the end result.

Fig. 48.2 Various experimental steps led to a new opioid, and ultimately to the useful series shown in Fig. 48.3

them to replace the methyl (CH₃) group attached to the N at the extreme left of the meperidine molecule (Fig. 48.1) with a benzene ring. They then added a C=O in combination with two CH₂ groups between the left benzene and piperidine rings of the first new compound. The resulting compound R951 (Fig. 48.2), showed a greater analgesic potency. Addition of another CH₂ group between the benzene and piperidine rings in R951 produced R1187 (Fig. 48.2), a less analgesic compound than R951. In 1957, Janssen chemists changed the C=O group attached to the left benzene ring in R951 to a C-OH group, producing R1406 (phenoperidine; Fig. 48.2). At that time phenoperidine was the most potent opioid in the world, having 20 times the potency of morphine [34]. It was introduced into Europe in 1964, but not the US, as a potent, fast acting, short lasting analgesic for anesthetic use. It is still used in Europe.

In 1960, the Janssen team modified the phenoperidine molecule to produce fentanyl (Fig. 48.3). Fentanyl was approved for use in Europe 3 years later [34, 57]. Subsequently, the Janssen team created sufentanil (synthesized in 1974, introduced into Europe in 1979 and the US in 1985), alfentanil (synthesized in 1976, introduced into Europe in 1983 and the US in 1987) and carfentanil (synthesized in 1974 introduced into veterinary [wild life immobilization] medicine in 1986; Fig. 48.3; Table 48.2) [57–61].

Fig. 48.3 Clinically useful opioids that resulted from the steps suggested in the previous figure. The first three were used in humans, the last, carfentanil, was used to produce immobilization in animals

Fentanyl's Approval in the US

The international healthcare conglomerate, Johnson & Johnson (J&J), purchased Janssen Pharmaceutica in July 1961 [34], providing Janssen with financial security and access to individuals within the J&J family, including Robert McNeill, the founder of the Philadelphia Company, McNeill Laboratories, purchased by J&J in 1959. In the mid 1960s, Janssen successfully launched fentanyl and droperidol as independent drugs in Europe [32–34, 57]. Janssen could not however, get Food and Drug Administration (FDA) approval for fentanyl in the US [34]. Robert Dripps, Professor of Anesthesiology at the University of Pennsylvania, felt that fentanyl was too potent, and caused muscle rigidity. These effects, he thought, increased the need for tracheal intubation and would lead to abuse problems. McNeill knew Dripps and introduced Dripps to Janssen, beginning a dialogue that led to a compromise. Fentanyl would be submitted for approval in combination with droperidol. When approved by the FDA in 1968, fentanyl became available combined with droperidol

in a ratio of 50:1 droperidol to fentanyl. The combination was called Innovar in the US and Thalamonal in other countries.

Why with droperidol, and why a 50:1 ratio? Janssen had consulted with Belgian anesthesiologist, George de Castro [34]. De Castro had tested Janssen's intravenous (IV) analgesics, hypnotics, and sedatives in patients—after animal testing in the Janssen laboratories. He used fentanyl in combination with droperidol in a neurolept-anesthesia technique popular in some Western European countries in the early to mid 1960s. Reviewing his clinical practice, he found that he used fentanyl and droperidol in approximately a 50:1 ratio, the ratio then suggested by Janssen to Dripps. Both knew that the recreational use of droperidol produced a “bad high” and believed that mixing droperidol and fentanyl would minimize any abuse potential. The FDA agreed and Innovar was approved for use in the US in early 1968 (personal communication, P. Janssen and T. Stanley). Four years later, fentanyl became available alone but for the next six years only as a 1 ml vial containing 50 μg [34].

Opioids as Supplements to Induction of General Anesthesia

Today's anesthesiologists often use opioids to enhance the induction of general anesthesia [10, 42, 62, 69, 70]. They use doses of opioids during induction that exceed those used for entire surgical cases in the 1950s, 1960s and 1970s, thereby providing analgesia and decreasing tachycardia and hypertension during induction (including rapid sequence induction) and maintenance of anesthesia. Such administration also reduces the requirements for hypnotics during anesthetic induction and maintenance as well. Such benefits explain the present popularity of opioid use [10, 42].

The transition from infrequent small doses of opioids during the 1960s and 1970s to the more frequent and larger doses used today took place largely during the 1980s [10, 42]. In November of 1979, Ted Stanley, having introduced high-dose fentanyl and oxygen anesthesia in the US [54–56], was invited to join Simon de Lange at the University of Leiden to evaluate the then new opioids, sufentanil and alfentanil. They first visited de Castro in Belgium since he had great experience with these and most other opioids. They discussed the properties and advantages of alfentanil and sufentanil with de Castro and watched him administer both agents during various surgical procedures in order to gain insight into his experience with them.

De Castro was most impressed with alfentanil because of its rapid onset of action (60–90 s) and short duration (3–5 min) after a bolus injection. In December 1979, he suggested that alfentanil should be effective as a sole anesthetic induction agent, as an analgesic component of nitrous oxide–opioid “balanced” anesthesia, and possibly as a sole opioid

Table 48.2 Potency and safety comparisons of morphine, meperidine and some Janssen analgesic compounds. (From Janssen Pharmaceutica and de Castro et al. [60], with permission)

Compound	Tail withdrawal reflex ED50 (mg/kg)	Potency ratio ^a	LD50 (mg/kg)	Therapeutic index
Meperidine	6.15	1.00	29.0	4.72
Morphine	3.15	1.95	223	71.0
Phenoperidine	0.12	51.3	4.69	39.1
Alfentanil	0.044	140	47.5	1,080
Fentanyl	0.011	559	3.05	277
Sufentanil	0.00067	9,180	17.9	26,700
Carfentanil	0.00037	16,200	3.13	8,460

anesthetic for cardiac surgery. He was also impressed with the potency and ability of relatively high doses of sufentanil to block hemodynamic and hormonal responses to “surgical stress.” He thought it would be useful as a sole or principal opioid anesthetic for cardiac and major vascular surgery. De Lange, Stanley, Stanski and others began a series of studies with alfentanil and sufentanil in January 1980 that spread to other centers in the US and Europe, changing the way clinicians viewed and used opioids [71–80]. It became clear that both alfentanil and sufentanil could be administered (like fentanyl) in doses that resulted in unconsciousness in less than five minutes (<2 min with alfentanil) without appreciable change in heart rate and arterial blood pressure.

Publication of hundreds of papers in the 1970s studying large doses of morphine as an “anesthetic”, and then similar studies with fentanyl in the late 1970s and early 1980s, began a new anesthetic paradigm. This continued with studies evaluating alfentanil and sufentanil as induction agents, as sole opioid anesthetics for cardiac surgical and other procedures in the 1980s. With regulatory approval and introduction of alfentanil and sufentanil into clinical practice in the mid-1980s, clinicians (especially those in the UK and US) became more comfortable with larger doses of the potent opioids. While no opioid became popular as a “sole induction agent” (other than in high-dose opioid–oxygen anesthesia for cardiac or major vascular surgery), a large dose use of these compounds to provide analgesia before and during induction/intubation and during the maintenance of anesthesia, did catch on.

Sufentanil

The remarkable increase of sales in fentanyl as it went “off patent” stimulated sales of generic versions of the drug in the early 1980s. Concurrently, the Janssen research and development team had another newer opioid, sufentanil (Fig. 48.3), that they felt was superior to fentanyl and had a patent life that extended until the mid 1990s [34]. They believed sufentanil would be a better opioid for cardiac and major vascular surgery than fentanyl because early studies indicated that sufentanil provided more cardiovascular stability and greater

suppression of hormonal stress responses than fentanyl [10, 42, 71]. In addition, sufentanil was significantly more potent (which at the time was considered the explanation for its hemodynamic and stress hormonal superiority), had a markedly higher therapeutic index (which they reasoned would make it a safer drug for clinicians), had a similar or possibly faster onset time and shorter duration of action than fentanyl, and did not increase plasma histamine or cause venodilation [34, 42, 71, 72].

While subsequent studies generally confirmed the advantages of sufentanil over fentanyl [81, 82], its approval by American and European regulatory authorities (in 1982 in Europe and 1985 in the US) and introduction into clinical practice, did not have a major impact on clinicians. Sufentanil was usually priced significantly higher than fentanyl, impeding its acceptance. In addition, the introduction of the beta blocking drugs at about the same time neutralized sufentanil’s hemodynamic and stress hormonal advantages over fentanyl. While sufentanil did and still does find a place in many cardiac anesthesiologists’ practices, it was never a major commercial success. Sufentanil and alfentanil’s poor commercial performances in the late 1980s and early 1990s convinced the Janssen company that further research in opioids for anesthesiology was not worthwhile. The similarly poor commercial performances of etomidate and droperidol caused the company to leave the anesthesiology field entirely in the mid 1990s.

Alfentanil

Janssen synthesized alfentanil in 1976 and introduced it in Europe in 1983, and in the US in 1987 (Fig. 48.3). Alfentanil offered a rapid onset (60–90 s), short duration (5–10 min when used as a bolus) and a high therapeutic index (1080), (Table 48.2) [34, 42, 73–79]. These features caused the Janssen Company to envision alfentanil as the perfect opioid for short surgical and outpatient procedures and the increasingly popular total intravenous delivery of anesthesia [34, 42]. When alfentanil was introduced in the US in 1987, the possibility of a “blockbuster” was considered likely. It didn’t work out that way.

Although a large bolus dose of alfentanil produced unconsciousness in a minute or so, it also produced muscle rigidity in 70–80% of patients [74]. As a result, alfentanil did not become popular as an induction agent. Alfentanil's quick onset and short duration has been valuable in single or few bolus doses as a sole analgesic agent or in combination with inhaled or intravenous hypnotics for balanced anesthesia. However, when used for 45–60 min or longer, either as a continuous infusion or as many boluses, alfentanil accumulates in tissues and its duration becomes prolonged [79, 80, 83]. This made alfentanil less desirable for TIVA (see below) especially relative to remifentanil which was introduced into clinical practice in 1996 [84–86]. Alfentanil has a niche today as a rapid onset/offset analgesic IV bolus prior to short painful procedures [10], but even in that application, remifentanil often supplants alfentanil.

Total Intravenous Anesthesia (TIVA) and Opioids

By definition, TIVA is used for both anesthetic induction and maintenance with intravenous drugs alone [87]. Therefore TIVA excludes the use of nitrous oxide or volatile anesthetics. While the first intravenous anesthetic, chloral hydrate, introduced by Pierre-Cyprien Oré in Paris in 1872, could produce complete anesthesia, mortality associated with its use dampened enthusiasm for its application and for the development of other intravenous anesthetics until the twentieth century [87]. The first intravenous non-opioids developed for anesthesia in the early 1900s (hedonal, a urethane derivative introduced in 1909) and the early barbiturates (in the beginning of the 1920s) were slow in onset, had a long duration of action (or both) and were not successful in clinical practice [87]. The 1930s introduction of the ultra-short acting barbiturates changed anesthetic induction in adults.

The re-introduction of opioids into operating rooms, especially in the US and the UK, the increasing popularity of “balanced anesthesia” worldwide, and the introduction of neurolept analgesia (anesthesia) in Europe in the 1950s, set the stage for TIVA. The first TIVA advocates (they did not call it TIVA) introduced “artificial hibernation,” “ataralgesia,” “narco-ataralgesia” and neurolept analgesia. These approaches used an opioid (usually meperidine, phenoperidine, or fentanyl) plus non-opioid intravenous hypnotics (tranquilizers, benzodiazepines and other similar compounds). The theory was to independently regulate each anesthetic component (unconsciousness, amnesia, the sympathetic nervous system, and muscle relaxation) with intravenous agents that targeted the specific component. But the cumulative effects of the intravenous agents of the times and inadequate methods of administration (intermittent-bolus administration) resulted in delayed awakening and often circulatory

depression. Accordingly, interest in TIVA waned until the 1980s when the introduction of computerized pharmacokinetic-driven infusion devices combined with better drugs stimulated new research [87].

In 1981, Helmut Schwilden showed that a computer-controlled infusion pump guided by the published pharmacokinetics of the drug could produce target plasma anesthetic (and analgesic) concentrations in specific populations [88]. This began the application of target-controlled infusion (TCI) which is also sometimes called computer-assisted continuous infusion (CACI). Jacobs, Reves and Glass coined the latter terminology in 1991 [89]. With this technique, the anesthesiologist chooses a plasma concentration of both a hypnotic and an analgesic, usually an opioid. The technique accounts for the patient's characteristics and the degree of anticipated surgical stimulation. The computer-driven infusion pump then adjusts the drug infusion rate to obtain the targeted plasma concentration as predicted by pharmacokinetic information known for a similar population of patients.

In 1992, Shafer and Stanski showed that computer simulation programs of continuous infusions of intravenous anesthetics (including opioids) increased the understanding of these drugs' clinical pharmacokinetics [90]. It became clear that the terminal half-life of an intravenous anesthetic does not predict the rate of decrease of its plasma concentration after discontinuation of administration. In 1991, Shafer and Varvel found that the duration of drug infusion influenced the immediate rate of decline of fentanyl, alfentanil and sufentanil effect-site concentrations during recovery [91]. In 1992, Hughes and colleagues introduced the concept of “context-sensitive half-times” (the time it takes for the plasma concentration of an opioid to decrease by 50% after its infusion is discontinued). The concept was also confirmed with intravenous hypnotics [92]. In 1994, Young and Shafer proposed the desirable pharmacokinetic properties that an intravenous opioid should possess for rapid onset and recovery [93].

Some advocates of TIVA believe that ultimate acceptance of the technique depends on closed-loop administration [87]. The development of a feedback control system for maintaining neuromuscular blockade using neuromuscular blocking agents (pancuronium) was first described in 1980 and was considered a breakthrough [94]. The absence of an adequate feedback signal for the development of closed-loop systems for the control of other components of the anesthetic state, hypnotic depth, and especially a measure of analgesia, have impeded the development of closed-loop TIVA systems [87, 95]. TIVA has become increasingly popular in Europe in the last decade despite less than ideal closed-loop systems. This has resulted from the introduction of short onset, short duration intravenous agents (particularly propofol and remifentanil), and the quantification of their pharmacokinetics, the invention of “brain monitoring devices”, and the development of “smart” infusion pumps.

Fig. 48.4 Remifentanyl shares several molecular characteristics with its sister opioids fentanyl, sufentanyl, and alfentanil (see Fig. 48.3)

Modern infusion systems permit a controlled delivery of intravenous drugs that is superior to intermittent manual injections [4, 10, 96, 97]. However, some clinicians argue that the benefits may not justify the increased cost of the drugs and devices, and the complexity of the systems utilized. Another argument against TIVA is predictability. As Schwilden (and others) have shown, kinetic models can be used to fairly accurately predict effect-site concentrations, but these are for populations, and individuals may deviate considerably from population predictions. At present, TIVA is more popular in Western Europe than the US and the rest of the Americas. An important reason for this is that the US FDA has not yet approved a TIVA device or infusion system whereas several systems have been approved in Europe.

Remifentanyl

Commercial disappointment was Janssen's principal reason for terminating research into opioids for anesthesiology in the early 1990s. In contrast, the commercial popularity of propofol as a component of TIVA induced Glaxo to seek an intravenous opioid that was superior to alfentanil and more like propofol [10, 83]. In the late 1980s, chemists at Glaxo (and concurrently at a US Army laboratory) synthesized phenylpiperidine compounds with significant analgesic activity that underwent ester hydrolysis by both plasma and tissue esterases [10, 83–86]. The best of the Glaxo series of compounds was remifentanyl (Fig. 48.4), a lipid-soluble weak base (octanol/water partition coefficient of 19.9 at pH 7.4). Its pKa of 7.1 means that a significant amount of remifentanyl exists in the un-ionized form at physiological pH, which explains its rapid onset of action. Remifentanyl is a typical μ receptor specific agonist. It is slightly less potent than fentanyl and has respiratory and cardiovascular actions like other fentanyl congeners. Remifentanyl has the highest

therapeutic index (33,000) of any opioid and possibly any intravenous agent ever evaluated in rats. This is probably related to its extremely short duration of action [10, 83–86].

Remifentanyl is the first true “ultra-short acting” opioid and was approved for use by the US FDA and many Western European countries in 1996–1997. Remifentanyl's introduction in Europe in the late 1990s succeeded principally because of the popularity of TIVA in many European countries and the usefulness that a rapid onset, short duration, “very titratable” opioid brings to clinicians experienced and skilled in TIVA [10]. In contrast, remifentanyl's introduction in the US was considered by Glaxo to be a failure. Sales of the drug were far less than Glaxo had hoped they would be and within a few years Abbott Laboratories bought the US rights to the drug. Remifentanyl is still not extensively employed in the US, being largely confined to a handful of centers where TIVA and TIVA-like techniques are common. It has also gained popularity for neurosurgical cases requiring both intense analgesia during surgery as well as rapid dissipation of the opioid effect and rapid awakening following anesthesia.

For clinicians not experienced with TIVA, the rapid recovery after either a bolus or infusion of remifentanyl is often a liability rather than an advantage since patients may have little or no postoperative analgesia unless the infusion is continued or another opioid is administered toward the end of the surgical procedure [98]. One subtle untoward effect accrues from the use of high infusion rates of remifentanyl, an effect appreciated in the past decade. The high blood levels of remifentanyl present during administration increase the tolerance to opioids in the postoperative period [99]. The resulting increased need for opioids to control postoperative pain can increase unwanted side effects such as postoperative nausea and vomiting.

Opioids and Perioperative Pain Control

Perioperative opioid use began in the mid-nineteenth century when (as described previously) morphine was administered intramuscularly in the preanesthetic period to speed induction and decrease ether or chloroform requirements [10–12, 15, 16]. In the first 70–80 years of the twentieth century, morphine and other opioids (hydrocodone and hydromorphone in the 1920s and meperidine in the 1950s) were used for postoperative analgesia. In contrast to this clinical use, little research focused on perioperative, particularly postoperative, pain management. This changed radically in the last 50 years [100].

The concept of perioperative pain management by anesthesiologists is now well established [100–102]. In the 1960s, postoperative analgesia usually consisted of a fixed modest intramuscular dose of morphine or meperidine given at set intervals prescribed by the surgeon in the “post

operative pain orders.” In 1973, Marks and Sachar [103] showed that more than 50% of patients were under-treated with this approach. In 1968, Roe demonstrated that small IV doses of opioids provided more effective pain relief than did conventional IM injections [104]. Nonetheless, in the 1970s, many surgeons considered IM opioid injections safe, useful and adequate and resisted changes to this form of delivery [100–102].

Studies in 1980 by Austin, Stapleton, and Mather [105, 106] showed that a fixed IM dose of meperidine produced 5-fold differences in peak blood concentrations, 7-fold differences in times to reach peak concentrations and 4-fold differences in serum meperidine concentrations required to produce analgesia in different patients. Other studies confirmed these findings with other opioids [100–102, 107]. As long ago as 1971, Bellville and colleagues showed that there was no correlation between gender and analgesic requirement and no justification for calculating analgesic doses based on body weight or surface area [108]. More recent work confirmed these findings [107]. Still, surgeons resisted change. In 1985, Catley et al. [109] and in 1989 Brose and co-workers [110] showed that apnea and abnormal respiratory patterns occurred frequently, and hemoglobin oxygen desaturation could be severe following IM opioid administration. Resistance to change then began to diminish.

Forrest et al. [111] in 1970 and Catling and co-workers [112] in 1980, showed that small intermittent intravenous bolus doses of opioids could abolish wide swings in blood concentrations of these drugs, minimize respiratory depression, and permit the titration of the drug to the needs of individual patients. This method of delivering opioids set the stage for the introduction of patient-controlled analgesia (PCA) [111, 112].

Patient Controlled Analgesia (PCA)

Recognition of the variability in postoperative opioid requirements due to differences in individual patient opioid pharmacokinetics and, pharmacodynamics, as well as anthropometric and personality factors (first noted in the late 1960s and early 1970s by Sechzer [113, 114] and Forrest [111] and later by others [112, 115]) led to a new approach to managing postoperative pain. This approach was initially called “demand anesthesia” and later “patient controlled anesthesia” (PCA). It employed negative feedback. When patients experienced pain they gave themselves pain medication, and when pain decreased they did not [112, 114].

Sechzer pioneered on-demand or PCA in 1968 by evaluating the quality of the analgesic response to small intravenous doses of opioids given by a nurse, on patient demand [113]. In 1971, the study was repeated except that a machine gave the opioids [114]. Sechzer noted that his “demand

anesthesia” system provided pain relief with smaller total drug dosages than that with conventional IM therapy. He also observed that post-operative analgesic requirements of patients were often cyclical and varied greatly among individuals [113, 114]. Clearly the frequent administration of IV doses of opioids by nurses to large numbers of patients was impractical and costly. As a result the late 1960s witnessed the development of new PCA technologies [107].

Three investigators developed the first PCA prototypes: Forrest et al in 1970 [111] (The Demand Drop master that automatically administered IV analgesic drugs when activated by pressing a button in a handgrip); Sechzer in 1971 [114]; and Kerri-Szanto in 1971 [115] (The Demanalg). These early devices consisted of electronically controlled infusion pumps connected to timing devices triggered by patients [107, 111, 114–117]. When triggered, each device delivered a preset amount of opioid medication [111–121]. These devices decreased the incidence of moderate/severe post-operative pain from 20–40% to less than 5% when compared to conventional IM therapy [111–122]. The first commercially available PCA pump, the “Cardiff Palliator” was developed at the Welsh National School of Medicine in 1976 [107, 117, 123]. Digital electronics controlled the dose and imposed a lockout interval (to minimize the possibility of an overdose), and recorded the time of dosing.

In the mid 1970s, pharmaceutical companies recognized the market possibilities for these devices [117], and the associated potential for sales of their opioid analgesics. Thus, Janssen’s Scientific Instruments division introduced the On-Demand Analgesic Computer (ODAC), and Pharmacia AB of Sweden developed the Prominect. The ODAC had the most sophisticated microprocessor of the time controlling its PCA device. The ODAC also had a pneumograph suspending drug administration if the patients’ respiratory rate decreased to less than a critical value. The ODAC could administer opioids at a low (background) fixed rate and/or at a rate that varied automatically with patient demand. These forays of Janssen and Pharmacia into PCA devices stimulated entry of other companies in the late 1970s and 1980s with increasingly sophisticated microprocessor-based devices [117]. These companies included Abbott with its LifeCare PCA, Bard with its Harvard PCA, and Leicester with its Mircopalliator and its Programmable On-Demand Analgesia Computer called PROPAC. With the acceptance of PCA as a superior method of providing postoperative pain relief, the PCA concept spread to the treatment of cancer pain, obstetric pain, and as an investigative tool in drug trials and comparisons of analgesic techniques [107, 117].

In the last 5 years, simplified non-electric, disposable PCA systems have been evaluated and some introduced into clinical practice [117, 124]. These cost-effective devices are appearing in outpatient settings and patients’ homes as well as hospitals. While On Demand or PCA therapy was initially

only administered via the intravenous route, because of advantages to patients and caregivers it is now used with alternative methods that include oral, inhaled, nasal, buccal, transmucosal, transcutaneous, subcutaneous, and epidural approaches [107, 117, 118, 125].

Alternative Methods of Opioid Delivery

In the last 20 years the cost of inventing and developing new drugs including opioids and other analgesic compounds has dramatically increased, with total costs exceeding a billion dollars [10, 67, 126]. The result is that most large pharmaceutical companies will only invest in drugs with potential annual sales of more than a billion dollars. For smaller pharmaceutical companies, developing older drugs in patentable newer drug delivery systems (especially if these systems provide advantages to patients and/or caregivers) is an attractive alternative to developing new drugs [10, 126], because today's cost of developing an older drug in a new delivery system ranges from only 15–35 million dollars [10, 67, 126].

Opioid Transdermal Drug Delivery

Although dermal ointments and creams for local (transdermal) application have been used for hundreds of years, the first transdermal patents were only issued in 1971. The FDA approved a scopolamine transdermal patch in 1979, for management of nausea [67]. Its advantages compared to oral administration included decreased GI degradation and first-pass hepatic metabolism, more stable plasma concentrations, and an impressive improvement in patient compliance through greater ease of administration. Its modest success convinced the Alza Corporation in the mid-1980s that an opioid pain patch might provide similar advantages [67, 126]. The Alza researchers recognized that a good transdermal opioid would have a high potency, low molecular weight, be highly soluble in both water and lipid (because of the lipid content of the skin), and produce little or no skin irritation [67, 126, 127]. Fentanyl had these characteristics [127–131]. A fentanyl patch was first studied in patients with acute post-operative pain but produced too much respiratory depression [129]. The first fentanyl patch (Duragesic) approved by the FDA and European regulatory authorities was used in opioid-tolerant patients having cancer induced chronic pain in the early 1990s [10, 126].

At the time of the fentanyl patch development in the mid 1980s, Alza was a small California company without a sales force. Alza approached Janssen Pharmaceutica to help sell its new drug. Janssen's US marketing and sales people conducted an in depth market analysis that predicted peak sales of approximately 80 million dollars/year (a large amount at

that time), but they had a hard time convincing Dr. Paul that this new way of giving fentanyl would be successful. Finally, he allowed the partnership to proceed. The resulting Duragesic eventually became the most successful analgesic/anesthetic pharmaceutical product ever introduced, with sales in 2004 (its last year of patent life) exceeding 2.4 billion dollars. The success of the patch caused generic companies to copy the Duragesic once it went "off patent", adding alternative opioids including sufentanil.

The fentanyl patch succeeded in chronic pain management because one patch lasted for 2–3 days. It was less useful for acute pain because it took 14–18 hours to produce steady state concentrations. This prompted some investigators (Ashburn, Streisand, Zhang and others) [132, 133] and companies (Alza, J&J, and Cadence) to study methods that would speed opioid passage across the skin. These efforts started in the late 1980s and continue to the present (Ted Schroeder, President and CEO Cadence Pharmaceuticals Inc. personal communication) [10, 132, 133]. Iontophoresis augments drug passage through the skin with a small electric current applied to salts such as morphine HCL and fentanyl citrate [132]. Using this technique, analgesic doses were effectively delivered to patients with post-operative pain and opioid plasma levels were shown to be directly proportional to the electric current utilized [132, 133]. Reliability of these devices has however been erratic and no iontophoretic device for opioid delivery has been approved for use in the US or Europe.

Oral Opioid Transmucosal Drug Delivery

Sufentanil's 1985 approval in the US and many European countries allowed research into delivery by nasal, buccal, or ocular mucosa as a premedicant or to produce rapid onset analgesia for acute pain [10, 34, 66–68, 126, 134–136]. These studies in adults and children proved that sufentanil could be useful for such indications. Since the compound had many years of patent life remaining, cooperation of the Janssen Company was required for development of an approved product. The Janssen company preferred to focus on sufentanil's approved intravenous uses rather than on novel methods of delivery and this halted further efforts in the mid to late 1980s.

Similarly, in 1984, Stanley thought to put fentanyl in a "child friendly" red lollipop-like form, a sweetened lozenge on a stick which was later called an "Oralet", but the Janssen company declined involvement [65–67, 126, 137–140]. Undeterred, Stanley persisted, forming a small new company, Anesta, to develop oral transmucosal fentanyl citrate (OTFC). Stanley believed that this simple non-invasive, easy to titrate approach could be quickly and easily removed by the patient or clinician when the desired effect was evident. It would offer a rapid onset (5–15) minutes and relatively short duration (1–2 hours).

The Oralet (Fig. 48.5) gained regulatory approval in 1993 for use as a premedicant before surgery and for painful procedures in children and adults [65–68, 137–142]. It was introduced later in 1993, but achieved only modest commercial success. OTFC was also studied and approved by the FDA in 1998 for breakthrough cancer pain [137, 140–142] in a different form called Actiq (Fig. 48.5). Actiq was a commercial success in the 2000s, and stimulated other pharmaceutical companies to develop competitive products (e.g., Cephalon's Fentora and Prostraken's Abstral) in the late 1990s. In 2012 there were six oral transmucosal products available for providing rapid onset analgesia. They included:

- Abstral®: a sublingual tablet
- Actiq: the original lozenge
- Fentora: a buccal tablet
- Onsolis: a buccal soluble film
- Subsys: a sublingual spray

Nasal Transmucosal Delivery

The nasal mucosa offers a larger area for drug absorption (400–600 cm²) than the buccal cavity and thus a potential for faster onset of drug action. The venous system atop the nasal cavity drains through the cribriform plate, directly into the forebrain. Accordingly, some investigators and small drug companies (in the late 1990s and 2000s) considered evaluating opioid nasal transmucosal products for premedication and analgesia and postoperative PCA [10, 126, 143–147]. However, weather (humidity changes) and infection can alter the nasal mucosal surface, and thus absorption can be changed (decreased) sometimes dramatically [66, 68, 125]. Several potent opioids administered by nasal sprays have been studied as analgesic premedicants before operation and for pain relief after surgery. Only butorphanol and fentanyl nasal sprays have achieved regulatory approval in the US. Fentanyl also as a nasal spray has been recently approved for PCA in some Western European countries. The difficulties of getting new opioid products through the regulatory bodies of the US and European countries (because of current fears of illicit use and abuse liability) has discouraged investment by pharmaceutical companies.

Opioid Delivery Through Other Tissue Surfaces

Over the last 10–15 years occasional researchers and companies (Inhaled Therapeutics, Alexa Pharmaceuticals) have considered the potential advantages (speed of onset, ease of use, low cost, improved safety) of delivering opioids to the trachea and the alveoli of the lung using hand held devices that provide inhaled powders, mists, vapors, crystals, or liposomes [66, 126, 148–152]. The devices produce particles sized so as to deposit in bronchioles or alveoli. Successful inhalation and absorption requires proper coordination with inspiration and some devices include strategies facilitating this goal. The same factors that govern control of other forms

Oralet

Actiq

Fig. 48.5 The Oralet mucosal delivery system had as its intended use opioid (fentanyl) premedication for anesthesia. The Actiq was to be used in the management of pain in patients suffering from chronic pain such as that resulting from cancer

of PCA apply. Presently, no pulmonary inhalant device providing an opioid for pain or premedication has successfully navigated the European or US regulatory process.

The rectal mucosa offers another surface for opioid delivery [153–155]. Rectal sedatives and hypnotics (methohexital, tribromethanol) were used in the past to premedicate children [154]. Rectal suppositories containing morphine, hydro-morphine, oxycodone, and oxycodone have also been studied and are currently available. Although the hydrogel formulation of rectal morphine has been used for premedication and analgesia in children [154], the rapid turnover of most outpatient and hospital pediatric surgical services make use of rectal administration of opioids impractical.

Oral Controlled-Release Medications

In the 1990s, Purdue Frederick, a large privately held International Pharmaceutical Company developed a sustained release morphine that achieved great popularity because one or

two pills per day produced analgesia for patients with chronic pain. Oxycodone was also studied and approved in an oral time-release tablet for chronic pain in the late 1990s. Several other companies developed similar morphine and other opioid sustained release products for chronic pain [156–162]. Some of these products have also been evaluated for pre-medication and post-operative analgesia, but have shown little advantage, although some data suggest that side effects may be less frequent after oral controlled release use of some opioids. Some time-release opioid products (oxycotin) have been abused, stimulating the development of abuse resistant controlled-release oxycodone pain capsules [162]. One was approved by the FDA in 2009 and another in 2011.

Delivery of Opioids to the Spinal Cord

In the 1980s, opioids, initially morphine, were delivered to the spinal cord via either intrathecal or epidural routes to produce long-term analgesia. A discussion of the history of this administration is found in Chapter 60 on pain management.

Some Final Thoughts on the History of Opioids

Opioids were given for pain relief in surgery for millenia before the demonstration of anesthesia by Morton in 1846. Morton's discovery transiently diminished the use of opioids for anesthetic purposes, but even in Snow's time the advantages accruing to the addition of morphine to ether or chloroform became obvious (see Chapter 49)—a greater ease of anesthetic induction and a decrease in the need for those vapors. The addition of scopolamine to morphine made for a lovely premedication, and some clinicians in the early 1900s used the combination to the exclusion of the inhaled anesthetics to produce “twilight sleep”. But the price was too great, increasing morbidity and mortality, probably from respiratory depression.

The use of opioids to complement or replace general anesthetics was also limited by morphine's slowness of entry into and departure from the brain, leading to a slowness of onset and offset of effect. The synthesis of new opioids, meperidine in the 1930s–1940s, fentanyl in the 1960s, and later its “sisters and brothers”, overcame these problems. Opening the door to an increasing intraoperative use of opioids, this culminated in the use of enormous (“industrial sized”) doses for anesthetic or near-anesthetic effects. Further facilitating the use of opioids was the discovery of opioid antagonists that could reverse unwanted effects such as respiratory depression. It also helped that drugs were developed to manage side effects such as nausea and vomiting.

Drugs complementing the “anesthetic” effects of opioids were discovered. Propofol produced sleep and amnesia. The

capacity to produce sleep and amnesia was far weaker in opioids, but opioids could produce analgesia where propofol could not. Both propofol and some of the newer opioids had kinetic properties allowing moment to moment control of their effect. In the 1980s, this led to the combined infusion of propofol and opioids to give total intravenous anesthesia (TIVA).

Finally, in the past few decades, new approaches in opioid delivery have broadened and enhanced their use. Think of patient controlled analgesia where pain is treated as it arises by the patient rather than by a person who can only ask about the extent of the pain suffered. Think of opioids introduced through mucous membranes for a rapid effect without the psychological trauma associated with the stick of a needle. Think of patches placed on the skin that deliver opioids to provide long term relief of postoperative pain, or more importantly, chronic pain from disease. And think of attacking pain by placing an opioid where receptors for the transmission of pain live, receptors in the spinal cord. It is almost magical.

Robert K. Stoelting

Summary

Morton's demonstration of the anesthetic effects of diethyl ether (ether) made painless surgery possible, but ether irritated the airways, often initiating laryngospasm and stimulating production of secretions. Premedication—the administration of drugs before induction of anesthesia—alleviated such problems.

Over the latter half of the nineteenth century, clinicians increasingly injected morphine and scopolamine or atropine before ether anesthesia. The capacity of morphine to depress breathing was of limited concern because ether did not appear to depress breathing. The rationale for using premedication before chloroform, was less compelling. Chloroform depressed breathing and did not irritate the airway or promote secretions. However, morphine plus scopolamine could decrease preoperative apprehension before anesthesia with either ether or chloroform.

Introduced in 1934, pentobarbital might be given as premedication in place of or in addition to morphine. It offered two advantages over morphine: greater sedation and much less postoperative nausea and vomiting.

The 1950s introduction of the non-pungent anesthetic halothane changed how and when premedication was used. The elimination of airway irritation on induction removed the need to diminish airway responses, leaving the issues of apprehension and the smooth transition from wakefulness to anesthesia.

The subsequent use of premedication reflected the advantages offered by new drugs, the increased use of same-day surgery, and the extended limits of patient age and suitability for surgical procedures. Perhaps most importantly, the focus of premedication shifted in timing. In the 1970s and 1980s, intramuscular injection of the longer-acting, slower-onset morphine or pentobarbital an hour before the induction of anesthesia gave way to intravenous injection of the shorter-acting, more rapid onset fentanyl (synthesized in 1960), moments before induction to diminish the sympathetic response to tracheal intubation. Similarly, in the 1980s, the new benzodiazepine, midazolam, was given intravenously shortly before induction of anesthesia to relieve apprehension, decrease nausea, and produce amnesia. Midazolam replaced older drugs because of shorter duration and less venous irritation. In children, midazolam was given orally to produce somnolence allowing easier separation from parents. The “pre” of premedication has become an integral part of the anesthesia process.

Introduction

Diverse reasons and changing purposes explain the history of preanesthetic medication—commonly described as “premedication”—the administration of drugs before anesthesia. The goals of premedication and the drugs used to achieve these goals evolved in parallel with (1) the changing pharmacologic profile of drugs used to produce anesthesia, (2)

the availability of new drugs for premedication, (3) changing surgical practice (e.g., outpatient surgery/anesthesia), and (4) changing aims (e.g., a greater focus on reduction of patient anxiety) [1].

Misconceptions have been and remain prevalent concerning premedication. Indeed, even today the use of certain drugs for premedication (principally belladonna drugs) continues although these drugs are no longer routinely indicated. Furthermore, evidence supporting the perceived value and effects of premedication at times is absent. Premedication may be ordered empirically, perhaps reflecting more the tradition and the habits of the practitioner (instilled from others during training) than evidence supporting these practices. In a 1955 editorial discussing premedication, Henry Beecher (Fig. 49.1) observed, “*Empirical procedures firmly entrenched in the habits of good doctors seem to have a vigor and life, not to say immortality of their own*” [2].

The author preserved the use of the word *narcotic* in this chapter as used by the authors of the articles referenced, recognizing that the current accepted designation is *opioid*.

Premedication is part of the history of anesthesia and thus deserves inclusion in our story. But it is more than part, more than a recitation of the drugs used at various times. Premedication responded to the anesthetics used, the evolution of anesthetic practice (e.g., the elimination of the preanesthetic visit; the shift to outpatient anesthesia), a greater focus on patient demands, and an increasing knowledge of drug pharmacokinetics and dynamics. As such the history of premedication also reflects the history of anesthesia.

Ancient Times

Prior to the discovery of anesthesia, alcohol and opium might be given before surgery. These could not substitute for anesthesia, but provided some comfort. Wedel suggested that “Opium in a moderate draft (might be given) to the patient on the night preceding the operation (amputation), for thus he bears the burning and cutting of the limb with a readier spirit, and various symptoms will be averted” [3]. But this

could hardly be called premedication in anticipation of anesthesia. The controlled administration of drugs before the induction of anesthesia—demanded the invention of a precision means of delivery, the hollow needle, invented by Francis Rynd in 1844, and the hypodermic syringe, introduced by Charles Pravaz in 1853 [4].

Premedication: The Ether and Chloroform Era

Induction of ether anesthesia is slow. Its pungency can cause coughing, breath holding and laryngospasm (closure of the larynx). It stimulates salivary secretions which, in turn, add to the potential for coughing, breath holding and laryngospasm. An inhalation induction of anesthesia with ether has one other drawback—it can be frightening, invoking a sense of claustrophobia and suffocation, a feeling of swirling down into a black hole. One of the editors (LJS) has never forgotten two terrifying childhood experiences—in each being restrained while desperately trying to breathe in the face of ether’s pungency. He heard a buzzing sound that increased to a crescendo in association with visual hallucinations—until unconsciousness blessedly intervened. Administration of a drug producing anxiolysis might have had a salutary effect on such fears. Anesthetists often ignored some of these untoward effects for a century, effects that should have mandated the use of drugs to speed induction, decrease the perception of pungency, decrease anxiety, and prevent secretions.

Over the last half of the nineteenth century clinicians increasingly injected morphine and scopolamine or atropine before ether anesthesia, scopolamine and atropine minimizing the production of secretions [5, 6]. We know from modern studies that premedication with morphine (and the siblings of morphine—opioids such as fentanyl) can minimize some of the problems noted in the preceding paragraph. Premedication with a standard dose of morphine decreases anesthetic (i.e., ether) requirement by approximately 10% [7]. That is, premedication with morphine provides a head start in the induction process. It also decreases the perception of pungency. Premedication with morphine or fentanyl decreases the incidence of coughing on induction of anesthesia with desflurane, an inhaled anesthetic that, like ether, is pungent (Fig. 49.2) [8].

Chloroform presents different problems. It is more potent and less pungent than ether, but it can induce premature ventricular contractions, especially in the anxious patient. Even with chloroform, the need to facilitate the induction of anesthesia remained. As with ether, morphine and atropine evolved as the premedication drugs most commonly selected for patients about to receive chloroform.

Premedication might be used for particularly difficult patients. Carl Uterhart (1835–1895)

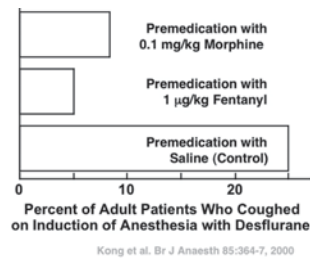

Fig. 49.2 Premedication with either morphine or fentanyl decreases the incidence of coughing on induction of anesthesia with the pungent anesthetic desflurane by 65 to 80%. (From Kong CF, Chew STH, Ip-Yam PC: Intravenous opioids reduce airway irritation during induction of anaesthesia with desflurane in adults. *Br J Anaesth* 2000; 85: 364–7, with permission.)

“...observed that the onset of the chloroform narcosis, which in alcoholics is known to be preceded by a severe and dangerous state of excitement, was extremely easy...after a small dose (of morphine). The state of excitement failed to appear; a quiet sleep with complete relaxation of all muscles occurred immediately after use of a few drams of chloroform” [9].

And we admire the advice of Joseph Clover, who in 1874 said

“I like to give a teaspoonful of brandy, without water, a few minutes beforehand, but not so much as a tablespoonful. If wine be given or if the patient must have some water in the brandy, then they should be given half an hour before inhaling, to allow time for absorption” [10].

In 1881, Henry Lyman gave similar advice for care preceding anesthesia with ether [11]:

“...there are many nervous individuals who cannot contemplate the approaching danger of operation without the greatest degree of agitation. Every possible effort should be made to calm such apprehensions. The tact of the surgeon will guide him to the methods best calculated to effect his purpose in this particular. The administration of a few doses of an alcoholic stimulant before inhalation is highly recommended as a means of tranquilizing a timid patient.”

In 1850, Lorenzo Bruno of Turin (Fig. 49.3) reported injection of morphine 1 hour before induction of chloroform anesthesia to “lessen psychic trauma” [12]. Claude Bernard (Fig. 49.4), Professor of Physiology at the Sorbonne had worked in Bruno’s clinic. In 1869, Bernard gave a series of lectures at the Collège de France describing the injection of morphine into animals to decrease the amount of chloroform needed for deep anesthesia [1, 13]. This led Labbé and Guyon to use morphine before chloroform anesthesia in humans, and in 1872 they described their experiences in four patients to the Académie des Sciences [14]. In the same year, Demarquay presented to the Académie des Sciences, his experience giving morphine before chloroform anesthesia [15]. He concluded that this practice added to the dangers of anesthesia and should not be done, but did not indicate the basis for his

Fig. 49.3 Lorenzo Bruno (1821–1900). (Courtesy of <http://www.comune.murazzano.cn.it/Contatti/tabid/1146/Default.aspx>, “L’illustrazione italiana”, Milano, Fratelli Treves, *Bibl. Sen.* 308/37 p. 356.)

conclusion. Perhaps he considered that morphine’s ability to depress breathing and thereby induce hypercapnia and hypoxia might lead to cardiac dysrhythmias in the presence of chloroform. Despite these explorations with premedication, its use was apparently not widespread before 1900.

In her review of developments in the last half of the nineteenth century, Duncum noted some peculiar beliefs regarding the combination of morphine and a belladonna drug, views that continued to the time (1956) when one of the editors (EIE) was a resident [16]. The view was that each drug counteracted the untoward effect of the other drug. For example, giving atropine or scopolamine would prevent the vomiting often associated with morphine. But some data suggested otherwise [17].

The 1880s to the 1950s

Like morphine, using atropine as part of the premedication has a long history. Professor Dastre, a French Physiologist

Fig. 49.4 Claude Bernard (1813–1878). (Courtesy of the Wood Library-Museum of Anesthesiology, Park Ridge, IL.)

who had worked with Claude Bernard, recognized that atropine prevented chloroform-induced vagal slowing of the heart [1]. In 1878 he described the use of atropine in his animal experiments, conducted under morphine narcosis and a small dose of chloroform [18]. Dastre could not interest Paris surgeons in his method but Aubert, a surgeon from Lyons, embraced Dastre's suggestions and described giving atropine 0.5 mg with morphine 10 mg to his patients 20 to 30 minutes before chloroform anesthesia [19]. He viewed its advantages as safety, rapid induction, quietness of the patient and reduced postoperative sickness.

In 1880, E.A Schäfer wrote that

"It is well known that atropin paralyses the cardiac inhibitory apparatus, and since it is probable that death in these (chloroform anesthesia) cases results from a stimulation of this apparatus...there undoubtedly seems good reason for the employment of atropin. But clearly, it should be given immediately before the administration of the chloroform, as a preventive..." [20].

Despite such advocacy, European surgeons were slow to embrace the use of premedication. There was also little enthusiasm in Britain. G Cockburn Smith investigated the action of hyoscine in France. In a letter to the *Lancet* in 1891, he wrote "...the extreme kindness of the (French) surgeons has enabled me to satisfy myself that the dangers of ether and chloroform can be greatly, if not entirely, removed by the injection of one centigramme of hydrochlorate of morphia and one milligramme of sulphate of atropia some twenty five minutes previously to their administration in adults" [21]. Smith's advice fell on deaf ears.

In 1900, Schneiderlin, of Emmendingen, Germany, introduced the combined injection of morphine and hyoscine prior to anesthesia. He had previously used the combination as a sedative to treat mental patients. He recommended small doses repeated several times, beginning sometimes on the day before operation. However it was the recommendations of Carl Hartog, who in 1903, advised routine administration half to three quarters of an hour before ether, that encouraged the increasing use of premedication in Europe.

In England, Dudley Buxton was the first to promote the use of morphine and hyoscine. In 1909, he wrote

"...a terrified patient after a sleepless night is in the worst condition for an anaesthetic and an operation. In such patients, I am convinced that the use of scopolamine and morphine injections before a general anaesthetic is valuable" [22].

The first enthusiasm for morphine and scopolamine premedication in the US arose in 1910. Clifford Collins of Peoria, Illinois reported on more than 1000 cases:

"Tablets are obtained containing a combination of scopolamin, 1/100 grain (0.065 mg), and morphin 1/6 grain (11 mg), and the solution is made just before it is administered hypodermically, which is done one and a half hours before the operation is begun...all necessary manipulations and handling of the patient in the preparation are completed before the hypodermic is administered. The room is darkened and everything is kept quiet, and he falls into a tranquil slumber. About twenty minutes before the operation, a layer of damp cotton is placed over the eyes and the patient is taken to the operating room and placed on the operating table..." [23].

A Sea Change Should Have Resulted from the Use of Intravenous Barbiturates and Less Soluble, Less Pungent Inhaled Anesthetics

In the mid-1930s, Waters' group [24] and Lundy and Tovel [25] reported that thiopental (Pentothal®), a short-acting intravenous anesthetic circumvented the claustrophobia and irritant effects associated with induction of anesthesia with ether. Anesthesia now could be induced quickly ("Count backwards from 100, please") and pleasantly. And in the 1920s and 30s, non-pungent inhaled anesthetics such as ethylene [26] and cyclopropane [27] were introduced into clinical practice. They were wonderful except that they exploded when touched by a spark. Still, just two or three breaths of cyclopropane could induce anesthesia.

Thus, the need for morphine and atropine before anesthesia was much diminished, perhaps gone. However, these discoveries of intravenous and non-pungent inhaled anesthetics did little to alter patterns of use that persisted in spite of diminished pharmacological need. Inertia is indeed a powerful force.

Halogenated Anesthetics and the Need for Routine Morphine Premedication

Fluorinated volatile anesthetics initially appeared in the early 1950s, presenting new pharmacologic characteristics (more potent, more rapid awakening, less airway irritation and fewer associated secretions). This altered the potential need for morphine and atropine. In 1951, RT Stormont, Secretary of the American Medical Association observed [28]:

“Narcotic drugs are often employed more or less routinely for preanesthetic medication without a full appreciation of their relative value for this purpose. The Council (Council on Pharmacy and Chemistry of the American Medical Association) has authorized publication of the following report with the view of encouraging additional well-controlled and critical studies in this and related fields.”

The report referred to by Stormont was: “Narcotics in Preanesthetic Medication” and the authors were Ellis N. Cohen and Henry K. Beecher (Fig. 49.1) [28]. These authors began by observing that the:

“Use of narcotics to support patients about to undergo anesthesia has a very long history; nevertheless there are adequate reasons for examining this practice objectively. Such an examination begins logically with questions as to the purposes of the practice, its undesirable effects, and whether or not there are better ways to attain the desired results.”

Cohen and Beecher observed that in the 1930s, some practitioners found that morphine decreased the quantity of anesthetic needed to achieve a desired level of cyclopropane and ether anesthesia [29, 30], while others reported that morphine contributed little, or not at all, to a reduction of the amount of ether required for a given plane of anesthesia [31, 32]. Given the ubiquitous use of morphine premedication (in 1951), Cohen and Beecher asked whether the basis for such use was valid. Accordingly, they studied 558 hospitalized patients undergoing surgery [28]. Three premedication solutions were given intramuscularly (one injection per patient): 15 mg morphine and 0.6 mg atropine, 90 mg pentobarbital and 0.6 mg atropine, or 0.6 mg atropine. The contents of the solutions were unknown to the floor nurse, patient and anesthesiologist. A preoperative interview was carried out in the operating room and the anesthesiologist recorded his/her view of whether morphine had been used in the premedication.

From the anesthesiologist’s perspective the characteristics of induction were similar in all three groups and there was equal satisfaction with all the premedication solutions including atropine alone [28]. Furthermore, 47% of the time the anesthesiologist could not determine if morphine had been administered and there was an equal tendency to confuse the presence of pentobarbital with that of morphine. Moreover, the anesthesiologist mistakenly thought 34% of

the atropine group had received morphine. The premedication did not affect venous blood concentrations of ether or cyclopropane during surgical anesthesia (i.e., did not appear to decrease anesthetic requirements).

Cohen and Beecher concluded that pentobarbital premedication was an effective and satisfactory substitute for morphine and was viewed as having fewer hazards. They further observed that their results should not imply that morphine was to be discarded entirely, but rather its use should be restricted to the few patients coming to surgery who were in pain.

This author (RKS) wonders if Cohen and Beecher would have reached the same conclusions if scopolamine rather than atropine had been administered with morphine in their study patients? When a calm and sedated patient is desirable, as before major and sometimes life-threatening surgery, the combination of scopolamine with morphine is highly effective and predictable.

Beecher further expanded his views on premedication in a 1955 editorial, emphasizing the need to reappraise the use of morphine [2]. He challenged traditional medical teaching that morphine produces euphoria in normal patients, citing “unpublished data” that morphine produced euphoria in only 10% of patients and dysphoria in 80%. Beecher argued that pentobarbital was better at producing euphoria. Furthermore, opioids like morphine produce nausea and vomiting while pentobarbital does the opposite [17]. In the editorial, the use of atropine for premedication was endorsed as promoting safety, by reducing airway secretions and blocking troublesome vagal reflexes.

In summary, Beecher concluded that narcotics were useful premedicants for the few patients in pain immediately preceding anesthesia [2]. For the typical patient, the oral use of a hypnotic on the evening before surgery (to promote a good night’s sleep), and again early on the morning of surgery, was desirable. According to Beecher, the best premedication consisted of a barbiturate (instead of a narcotic) given intramuscularly along with atropine.

An Alternate View of Premedication in the 1950s

Not everyone agreed with Cohen and Beecher. A 1959 report by John Adriani (Fig. 49.5) and O. Horace Yarberry [33] argued that misconceptions concerning premedication were prevalent, and that it was often ordered empirically and without a rational basis. Their perception of premedication often differed from those of Cohen and Beecher [28], although both groups had the same premedicants in mind. Adriani and Yarberry argued for the use of depressants (narcotics and hypnotics) to provide psychic sedation (anxiolysis) and belladonna alkaloids to suppress secretions:

Fig. 49.5 John Adriani (1908–1988). (Courtesy of the Wood Library-Museum of Anesthesiology, Park Ridge, IL.)

“Despite prejudice against narcotics they remain the most effective agents available [2, 28]. Premedication should relieve anxiety. Narcotics produce euphoria and an air of indifference unmatched by other depressant drugs. (and) Barbiturates are largely hypnotic. They do not alter the patient’s attitude toward his environment as well as the narcotics.” All these views disagreed with those of Cohen and Beecher.

Adriani and Yarberry believed that premedication supplied four important elements: psychic sedation, decreased secretions, decreased requirement for general anesthetics (especially important with less potent anesthetics such as nitrous oxide and ethylene which otherwise might limit oxygen availability), and suppressed vagal and other autonomic reflex activity. They argued for individualizing premedication for a particular patient and anesthetic technique. One of the editors of the present book (EIE) remembers the preanesthetic “rounds” guided by an individual faculty, and the vigorous discussion of what and how much premedication should be given to the patients having anesthesia the next day. “It probably was overkill, but we had great fun!”

Adriani and Yarberry argued both for and against present practices. They agreed with the importance of psychic sedation, choosing narcotics and hypnotics for this purpose and

giving belladonna alkaloids to all patients. On the other hand, they believed that “Obviously, newborns, small infants, the aged, and patients who are anoxic, in shock, or otherwise acutely ill are intolerant to and should not have narcotics or other depressant drugs.” Today’s anesthetist might have a more sanguine view. Adriani and Yarberry believed that “Scopolamine enhances the effects of narcotics and hypnotics and produces amnesia. (It clearly does produce amnesia, but enhancement of narcotics is questionable.) Also, it has superior drying effects and causes less increase in pulse rate. Atropine accelerates the pulse.” [This author (RKS), again notes that Cohen and Beecher did not consider this perceived advantage of scopolamine, in evaluating only atropine] [28].

Scopolamine use can come with a price. EIE remembers that in his residency (1956–8)

“Someone from the Department of Pharmacology at the University of Iowa called the anesthesia attending in the operating room and said they’d made a mistake. They’d intended to give medical students 0.1 mg scopolamine to illustrate its drying effect but they slipped a decimal point and gave 1.0 mg, and now they had a lot of loony students and could the Department of Anesthesia help, please? I think the students stayed in the recovery room for several hours. They all returned to sanity, and I believe all got A’s in their pharmacology course.”

Adriani and Yarberry concluded that premedication was part of the anesthetic [33]. The desired goal of premedication was tranquility and amnesia without loss of consciousness. They argued that narcotics combined with belladonna alkaloids constituted the most reliable agents for premedication. They contradicted the conclusions of Cohen and Beecher [28].

In Great Britain and many other non-US countries, the common premedication narcotic at mid-century was papaveretum, marketed as Omnopon or Pantopon. Papaveretum is a mixture of alkaloids, but is primarily morphine with small amounts of papaverine and codeine. It was usually given in combination with scopolamine in a mixture commonly known as “Om and Scop”.

A Personal Anecdote from the 1950s

Premedication comes in many flavors. One unusual flavor may be the technique described to RKS by an anesthesiologist and close friend (VK Stoelting) for managing patients considered to be at risk of thyroid storm (a dangerous condition that produces hyperactivity) on induction of anesthesia. It was thought that patient apprehension engendered the storm. Such patients would be admitted to the hospital several days before the scheduled surgery. Every morning a nurse would administer a saline enema, and the patient ultimately accepted this as routine. On the morning of the scheduled surgery (schedule not known to the patient), the nurse administered an anesthetic (Avertin®) rather than

saline in the enema and the patient “was delivered to the operating room” deeply sedated and at a lowered risk of thyroid storm. This was known as “stealing the patient to the operating room.”

Rectal Premedication

In 1913, James Gwathmey proposed premedication with rectal chloroform or paraldehyde in olive oil, followed 30 minutes later by an injection of morphine and atropine. Chloroform is a combination of chloroform and acetone.

Avertin was developed in the late 1920s and was used as a rectal premedication or anesthetic as indicated by the above anecdote, particularly in Europe. The rapid-acting barbiturates introduced in the 1930s could also be given rectally to produce sedation, and partially displaced this use of Avertin. However, Avertin continued to be used, especially in Germany, as a background narcotic, amnesic and antiemetic. The introduction of midazolam for anesthetic purposes late in the 1970s, extended to premedication via the rectal route, an approach popular in children in many countries, especially in Scandinavia and the US.

Pre-anesthetic Visits Recognized as Premedication in the 1960s and 1970s

Up to the 1960s and 1970s, anesthesiologists prepared their patients emotionally for anesthesia and surgery with various combinations of narcotics and hypnotics. Egbert et al. evaluated the psychological effects of the preoperative visit by the anesthesiologist versus pentobarbital for premedication [34]. Patients receiving pentobarbital 1 hour before an operation became drowsy, but it could not be shown that they became calm. Patients having a preoperative visit by an anesthesiologist who informed them about the events that were to take place and the type of anesthetic to be administered, were not drowsy but were more likely to be calm preoperatively. Eckenhoff and Helrich observed that “the anesthetist should never underestimate the value of the pre-anesthetic visit” [35].

Leigh et al. further supported the value of the preoperative visit. They measured anxiety levels in patients who received preoperative reassurance from a member of the hospital staff versus a control group given no such support [36]. The group given preoperative reassurance had lower anxiety levels than those not receiving reassurance either from a member of staff or from an information booklet.

The increasing frequency of outpatient surgery and admission to hospital on the day of elective surgery, has limited the opportunity for anesthesia professionals to visit with the patient preoperatively. It is no longer possible to predictably make use of the calming value of the preoperative visit.

Today’s anesthesia professional may first meet the patient a few minutes before the scheduled surgery, and premedication, if any, is pharmacologic rather than psychological.

Fluorinated Anesthetics and Barbiturates Decrease the Need for Routine Atropine and Other Premedication

As halothane in the 1960s (later supplanted by enflurane in the 1970s, and isoflurane in the 1980s) complemented by thiopental for induction of anesthesia replaced chloroform, ether and cyclopropane, the routine use of premedication with atropine waned. Several investigations challenged its use, suggesting that undesirable effects outweighed potential benefits [37–39]. In a double-blind investigation in 250 adult males 0.6 mg atropine did not alter the incidence of traction reflexes (slow heart rate and low blood pressure), bradycardia (slow heart rate), or cardiac dysrhythmias compared with patients not receiving atropine [38]. Although secretions were decreased, eliminating ether from practice removed the need for atropine, at least for a time. The development of the pungent anesthetic desflurane might suggest otherwise. Still, premedication with atropine is rare today.

In 1977, Forrest et al. [40] characterized preoperative medication as a combination of two or more drugs from different pharmacologic groups (sedative, tranquilizer, analgesic, vagolytic) with a variety of combinations prescribed for patients facing essentially the same type of operation. The variety suggested an absence of agreement about indications for premedication. Another reason for the variety was that clinical investigations of drug efficacies lacked both definition and persuasiveness, despite the use of objective measures or because of the use of subjective responses [40]. To overcome these limitations, Forrest et al. [40] designed a controlled, double-blind study of six commonly used premedicants, evaluating their effects on sleepiness, apprehension, restlessness and confusion, and determined the incidence of side effects. The medications were barbiturates (pentobarbital, secobarbital), diazepam, hydroxyzine, and opioids (morphine and meperidine) administered at different doses and compared to a placebo.

The results were surprising. All the drugs except diazepam increased patients’ subjective ratings of sleepiness. None significantly affected patient reports of apprehension compared with placebo. These results conflicted with clinical impressions and with other reports that these drugs decreased preoperative anxiety (e.g., see Eger and Keasling) [41]. Anesthesiologists rated all treatments, including placebo, as satisfactory for ease of induction of anesthesia. This probably reflected the use of potent intravenous induction drugs which obviated the need for the assistance of premedication in the induction process. The only frequently observed side

Fig. 49.6 Paul White. (Courtesy of the Wood Library-Museum of Anesthesiology, Park Ridge, IL.)

effects found with all six drugs *and the placebo group* were dry mouth and slurred speech [40, 42].

Pharmacologic and Clinical Goals of Premedication in the Present Era

In 1986, Paul White (Fig. 49.6) reviewed the pharmacologic and clinical goals of premedication [42]. He observed that the rationale for preoperative medication arose during the days of ether and cyclopropane anesthesia. To minimize side effects of induction of anesthesia by inhalation of these anesthetics (i.e., without induction of anesthesia with barbiturates), anesthesiologists brought patients heavily sedated and with a dry mouth to the operating room. Inertia and conservatism perpetuated the choice of drugs to the 1980s, often continuing the use of a sedative-hypnotics, opioids, tranquilizer, and/or belladonna drugs. As noted above, there was no general agreement about the indications for premedication although it was generally agreed that patient apprehension was a major factor that should be controlled in the preoperative period.

White argued that the rational use of drugs for premedication allowed the patient to enter the operating room with minimal apprehension, sedated but easily aroused and co-

operative without uncomfortable side effects. From the patient's point of view, lack of recall and relief of anxiety were the primary objectives of premedication. White saw additional new goals: to decrease gastric fluid pH and volume (histamine H₂-receptor antagonists, antacids, gastrokinetics), and to prevent postoperative emesis. Further, he saw that premedication for outpatients might differ from premedication for patients having operations in the traditional hospital setting. White's views might contrast with those of others who prefer to limit sedation in order to accomplish a more rapid and complete early recovery from anesthesia. There are no unmixed blessings!

White's review antedated the use of propofol, the intravenous drug now used for induction, and sometimes maintenance, of anesthesia in most adult patients. Propofol is an antiemetic, considerably decreasing patients' tendency to nausea and vomiting. Propofol has an added benefit—its effects are more short-lived than those of any other intravenous induction agent.

The now prevalent use of the anxiolytic drug midazolam also provides antiemesis as an additional benefit. Currently, it is sometimes the sole premedication used. It belongs to a class of drugs called benzodiazepines, a class that also includes diazepam (Valium®). But again, nothing is for free; benzodiazepine premedication may increase the incidence of postoperative agitation (Fig. 49.7) [43].

Although not traditional premedication, other drugs are often administered at the time of premedication. For example, oral medications that the patient may be taking for control of medical diseases (antihypertensives, antidysrhythmics, antidepressants, statins, steroids etc.) may be administered with up to 150 ml of water in the hour preceding induction of anesthesia [44]. For insulin-dependent diabetics, it is common to administer insulin in the perioperative period. For patients with known or suspected coronary artery disease, preoperative beta-blockers may be added to the premedication. Protection is probably the result of a drug class effect or hemodynamic effect rather than use of a specific beta blocker. Like beta-blockers, statins have been recommended preoperatively in patients with cardiovascular disease [45]. Prophylactic antibiotics are often administered immediately before induction of anesthesia. And anticoagulents may be given prior to anesthesia to reduce the likelihood of postoperative deep venous thrombosis. Administration of such drugs broadens our notion of what constitutes premedication [43].

Reprise

Preanesthetic medication, the giving of drugs before anesthesia, evolved from trial and error in the days of ether and chloroform to a somewhat amorphous present state that invokes both "art and science" [46]. Newer anesthetics, inhaled

Fig. 49.7 Premedication with benzodiazepines may increase postoperative agitation. (From Lepouse C, Lautner CA, Liu L, Gomis P, Leon A: Emergence delirium in adults in the post-anaesthesia care unit. *Br J Anaesth* 2006; 96: 747–53, with permission.)

and intravenous, influenced the choice of premedication. A further modifying choice was the mid-twentieth century recognition of the importance of the pre-anesthesia visit by the anesthetist. Prompting still further change, was the evolution of outpatient anesthesia and the discovery of newer premedications such as midazolam.

Initially, premedication didn't exist other than as the occasional oral administration of a dollop of alcohol or a bit of opium/morphine. With time, the properties of ether and chloroform prompted administration of various premedications. Atropine or scopolamine were used to decrease the secretions induced by ether. Morphine was used to decrease the perception of pungency and accelerate induction. Morphine also hastened recovery, because less ether and chloroform were required. Things might have—but didn't—change with the 1920s-1930s introduction of non-pungent anesthetics and especially intravenous inductions of anesthesia with barbiturates. Inertia supported the continued use of a belladonna-morphine-hypnotic triumvirate. This support eroded with the addition of modern (fluorinated) inhaled anesthetics, most notably halothane, to the smooth induction provided by thiopental. The need for atropine disappeared. Outpatient anesthesia arose in the 1970s and 1980s, imposing realities of economic and time constraints limiting the ability of the anesthesia professional to provide psychological preparation or administer of drugs more than a few minutes before the scheduled surgery. We've come nearly full circle from the initial days of anesthesia with no premedication, through a period of considerable premedication to a present time of perhaps a single drug to allay apprehension.

A History of Neuromuscular Block and Its Antagonism

50

James E. Caldwell

Summary

Fifteenth century South American explorers knew of the arrowhead poison “ourari” or curare. The eighteenth century physician Bancroft brought samples of crude curare from South America, and in 1808 Brodie showed that it was safe if ventilation continued artificially. In 1846, Bernard demonstrated that curare acted where the nerve impulse reached the muscle, the neuromuscular junction.

In 1912, surgeon Lawen used curare for tracheal intubation and surgical procedures. The idea did not catch on! In the 1930s, Gill brought curare from South America to the US. With Squibb chemists, pharmacologist McIntyre purified the crude extract as Intocostrin, which Holaday assayed for potency with the rabbit head drop test. By standardizing the concentration, this allowed “Intocostrin’s” study. In 1939, psychiatrist Bennet reported that Intocostrin prevented compression fractures from convulsive therapy. Cullen then tried Intocostrin in dogs, but because it seemed to cause bronchospasm said it had “*no place in anesthesia.*”

In 1942, anesthesiologists Griffith and Johnson safely gave Intocostrin to 25 patients anesthetized with cyclopropane. In 1946, several investigators given curare noted that it did not decrease consciousness. In 1954, Beecher and Todd reported “curare” deaths, and it was soon appreciated that curare’s safe use required control of ventilation and neostigmine to antagonize residual effects.

Succinylcholine was introduced in 1951, after Bovet observed its paralyzing action. Bowman developed the long-acting and cardiovascularly active aminosteroid relaxant pancuronium in the 1960s. Savage designed a relaxant to supplant pancuronium, leading to the 1980s release of vecuronium. Payne and Hughes then described atracurium, whose chemical breakdown via Hofmann elimination could terminate its action. In 1988, Savarese described the short acting mivacurium, but slow onset ensured a limited commercial life. Rocuronium, a nondepolarizing drug with a faster onset and lack of adverse effects, was released in the 1990s. Cisatracurium was released in the 1990s. It had fewer side-effects than atracurium. In 1999, the fast onset rapacuronium was released but was soon withdrawn because it caused bronchospasm in children.

The need for clinical monitoring of neuromuscular blockade led Ali, Utting, and Gray to develop the train-of-four ratio test in the 1970s. In the late 1970s and the 1980s, Miller, Benet, and Sheiner invented concepts explaining the interaction of relaxant pharmacokinetics and pharmacodynamics.

In 2001, Bom described sugammadex, a drug with a ring structure that inactivated rocuronium by capturing every rocuronium molecule, thereby quickly and completely reversing blockade. In 2004, Savarese and his group described relaxants rapidly inactivated by endogenous or exogenous cysteine.

The First Few Centuries: 1495–1900

It took 450 years from European observations of curare poisoning to the introduction in 1942 of a purified extract of curare into anesthesia practice. In subsequent years, more than 30 different muscle relaxants (we will use “muscle relaxants” or just “relaxants” in place of the more correct “neuromuscular blocking drugs”) were tried in clinical practice (Table 50.1)

[1]. Most failed to achieve widespread use, and successful relaxants often fell into disuse, superseded by superior drugs. This essay traces the path that took these compounds from “poisons” to mainstays of modern anesthesia practice.

In the Beginning

“The natives poisoned their arrows with the juice of a death-dealing herb. In a twinkling the forty-seven Spaniards were pierced with arrow-wounds, before they could protect themselves with their shields. There was but one man who survived, all the rest perishing from the effects of the poison.”

Table 50.1 Relaxant and reversal drugs used clinically at some time

Relaxants			Reversal Drugs
Alcuronium	Diadonium	<i>PANCURONIUM</i>	<i>NEOSTIGMINE</i>
Amidonium	Dipyrandium	Pipecuronium	Edrophonium
Anatruxonium	Duador	Quilidium	Pyridostigmine
<i>ATRACURIUM</i>	Fazadinium	Rapacuronium	Galanthamine
Benzoquinonium	Laudexium	<i>ROCURONIUM</i>	4-aminopyridine
C-Toxiferin	Maluetin	Stercuronium	3:4-diaminopyridine
<i>CISATRACURIUM</i>	Metocurine	<i>SUCCINYLCHOLINE</i>	<i>SUGAMMADEX</i>
Cycobutonium	<i>MIVACURIUM</i>	Tercuronium	
Dacuronium	Myanesin	Toxiferine	
Decadonium	Mytolon	Tubocurarine	
Decamethonium	N-methyl Tubocurarine	<i>VECURONIUM</i>	
Doxacurium	Nubitanium		

Drugs in capitalized italics are in current use

Thus was the existence of a paralyzing drug revealed to Europeans by Pieter Martyr D'Anghere in his fifteenth century treatise *De Orbe Novo*. Rather than traveling with the conquistadores like embedded modern day correspondents, D'Anghere simply interviewed those returning from the "New World." A century later, in 1594, Sir Walter Raleigh returned from an incursion into now Venezuela and described a tribe he encountered, the Aroras, as "*people who used strong poison in their arrows.*" Lawrence Keynes, one of Raleigh's lieutenants, named this strong poison "ourari", literally the "bird-killer." One can imagine the transliteration of ourari into curare.

Two plant groups, *Chondodendron Tomentosum* and *Strychnos Toxicaria* supplied the poison. The ritual preparation of the poison took several days. An apocryphal story has it that some tribes sequestered old women with the necessary knowledge and skills throughout the process of manufacture. The resulting condition of the women defined the potency of the tarry substance produced. If they still stood and appeared relatively healthy, the batch was deemed insufficiently potent and discarded. In contrast, if the women were weak, unable to stand, the poison was deemed acceptable. Given these working conditions, it is surprising that any of these women lived to become old and experienced. Having passed this first potency test, a frog was pricked with the poison, and the number of leaps the frog then made, before expiring, quantified the potency. The laborious process, and the limited availability of old women, made the toxin valuable. Its use was commonly restricted to hunting and not warfare.

Although von Humboldt in one place in his book partially confirms the above apocryphal story in which old women made and were the test subjects for establishment of potency of the curare preparation, in another place he denies that such testing could be possible [2]. Charles Waterton adds to the latter view, stating that women and young girls were excluded from the preparation of the curare concentrate [2].

Given the highly ionized nature of curare and other muscle relaxants, it is difficult to imagine how curare could be vaporized. If this is correct, then inhalation of curare in the vapors made in the process of purification seems unlikely.

Over the next four centuries, more reports and crucial observations were made. The poison was not toxic if ingested, inhaled, or applied directly to or injected into a nerve [3]. Also, after poisoning with curare, the heart continued to beat, and artificial respiration saved the animal from death [4, 5].

Eighteenth and Nineteenth Centuries: Early Scientific Investigations

Explorers Discover and Bring Back Curare

Explorer-scientists, including Charles-Marie De La Condamine, Edwin Bancroft, and Charles Waterton, travelled extensively in different areas of South America. They provided the raw material to European pharmacologists and physiologists who undertook the initial studies of curare. These hardy explorers often put themselves at personal risk; the Amazonian forest was an inhospitable place, and working with the raw material was dangerous. The French scientist FD Herissant describes how he and his assistant became weak and almost unconscious while boiling the crude curare extract in order to create a concentrated mixture. "*A pint of good wine and sugar*" cured both investigators.

The eighteenth century physician, Edwin Bancroft, brought back samples of crude curare from South America for study. He was the first to thoroughly report the diverse tribal methods of preparation and storage of the curare. The natives used a variety of vessels for storage of the curare preparation: a clay pot (pot curare), a calabash gourd (calabash curare), or a hollow piece of bamboo (tube curare,

hence “tubocurare”). His son, Edward Bancroft provided samples to the English surgeon, Benjamin Brodie, who made the crucial observation that animals poisoned with curare could be kept alive by inflating their lungs [5]. Brodie also suggested treatment of tetanus with curare [6].

1814

No early explorer was more colorful than Charles Waterton, an English nobleman who managed his family’s estates in South America. His exploits included scaling the dome of St. Peter’s Cathedral in Rome, much to the displeasure of the Pope. While in Guiana, he showed that curare was effective in many species, including large animals. He witnessed Brodie and William Sewell’s famous 1814 public demonstration of the effect of curare on a donkey.

“A she ass received the wourali poison in the shoulder and died in apparently 10 minutes. An incision was made in its windpipe, and through it the lungs were regularly inflated for two hours with a pair of bellows. Suspended animation returned. The ass held up her head and looked around.”

The ass “now named Wouralia” was put out to graze at Walton Hall, on the estate of Earl Percy, who stated, “No burden shall be placed on her and she shall end her days in peace.” Wouralia lived on in this happy state for almost 25 more years [7].

1838

Twenty years after the “Wouralia” demonstration, Sewell, a veterinary surgeon, used curare to treat two horses with tetanus. Both animals died. Despite this failure, curare was later used in humans to treat disorders involving spasticity. None proved successful.

1846

In 1846, the French polymath Claude Bernard (1813–1878) discovered the site of action of curare (Fig. 50.1) [8]. In curarized (paralyzed) frogs, he noted that electrical impulses still passed down the motor nerves [8], and that electrical impulses applied directly to the muscle caused contraction. He concluded that curare acted where the nerve impulse reached the muscle, the neuromuscular junction. It was not until the 1930s that Henry Dale and others showed that acetylcholine released from the motor nerve terminal effected neuromuscular transmission, and curare acted by blocking acetylcholine receptors.

1858

The surgeon Lewis Sayre, and his house officer FA Burrell, at Bellevue Hospital New York, took up Brodie’s suggestion that curare might be used to treat tetanus. In a patient with tetanus, the standard treatments of brandy, beef tea, (by both

Fig. 50.1 Claude Bernard in his laboratory. The drawing shows the equipment he used to demonstrate the site of action of curare at the neuromuscular junction. (Courtesy of Wellcome Images UK.)

mouth and per rectum) had failed. Four applications of a dilute solution of the “woorari” poison were applied directly onto the hand wound through which the original infection occurred. The patient died during a severe spasm shortly thereafter [9]. Despite such setbacks, the search for a therapeutic use of curare in spastic conditions such as chorea, rabies, epilepsy and strychnine poisoning continued. But curare extract sufficient to decrease spasticity inevitably produced fatal respiratory failure.

1860s

The Edinburgh scientists Thomas Fraser and Alexander Brown made the next breakthrough demonstrating that conversion of alkaloids with tertiary (three atom) nitrogen groups (e.g., atropine or morphine) to a quaternary (four atom) form produced compounds with curare-like activity [10]. This first demonstration of a structure-activity relationship in medicine was fundamental to drug development a century later.

Fig. 50.2 Two scientists at either end of the Hofmann elimination story. August Hofmann (*left*) described the reaction that bears his name, in 1907 (photograph from fineartamerica.com). John Stenlake (*right*) used the reaction described by Hofmann in the development of atracurium more than 70 years later (1981). (Image of August Hoffman is courtesy of Wellcome Images UK.)

1900–1940: Some False Starts

First Medical Trials with Curare

Despite poor therapeutic experiences, many considered using the curare “poison” for medical purposes, but its inherent dangers made it unsuitable as a drug for *trial and error* experimentation. Nonetheless, we were getting nearer to the discovery of the beneficial uses of curare.

1906

In 1906, the chemist August von Hofmann synthesized quaternary amines (Fig. 50.2). Muscle relaxants have this structure [11]. He also described the capacity of increased pH and temperature to break down a quaternary amine to a tertiary amine, the eponymous Hofmann reaction. More than seventy years later, John Stenlake (Fig. 50.2) at the University of Strathclyde in Glasgow made use of this reaction in the design of the then revolutionary drug, atracurium [12].

Also in 1906, the pharmacologists R Hunt and R Taveau synthesized succinylcholine and studied it in animals [13]. However, their anesthetized animals had already been paralyzed with curare, and thus they did not observe succinylcholine’s neuromuscular effects. They did observe that it slowed the heart but otherwise thought it an uninteresting drug. In 1941, D Glick noted that cholinesterase metabolized succinylcholine, but again missed succinylcholine’s neuromuscular blocking properties [14].

1912

Arthur Lawen (a colleague of the more famous Trendelenberg), a surgeon in Leipzig, used curare to “soften” the abdominal muscles to facilitate wound closure. He even practiced tracheal intubation and controlled ventilation. However, supplies of curare were unreliable and its potency variable so he abandoned the practice [15]. Some anesthesiologists might find it hard to accept that the first physician to use curare in the operating room was a surgeon.

1928

Francis de Caux, an anesthetist at the North Middlesex Hospital in London, gave curare to patients [16]. Supplies and purity were variable, and he treated only 7 patients:

“When I used Curare in 1928 I used a watery extract of crude curare made by the North Middlesex Hospital Dispensary. It was because there was no method of standardization that we dropped the method because of the inconsistent results obtained—I wrote to two firms Hoffman la Roche and Zimmermans, I believe, who were not very helpful.”

He did not publish his results, and 14 years passed before Griffith and Johnson repeated his experiment in Montreal.

1930s

The use of curare was refined by trial and error until it could be applied safely, but not successfully, in patients with tetanus and other spastic disorders. Interestingly, a group of pathologists (no doubt familiar with the consequences of the failed treatments of tetanus) led by Howard Florey suggested the

Fig. 50.3 Harold King was the first to isolate and describe the structure of curare. He actually made a minor error and described the group circled as quaternary when in fact it is a protonated tertiary group. This misled scientists for the next three decades to incorrectly think that drugs that had a tertiary group at this site would not be relaxants

Nitrogen group originally described as quaternary by King in 1935. In fact, *in vivo*, it is a protonated tertiary group.

humane treatment of patients with tetanus by a combination of general anesthesia, paralysis with curare, and artificial ventilation with an iron lung. Although they never tried it, they had predicted what would become standard ICU practice [17].

1935

In 1935, Harold King (1887–1956) extracted tubocurarine from a crude preparation of unknown origin. From the information he gathered, he published an erroneous chemical structure of tubocurarine (Fig. 50.3) [18]. King proposed that curare had quaternary nitrogen groups at each end of the molecule (i.e. it was *bisquaternary*). This notion underlay the subsequent development of new muscle relaxants [18]. Discovery of this error in 1970 facilitated development of a new generation of monoquaternary relaxants, the prototype being vecuronium. Although in 1935, large-scale production of tubocurarine was not possible, there followed a string of fortunate circumstances, leading to the first public demonstration of curare in humans.

1938

Richard Gill solved the problem of inadequate supplies of crude curare. In the course of South American travels, Gill learned how to make crude curare, becoming an honorary witch doctor in the process. When he developed multiple sclerosis he saw the potential for a cure in curare. He brought substantial supplies of curare extract back from Ecuador but the firm Merck that had agreed to process his samples changed their mind and instead pursued investigations into a different plant alkaloid, “erythroidine”.

Gill then offered his supplies to various investigators, including AR McIntyre, Chair of Pharmacology at the University of Nebraska. McIntyre had a research grant from the

pharmaceutical company Squibb, and they collaborated to purify the crude extract. A Squibb chemist, Horace Holaday, devised the rabbit head drop test (the name describes the test) to assay the potency of the purified drug [19]. Aliquots of the Intocostrin were administered to the rabbit until the neck muscles no longer kept the head up. Purifying the curare and defining its potency opened the door to therapeutic success.

Success at Last

The psychiatrist Abram Bennet was a colleague of Michael Burman, an orthopedic surgeon who had reported his use of curare in childhood spasticity. Bennet saw a potential for the use of curare to minimize the traumatic consequences of convulsive shock therapy [2, 20]. Metrazol-induced convulsions produced a 40–50% incidence of compressive spinal fractures. As reported by Bennet, curare prevented these fractures [20]. Such results showed the effectiveness of curare, and probably preserved the practice of convulsive therapy.

The 1940s: It All Comes Together

Because de Caux had not published his results, the work had gone unnoticed, and curare was not used in anesthetic practice. Serendipity triggered a change. In 1940, Bennett showed a film of his use of curare to the 91st annual session of the New Jersey Academy of Science. Present was Lewis Wright, Medical Advisor to the pharmaceutical company Squibb. Wright thought curare might be useful in anesthesia. He obtained a preparation of curare, Intocostrin, and donated some to EA Rovenstine at New York University.

Rovenstine instructed his resident EM Papper to try Intocostrin in two patients. Both patients became apneic, and Papper had to manually ventilate their lungs overnight. Stuart Cullen at the University of Iowa, also received Intocostrin, used it in dogs, and pronounced “*Intocostrin has no place in anesthesia*” because the dogs developed bronchospasm. Things did not look good for curare, but this then changed dramatically.

1942 Griffith and Johnson: The Report That Changed Everything

In 1942, a modest paper, brief and to the point, altered forever the practice of anesthesia [21]. With little fanfare, no IRB approval, no oversight, and no previous experience, Harold Griffith and Enid Johnson at the Homeopathic Hospital of Montreal administered Intocostrin to 25 patients anesthetized with cyclopropane. All patients breathed spontaneously throughout surgery, none had their tracheas intubated, and some were challenging (e.g., a 112 kg patient for hemorrhoidectomy and an “...*extremely obese woman...*” for dilatation and curettage.) Griffith opined: “*we have been so much impressed by the dramatic effect produced in every one of our patients that we believe this investigation should be continued.*” It is tempting to speculate on what might have followed had any of these patients died from what Beecher might have labeled a “curare death” (see below).

In 1943, two chemists at Squibb purified d-tubocurarine from the bark of *Chondodendron Tomentosum*. King had extracted the same compound in 1935 but had not known the source of his preparation. The purified d-tubocurarine had 6 times the potency of Intocostrin, and soon replaced it.

1946

In Great Britain, TC Gray and J Halton published an enthusiastic report of the use of both Intocostrin and the purified d-tubocurarine [22]. In 1946 and for sometime thereafter, most patients given curare breathed spontaneously, often without tracheal intubation. It required great skill and vigilance to administer the drug safely, a point made forcibly by Gray and Halton. By 1952, it was appreciated that safe use required control of ventilation [23]. Safety also mandated the postoperative use of doses of up to 5 mg neostigmine to antagonize the residual effect, a use advocated in 1946 [24].

What Does Paralysis Feel Like?

To better understand the patient’s potential perception of curare’s effects, some doughty clinicians submitted to paralysis

while awake. In 1943, Helen Barnes underwent laryngoscopy after her colleagues gave her 4 ml of Intocostrin IV while she was awake. Her colleagues passed a laryngoscope and viewed her vocal cords with ease. She then used Intocostrin to facilitate tracheal intubation in 5 patients [25], recognizing that these doses of curare necessitated pharmacologic reversal with neostigmine. In 1946, Frederick Prescott, a pharmacologist at the Westminster hospital in London, submitted to awake paralysis with Intocostrin, a reportedly unpleasant experience during which he remained aware [24].

Despite the reports of Barnes and Prescott, some clinicians believed that curare depressed the central nervous system and could produce anesthesia, and many patients suffered awareness under anesthesia in those early years. “*I...was awakened by the most excruciating pain in my tummy. It felt as if my whole insides were being pulled out...*” [26].

Scott Smith, a pediatric anesthesiologist in Salt Lake City thought that curare anesthetized babies because they remained immobile during surgery. To test his belief he had colleagues completely paralyze him with curare with support of his respiration by bag and mask [27]. In contrast to what he expected, he perceived touch and pain throughout his paralysis and required tracheal intubation.

Many anesthetists initially thought that the use of muscle relaxants was inherently unsafe, a correct perception for partially paralyzed patients allowed to breathe spontaneously and whose tracheas were not intubated. Some suggested that curare had inherent cardiotoxicity [28]. However in the ten years following its introduction, it became clear that inappropriate use rather than curare caused the problems.

1947

The enthusiastic adoption of curare soon strained supplies, and the need for a synthetic drug became apparent. In response, the Swiss chemist, Daniel Bovet (1907–1992), and his group created gallamine [29]. Gallamine had some clinical success, but Bovet’s work in the next decade with the older drug, succinylcholine, had a much greater impact.

The 1950s: Things Nearly Come Undone

Succinylcholine Appears in 1951

The decade opened propitiously, with the 1951 clinical introduction of succinylcholine. Although succinylcholine was first synthesized in 1906, it fell to Bovet in 1949 to observe its paralyzing action [30]. This observation, and his earlier discovery of gallamine, resulted in his 1957 Nobel Prize for Medicine.

In contrast to Intocostrin, succinylcholine received a warm welcome. Frances Foldes stated “*Its use is not accompanied by unwanted side-effects and the incidence of post-operative*

complications after its use is low”[31]. But first impressions can be deceptive. Subsequently, numerous adverse effects of succinylcholine were identified [6]. One, prolonged block in patients with plasma cholinesterase deficiency, was an early example of the influence of pharmacogenetics, a term coined in 1957 (see Chapter 44 on A History of Pharmacogenomics Related to Anesthesiology). The familial nature of prolonged block was soon identified [32], and its relation to atypical cholinesterase demonstrated [33].

Curare and Mortality

In 1954, the “honeymoon” ended. Beecher and Todd reported a six-fold increase in “anesthesia-related” deaths in patients receiving “curare” [28]. To Beecher and Todd, “curare” encompassed d-tubocurarine, Intocostrin, dimethyl-tubocurarine (metubine), gallamine, succinylcholine, and decamethonium: the overall risk of death from anesthesia at that time was 1 in 2100 (far greater than today), but in a patient given curare the risk increased to 1 in 370. No cause was determined, and the increased mortality was not related to the patient’s medical status, experience of the provider, or any other factor that could be identified. Reversal with an anticholinesterase was not reported in the study and presumably was not accomplished. The failure to administer neostigmine almost certainly underlay the lethality of the administration of curare, but in the opinion of the authors, most of the anesthesia-related deaths were from cardiovascular collapse, not respiratory insufficiency. This finding could have ended the clinical use of muscle relaxants, but Beecher and Todd wisely avoided simplistic conclusions. Although the use of relaxants increased anesthesia-related mortality, it did not appear to increase, indeed possibly decreased, overall operative mortality, a point argued forcefully by Abajian and colleagues in a rebuttal paper [34]. Beecher and Todd presciently reasoned that if curare caused an anesthesia-specific problem then the professionalism of anesthesiologists would compel them to investigate, understand, and resolve it.

Mechanisms and Murder in 1956

The depolarizing action of succinylcholine was not immediately appreciated. William Paton delineated relaxants into depolarizing and non-depolarizing drugs in 1956 [35]. Non-depolarizing drugs had a bulky structure (were pachycurares); depolarizing drugs had a long narrow structure (were leptocurares). We are still not sure how relaxants work. Do they enter and plug up ion channels? Do they compete with acetylcholine for receptors on the motor nerve terminal? Do they block the release of acetylcholine? Probably all of the above, and more [36].

In the body, succinylcholine quickly degraded to the naturally occurring compounds choline and succinate. Their natural nature made them nearly undetectable and possibly made succinylcholine the “ideal murder weapon.” Lurid cases of suspected murder by succinylcholine have occurred. In 2007 a Nevada jury convicted critical care nurse, Chaz Higgs, of first degree murder in the death of his wife, Kathy Augustine, a prominent Nevada political figure. The murder weapon was a syringe of succinylcholine [37].

1958

One limitation of curare had been its capacity to cause histamine release and ganglionic blockade—with subsequent low blood pressure and bronchospasm (asthma). One plant species providing raw curare was *Strychnos Toxicifera*. Another alkaloid, *alcuronium*, extracted from this plant was introduced in 1958. Alcuronium had properties similar to tubocurare but significantly less propensity to produce histamine release and ganglion blockade [38].

The 1960s: Pancuronium, Drug Design, and David Savage

Structure-Function and Steroidal Molecules

This decade saw structure-function analysis applied to drug design. The discovery of a steroidal alkaloid malouetine prompted development of steroid molecules with curare-like effects. In 1935, King had described the structure he thought was required in a neuromuscular blocking drug: two quaternary nitrogen groups separated by a distance (interonium) of 1.4 to 1.5 nm. The interonium distance proved to be more flexible than King predicted, for pancuronium being 1.05 nm and for fazadinium 0.7 nm [39, 40]. The general structure had two acetylcholine-like groups separated by an appropriate distance, and had to be bulky (pachycurare) to confer non-depolarizing characteristics. William “Bill” Bowman was a gifted pharmacologist at the University of Strathclyde in Glasgow, Scotland, who had worked with Paton on curare-like drugs. Bowman considered that the rigid steroidal androstane molecule was the perfect skeleton on which to place the quaternary nitrogen groups to create a muscle relaxant drug.

It was these structural “rules” and Bowman’s idea to use the androstane nucleus that led to the development of the aminosteroid relaxant pancuronium by Hewett and Savage [41]. Pancuronium obeyed the rules except for its short interonium distance. This shortness conferred high potency and was long enough to avoid producing ganglionic blockade. Soon after the report of its clinical use in 1967 [42], pancuronium supplanted curare and gallamine for use in patients. Although devoid of ganglionic blocking effects, it had both vagolytic and sympathomimetic activity, but did not

Fig. 50.4 David Savage and his creations, pancuronium and vecuronium. Vecuronium was originally rejected because it was monoquaternary (one *red* group) as opposed to the bisquaternary pancuronium (two *red* groups). Sadly, the laboratory where he worked, and where these drugs were developed has recently closed due to mergers within the pharmaceutical industry

produce the hypotension associated with d-tubocurarine, or as much tachycardia as seen with gallamine.

David Savage

The success of pancuronium heralded the emergence of West Scotland as the epicenter for muscle relaxant development for the next 25 years. Leading this effort was David Savage, the principal chemist-scientist working on these compounds at Organon's research laboratories (Fig. 50.4). He had notable and inventive enthusiasm. He claimed, a bit (but just a bit) tongue in cheek, that using an androstane (steroid) backbone he could create a drug that would work at any receptor. He said that for fun he had made and tested a steroidal appetite suppressant in rats. It was all too good; the rats starved to death! He was also a *bon viveur*. For one particular experiment he needed a small pressure vessel to contain the reaction. The ideal vessel turned out to be a champagne bottle, and of course the contents had to be drunk first.

Savage had the then novel insight that scientists and clinicians should work together to develop drugs clinicians needed. So he worked closely with anesthesiologists: Leslie Baird at Glasgow Royal Infirmary, and Ronald Miller in San Francisco. There is a story that one of the brain storming sessions occurred at a local bar. Purely by chance, David Savage and a local anesthesiologist struck up a conversation, and started discussing curare and the neuromuscular junction. In the course of the conversation many novel drug structures, probably including a pancuronium prototype, were written down on paper napkins. So engrossed were the two men that they had to be asked to leave several hours later, as the bartender wanted to close up. Many clinician colleagues of David Savage describe similar "design" sessions, where they would

articulate their needs for a drug, and David would draw putative structures. To further scientist/clinician interaction, Savage organized the 1st International Neuromuscular Meeting, bringing clinicians and scientists together in London in 1975.

Like its peers, pancuronium had too long a duration of action because its elimination was primarily via the kidney. Continued research at the Scottish facility solved this problem, leading to the development of two successful drugs, vecuronium and rocuronium, and one ill-fated drug, rapacuronium [43].

Up to the 1970s, clinicians had no practical way of monitoring relaxant effect, except for subjective clinical signs such as abdominal muscle relaxation or adequacy of spontaneous respiration. The need to develop a method of monitoring the residual effects of such powerful drugs was addressed in the next decade.

The 1970s: Monitoring; Ideal Drug; Pharmacokinetics and Pharmacodynamics

Monitoring

In the 1950s and 1960s, clinical acumen and judicious dosing guided the administration of muscle relaxants. The first monitors of neuromuscular function were simple nerve stimulators [44]. They required subcutaneous needles for nerve stimulation. The need to define a control response before relaxant administration made them impractical for normal clinical use. In the 1970s, this led Hassan Ali to develop the train-of-four ratio (TOF; Fig. 50.5) [45]. Ali used the known effect of repeated stimulation (repeated stimulation produces a decreasing contraction in a partly paralyzed muscle) in a clinically useful way [46]. Patients received four stimuli at 2 Hz (0.5 s intervals) and the ratio of the fourth response (T4)

Fig. 50.5 Significant figures in the modern history of neuromuscular function. Hassan Ali in Boston developed the concept of the train-of-four ratio to quantify block. Jørgen Viby-Mogensen in Copenhagen took this work further and developed the techniques of post-tetanic count to quantify profound block, and double burst stimulation to facilitate clinical detection of low levels of residual block. John Savarese, originally in Boston and later in New York developed mivacurium and has had a career-long pursuit of a type A fast-onset short acting non-depolarizer muscle relaxant. Finally, Anton “Ton” Bom, a native of Holland, working in Scotland, changed the whole concept of relaxant reversal with the discovery and development of sugammadex

Fig. 50.6 The three most common stimulation modalities in neuromuscular monitoring are single twitch height, train-of-four and tetanus at 50 Hz. They have a fairly reproducible relationship to one another and to the fraction of acetylcholine receptors that need to be blocked (occupied) by the muscle relaxant for a given effect. (From an online lecture Thompson C: Monitoring the Neuromuscular Junction, University of Sydney, 2010, with permission.)

to the first (T1) was measured. A material decrease, especially below 0.7, indicated residual paralysis.

This useful ratio (Fig. 50.6) correlated with other indices of muscle function, including the absolute decrease in strength of the muscle contraction, the decrease in response to tetanic stimulation, and deteriorating pulmonary function [47, 48]. Because it provided its own internal control, it did not require a baseline measurement. The response could be either mechanical force, or electromyography. It also discriminated between succinylcholine-induced block (minimal fade) and depolarizing (marked fade) block. TOF assessment persists as the mainstay of clinical monitoring.

The Ideal Drug

In the 1970s, clinicians could choose a short-acting drug (succinylcholine) or longer acting (nondepolarizing) drugs. All had side effects. This unsatisfactory situation led to the concept of the ideal drug by Karis and Gissen in 1971 [49]. Their criteria have stood the test of time and are still quoted today (Table 50.2), with the notable exception that a demand for fast onset was absent.

Savarese and Kitz elaborated on these concepts in 1975 [50], adding their belief that one drug could not be ideal for all clinical situations. They defined three categories of ideal drug, A, B and C. Type A was a non-depolarizing succinylcholine (rapid onset, rapid offset). Type B had a duration of action approximately half that of curare or pancuronium, and soon became a reality with the introduction

Table 50.2 Definition of the “Ideal Drug” Karis and Gissen

Criterion	Comment
1. Competitive non-depolarizing	Avoided complications of depolarizing action
2. Recovery not organ-dependent	Fulfilled by atracurium and mivacurium
3. Breakdown products inactive	Fulfilled by rocuronium and cisatracurium
4. Relatively short duration	Fulfilled by intermediate acting drugs
5. Highly specific	Delayed development of drugs with fast onset
6. Reversible by anticholinesterase	Did not foresee alternatives

of vecuronium and atracurium. Type C was long acting and without adverse cardiovascular effects, anticipating pipercuronium and doxacurium which arrived approximately 15 years later. John Savarese has crusaded for a Type A drug, and, as we shall see, his efforts may be close to fruition.

Defining the direction for new drugs pressured the pharmaceutical industry to synthesize products that would meet the challenges implied by the definitions. As noted earlier, Savage facilitated the dialogue between clinicians and industry by organizing the 1st Neuromuscular Meeting in London in 1975, just when the concept of the “ideal relaxant” was described. Few at the meeting appreciated the impending “revolution” in neuromuscular pharmacology—the era of the intermediate-acting relaxant was about to dawn.

Fig. 50.7 The University of California San Francisco threesome that significantly advanced the scientific understanding of the pharmacokinetics and pharmacodynamics of muscle relaxants in the 1970s. Leslie Benet created the pharmacokinetic concept of “Clearance.” Concurrently, Lewis Sheiner pursued the science of drug concentration-effect relationships, developing sophisticated modeling tools. Finally, a young clinician/scientist Ronald Miller, freshly back from Vietnam, had many questions relating to the clinical behavior of muscle relaxants and their antagonists. Good fortune brought together a clinician with important questions and scientists with the talents to develop the tools to address those questions

Pharmacokinetics and Pharmacodynamics

Until the 1970s, there was but a rudimentary understanding of drug actions, and of the interaction of biodisposition (pharmacokinetics) and effect (pharmacodynamics). Developments at the University of California San Francisco (UCSF) changed this (Fig. 50.7). Leslie Benet developed and refined the science of pharmacokinetics and pharmacodynamics, creating the concept of drug “Clearance.” Concurrently, Lewis Sheiner pursued the science of drug concentration-effect relationships. And a young clinician/scientist Ronald Miller, freshly back from Vietnam, had a mind full of questions relating to the clinical behavior of muscle relaxants and their antagonists. These circumstances fortuitously combined a clinician with important questions and scientists with the talents to develop the tools to address those questions. The breakthrough was to measure both the effect of a drug and the concentrations associated with the effect, and to make inferences as to how underlying conditions (e.g., renal or hepatic failure) influenced these. The first paper applying these techniques focused on the impact of renal failure on the pharmacokinetics of tubocurare [51].

A problem remained: the concurrent measurement of the concentration of a drug at its site of action (e.g., the neuromuscular junction) and the effect of that concentration. The researcher couldn’t sample the neuromuscular junction. Sur-

rogate measures (e.g., the concentration in blood) had to serve instead. That was fine (sort of) if there were equilibrium between the blood and the neuromuscular junction, but how could one be sure? Sheiner and Stanski published an important paper in 1979 that provided the “missing link” between concentration and effect [52]. The authors in this paper recognized that initially the concentration at the neuromuscular junction (and the effect) lagged behind what the anesthetist gave and was in the blood. During recovery, the opposite was true. The paper demonstrated how one could calculate the concentration and effect at the neuromuscular junction by knowing the effect during input and output. This model has broad applicability to any situation where the drug concentration is measured in one place and its effect takes place at another.

The 1980s: Advances, Complacency, and Monitoring Techniques

1980: Vecuronium

Jan Crul and Leo Booij published the first clinical report of vecuronium’s actions in 1980 [53]. Vecuronium provided the first major advance in non-depolarizing muscle relaxants since 1942. Clinicians now had a relaxant with an intermediate duration of action. Two critical observations enabled the development of vecuronium. First, Everett et al. corrected

the error in tubocurarine's structure that King had made [39], leading to renewed interest in monoquaternary drugs such as vecuronium. Second, it was realized that the vagolytic and neuromuscular blocking effects of pancuronium could be separated by specifically designing a molecule with greater affinity for the acetylcholine receptors at the neuromuscular junction than at other sites [54, 55]. These insights led to vecuronium, a drug with the same neuromuscular blocking potency as pancuronium, but with only 1/20th the vagolytic effect. To this day vecuronium remains the model for a "clean" (relatively few side effects) relaxant.

Vecuronium had another important property, a duration of action less than half that of pancuronium. Its monoquaternary structure permitted elimination by both the liver and the kidneys (pancuronium elimination is predominantly renal), leading to a shorter and more certain duration of action [56].

1981: Atracurium

As vecuronium emerged from Organon's laboratories, a similar major advance, the synthesis of atracurium, was under development at the University of Strathclyde in Glasgow. Like vecuronium, it had an intermediate duration of action, but one based on a unique method of elimination [12]. August Hofmann synthesized the first quaternary amines, the general group to which all muscle relaxants belong [11], in 1851. He described a novel reaction in the degradation of such amines ("Hofmann Elimination"), in which two parts of the molecule fall off, leaving behind a double bond. But the reaction only took place at high temperatures (e.g., 100°C), and in an extreme alkaline environment (pH 12–14), thus seemingly having no immediate application in biology. A hundred years later, John Stenlake searched for a neuromuscular blocking drug that would break down *in vivo* by Hofmann elimination (Fig. 50.2) [12].

The observation that the plant alkaloid petaline could degrade by Hofmann elimination at physiologic pH and temperature prompted the search, culminating in the creation of atracurium. Atracurium was the first muscle relaxant whose elimination depended on neither enzyme nor organ function; a remarkable breakthrough [57]. Previously, muscle relaxants could only be eliminated when in the circulation, exposed to either enzyme degradation (succinylcholine) or elimination by kidney and/or liver (all the non-depolarizing drugs). Because atracurium broke down at body pH and temperature, its elimination occurred everywhere in the body [57].

In 1981, James Payne and Robert Hughes reported the first application of atracurium in patients [58]. Clinical neuromuscular block had entered a "golden age": vecuronium had no cardiac effects, and atracurium elimination did not depend on organ function. Savarese and Kitz's Type B ideal relaxant had been realized. However, whether vecuronium

and atracurium were free of biologically active by-products (criterion # 3 of Karis and Gissen; Table 50.2) remained a question.

Vecuronium undergoes deacetylation to an active metabolite with 50% of vecuronium's potency [59]. This might be a clinical problem for prolonged relaxation as in the ICU, and we will hear more of that later. Atracurium's metabolism by Hofmann elimination produced a compound called laudanosine, an analeptic. Could it antagonize anesthesia or cause seizures [60]? This argument, debated over several years, was finally settled with the conclusion that there was nothing to worry about in the operating room. There remained in some people's minds, a concern about long-term use in the ICU, but that use was about to end anyway.

Mivacurium

As vecuronium and atracurium were pursued in Scotland, John Savarese and his group in Boston synthesized bulky bisquaternary esters looking for drugs with a short duration of action [61], an enduring interest of Savarese (Fig. 50.5) [62]. Not surprisingly he defined Type A as a necessary element of an ideal relaxant. This so-called "non-depolarizing succinylcholine" proved difficult to develop. Savarese's collaboration with Burroughs-Wellcome would lead to the introduction of mivacurium, which like succinylcholine is metabolized by plasma cholinesterase.

While mivacurium had the sought-after short duration of action [63], it did not have a fast onset, and this limited interest in its use. Mivacurium took about twice as long as succinylcholine to act, its duration of action was twice as long, and if the patient had a cholinesterase deficiency, block would last twice as long. With shorter duration, onset time took up a greater proportion of the total duration. To get a faster onset and better intubating conditions, clinicians increased the dose but then ran into problems with histamine release. Mivacurium's manufacture in the US ended in 2006 because of insufficient demand. It continues to be available in other countries.

Failure of Doxacurium and Pipecuronium

The 1980s also saw the introduction of two ultimately unsuccessful drugs, pipecuronium and doxacurium. Vecuronium's popularity, lack of cardiovascular effect, and modest duration of action suggested the possibility that there might be a clinical need for a "clean" long-acting relaxant (*i.e.* pancuronium without side effects), the Type C drug described by Savarese and Kitz in 1975. The steroidal drug pipecuronium from Hungary, and the benzyloisoquinolinium drug doxacurium from the US resulted [64, 65]. But both drugs arrived

ten years too late because clearly vecuronium and atracurium met any clinical need that doxacurium or pipecuronium might serve. They were doomed to obscurity.

New Monitoring Modalities

The Danish anesthesiologist Jørgen Viby-Mogensen (Fig. 50.5) and his creative and productive research group had a particular interest in monitoring neuromuscular block. In the 1980s and 1990s, they built on the work of Ali to develop new monitoring modalities. Perhaps the intermediate duration of action of vecuronium and atracurium led to a fascination with deep levels of block. Monitoring post-tetanic responses enabled measurement of block in the absence of Ali's train-of-four (TOF) responses [66]. By monitoring post-tetanic responses, clinicians could control administration of enormous doses of relaxant, doses paralyzing even the diaphragm [67]. Neuroanesthesiologists used this technique to eliminate all possibility of movement during neurosurgery. Inevitably, this technique delayed reversal of the block [68].

Double-burst stimulation added another modality: two short tetanic bursts were felt as two responses [69]. Double-burst stimulation proved more sensitive than TOF at identifying residual block [69]. While these monitoring techniques are used quite commonly in academic centers in Europe they have had little penetration in other types of practice, or in other parts of the world.

Children Get Attention

In the 1980s, neuromuscular studies in pediatric patients started in earnest [70–74]. Up to this time there were few studies in children, perhaps in part because of the emotional stress surrounding informed consent from parents, and assent from older children. In addition, the smaller blood volume of children and infants limited studies requiring blood sampling. Notwithstanding these difficulties, the UCSF mathematician-pediatric anesthesiologist, Dennis Fisher and his colleagues characterized the pharmacodynamic/kinetic effects of both relaxants and antagonists in children, and studied placental transfer of vecuronium and pancuronium.

Various studies in the 1980s showed that children are not simply small adults. Younger children are more likely to have greater sensitivity to relaxants, and to have altered biodisposition and rate of elimination [72, 75, 76]. Onset of paralysis is shorter and duration longer in infants than in children and adults [71]. Fisher et al. also showed that, contrary to popular belief, children do not need disproportionately large doses of neostigmine, but in fact responded in much the same way as adults [73]. During Caesarean section under general anesthesia, there is measurable placental transmission of muscle

relaxant to the fetus, but there do not appear to be adverse clinical effects on the newborn [70].

In the 1990s, the effects of relaxants in children would be studied in the OR, the ICU and the Emergency Department [77–79], and the unique response of children to monitoring would be evaluated [80]. For the first time, children were included in early Phase 3 clinical trials, specifically during the assessment of rapacuronium [81]. Subsequent events would show the irony of this development.

Antagonists

The need to give drugs that reversed the paralyzing effects of muscle relaxants—to “unparalyze” patients at the end of surgery—has been appreciated since the early days of relaxant administration. Reversal drugs have been the neglected half of the muscle relaxant/reversal combination. They fall into three categories, anticholinesterase drugs (that block the destruction of acetylcholine), the aminopyridines (that increase acetylcholine release), and sugammadex (which captures and thereby inactivates the relaxant.) Aminopyridines have found little clinical application for this use and will not be discussed further.

The pharmacokinetics and dynamics of anticholinesterase drugs were largely defined in the 1980s using the tools developed at UCSF (Fig. 50.7). Several conclusions resulted. First, the anticholinesterase effect of these drugs underlies their action [82]. Second, neostigmine more effectively antagonizes profound block than does edrophonium [83]. Third, their actions usually outlast those of the muscle relaxant [82]. Finally, there is a ceiling to their capacity to produce reversal, resulting in inadequate reversal of profound block [83, 84]. One might think of inadequate reversal as consequent to three factors. First, there is a maximum rate at which acetylcholine that can be released from the motor nerve terminal. Second, even in the absence of cholinesterase, the acetylcholine will rapidly diffuse out of the neuromuscular junction and the equilibrium between rate of release and rate of diffusion away sets an upper limit to the concentration that can be achieved at the neuromuscular junction. Finally, because the interaction between muscle relaxant and acetylcholine is competitive, if the maximum acetylcholine concentration is insufficient to antagonize the concentration of relaxant, then inadequate reversal will be the consequence.

Inadequate reversal in some patients has been a long-known clinical fact of life, a fact potentially leading to disasters, including death. The introduction of vecuronium and atracurium led to complacency. Their short duration of action might be thought to guarantee recovery, but Bevan and others showed that this was not the case [84]. Indeed, not even the short-acting mivacurium was immune from inadequate recovery if reversal was omitted [85]. Adequate reversal was

Fig. 50.8 The striking relationship between the potency of a neuro-muscular blocking drug and its onset time [84] for the aminosteroid group of relaxant compounds. The fast onset drugs rocuronium and rapacuronium were not in the original study, and are included for reference. A similar relationship is found for the benzyloquinoline compounds. (Created with data from Bowman et al. 1988 [84].)

an area in need of pharmacological innovation. This came in the 2000s with the development of sugammadex.

Potency Versus Onset Time

By the end of the 1980s, clinicians had type B and type C, but not type A drugs. Indeed, fast onset continued to elude the chemists. In part this was due to condition # 5, high selectivity, set by Karis and Gissen [49]. This had always been assumed to correlate with high potency. High potency and greater selectivity for one receptor over others would be accompanied by fewer adverse effects. William (Bill) Bowman, a physiologist at the University of Strathclyde then made an observation that reversed this view.

The Organon R&D laboratories had synthesized many relaxant compounds in the steroidal series. Bowman observed that their potencies correlated inversely with onset time (Fig. 50.8) [86]: the more potent a relaxant, the slower its onset. This observation undermined the search for drugs with greater potency. As a result, ORG 9426 was identified and released in the 1990s as rocuronium, a nondepolarizing drug with a faster onset.

The 1990s: Fast Onset At Last; Problems in the Intensive Care Unit (ICU)

Rocuronium

Rocuronium showed that low potency, fast onset, and lack of adverse effects could be combined. Because it had an onset

time approaching that of succinylcholine, a nondepolarizing drug could be used for rapid-sequence intubation [87]. Doses of 1.0–1.2 mg/kg produced good conditions for rapid-sequence tracheal intubation, a first for a non-depolarizing drug [88].

Another new drug further illustrated the link between onset and potency. Cisatracurium was a single isomer isolated from atracurium, itself a mixture of 10 isomers [89]. Having a 5-fold greater potency than atracurium, it had a lesser tendency to release histamine [90]. However, the greater potency slowed onset, requiring larger doses to give acceptably brief onset times [91]. It has succeeded clinically because it is a “cleaner” atracurium and because, like atracurium, its elimination is largely organ independent.

Which to choose between the new guys on the block, rocuronium or cisatracurium? For some clinicians the onset time of rocuronium was most important; for others the more predictable recovery of cisatracurium was of overriding concern [92]. Most clinicians are happy to have both available.

ICU Problems

The otherwise “safe” use of muscle relaxant in the operating room motivated expansion of their use into ICUs. Rather than give patients depressant sedative drugs, paralysis could be used to facilitate ventilation. Relaxants, usually pancuronium and vecuronium, were used in virtually every ICU in the 1980s and 1990s [93]. Although Barnes, Prescott and Smith in the 1940s had shown that muscle relaxants did not provide sedative or analgesic effects, remarkable misconceptions existed among ICU caregivers regarding the properties of muscle relaxants. A 1980 study revealed that 5% of ICU physicians thought that pancuronium had analgesic properties, and 50% thought it was an anxiolytic [94]. A different effect provided another problem.

In 1985 Op de Coul identified significantly prolonged paralysis in patients receiving large doses of muscle relaxants in the ICU [95]. Weakness persisted for weeks after cessation of relaxant administration. Others confirmed the existence of this problem, finding that it occurred with all relaxants. Drugs that were safe and efficacious when used short-term in the operating room assumed a different safety profile with long-term use [96].

Patients recovered from the problem that brought them to the ICU, but were left with a paralysis that could last for weeks or months. Particularly bad was the combination of muscle relaxants plus steroids for treatment of severe asthma, a treatment requiring tracheal intubation and artificial ventilation [96]. After Segredo et al. published their work in the *New England Journal of Medicine* in 1992, the problem received greater notice [97]. The weakness had more than one form, including prolonged neuromuscular block, or

motor neuropathy (something wrong with the nerve going to the muscle), or myopathy (something wrong with the muscle). As might be imagined, risk increased with larger relaxant doses, longer durations of administration, concomitant use of steroids, and renal failure. The use of muscle relaxants in ICUs decreased dramatically. When relaxants were indicated, the doses were kept small, and drug “holidays” were allowed, to permit the neuromuscular junction to have intermittent periods of normal function. The problem then largely disappeared.

Tracheal Intubation Without Relaxant

The 1990s proved yet again that tracheal intubation doesn't require relaxants [98]. In the era before relaxants, tracheal intubation was accomplished under deep, usually ether, anesthesia. The existence of propofol, potent short-acting opioids and sevoflurane enabled a return to those days of yesteryear.

In adults, propofol and remifentanyl could provide excellent intubation conditions. The price was cardiovascular depression, since intubation depended on “deep” anesthesia [98]. In children, intubation solely with sevoflurane was successful, and remains a mainstream clinical technique [99]. In adults, intubation without relaxant fell out of favor since, compared to techniques using a muscle relaxant, it was associated with a greater risk of laryngeal injury [100, 101].

1999 and Rapacuronium

The decade went out with a bang. It appeared that the Type A drug had been found. The inverse relationship between potency and onset was pushed even further with the development of the drug rapacuronium. Its low potency enabled a fast onset, and it had a duration of action that made it a type A drug [102].

By the end of the 1990s we were feeling pretty good. We had drugs for virtually every clinical situation and good monitoring techniques. We thought we had solved all the problems, and that there was perhaps not much more going to happen in the world of muscle relaxants. We were in for unpleasant surprises.

The New Millenium: Uncertainty and a Revolution (Sugammadex)

Rapacuronium Withdrawn

A stunner opened the 2000s. The manufacturer of rapacuronium, the first true Type A drug, abruptly withdrew the drug on 27 March 2001 because of reports of severe bron-

chospasm, particularly in children [103]. Because the incidence was small, the number of subjects in the clinical trials preceding rapacuronium's release was insufficient to reveal the problem. However, when approved and used in hundreds of thousands of patients, this rare but serious problem became apparent.

Histamine release did not underlie the bronchospasm, also conspiring to conceal the cause. Measurements of histamine revealed nothing. It was reported in 2005 that rapacuronium activated cholinergic M3 receptors in the smooth muscle of the lung [104]. Karis and Gissen (condition #5; Table 50.2) had recognized that less potent drugs might be less specific for their primary target and risk being active at similar receptors in other systems. Such was the case with rapacuronium.

Allergic Responses?

The withdrawal of rapacuronium was first in a series of setbacks for muscle relaxant drugs. Reports came from France [105] and then Norway [106] concerning severe allergic responses to rocuronium. Reports from other European countries were few. In the largest market, the US, rocuronium seemed free of reports of allergic responses. What was going on? The fascinating story combined a real effect with some over-zealous diagnosis.

The diagnoses of rocuronium sensitivity were made using a skin test with a high sensitivity and low specificity, translating into a lot of false positive results [107]. After refining the skin tests the incidence of false positives decreased significantly [107, 108]. A clinically reliable test would be to repeat administration of a small dose of rocuronium (provocation test), in those who had putatively suffered an allergic response, to observe any recurrence of a reaction. This test was not performed because it was believed that the risk was not justified.

A current explanation for the geographic mal-distribution of individuals having the allergic responses is that some non-relaxant drugs provide a sensitizing exposure that makes a patient vulnerable to the subsequent administration of a muscle relaxant. Such a drug is pholcodine, which was in common use in Norway and France as a cough suppressant. It was not available in Denmark, which had no substantiated reports of allergy to rocuronium.

The false perception remains that muscle relaxants are the commonest cause of severe allergic responses in the operating room. However, some results from Denmark challenge this belief, and results from two studies are particularly important [109, 110]. First, data gathered by the central allergy response unit in Denmark suggest that muscle relaxants cause fewer allergic responses than first thought, muscle relaxants being third after chlorhexidine and fentanyl. The second paper examined whether the drug reported to cause the allergic response

was in fact the cause. The drug originally reported as the cause was incorrect in more than half the cases [110].

Why Can't We Reverse Relaxant Block?

Since publication of the TOF ratio method in the 1970s, a TOF ratio of 0.7 had been accepted as indicating adequate recovery of neuromuscular function [111]. Lars Eriksson and then Aaron Kopman challenged that belief at the end of the 1990s [112, 113]. Complete recovery of neuromuscular function had not occurred at a TOF of 0.7, and in fact required a TOF ratio of greater than 0.9. In addition, even careful intraoperative monitoring of neuromuscular function could not eliminate the occurrence of residual block [114].

Entering the 2000s, many anesthetists considered that neuromuscular function in a patient given a muscle relaxant (with the exception of succinylcholine) could not be rapidly restored to the pre-relaxant state. They considered that pharmacological reversal with neostigmine, was not as reliable as previously thought [115]. A full reversal dose of neostigmine, given even after 4 TOF responses were present, did not guarantee rapid recovery to a TOF ratio of 0.7, and particularly not to the newly recommended ratio of 0.9. The age of uncertainty about relaxant reversal was upon us [116].

The method of antagonism of block had significant limitations, most prominently incomplete efficacy against profound levels of block. Users of intermediate-duration relaxants had incorrectly believed that residual paralysis would not be a problem. This belief sometimes led to failure to antagonize residual block, with a consequent persistent incidence of some degree of paralysis with all neuromuscular blocking drugs [117]. As patients became increasingly obese, with less pulmonary reserve (and especially after abdominal or thoracic surgery), the problem of inadequate reversal became more apparent, and of greater clinical import [118].

In particular circumstances, neostigmine might itself produce paradoxical weakness. In 1980, Payne and others showed that neostigmine alone, without previous administration of a relaxant, could produce mild weakness [119]. Caldwell later found that administration of neostigmine to a patient with a TOF ratio equal to or greater than 0.9 could decrease the TOF ratio [120]. In studies of airway muscle [121, 122], Eikermann elegantly showed that excessive neostigmine could decrease pharyngeal muscle tone, and diminish the ability to maintain an open airway.

Nonetheless, clinicians continued using the same drug, neostigmine, that they had used in the 1940s, a drug that could not be guaranteed to produce adequate recovery, even with careful attention to monitoring relaxant effect. In contrast, over the same period, muscle relaxants had gone through quite dramatic development and improvement. The time was ripe for new pharmacology applied to relaxant reversal.

Fig. 50.9 How sugammadex terminates the action of rocuronium. In brief, the sugammadex molecule was designed specifically to accommodate (encapsulate) one molecule of rocuronium. Once the bulk of the rocuronium molecule enters the sugammadex molecule, negatively charged groups (-ve) on the sugammadex molecule are attracted to the positively charged terminal group (+ve) of the rocuronium, and lock it in place. If sufficient sugammadex is given to encapsulate all rocuronium molecules, reversal of block is almost immediate and complete. This was the first major pharmacological breakthrough in reversal since the introduction of muscle relaxants to anesthesia in 1942

2001

There was little indication of the excitement to come when the 7th International; Neuromuscular Meeting opened in Belfast in 2001. At that meeting, the Dutch pharmaceutical chemist Anton “Ton” Bom (Fig. 50.5) made a fascinating presentation. He had been conducting experiments with rocuronium, at the Organon research laboratories in Scotland, and things were not going well. He was having difficulty dissolving rocuronium in the medium he was using. From a brief literature review, he discovered a group of compounds, the cyclodextrins that had been used as solubilizing agents. The cyclodextrins are doughnut shaped molecules that solubilize drugs by incorporating the drugs’ lipophilic part inside the hole in the doughnut, leaving only the hydrophilic end exposed. However, he found that after mixing with cyclodextrin his rocuronium solution had lost potency. Bom then had a “Eureka” moment. He realized that if he could design a cyclodextrin that would similarly attract and then trap rocuronium then he had a perfect mechanism for reversal of neuromuscular block (Fig. 50.9). His insight produced the first significant pharmacologic development in relaxant reversal in 60 years.

He and his collaborators experimented with different cyclodextrins, finally arriving at the drug sugammadex. Sugammadex is a gamma cyclodextrin, a ring structure composed of eight sugar molecules. Since each sugammadex molecule captures one rocuronium molecule, any concentration of rocuronium could be inactivated by an appropriate dose of

sugammadex. If that reasoning was correct, it would be possible to quickly restore the patient's neuromuscular junction to the state before muscle relaxant had been given *i.e.* there should be complete reversal of neuromuscular block. Several experiments supported that view [123]. We now had two drugs; rocuronium and sugammadex, which when used in combination provided the “ideal drug”. This new pharmacologic approach may be the most innovative discovery since the introduction of muscle relaxants to clinical practice.

2008

Sugammadex was approved for clinical use in 2008 and is now available in over 50 countries—but not the US. The failure of the Food and Drug Administration to approve sugammadex was a great surprise to all who had been involved in the drug's development. The official reason was concern over the possibility of hypersensitivity reactions in some of the experimental subjects. To the best knowledge of the author, there had been no serious adverse events with the drug during the clinical trials. Of note, there have been few reports of adverse clinical events with sugammadex from the more than 50 countries where it is now approved.

Gantacurium and Cysteine Adduction

Concurrent with the development of sugammadex, as part of their 30-year quest for a Type A drug, Savarese and his group continued their development of benzyloisoquinolinium compounds [124]. The chlorofumarate compounds gantacurium and CV002 resulted from these efforts [125]. These compounds bear a resemblance to mivacurium and undergo a unique, rapid inactivation *in vivo* by adduction to endogenous cysteine. In addition, administration of exogenous cysteine accelerates their inactivation. As with sugammadex, the combination of gantacurium, and exogenous cysteine administration has the potential to rapidly return neuromuscular function to a normal state. This drug combination is currently in clinical trials.

The Future

It took five centuries from the first reports of “death-dealing” arrow poison to the clinical use of curare. The next 70 years saw the evolution of newer, safer, better relaxants and an increased understanding of their actions. The discovery of sugammadex and chlorofumarate drugs reveals continuing innovation in neuromuscular pharmacology.

Where will the next generations of drugs that provide skeletal muscle relaxation act? Perhaps these drugs will work on the spinal cord or in the brain. Might we have drugs working preferentially at one or more groups of muscles,

for example the laryngeal adductors, to facilitate tracheal intubation—but not the diaphragm—so breathing would remain normal. Even further out, might we develop inactive pro-drugs, which would be activated only when needed, and turned off when no longer required?

Reflections and Conclusions

Curare had a long gestation period from the fifteenth century until its birth into anesthesia practice in 1942. In the last century we have witnessed the evolution of one of anesthesia's greatest stories—unraveling the mysteries of neuromuscular blocking drugs and their use in everyday clinical practice. Some characteristic patterns have marked the development of these drugs.

Little Is New Under the Sun (At Least Not Very Often)

Each generation thinks it is first with a particular idea. Most ideas have been conceived before, but with poor timing. In 1912, a surgeon Arthur Lawen used curare, tracheal intubation, and assisted ventilation for surgical procedures *i.e.* long before this became standard practice in anesthesia. The idea did not catch on at first.

Every Change Carries the Risk of Unintended Consequences

A good, even revolutionary, drug may produce effects that outweigh its benefits. Doubtless many patients died from the effects of curare in the 1940s and 1950s. Later during the decades of the 1960s–80s, patients in intensive care units were certainly harmed by drugs that, at the time, had a good record of safety in the operating room. Finally, in the past decade rapacuronium, despite its unique properties, was withdrawn because of rare but serious adverse effects.

Many Major Breakthroughs Are Accidental

The first formal use of curare in anesthesia in 1942 resulted from a series of coincidences rather than a directed program of research and development. Fast onset was developed after a simple insight by Bowman in the 1990s, an insight contrary to accepted wisdom. At the beginning of this decade, sugammadex resulted from Bom's openness to the chance discovery of an interaction that no one had been pursuing. The next major discovery may be just as revolutionary—and fortuitous—for someone open to the discovery.

Persistence Pays Dividends

In the 1930s, it was the persistence of Richard Gill in pursuit of a cure for his multiple sclerosis that led him to bring from South America, sufficient curare extract to enable its development for clinical use. It was Stenlake's tenacity in the 1970s that resulted in the development of atracurium. He was able to create a drug that degraded via Hofmann elimination, a process that previously functioned only in temperature and pH ranges far outside the physiologic domain. Finally, John Savarese and his group may be on the verge of developing a fast onset, short-acting nondepolarizing drug, more than 30 years after he first described the clinical need for such a compound.

Kenneth Drasner

Summary

In 1862, von Schroff found that cocaine numbed the tongue. In 1880, von Anrep recommended testing cocaine as a local anesthetic. No one listened. Koller's 1884 report that cocaine induced corneal insensibility enabled ophthalmological procedures and marked the discovery of local anesthesia. In 1884, Halsted and Hall produced peripheral nerve blocks with cocaine. Corning in 1885 and Bier in 1898 used it for spinal anesthesia. Increasing reports of central nervous system and cardiac toxicity accompanied cocaine's expanded use. Toxicity and addiction stimulated the search for alternative local anesthetics.

Einhorn patented the first new useful local anesthetic, the ester procaine, in 1904. Procaine's short duration of action limited clinical utility, a limitation Eisleb's 1928 synthesis of tetracaine overcame. However, tetracaine proved toxic if used in high-volume peripheral blocks. Lidocaine, introduced in 1948, had an amide rather than an ester linkage, imparting greater stability and eliminating concern of allergic reactions from p-aminobenzoic acid, a breakdown product of the ester compounds. Ironically, chlorprocaine (released in 1952) reverted to the ester linkage, but its rapid degradation by plasma esterases decreased the risk of systemic toxicity. Regrettably, neural injury occurred when a large dose of chlorprocaine intended for the epidural space was administered intrathecally.

Bupivacaine, a longer-acting amide anesthetic was released in 1963. Associated untoward cardiac effects were reported in the 1970s. Modifications in practice decreased the risk of these effects. Stereochemical strategies further decreased risk, resulting in levobupivacaine which had less affinity for cardiac sodium channels. The 1996 release of ropivacaine, an S (–) enantiomer followed these observations. In 1998, Weinberg suggested that intravenous infusion of lipid could decrease the availability of local anesthetics and thereby treat toxicity.

Toxic reactions with spinal lidocaine resulted in its near abandonment as a spinal anesthetic. Toxicity took two forms: a rare serious neurologic injury reported in 1991; and a frequent postoperative pain/dysesthesia reported in 1993. Ironically, chlorprocaine, once the “poster child” for local anesthetic toxicity, appears from studies reported in 2004, to be a serious contender to replace lidocaine. The dose required for spinal anesthesia is 10-fold less than that associated with injury following inadvertent intrathecal injection during epidural anesthesia.

As apparent from this story, toxicity, rather than efficacy, directed the evolution of these compounds. Importantly, present data suggest that neurotoxicity does not result from blockade of voltage-gated sodium channels, thus opening the way to the development of local anesthetics with therapeutic advantages.

The Origins of Local Anesthesia

Just as Morton's historic use of ether four decades previously marked the birth of general anesthesia, Joseph Brettauer's (1835–1905) demonstration of cocaine-induced numbing of the cornea on September 15, 1884, marked the birth of local anesthesia [1]. The event took place before the Ophthalmological Congress in Heidelberg, on a patient from the Heidelberg Eye Clinic. Carl Koller (1857–1944; Fig. 51.1),

Brettauer's Viennese colleague, had performed the work enabling this demonstration, but lacked the funds to attend the meeting. This demonstration prompted an immediate wave of experimentation, development, and clinical application. Henry Noyes (1832–1900), a renowned American ophthalmologist, attended the meeting and sent an account in a letter published less than a month later in the *New York Medical Record*. He commented, “The future which this discovery opens up in ophthalmological surgery and medication is obvious. The momentous value of the discovery seems likely to be in eye practice of more significance than has been the discovery of anesthesia by chloroform or ether in general surgery and medicine”. More than 60 publications concerning the use of cocaine as a local anesthetic appeared in 1885 [2].

Fig. 51.1 Carl Koller (1857–1944) is recognized as the discoverer of the usefulness of cocaine for local anesthesia. (Courtesy of the National Library of Medicine, Bethesda, MD)

While Koller is recognized as the “discoverer of local anesthesia”, this title may be no more valid than recognizing Christopher Columbus as the discoverer of America. Other investigators had noted the local anesthetic properties of cocaine and its potential uses before Koller’s experiments and clinical application. Nonetheless, Koller was responsible for delivering cocaine as a local anesthetic into clinical practice. Perhaps a more appropriate title might be “discoverer of clinical local anesthesia”. As with the ether story, a surprisingly long time extended from the recognition of cocaine’s potential as an anesthetic, to the translational event bringing it into clinical use.

Although the first verified use of the coca plant (*Erythroxylum coca*) around 500 CE was established by its presence in an ancient Peruvian gravesite [3], its stimulant properties were recognized more than two millennia earlier. The Incas considered the plant to be divine, referring to the plant as khoka, or “the plant”, translating to the term coca by Europeans [4]. It was used in religious ceremonies, and described as “that heavenly plant which satisfies the hungry, strengthens the weak, and makes men forget their misfortunes” [5]. Some early European explorers shared such sen-

timents. For example, Paolo Mantegazza (1831–1910), was an Italian pathologist, anthropologist, writer, and member of Parliament who worked in Argentina from 1854 to 1858. He had extensive experience with coca, and published a monograph on his return to Italy “On the hygienic and medicinal virtues of coca”. His descriptions are astounding:

“...some of the images I tried to describe in the first part of my delirium were full of poetry. I sneered at mere mortals condemned to live in this valley of tears while I, carried on the wind of two leaves of coca, went flying through the spaces of 77,438 worlds, each more splendid than the one before. An hour later, I was sufficiently calm to write these words in a steady hand ‘God is unjust because he made man incapable of sustaining the effect of coca all life long. I would rather have a life span of ten years with coca than one of 1000000....(and here I have inserted a line of zeros) centuries without coca’.”

The German chemist Friedrich Gardeke (1828–1890) was first to extract the active ingredient of the coca plant, doing so in 1855. He named it erythroxyline [1]. Shortly thereafter, Carl von Scherzer (1821–1903), returning from an expedition on the frigate Novarra, delivered an abundant supply of the plant to the chemist, Friedrich Woehler (1800–1882), who asked his assistant, Albert Niemann (1880–1921) to extract the alkaloid [6]. Niemann or perhaps Woehler named the product cocaine, a name with greater appeal than erythroxyline. Niemann also chewed some of the isolated compound and reported, “It numbs the tongue, and takes away both feeling and taste” [7]. In 1862, Karl von Schroff (1802–1887) reported to the Viennese Medical Society, describing the numbness cocaine produced when applied to the tongue. However, no Viennese then applied cocaine for the relief of surgical pain.

In 1868, T Moreno y Maiz [8], later the Physician-in-Chief of the Peruvian Army, reported the first systematic investigations of the anesthetic properties of cocaine. In frogs he noted that,

“Notwithstanding that the spinal cord remains intact, we nevertheless observe disappearance of sensibility in the injected limb. It is therefore on peripheral sensibility that cocaine acetate appears to act. Furthermore the local action of the substance is very evident. Could it be used as a local anesthetic? One cannot reply on the basis of so few experiments; it is the future that will decide.” [8]

These animal experiments also described cocaine’s capacity to produce generalized irritability and convulsions, and self-experimentation confirmed the induction of a feeling of well-being, but Moreno y Maiz did not apply cocaine for the relief of surgical pain. Missed the gold ring, he did.

In 1880, an Estonian, B. von Anrep [9] (1852–1927) described the potential of cocaine to produce anesthesia, but failed to recognize the importance of this observation:

“After studying the physiological actions of cocaine in animals I had intended to investigate it also in man. Various other activities have so far prevented me from doing so. Although

the experiments on animals have not had any practical consequences, I would recommend that cocaine be tested as a local anesthetic.” [9]

Von Anrep did not take his own advice, with respect to surgical anesthesia although he did use it for the treatment of pain.

Koller’s interest in cocaine came by way of Sigmund Freud (1856–1939), a senior colleague and friend. Freud was interested in cocaine taken orally as a possible therapeutic for various conditions including fatigue, dyspepsia, hysteria, and headaches. He also advocated its use for management of morphine addiction, prescribing it for his colleague, the notable pathologist Ernst Fleischl von Marxow (1846–1891). Von Marxow had become addicted to morphine used to treat neuropathic pain after a thumb amputation [2]. Although cocaine addiction substituted for morphine addiction, it also resulted in Von Marxow’s untimely death.

While primarily interested in cocaine’s systemic effects, Freud alluded to its anesthetic properties in his 1884 publication *Über Cocain*, commenting “Indeed, the anesthetizing properties of cocaine should make it suitable for a good many further applications”. He encouraged two colleagues, Leopold Königstein and Koller, to investigate cocaine’s use in ophthalmological surgery, but the former’s interests focused on the treatment of pathological conditions. Freud’s role in prompting Koller’s investigations of cocaine are not entirely clear, but what is clear is Freud’s comment, that the discovery of topical surgical anesthesia belongs to Koller [10].

A colleague of Koller’s remarked on cocaine’s numbing effect on the tongue [1]. Koller confirmed the resulting lack of sensitivity with self-experimentation, commenting, “At that moment it flashed upon me that I was carrying in my pocket the local anesthetic for which I had searched some years earlier. I went straight to the laboratory... and instilled this into the eye of the animal.” He performed the first surgical procedure under cocaine anesthesia on a patient with glaucoma on 11 September 1884, four days before the historic Heidelberg demonstration.

It is difficult to understand the inordinate time passing between the recognition of cocaine’s anesthetic properties and its clinical application. Perhaps Winston Churchill summarized it: “Men occasionally stumble over the truth, but most will pick themselves up, and hurry along as if nothing happened”.

Although Koller won fame for his introduction of one of the most important contributions to medicine, he never obtained a much-desired assistantship in the University of Vienna Eye Clinic. In addition to being Jewish (hardly an asset during that period in Austria), his daughter described him as “a tempestuous young man, and one who could never be compelled to speak diplomatically even for his own good” [1]. Any hope for an appointment evaporated with an incident that put his career in jeopardy. A disagreement over

patient management caused another physician to call him either a “Jewish swine” or an “Impudent Jew.” Koller hit the offender in the face. The two were reserve officers in the Austrian army and settled the matter with a sabre duel—ending after three thrusts, with Koller inflicting wounds on his opponent’s head and upper arm. Koller was not wounded, at least physically, but was charged with criminal offences, which were later withdrawn [1]. Koller emigrated to New York, where he maintained a successful practice and died in 1944. He was awarded the American Ophthalmological Society’s first Gold medal in 1921.

Cocaine’s ability to induce insensibility was soon used for other clinical applications, including topical anesthesia in diverse areas (e.g., mucosal surfaces of the nose, throat, and urethra). Techniques for spinal anesthesia and peripheral nerve blocks were also developed, the former championed by J. Leonard Corning (1855–1923) and August Bier (1861–1949), and the latter by William Halsted (1852–1922) and Richard Hall (1856–1897).

The Emergence of Toxicity

At its introduction into clinical medicine, cocaine was thought to be remarkably safe, indeed, beneficial to health. It enjoyed widespread popularity outside mainstream medicine, notably in Vin Mariani (Fig. 51.2), a popular French tonic composed of Bordeaux wine infused with coca leaves. Such notables as Thomas Edison, Jules Verne, Rodin, HG Wells, and Pope Leo XIII (Fig. 51.3) consumed and endorsed the drink. Robert Louis Stevenson is supposed to have written “Dr Jekyll and Mr Hyde” under the influence of cocaine. It inspired John Pemberton’s Coca Wine in Atlanta, Georgia. And after the introduction of prohibition in Atlanta and Fullerton County in 1886, a non-alcoholic version of the drink premiered as Coca Cola. Coca Cola continued to contain cocaine until 1903.

Many physicians also initially believed cocaine was relatively innocuous. As late as 1886, one practitioner reported to the New York Neurological Society that “I do not believe that any dose could be taken that would be dangerous” [11]. However, increasing reports of central nervous system and cardiac toxicity accompanied its expanding use. In 1887, speaking before the Kings County Medical Society, Jansen Mattison (1845-?) related 50 cases of toxicity, including 4 fatal cases. By 1891, this number had increased to 126 [11]. The significance of these complications can be appreciated by Mattison’s comment that “the risk of untoward results have robbed this peerless drug of much favor in the minds of many surgeons, and so deprived them of a most valued ally.” Mattison dismissed the often-held belief that toxicity was due to impurities: “It has a killing power, per se, and the purer the product, the more decided this may be.”

Fig. 51.2 Vin Mariani “fortified and refreshed body & brain” with its wine and cocaine content. (A lithograph created by Jules Cheret, printed in 1894)

The Search for Less Toxic Local Anesthetics Begins

Toxicity and emerging issues of addiction stimulated the search for alternative topical-local anesthetics. Early investigations of natural products identified tropocaine, an alkaloid isolated from a different variety of coca, but this compound had no therapeutic advantage over cocaine [4]. Synthetic chemistry proved more fruitful. Mimicking the chemical structure of cocaine, synthetic strategies focused on benzoic

acid esters. In 1890, Eduard Ritsert created benzocaine. However, its poor water solubility made it suitable only for topical anesthesia, an application sunburn sufferers still find useful. Similar synthetic efforts by Alfred Einhorn (1856–1917) and colleagues (in the employ of the Bayer Company, originally a dye works founded by Friedrich Bayer and Johann Weskott in 18631) resulted in procaine, one of 18 related compounds patented in 1904 [7].

¹ It has no connection to Adolf von Baeyer.

Fig. 51.3 Pope Leo XIII recognized the benefits received from Vin Mariani. (From an advertisement that was printed in 1899)

Shortly after its introduction, Heinrich Braun documented the effectiveness and reduced toxicity of procaine relative to cocaine [12]. Procaine however, lacked cocaine's vasoconstrictive properties (which slow its removal into the bloodstream), and Braun made prescient comments concerning toxicity and the potential utility of epinephrine:

"The new drug by itself cannot substitute for cocaine. To obtain results similar to those with cocaine one would have to increase the concentration and dose so much that the lower toxicity would be rendered illusory. Fortunately, this drawback can be readily overcome with the addition of epinephrine." [12]

Although procaine had a greater therapeutic index than cocaine, this advantage did not eliminate concerns for toxicity. In response, the American Medical Association established the Committee for the Study of Toxic Effects of Local Anesthetics, under the leadership of Emil Mayer. The first publication of the committee described 43 deaths associated with the use of local anesthetics. The anesthetic was judged to have caused all but 3 deaths, including 2 that clinicians had attributed to "status lymphaticus" [13].

Although seizures (convulsions) or respiratory failure were usually the first or sole manifestation of toxicity, in some cases cardiac arrest occurred before apnea, and without convulsions. Medical errors (administration of the wrong drug or of an overdose) caused several deaths. Frequently, incorrect drug administration followed misinterpretation of verbal orders. Excessive doses of anesthetic were also administered due to lack of labeling of anesthetic solutions. The resulting recommendations for preventing such incidents (e.g., solutions should be uniquely identifiable with respect to drug and concentration, verbal orders should be minimized) paralleled modern National Patient Safety Goals. (The more things change the more they remain the same.) The committee's

review appeared to confirm cocaine's greater toxicity: although it was used less often than procaine, cocaine was associated with the majority of cases. The committee did not recommend abandoning the use of cocaine, but its recommendations effectively eliminated widespread use of cocaine as an injectable anesthetic.

The report by Mayer's committee did much to change practice and reduce the toxic manifestations of local anesthetics. However, procaine's short duration of action limited its clinical utility. This set the stage for the introduction of tetracaine, a compound synthesized in 1928 by Eisleb, and introduced into clinical practice four years later [14]. While tetracaine represented a step forward (it had a longer duration of effect than procaine), it was toxic if used in a high volume for peripheral blocks. As with procaine, its ester linkage rendered it somewhat unstable and thus not amenable to repeated sterilization by autoclaving. These characteristics ultimately led to more limited use, primarily as a spinal anesthetic, for which it still finds some application. A similar fate befell dibucaine, a compound synthesized by Meischer and introduced into clinical practice by Uhlmann.

The Woolley and Roe Case: A Major Setback for Local Anesthesia

Spinal anesthesia served as the spearhead for local anesthetic development. Sporadic reports of neurological sequelae may have tempered enthusiasm but did little to impact the use of this invaluable technique. However, the tragic occurrence of paraplegia in two patients (Albert Woolley and Cecil Roe) on a single day in 1947 at Chesterfield Royal Hospital culminated in a landmark legal case, which would profoundly impact spinal anesthesia, not just in the UK, but also throughout the world. The court ruled in the physician's favor, believing the weight of evidence overwhelming supported contamination of the anesthetic as the etiology of injury [15]. This was thought to occur from phenol used for sterilization penetrating through invisible cracks in the anesthetic ampoules. Although others have challenged this theory, alternative explanations have largely focused on contamination of the equipment used to deliver the local anesthetic rather than the anesthetic solution, again exonerating the local anesthetic [15]. Most critically, more modern techniques of ensuring sterility eliminated such risk, enabling spinal anesthesia to be conducted with impressive safety in modern practice.

Introduction of Amide Anesthetics

The commercial release of lidocaine in 1948 heralded the modern local anesthetics. Unlike procaine and tetracaine which had ester linkages, lidocaine had an amide linkage,

and consequently a greater stability and longer shelf life. And unlike procaine, it did not break down to p-aminobenzoic acid, a compound believed responsible for allergic reactions. Lidocaine was not the first amide anesthetic; Niraquine, a compound abandoned because of its local irritant properties was introduced in 1898 [4].

The development of lidocaine emerged from studies of mutant barley [16, 17]. Synthesis of analogs of alkaloid isolated from these plants yielded LL30, named for the two chemists responsible for the synthesis and discovery of local anesthetic properties, Nils Löfgren (1913–1967) and Bengt Lundqvist. Lundqvist was a young chemistry student, who came to Löfgren's laboratory after the latter had synthesized LL30. Lundqvist sought something that he could experiment with, and Löfgren gave him some of the LL30. With little research money available, and no laboratory animals, Lundqvist borrowed some texts on local anesthesia from a medical student friend, and took the LL30 home. There he supposedly performed digital and spinal blocks on himself! How he would perform a spinal block on himself is unclear—it is said that he used a mirror; perhaps he had help! He then told Löfgren that LL30 was the best local anesthetic substance that existed. Also interesting is the opportunity that Pharmacia passed up by not buying the patent when it was offered to them! LL30 was named Xylocaine, or lignocaine or lidocaine.

Löfgren was a dedicated researcher, brilliant lecturer, and gifted musician. He became wealthy as a result of his discovery of lidocaine, but was increasingly frustrated with academic bureaucracy. During an episode of depression, he took his life in 1967. Lundqvist was a champion fencer, and keen sailor. At the age of 30, he suffered a head injury from which he died. His family used the royalties from his discovery to establish a fund to pay for the studies of many young and promising chemistry students [18].

In 1943, Astra Pharmaceuticals acquired the rights to lidocaine. Torsten Gordh Sr. (1907–2010) commented (personal communication): “Before lidocaine, Astra was a small local drug firm. Lidocaine was the start of ASTRA as a world wide company.” The initial animal experiments performed by Leonard Goldberg, and the clinical studies undertaken by Gordh in 1945, showed that lidocaine had a greater therapeutic index than procaine [17]. Gordh (personal communication) described his studies as follows:

“Several hundred intracutaneous and subcutaneous tests were carried out in volunteers, using different concentrations of lidocaine versus procaine, all in a double blind fashion. Then 400 clinical infiltration anesthetics were given with lidocaine without adrenaline, and another 405 with addition of adrenaline. Effects were also assessed in brachial plexus blocks, sacral blocks, and spinal anesthetics.”

For the next half century, lidocaine stood as the “gold standard” for safety, enjoying enormous popularity, and provid-

ing a template for future local anesthetic synthesis. The full “Lidocaine story” is in “Xylocaine—a discovery, a drama, an industry” by Lundkvist and Sundling—1993, published at the 50-year anniversary of the original synthesis of lidocaine.

A Late-Arriving Ester

Although chlorprocaine was a reversion to the ester linkage, it became popular because of, rather than despite, its inherent instability. Francis Foldes and co-workers demonstrated that plasma esterases degraded chlorprocaine four times faster than procaine, translating to a lethal dose twice that of procaine despite chlorprocaine's greater potency [19]. Confirming this reduced potential for systemic toxicity, Ansbro et al. found that the incidence of toxic reactions with epidural administration of chlorprocaine was roughly 1/20th that of lidocaine [20]. Chlorprocaine gained widespread use in obstetrics, where its rapid degradation virtually eliminated concerns for fetal exposure.

The Long Acting, Lipid-Soluble Amides and Cardiotoxicity

The next major milestone in local anesthetic history was the development of bupivacaine, a longer-acting, lipid-soluble anesthetic released into clinical practice in Scandinavia in 1963. A similar agent, etidocaine was released shortly thereafter, but failed because it inhibited motor function more than sensory function (i.e., a patient might feel but not be able to move!) In laboratory studies, bupivacaine's systemic toxicity appeared to be equivalent to that of tetracaine and four times greater than that of mepivacaine (paralleling their relative potency) [21].

Unfortunately, clinical experiences revealed a particular potential for cardiotoxicity with bupivacaine. The first serious adverse events were reports of bradycardia and fetal demise after paracervical blocks. However, this complication was not unique to bupivacaine, nor was this complication initially described with bupivacaine [22]. In fact, it remains unsettled as to whether bupivacaine poses a greater risk than other anesthetics used for this procedure. Other early reports of adverse events associated with these lipid soluble anesthetics seemed to reflect the expected incidence of central nervous system toxicity, cardiovascular effects consistent with the physiological effects of anesthetic block, or more serious complications ascribed to patient morbidity. None of these explanations accounted for the cardiac arrest of a healthy 31-year-old man following caudal anesthesia reported by Prentiss in 1979 [23]. Despite a negative test dose, convulsions progressed almost immediately to ventricular

fibrillation after administration of 25 ml of 1% etidocaine. The patient's complete recovery following a 75-minute resuscitation is a tribute to remarkable care. Prentiss dismissed hypoxia as a potential cause, and his insightful conclusions regarding the direct effect of this lipid-soluble, highly-bound anesthetic were eclipsed by the seminal editorial published by George Albright [24] later that year.

Albright's editorial reviewed the cardiac arrest reported by Prentiss and five other similar cases, four of which had not been previously reported. Albright proposed that these local anesthetics were uniquely cardiotoxic, in that they could induce simultaneous seizures and arrest, in the absence of hypoxia. Although the editorial was harshly criticized, experimental studies and clinical experience proved Albright correct. For example, de Jong found that doses of bupivacaine and etidocaine as low as 2/3 of those producing convulsions could induce arrhythmias, while the margin between central nervous system and cardiac toxicity for lidocaine was 2.5 times wider [25].

Within 4 years, the Food and Drug Administration learned of 12 cases of cardiac arrest (10 fatal) associated with obstetrical use of 0.75% bupivacaine (the highest concentration available) [26]. Albright reported an additional 8 cases (6 fatal). The FDA then banned the use of 0.75% bupivacaine for obstetrical anesthesia, and advised against the use of any concentration for paracervical blocks or intravenous regional anesthesia [27]. The reports surrounding these cases also led to widespread use of the test dose and incremental injections as standards for anesthetic practice. These modifications proved effective, but not foolproof.

Chlorprocaine Neurotoxicity

Add a new crisis to the toxicity story. Ravindran [28] and Reisner [29] described neurologic deficits following inadvertent intrathecal injection of solutions of Nesacaine-CE (a chlorprocaine solution containing 0.2% sodium bisulfite) intended for epidural administration. Although some of the cases lacked definitive evidence for intrathecal injection, and hypotension or total spinal anesthesia complicated other cases, it seemed clear that injury resulted from the toxicity of the anesthetic solution. Subsequent experimental studies produced conflicting results: some implicated the anesthetic, others suggested the bisulfite preservative was responsible [30]. This controversy regarding the potential neurotoxicity of Nesacaine-CE resembled earlier concerns generated by problems associated with the use of hyperbaric Durocaine for spinal anesthesia reported by Ferguson and Watkins in 1937 [31]. Here, too, the issue of whether toxicity resided in the anesthetic (10% procaine) or the vehicle components (15% ethanol, glycerine, and gum acacia) was never fully

resolved, although some experiments in cats demonstrated that 10% procaine induced similar neurologic impairment, while the vehicle did not [32].

These reports of injury associated with the use of epidural chlorprocaine led to more restricted use—but stay tuned, chlorprocaine did not disappear.

Synthetic Strategies to Reduce the Risk of Systemic Toxicity

Pharmaceutical company-supported research turned to decreasing the cardiotoxic potential of the long-acting amides while maintaining their desirable qualities. One method relied on stereochemistry. Isomeric compounds have the same molecular formula. Isomers having atoms connected by the same sequence of bonds but with different spatial orientations are called stereoisomers. Enantiomers are a subset of stereoisomers existing as mirror images. Enantiomers have identical physical properties except for the direction of the rotation of the plane of polarized light. This property is used to classify the enantiomer as dextrorotatory (+) if the rotation is to the right or clockwise, and as levorotatory (−) if it is to the left or counterclockwise. A racemic mixture contains equal parts of enantiomers and is optically inactive because the rotation caused by the molecules of one isomer cancels the opposite rotation of its enantiomer. Such chiral compounds can also be classified by their absolute configuration: R (Latin: *rectus*, or right) or S (Latin: *sinistra*, or left). The term chiral is derived from the Greek word for “hand,” because, like right and left hands, these forms are non-superimposable mirror images.

Bupivacaine is a racemic mixture, and investigations revealed that the S (−) enantiomer was less cardiotoxic than its R (+) mirror image, with subsequent marketing as (generic and trade names) levobupivacaine and Chirocaine[®], respectively. Marketing of ropivacaine, an S (−) enantiomer, with slightly lesser potency than bupivacaine shortly followed. The substantial literature regarding the relative cardiotoxicity of these compounds indicates that the S (−) enantiomer is modestly less toxic [33]. In addition to this more favorable affinity for neuronal vs. cardiac sodium channels, ropivacaine has a greater propensity to produce vasoconstriction, which might reduce cardiotoxicity. Some electrophysiologic evidence suggests the possibility that ropivacaine preferentially blocks C fibers, implying a greater differential block (sensory > motor). However, when reduced potency is factored in, clinical studies suggest that any benefit over bupivacaine with respect to differential block is marginal, at best. As might be anticipated, these enantiomeric anesthetics have found their greatest use in epidural anesthesia and high-volume peripheral blocks.

Lidocaine's Fall from Grace for Spinal Anesthesia

A 1991 report described four cases of cauda equina syndrome (a clinical manifestation of injury of the nerves emerging from the end of the spinal cord) after continuous spinal anesthesia. This expanded concerns for anesthetic neurotoxicity beyond the use of chloroprocaine. Surprisingly, three of these cases, and several subsequently reported, implicated lidocaine, the “gold standard” of safety for nearly half a century [34]. In these cases, relatively large doses of lidocaine were administered through newly marketed small-bore (28-gauge) catheters designed specifically for continuous spinal anesthesia. Ken Drasner in collaboration with Kendall Healthcare's R&D team headed by Jim Cianci developed the catheters. The manuscript describing the use of the new catheter was never published. It was replaced with a manuscript describing the cases of injury collected by Drasner from three institutions, and first-authored by his research fellow, Mark Rigler [34]. This report suggested that repetitive injections, in combination with maldistribution of anesthetic, led to localized toxic concentrations in the subarachnoid space. Within a year, 8 additional cases were reported, leading to withdrawal of the catheter from the market [35].

The new catheter was not the only culprit. A case of injury to the lumbosacral roots (cauda equina syndrome) resulted when lidocaine was injected intrathecally as a (larger) dose intended for epidural administration [36]. A subsequent prospective study of regional anesthesia in France by Auroy et al. generated concern that lidocaine, itself, might induce permanent neurologic deficits, even at doses recommended for single-injection spinal anesthesia [37]. These findings led to recommendations for a reduction in the maximum acceptable dose [38].

In addition to the rare permanent spinal nerve injury associated with large doses of intrathecal lidocaine, it soon became evident that minor complications commonly follow modest doses of spinal lidocaine. In 1993, Markus Schneider and colleagues reported cases in which pain and/or dysesthesia in the buttocks and lower extremities appeared after a single intrathecal injection of lidocaine [39]. They suggested that these symptoms represented a transient neurotoxic effect of lidocaine and proposed the term “transient radicular irritation”, later changed to the less specific “transient neurologic symptoms” (TNS). Karl Hampl et al., found a remarkable 37% incidence of TNS with lidocaine, while only 1 of 150 patients receiving bupivacaine was symptomatic [40, 41]. Julia Pollock and colleagues confirmed these findings [41], suggesting that the position of the patient's legs during knee arthroscopy was a risk factor for symptoms, similar to that associated with lithotomy by the Basel group. A large epidemiological study of 1863 patients organized by Drasner and John Freedman identified two additional risk factors, outpatient status and obesity [42]. The reason for

the enhanced risk in outpatients has yet to be established. Perhaps it results from greater invasive surgery performed on inpatients, where more intense postoperative pain could serve to distract or require more aggressive pain management, thus masking these symptoms.

Chloroprocaine Spinal Anesthesia: Back to the Future

The rare major injury with spinal lidocaine coupled with the common occurrence of TNS, created dissatisfaction with lidocaine as a spinal anesthetic. Although little evidence linked bupivacaine to toxicity, the long recovery time after its intrathecal injection made it less than ideal for short duration or outpatient procedures, procedures increasingly more common. The need for a suitable short-acting spinal anesthetic rekindled interest in chloroprocaine. How ironic that attention focused on an anesthetic, long considered the “poster child” of anesthetic neurotoxicity, to replace the “gold standard” of safety, lidocaine! Dan Kopacz, whose group at Virginia Mason conducted rigorous systematic investigations of chloroprocaine, championed its use in 2004 [43]. Published in two series of several manuscripts, their results give a picture of a spinal anesthetic well suited for outpatient procedures: a duration of action shorter than lidocaine with minimal, if any, risk of TNS.

The rationale for using chloroprocaine despite prior reports of neurologic deficits was based on the assumption that the previous injuries resulted from the bisulfite preservative and not chloroprocaine. As discussed earlier, previous work did not necessarily support this assumption. However, the most widely referenced work, experiments reported in 1984 by Gissen from an *in vitro* model, appeared to exonerate the anesthetic [44]. A 2004 report using a more representative *in vivo* model not only failed to support this conclusion, but demonstrated bisulfite to be neuroprotective [45], which may not be surprising given that it is an antioxidant. What might the reader carry away concerning the current use of chloroprocaine? On a mg for mg basis, chloroprocaine is most likely as toxic as lidocaine [29], and if modest doses are used (≤ 60 mg), the risk of neurotoxicity is likely to be low. This concept is currently being tested in clinical practice by off label use. As the role of bisulfite remains a little uncertain, and the entire supportive off label clinical experience has been with a preservative-free formulation, current recommendations suggest the use of a solution devoid of preservatives.

Lipid Resuscitation

Is there a remedy to local anesthetic induced cardiotoxicity? Apparent cardiotoxicity followed administration of an

extremely low dose of bupivacaine (22 mg) in a patient with carnitine deficiency. Weinberg postulated that this metabolic derangement enhanced toxicity because of myocardial accumulation of fatty acids [46]. He hypothesized that giving lipid would *potentiate* cardiotoxicity. But his experiments to test this hypothesis gave an opposite answer—administering lipid afforded protection [47]. His follow-up studies confirmed this observation [48], and clinical confirmation came eight years later in a sentinel case reported by Rosenblatt [49]. The mechanisms by which lipid is effective is incompletely understood, though the predominant effect likely derives from lipid in the blood combining with local anesthetic, thereby removing it from where it causes harm (i.e., the lipid acts as a “sink”). Thus, it not only may be effective against local anesthetic central nervous system toxicity [50], but against untoward effects of non-anesthetic as well as anesthetic lipophilic drugs [51].

Systemic Local Anesthetics: Not Always a Bad Thing

Although this chapter has focused on the use of the local anesthetics to induce neural blockade resulting in anesthesia in a restricted region, these compounds also have potential beneficial effects that can be achieved through systemic administration. In addition to the well exploited effects of lidocaine on cardiac conduction, relatively low concentrations can decrease anesthetic requirement [52], reduce postoperative pain [53], and decrease chronic pain [54, 55]. The last of these derives from the fact that local anesthetics can suppress abnormal ectopic discharge by blocking sodium channels at concentrations much lower than those needed to block propagation of action potentials in normal nerves. Therefore, these drugs can be given systemically to produce salutary effects without inducing failure of normal nerve conduction. With respect to systemic effects, the following rank ordering of anesthetic effects on pain has been suggested: (1) small doses may suppress ectopic impulse generation in chronically injured peripheral nerves; (2) moderate doses may suppress central sensitization and central neuronal hyperexcitability; (3) large doses have general analgesic effects; (4) very large doses are associated with seizure activity, cardiac arrhythmias, and cardiovascular collapse [56].

The Future

Two pharmacophores, compounds with amide versus ester linkages, have supplied most of the local anesthetics of the last century. Much of their history has been driven by the discovery of individual members of each family and by exploration of issues of safety, rather than efficacy. Despite

their seeming safety, these compounds have a relatively narrow therapeutic index. A fundamental question is whether a common mechanism mediates toxicity and effect. If so, they are inextricably linked, and a narrow therapeutic index is inevitable. However, Shinichi Sakura in Drasner’s lab demonstrated that neurotoxicity does not result from blockade of the voltage-gated sodium channel [57], the basis for local anesthesia. Development of anesthetics with greater therapeutic advantage is thus a realistic goal.

Jerry A. Dorsch and Susan E. Dorsch

Summary

The first anesthetists delivered ether and chloroform from handkerchiefs, towels or inhalers, and nitrous oxide from large reservoirs such as bladders. In 1847, Snow devised a temperature-compensated vaporizer that delivered fully saturated ether in air. Clover improved matters in 1877 by adding liquid chloroform to a large measured gas volume to produce a known concentration. Except for the French Ombrédanne ether inhaler, the United Kingdom provided most advances in vaporizer equipment. Delivered concentrations of anesthetic were usually inexact until 1951 when Morris introduced the Copper Kettle vaporizer to deliver a concentration that could be precisely calculated. In the mid-1950s, Cyprane produced the Fluotec, a “variable bypass vaporizer” that allowed the user to set any desired concentration, eliminating the calculations required with the Copper Kettle.

Early nitrous oxide anesthesia produced insensibility partly from hypoxia. In 1868, Andrews suggested adding oxygen, but no convenient method to do so was available until the 1880s when steel cylinders to contain liquid nitrous oxide and compressed oxygen enabled the delivery of roughly controlled nitrous oxide concentrations. Flowmeters were needed. Cotton and Boothby devised a sight-feed device for visualizing gas flow. In 1913, Gwathmey adapted this as a bubble flowmeter, and Heidbrink improved this device. In 1908, Koppers introduced what became the primary method of measuring gas flow for most of the twentieth century, the rotameter. In the twenty-first century, electronic flow control replaced the rotameter.

Anesthesia breathing systems replaced simple inhalers. Anesthesia providers increasingly used carbon dioxide absorption systems to minimize delivery of expensive or explosive anesthetics. Water’s to-and-fro system competed with the circle system suggested by Jackson in 1916. In 1926, Dragerwerk of Germany developed the first circle breathing system for use on their anesthesia machine. In 1954, Mapleson classified and clarified the function of breathing systems without absorbents. Perhaps the most important development shaping today’s anesthesia machines was the 1979 adoption of an anesthesia machine standard written jointly by clinicians and industry engineers. This standard eliminated potential dangers with previous machines.

For many years, anesthesia machines and monitors were sold separately. Displays, controls and alarms of different devices varied, predisposing to confusion and difficulty in management. In the 1990s the distinction between anesthesia machine, ventilator and monitors started to blur. All were integrated into an “anesthesia workstation” so that all modalities were controlled and displayed consistently and in one place, with alarms coordinated and prioritized. Anesthesia delivery systems continue to evolve in ways that improve safety.

Introduction: Early Inhalers

On 16 October 1846, William Morton conducted the first successful public demonstration of surgical anesthesia [1]. That demonstration had two crucial elements. The first was ether’s miraculous anesthetic effect. The second was a device that delivered ether in concentrations sufficient to

produce anesthesia without killing the patient. The original device (Fig. 52.1) was a glass globe with two necks. The patient breathed in from a brass tube attached to one neck and air entered through the other. The globe usually contained a sponge soaked with ether [2]. The sponge restrained the liquid within the globe—otherwise if tipped the wrong way, the patient might inhale liquid ether. Completing the device were two leather valves in the brass tube, directing the flow of the ether-containing air to the patient, and diverting the expired breath into the room.

Morton’s carefully made device (he was late for the first demonstration because his instrument maker was adding last-minute improvements) provided no way of accurately

Fig. 52.1 This replica of Morton's Inhaler shows the reservoir (globe) that contained the ether. The mouthpiece is to the left. A sponge was often placed in the globe, increasing the surface available for vaporization, but more importantly holding the ether so that liquid anesthetic would not be inhaled. (Courtesy of Wood Library-Museum of Anesthesiology, Park Ridge, IL.)

controlling the ether concentration inhaled by the patient. It was made of glass, a poor conductor of heat. Cooling of the ether caused by its vaporization decreased the delivered concentration. Morton had little or no understanding of the physics involved. This limitation did not apply to the next character in our story.

News of the discovery of anesthesia quickly reached Britain. Physician John Snow appreciated the great significance of the discovery and set out to apply it in his practice. Unlike Morton, Snow understood the physical principles needed to deliver a controlled concentration of ether (or chloroform) and in 1847 constructed an elegant ether inhaler (Fig. 52.2). Air entered the vaporizer and passed through a metal spiral to maximize contact between the air and the ether, thus ensuring a saturated output (i.e., a constant output if the temperature was held constant). Snow immersed the vaporizing chamber in a water bath, to stabilize the temperature. He added a crude means (see below) to dilute the concentration delivered to the patient and connected the vaporizer to the patient with tubing of sufficient width to minimize resistance to breathing. This tubing was connected to a mask edged with leather that molded to fit the patient's face. Some of these features in Snow's vaporizer applied principles used in modern vaporizers.

Snow's vaporizer allowed administration of a constant maximum concentration of anesthetic, useful for induction of anesthesia with ether, the agent for which it was originally devised. The high solubility of ether in blood limited the rate at which induction could be accomplished, and although high concentrations could irritate the airway, they hastened the process. Induction was the principal focus because early in the history of anesthesia, most operations were brief. The introduction of chloroform changed things. Airway irritation was minimal. Unlike ether, chloroform profoundly depressed the heart, making it important to not deliver a maximum concentration for too long. Snow solved this problem by adding a valve on his facemask that could be opened to dilute the delivered anesthetic with room air. Still, control over the delivered concentration was crude.

Joseph Clover solved some of these problems but added others. In 1877, he invented an "inhaler" for chloroform. By

Fig. 52.2 Snow's Inhaler. The air inlet was on the peripheral side (at the right). The drum contained a metal spiral with five turns. This allowed the air to become saturated with anesthetic vapor. Note the wide bore tube which extended from the center to the patient mask. (From Snow J: *On the Inhalation of the Vapour of Ether in Surgical Operations: Containing a Description of the Various Stages of Etherization, and a Statement of the Result of Nearly Eighty Operations in Which Ether Has Been Employed In St. George's and University College Hospitals*. London: John Churchill; 1847. pp 1–88.)

putting a measured amount of liquid chloroform into a large reservoir bag of known volume, he could produce a large amount of chloroform vapor in air at a known concentration. The bag was connected to a face mask, including a leaflet valve that allowed exhalation into the operating room. Air could be admitted from the room (thereby diluting the chloroform concentration) by turning the leaflet to the side. Interestingly, the mask and bag connectors had 22 mm diameters, the dimension used today and one that did not impose significant resistance to breathing. Unfortunately Clover's device was cumbersome and had limited popularity. Clover died in 1882 and was buried 200 yards from Snow's grave. One wonders what conversations they have when all is quiet.

Nitrous Oxide

Horace Wells had failed in his January 1845 attempt to demonstrate the anesthetic properties of nitrous oxide. The audience ridiculed Wells, calling the demonstration a humbug, and for nearly two decades nitrous oxide lapsed into obscurity. Gardner Colton resurrected nitrous oxide in the early 1860s. He gave it to more than 100,000 patients for dental procedures without, it is said, a fatality—a remarkable record.

Several problems surrounded the early use of nitrous oxide. First, in normal patients, the anesthetizing partial pressure exceeds atmospheric pressure. To achieve anesthesia, the earliest users administered 100% nitrous oxide, a lethal concentration if given for more than a minute or two because of the associated lack of oxygen. Nonetheless, nitrous oxide in air or occasionally 100% nitrous oxide for induction was

used until the 1940s, with anesthesia resulting from a combination of nitrous oxide and hypoxia.

Second, because nitrous oxide was a gas, it could not be conveniently stored. It could be manufactured on the spot by heating (with great care, as the process could result in an explosion) ammonium nitrate in a retort [3]. The resulting nitrous oxide was purified by washing it in various reagents and stored in a reservoir—at first a bag made from oiled silk or animal bladders, and later in a gasometer (a small version of the enormous cylinders we see that are used to store natural gas). In 1865, the SS White Dental Manufacturing Co of Philadelphia made a storage bag. A valve was attached to the bag to control the release of the gas to the patient through a wooden mouthpiece. The patient held the mouthpiece with one hand while the nostrils were held closed with the other hand or a nose clip, in order to prevent air dilution. The clumsiness of this system limited its popularity.

The development of low pressure compressed gas cylinders in 1868 decreased the clumsiness; away with the cumbersome bladder/bag. In 1870, nitrous oxide was liquefied. Liquid nitrous oxide was supplied in cylinders by both Coxeter and Son, and Barth in Great Britain. By 1873, Johnson Brothers of New York were supplying similar cylinders to the American market. An attachment to the cylinder led to a large reservoir bag attached to a mask [4]. There was a supplemental bag, a valve to admit nitrous oxide directly into the mask, and an evacuation valve.

Why were these considerable efforts made, to overcome the difficulties and limitations imposed by the large volumes of nitrous oxide needed to provide anesthesia? Nitrous oxide offered two advantages over the then-popular ether: it acted quickly and didn't irritate the airway. These properties complemented those of ether, reducing the slowness and untoward respiratory effects of ether, which were particularly problematic during induction. Around 1876, Clover designed a portable apparatus to deliver nitrous oxide and ether. A nitrous oxide cylinder supplied gas to an ether vessel (vaporizer) with a 6 liter bag connecting the vaporizer to a mask. Air or the nitrous oxide-ether combination could be admitted to the bag. Inadequate oxygen (hypoxia) evidenced by cyanosis caused the patient to breathe more, accelerating the uptake of anesthetic. When marked cyanosis occurred, fresh air was admitted by lifting the face mask.

A few perceptive people recognized the problems imposed by the lack of oxygen. It is not known when oxygen was first used with chloroform, but Snow used it in an unsuccessful resuscitation of a patient given chloroform. In 1868, Edmund Andrews, a Northwestern University surgeon, suggested adding oxygen to nitrous oxide. So did Paul Bert and Clover. In 1879, Bert combined 15% oxygen with 85% nitrous oxide to produce anesthesia in a pressure (hyperbaric) chamber. But such an approach was a logisti-

cal nightmare. A more practical solution was to go back to a combination of nitrous oxide, oxygen, and ether (called gas, oxygen and ether or GOE). Such a solution was not practical before 1885 when oxygen became available in cylinders. But GOE was not immediately adopted because the importance of using oxygen with nitrous oxide was not widely appreciated until after the turn of the twentieth century. Anesthesia providers continued to use nitrous oxide and air, not recognizing the potential negative effect on patient intelligence.

The availability of both nitrous oxide and oxygen in cylinders meant that large volumes of each could be stored efficiently, and this allowed development of apparatus delivering both. In 1886, Viennese dentist HT Hillischer produced the first machine dispensing both nitrous oxide and oxygen and coined the term "Schlafgas" (sleeping gas) to describe nitrous oxide. He found it best in most cases to commence with 10 percent oxygen/90 percent nitrous oxide, and to gradually increase this to 15 or even 20 percent oxygen. In dealing with alcoholic subjects and others resistant to the influence of nitrous oxide with 10 percent oxygen, he reduced the oxygen to 5 percent or even lower. If breathing became labored, or cyanosis appeared, he increased the percentage of oxygen. Hillischer used a proportioning valve to achieve the target percentages of oxygen. But his proportioning valve was a crude device. Something better was needed.

In 1885, SS White patented what today's clinicians might recognize as an anesthesia machine. Gases were supplied from cylinders to separate inflatable bags then directed to a mixing chamber between the oxygen and nitrous oxide controls and delivered to the patient through wide bore tubing. The tap on the nitrous oxide bag needed to be fully opened, and a similar tap for oxygen allowed a variable flow according to uncalibrated gradations on a semi-circular gauge plate. By 1910 the SS White anesthesia machine had yokes for 4 cylinders, and reducing valves (pressure regulators) that decreased the high but variable pressure of gas from cylinders to a lower more constant level [5].

Gas Flow Measurement

Early anesthetic apparatus lacked a means to deliver precisely known flows (and therefore concentrations) of oxygen and nitrous oxide in the gases presented to the patient [6]. In 1902, dentist Charles Teter developed a gas machine that delivered a variable mixture of oxygen and nitrous oxide, each controlled by separate but coarse valves. There was no indicator of percentage or flow [7]. In 1916, after observing the principles of a mercury sphygmomanometer, Teter added mercury columns to his machine, calibrated to indicate gas flows.

Another dentist, Jay Heidbrink, purchased one of Teter's machines in 1906, and set about improving it. He reasoned that better accuracy could be achieved by equalizing the pressure in the two bags supplying gas from the cylinders to the adjustable valves, and that the valves could be engineered to give finer control. An additional problem was moisture in the nitrous oxide, which often led to freezing of the nitrous oxide valve. Heidbrink solved this by placing an electric light bulb in the mixing chamber. Still, the machine had no indicator of gas flow. He achieved an acceptable calibration of flow control by adopting commercially available pressure-reducing valves and further refining the control valves. His first commercial machine was the Model A, introduced in 1912. He sold them for \$1 per pound weight, \$32 each.

In 1911, Frederick Cotton and Walter Boothby developed the first anesthesia machine that provided a visible indication of the rate of flow of nitrous oxide and oxygen. Each gas was fed separately into a water-filled glass mixing chamber. The rate of bubbling in the "bubble bottle" allowed an estimation of the flow and proportion of the gases. After exiting the first mixing chamber, a portion of the gas mixture could be directed through another chamber containing ether before rejoining the main gas stream.

In the following year, James Gwathmey improved on Cotton and Boothby's idea by placing "bubble tubes" for each gas within the water sight feed bottle. Each tube had five holes, allowing from one to five streams of bubbles to be seen, thus indicating the gas flow. This was the forerunner of the 1917 Boyle apparatus, developed by Henry Boyle after meeting Gwathmey and purchasing one of his machines in 1912. James Gwathmey was one of the first physicians to practice anesthesia full time. He was president of the New York Society of Anesthesiologists, the forerunner of the American Society of Anesthesiologists.

Richard von Foregger (1872–1960), was born in Vienna, studied chemistry and emigrated to the US in 1898 [8]. In 1905, he began development of an oxygen generator using "oxone" or fused sodium peroxide. In 1907, he met Gwathmey, by which time the oxygen generator was a commercial success. In 1909, they produced an ether-oxygen device using an oxygen generator. On several occasions, Foregger and Gwathmey took the generator to Madison Square and administered oxygen to runners in 10-mile relay races and 6-day bicycle races. In 1914, Foregger established the Foregger Company and began manufacturing Gwathmey's anesthesia machines.

Foregger later developed the water depression flowmeter A competing CIG flowmeter is shown in Fig. 52.3. Gas flowing past a restriction in the top of the flowmeter depressed the water level in a tube submerged in a water-filled container, in proportion to the gas flow. This worked

Fig. 52.3 In these CIG water depression flowmeters, the water meniscus was at the black line just above the mark indicating a 1 liter per minute flow rate when there was no gas flow. Flow depressed the meniscus non-linearly, with the greatest change occurring at the higher flows (the opposite of what might be desired)

well as long as the flow did not exceed that which produced the maximum intended depression of the water level in the tube. Flows exceeding that limit forced gas into the water-filled container with a violence that depended on the flow. In some training programs no resident entered the "anesthetic brotherhood" until he had fully opened the oxygen valve to the flowmeter, blowing water all over the operating room.

Dry Flowmeters

Karl Kuppers in Germany, introduced the rotating bobbin flowmeter, the "Rotamesser", in 1909 for industrial purposes, and gynecologist Maximilian Neu used it in an anesthesia apparatus in 1910 [9]. It went into commercial production, but did not become widely known. Rotameters were not used again until 1937, when once more they were adapted to anesthesia machines, this time in Britain.

Fig. 52.4 As shown on the oxygen flowmeter on the right, gas flow through these Heidbrink flowmeters caused the indicator to rise in the tube. Note that one flowmeter (flowmeter number 3 in the illustration) could be used for either helium or carbon dioxide

American anesthesia providers working in British hospitals during World War II gained experience with rotameters and recognized their advantages. They were first used in American machines in 1950 by Foregger, and quickly became the gold standard for measuring gas flows.

In 1933, Heidbrink invented a tapered tube flowmeter (Fig. 52.4; really a variant of the rotameter), where a disc was attached to a stem, the disc rising in the tapered tube with increasing gas flows, the tip of the stem indicating the flow on a calibrated scale. It presented a graded visual display of flows for oxygen and nitrous oxide, the gases merging as they exited from the flowmeters. An improved version appeared on his Heidbrink machine in 1938.

The Coxeter dry bobbin flowmeter (1933) consisted of a glass tube of uniform diameter with 24 small holes in the wall. An H-shaped bobbin in the tube rose with increasing gas flow, the flow exiting the tube through the holes. As flow increased, the bobbin rose and more gas left the tube through the holes. This flowmeter was relatively inaccurate because friction or dirt between the bobbin and the wall impeded the rise or fall of the bobbin. Since the bobbin moved in steps from hole to hole, it could not measure intermediate flows, and was inaccurate at low flows. These flowmeters were used in the 1933 Boyle machine that was the forerunner of the modern anesthesia machine. It is said that Boyle placed the oxygen flowmeter on the left because he was left handed. Machines manufactured in the US placed it on the right.

The Connell flowmeter was patented in 1934. The six-inch flow tube contained two ball bearings that rose with increasing flow inside a tilted glass tube with a tapered bore. Two ball bearings were needed to ensure steady movement and prevent each ball from oscillating in the tube. Gas flow was noted by the point where the two balls touched. Foregger also marketed a flowmeter that was inclined at an angle

Fig. 52.5 In Foregger and Connell flowmeters one or two balls rose with increasing flow, and the flow was read at the juncture of the two balls. At the right is a Copper Kettle vaporizer. At the front of the machine is the on-off valve that controlled flow to the vaporizer. The flowmeter for the Copper Kettle is at the left. Note the thermometer at the top of the Copper Kettle

and used a ball indicator (Fig. 52.5). It also had shape-coded flow control knobs.

Ultimately, the rotameter became the most popular means of measuring gas flow in anesthesia, appearing on virtually all anesthesia machines up to the end of the twentieth century, when electronic measurement devices and displays replaced tapered tubes.

Intermittent Flow Machines: A Digression

The machines described above delivered a constant flow of gas, much of which was wasted [10, 11]. Intermittent flow machines were devised to decrease this waste, and supply only what the patient needed. They delivered a controlled mixture of gases in a volume “demanded” by the spontaneously breathing patient. They featured a mixing device for oxygen and nitrous oxide. The McKesson Nargraf machine (see Fig. 6.3) was the most popular. It could be set to deliver an oxygen percentage from 0% to 100%. The negative pressure generated by the patient during inhalation initiated gas flow from the machine. The flow ended when the patient stopped inhaling. A one-way valve at the patient end of the breathing system opened, so that exhalation to the room could occur.

One of McKesson’s techniques, referred to as secondary saturation, used 100% nitrous oxide until severe cyanosis and muscular rigidity or spasm appeared. Oxygen was then added to the inhaled mixture. It was an exciting approach to anesthesia, but most anesthesia providers preferred not to bring their patients so close to death. Also, it was difficult to deliver a potent anesthetic [12]. Of note, with this apparatus

and technique, anesthesia with halothane could be induced in 11 seconds. There is much more to the McKesson history, including the fact that the McKesson Nargraf machine in 1930 incorporated automated anesthesia record keeping.

The Evolving Anesthesia Machine

Anesthesia machines began to take the form initiated by the Boyle machine. In early machines, the Boyle bottle and direct-reading vaporizers like the Fluotec could be placed in the tubing between the machine outlet and the breathing system. If the gas flow in the fresh delivery tubing from the machine was attached (incorrectly) to the outflow connection to the vaporizer, a higher-than-expected output could result. In addition, these vaporizers handled the high flow from the oxygen flush poorly. Coxeters, the manufacturers of the Boyle machine, continuously modified and improved it. By 1927, the rubber hoses had been replaced by a large bore rigid tube between the flowmeters and the vaporizers. Later, the whole apparatus was incorporated into a table on wheels. The Boyle configuration persisted until the 1990s when major changes in anesthesia machines began to appear.

In 1978, Jeff Cooper and his colleagues at the Massachusetts General Hospital exhibited a completely computer-controlled anesthesia machine (the Boston Anesthesia System or MGH machine) [13]. It was never used for humans but was the first to suggest that a computerized machine was possible. In the 1990s anesthesia machines began to incorporate microprocessor-based technology. Computerized ventilators allowing the choice of various ventilatory modes appeared on many machines, and computer-controlled flowmeters working from flow sensors began to replace the rotameter.

Vaporizers

As noted earlier, Snow devised a vaporizer/inhaler for ether that incorporated many features present in modern vaporizers. They included a spiral gas passage to ensure saturation of gases flowing through the vaporizer, and a water bath surrounding the vaporizer to provide better temperature stabilization. Snow differed with another anesthetic great, Sir James Simpson, who said that simpler was better, that a few drops of chloroform on a handkerchief sufficed, and all that complicated apparatus was unnecessary. Simpson's simplistic view often prevailed in the early days of anesthesia. Anesthesia was frequently delivered by a handkerchief or a more sanitary variant that used a gauze placed over a wire frame, such as the Schimmelbusch mask (Fig. 52.6), into the 1950s.

Fig. 52.6 This Schimmelbusch Mask was used to administer ether or chloroform. A gauze or handkerchief was placed over the wire frame and liquid anesthetic dripped onto it. One problem was that as fluid was poured onto the gauze or handkerchief it flowed down to the sides, leaving a dry patch through which the patient breathed. The rim served as a trough to catch surplus fluid

For a time, Snow's ideas were largely forgotten. Apparatus for vaporizing liquid anesthetic agents was crude and inexact. Of necessity, the anesthesia provider's observations of the patient's anesthetic depth (e.g., Snow's degrees and Guedel's signs and stages of anesthesia) were used to determine the amount of anesthetic to deliver.

In 1902, Dragerwerk developed a drip feed injector to administer ether or chloroform. The drops could be counted and thus the volume of agent added to the gases breathed by the patient could be calculated. But who had time to count the drops and then calculate (taking into account the flow of diluent gases) the actual concentration of anesthetic inhaled by the patient? Observations of the patient's clinical signs still governed the amount of anesthetic delivered.

A Parisian surgeon, Louis Ombrédanne, introduced a new ether inhaler in 1908 [14]. He criticized previous inhalers "...as these are not provided with means of admission of fresh air; they rapidly produce cyanosis if one does not constantly raise the mask from the face." Ombrédanne's inhaler/vaporizer avoided delivery of hypoxic gas mixtures by admitting air. It became the most commonly used apparatus for ether delivery in France and Latin America, and aided in the conversion from chloroform to ether. It continued to be used for a half century.

The Boyle Bottle (Fig. 52.7) appeared in 1917, and consisted of a glass bottle (the vaporizing chamber) that held the liquid anesthetic (any could be used). A controllable fraction of the gas to be delivered was diverted through the bottle, which was fitted with a plunger and cowl that could direct the gas flow close to the surface of the liquid—or under the liquid surface, resulting in a greater amount of agent being vaporized. Heat loss occurred during vaporization, and the decreased temperature decreased vaporization of the liquid anesthetic, and thus the concentration added to the diverted gases. The anesthesia provider often placed a pan of hot water around the outside of the bottle (there was a formal arrangement that permitted this to be done easily) to warm it, but the

Fig. 52.7 Rotameters were used on this Boyle machine. Gas issued to the right of the flowmeter bank through valve-levers that could direct none to all of the flow through each of the two glass Boyle bottles (one here for halothane and the other for ether) in series to its right. In this photograph, the levers are down (off). Vaporization could also be increased by lowering a plunger that forced the gas directed through the vaporizing chamber to bubble through the liquid anesthetic

bottle was composed of glass, a poor heat conductor. Snow also incorporated a pan of water around his vaporizer, but he made his vaporizer of copper, a good conductor of heat. The anesthesia provider using the Boyle Bottle could not know the concentration of anesthetic delivered. The patient's clinical signs guided how much should be administered.

The Boyle bottle could be placed inside a rebreathing absorption system ("in-circuit"), but was normally outside the system or used with a non-absorption system (no carbon dioxide absorption by soda lime). Simpler versions of the Boyle bottle with small liquid capacities (Rowbotham, Goldman) were used in British circle breathing systems.

The Ohio #8 bottle (Fig. 52.8) was one of the most popular in-circuit vaporizers in the 1940s and 1950s in North America. Its sister, the Goldman, was used throughout the rest of the world. Both were glass bottles containing a wick to maximize the surface available for vaporization of the liquid anesthetic, usually ether. There was no way to provide temperature compensation. A control dial atop the vaporizer allowed the anesthesia provider to divert any proportion from none to all of the inspired gases through the vaporizing chamber. Since this was an in-circuit vaporizer, some anesthetic vapor returned to it during the next inspiration, adding to the imprecision of vapor delivery. This could be dangerous because vaporizer output was directly tied to minute ventilation, and lethal concentrations of anesthetic could be delivered, especially with controlled ventilation. This device was especially dangerous when used with a potent volatile anesthetic having relatively low blood solubility and a relatively high vapor pressure such as halothane. Again, the patient's clinical signs were used to guide the amount of anesthetic delivered. Exhaled gases contain water vapor,

Fig. 52.8 Ohio #8 bottles were placed in the breathing circuit, usually on the inspiratory side. The gases flowing past the vaporizer could be diverted through the glass bottle by rotating the lever atop the vaporizer. The amount of gas diverted was proportional to the degree to which the lever was turned. Note the wick used to increase vaporization. As with the Boyle bottle, one could increase or decrease the amount of anesthetic administered (by increasing or decreasing diversion), but the resulting concentration delivered to the patient was unknown

and when passing through the vaporizer the water would dissolve in the liquid anesthetic. Large amounts of water can dissolve in ether. The ether would be diluted and its vapor pressure lowered, limiting the level of anesthetic that might be achieved at a particular setting of the indicator dial.

In the 1950s, a major advance occurred with the development of the Copper Kettle vaporizer by Lucien Morris [15]. This change was so important that Chapter 53 in this book is devoted to this invention. The Copper Kettle vaporizer was the first to deliver a known output of anesthetic at any flow rate or vaporizer temperature. As with the Boyle bottle, any liquid anesthetic could be used. There were two gas flows. One was independent of the vaporizer (the diluent or bypass flow), and the other was the flow through the kettle. The kettle containing liquid anesthetic was made of copper attached to a copper tabletop (hence the name). Copper was chosen because of its high thermal conductivity, allowing the temperature (and therefore the vapor pressure) of the liquid anesthetic within the kettle to remain relatively constant (as in Snow's inhaler—at least someone listened). The anesthesia provider knew the flow to the kettle and its temperature from a thermometer in the vaporizer wall. Assuming that the gas exiting the kettle was fully saturated with anesthetic, calculation of the added volume of anesthetic was possible. For example, if 100 ml of gas were directed to a kettle containing halothane, then the exiting gas would contain 33% of an atmosphere of halothane (its vapor pressure) and the volume of halothane vapor would be 50 ml (i.e., $50/(100+50)=0.33$ or 33%). Add this to a diluent flow of 5,000 ml and the delivered concentration approximated 1%. Vapor output remained constant with the Copper Kettle.

Most clinicians were accustomed to the concentration decreasing as the liquid cooled, and sometimes were surprised to achieve a greater-than-expected anesthetic depth when using the Copper Kettle.

Ohio Medical Products Corporation soon marketed a vaporizer called the Vernitrol that was similar to the Copper Kettle. Two Vernitrol's (for two anesthetics, perhaps halothane and ether) could be placed on an anesthesia machine, each with its own flowmeter. Copper Kettle and Vernitrol vaporizers continued in common use until the 1980s. The Ohio DM 5000 anesthesia machine, introduced in the late 1960s, featured the last of the kettle-type vaporizers. The vaporizer was heated to maintain a constant temperature and provide an accurate agent concentration. On this machine, the vaporizer flowmeter indicated ml of vapor emanating from the vaporizer rather than ml of oxygen going into the vaporizer, as was the case with the Copper Kettle. If the same calculations as those for the Copper Kettle were used with the DM 5000, the patient would receive a much higher anesthetic concentration. Having a mix of machines within an OR suite sometimes resulted in anesthesia providers moving from one operating room to another without realizing that the output of the vaporizer was double or one half of that in the room from whence they came. This resulted in several deaths and a number of cases of patient awareness. Some anesthesia providers called the DM 5000 "the widow maker".

In the 1950s, Cyprane in England produced the Fluotec vaporizer (Fig. 52.9), a so-called "variable bypass vaporizer" that allowed the user to directly set the desired percentage of agent—thus eliminating the calculations associated with the Copper Kettle and Vernitrol. Incremental improvements further increased the output stability, so that it remained relatively constant despite variations in fresh gas flow and temperature. It was the first vaporizer designed and calibrated for use with only one anesthetic agent. Other companies also developed direct-reading vaporizers, such as the Foregger Fluomatic and the Dragerwerk Vapor. A potential problem with the Fluotec (and other "Tec" type vaporizers) was that any volatile anesthetic could be poured into the vaporizing chamber. Of course this would result in an anesthetic concentration different than that on the dial—greater if the vapor pressure of the agent was greater than that of the agent for which the vaporizer was calibrated, and vice versa. This problem was partially solved using a keyed system on both the bottle and the vaporizer (see also Chapter 66 on the contributions of industry to the history of anesthesia.).

Desflurane was introduced in the late 1980s. Since it had a boiling point near room temperature, it could not be used in the usual variable bypass vaporizer. This problem could be solved by either cooling the agent to a point well below room temperature, or by heating it to well above room temperature so that the vaporizing chamber delivered 100% agent as a gas. Heating was chosen. An amount of pure vapor,

Fig. 52.9 Fluotec Mark II Vaporizer. Note the card chained to the vaporizer with a graph showing how fresh gas flow affected the vaporizer output. A predictable (flat line) output was accomplished at inflow rates of 1–2 l/min or more for this early model. Later versions produced constant known outputs at flows as low as a few 100 ml/min

determined by the concentration dial, was added to the fresh gas passing through the vaporizer.

Until the middle 1990s, vaporizers were mechanically controlled by altering the relative flows through the bypass and the vaporizing chamber. The Physioflex anesthesia machine was the first to use computer control of vapor concentration in a totally closed rebreathing absorption circuit with constantly circulating gas. Using feedback from agent monitors, a computer directed the vaporizer to inject liquid anesthetic directly into the gas stream in an amount sufficient to produce the agent concentration dialed on the anesthesia machine.

A new variable bypass vaporizer, the ADU, became popular in the 2000s [16]. It differed from the "Tec-type" devices in that the output was governed by computer control of the flow issuing from the vaporizer sump and the flow that bypassed the sump, doing so in a manner that produced the output concentration of anesthetic prescribed by the dial setting. This meant that any volatile anesthetic, including desflurane, could be used. The ADU vaporizer was separate from the anesthetic sump. A given sump was specific for a given anesthetic, and when the sump was attached to the vaporizer,

the vaporizer recognized the anesthetic by the identity of the sump (oh, those computers!)

Breathing Systems

Systems Without Carbon Dioxide Absorption

The preceding discussions focused on the anesthetic machine, the large and expensive device concocting a mixture of known concentrations at a controlled flow rate. In order to produce anesthesia, this mixture must be transported to the patient. The delivery vehicle is the breathing system with the interface being a mask, a supraglottic airway device (such as the laryngeal mask airway) or a tracheal tube.

Morton, Snow and Simpson used non-rebreathing systems where the anesthetic mixture was inhaled and then exhaled to ambient air. There were exceptions. Patients breathing from bags containing nitrous oxide might rebreathe some of the gas they exhaled. And some of the systems delivering potent vapors did not have valves to prevent rebreathing.

Over the years various other systems developed. In 1954, WW Mapleson analyzed and classified the various systems that did not have carbon dioxide absorption, and suggested the fresh gas flows needed to minimize rebreathing of exhaled carbon dioxide [17]. These seemingly uncomplicated devices had many advantages, being lightweight and relatively simple. Today, however, they have largely disappeared because they required high flows, potentially increasing the cost of anesthetic delivery to \$100 per hour or more! High flows also increased contamination of the atmosphere with anesthetic gases and vapors, a matter of rising environmental concern. Some of these systems linger today in the form of the Mapleson D and E systems used for pediatric anesthesia, or to supply oxygen during patient transport or emergency situations when the primary source of anesthesia malfunctions.

Systems with Carbon Dioxide Absorption

In 1903 Drägerwerk developed a device to absorb carbon dioxide from rebreathed gases using soda lime (mostly calcium hydroxide spiked with a bit of sodium and potassium hydroxide). Miners carrying oxygen cylinders used this device underground. Oxygen was added to the breathed gas to make up for the oxygen taken up by the miner. This invention was not immediately applied to anesthesia breathing systems because anesthetics were relatively inexpensive (Crawford Long charged \$0.25 for the ether he used to anesthetize James Venable). In addition, chloroform, which was commonly used at that time, reacted with soda lime to produce the nerve gas phosgene.

In 1916, Dennis Jackson demonstrated an apparatus equipped with a device for absorbing carbon dioxide, but he used a solution of alkali, an approach difficult to apply in

Fig. 52.10 In the to-and-fro system developed by Ralph Waters, the carbon dioxide absorbent was placed in the large canister. The patient breathed back and forth (to and from the reservoir bag attached to the distal end of the canister) through this valveless system. There were two problems with this elegantly simple system: 1) The absorbent at the proximal (patient) end of the canister exhausted first, increasing the dead space. 2) The absorbent tended to settle, resulting in a low resistance pathway at the top of the absorber

practice. In 1923, Ralph Waters introduced a breathing apparatus with an absorber between the reservoir bag and the fresh gas inlet (Fig. 52.10) [18]. The absorber contained soda lime, and although this “to-and-fro” system worked, it was cumbersome and became progressively less efficient (absorbed less carbon dioxide) with continued use. Although it remained of academic interest and was buoyed by Waters’ great imprimatur, it gradually fell out of favor. It was used as recently as the 1970s for patients with pulmonary infections since it could be cleaned easily.

In 1926, Drägerwerk of Germany developed the first circle breathing system for use with their Model A anesthesia machine. There were separate hoses for inhalation and exhalation; low resistance, thin mica unidirectional valves that forced the gases to move in a circle; a canister for the soda lime; a reservoir bag, and a pressure-limiting valve—all components found in circle systems today. It also included an absorber bypass to allow deliberate rebreathing of carbon dioxide. The bypass was included in many systems, but caused problems because it was often inadvertently left in the bypass position. As a result, it was removed from circle systems in the US. It was reintroduced in the twenty-first century, to allow the absorbent to be changed during an anesthetic. The risk associated with its being inadvertently left in the bypass position was lessened by the routine use of carbon dioxide monitoring.

For a time, large absorbent canisters were in vogue. Wrongfully, it was thought that soda lime would regenerate since the color indicator (indicating exhaustion of the absorbent) returned to white after a period of non-use. James Elam and Elwyn Brown designed and advocated the use of large absorbers, particularly two large canisters in series [19].

These allowed nearly complete absorbent exhaustion before the upstream canister needed to be changed. The presence of the second canister ensured that no carbon dioxide would be rebreathed.

A controversy arose in the 1990s regarding the reaction of sevoflurane with an absorbent—either Baralyme[®] or soda lime - to produce a nephrotoxin called compound A [20], and the reaction of several anesthetics (particularly desflurane) with desiccated Baralyme[®] or soda lime to produce carbon monoxide [21]. These problems led to the development of new absorbents (e.g., Amsorb[®] in 1999) that, even when desiccated, did not react with the anesthetic [22]. In the early 2000s, several fires and explosions occurred during the use of sevoflurane [23]. The problem was traced to a triple combination of sevoflurane, desiccated but otherwise fresh Baralyme[®], and low fresh gas flows. Baralyme[®] was removed from the market and the problem disappeared.

Scavenging Systems

Before the late 1960s there was little concern about the effects of occupational exposure to trace concentrations of anesthetic gases. Then a report on health problems in Russian workers exposed to anesthetic gases and vapors was published [24]. Investigators from other countries confirmed that there might be adverse effects in anesthesia providers. As a result, devices for scavenging and removing gases from the operating room quickly came into use.

Corrugated Tubing and the Reservoir Bag

Winston Churchill said “Out of intense complexities, intense simplicities emerge.” The anesthetic circuit has evolved by trial and error into a system of considerable efficiency and utility. Some of the principles of the anesthetic circuit have been known since the time of Snow who maintained that significant resistance to breathing should not be imposed by the anesthesia system. Thus the tubing used to conduct gases to and from the patient must be of large diameter. Pictures of early devices do not show a crucial characteristic of modern tubing: corrugation. A corrugated tube resists kinking, and for the better part of the last century, corrugated tubing has been used.

The circle system became more popular after ethylene and cyclopropane were introduced into anesthesia practice, in 1923 and 1934. Exposing these gases to a spark could produce an explosion that could kill or injure patients and clinicians, a disaster that led to the cessation of the use of cyclopropane in Latin America in the late 1930s. To minimize the chance of a spark from a static electric charge, the anesthetic machine and everything connected to it were made

conductive. Thus the corrugated tubing and bags were composed of black (carbon) conductive rubber. Anesthesia personnel wore conductive shoes that grounded the clinician to the floor, and wet sheets were draped around the anesthesia machine and operating room table, as well as on the floor, for personnel to stand on to prevent static sparks from being generated. Special non-sparking electrical power switches, using mercury in a sealed glass tube, were used in operating rooms. As the 1960s came to an end, so did use of ether, ethylene, and cyclopropane—and the need for conductive rubber and other measures. Halothane swept all the explosive anesthetics aside and lightweight disposable tubes and bags came into vogue.

And what of the mundane reservoir bag? To best serve the anesthesia provider and patient, it needs to be of sufficient size to hold enough gas to allow deep respiration. In the 1950s, 10 L reservoir bags were available. These were cumbersome, difficult for the anesthesia provider to grasp, and made it difficult to see how deeply the patient was breathing. As Goldilocks would say, the reservoir bag should be not too small, not too large, but just right. And so, today, it is usually three liters for adults, and smaller for children.

Standardization, Information Technology, and Modern Anesthetic Machines

Perhaps the most important development shaping today’s anesthesia machines was the 1979 adoption of the first anesthesia machine standard. Clinicians and industry engineers examined problems with previous machines that could have or did lead to patient mortality and morbidity. The standard aimed to eliminate or warn of serious problems. Some of the requirements in the standard included flowmeters in series instead of in parallel, fluted oxygen flow control knobs for tactile feedback, a means to prevent administration of a hypoxic mixture, and color-coded flowmeters. Machines manufactured after publication of this standard needed to meet all the requirements of the standard.

For many years, anesthesia machines and monitors were sold separately. Buying the “best of breed” equipment for each use allowed healthcare facilities to distribute spending over time. But monitors stacked on anesthesia machines or separate carts were difficult to manage. Cables from different monitors caused what came to be known as the “spaghetti syndrome”, and the whole array was referred to as a “Christmas tree” [25]. The combined collection of devices could turn into a disotheque of buzzers, bells and flashing alarm lights, with important information scattered over the separate units. Displays, controls and alarms of different devices varied, leading to confusion and management problems. In the 1990s, the distinction between anesthesia machine, ventilator and monitors started to blur. All were integrated into an “anesthesia

Table 52.1 Timeline

1846	William Morton publically demonstrates ether anesthesia.
1847	John Snow constructs an inhaler for constant vaporization of ether.
1865	SS White manufactures a storage bag for nitrous oxide.
1868	The Coxeter and Barth companies provide compressed gas in a cylinder.
1868	Edmond Andrews suggests adding O ₂ to N ₂ O.
1870	Cylinders of liquefied N ₂ O become available.
1877	Joseph Clover invents a chloroform inhaler giving a known concentration.
1879	Paul Bert gives 15% O ₂ with N ₂ O to produce anesthesia in a pressure chamber.
1885	Coxeter of London makes O ₂ available in cylinders.
1885	SS White develops the first machine where O ₂ and N ₂ O are mixed in a chamber and then administered to the patient.
1886	Hillischer develops a machine to deliver both O ₂ and N ₂ O.
1886	Gwathmey develops a nitrous oxide-oxygen apparatus with control valves for the gases and a bubble flowmeter.
1893	Hewitt develops a N ₂ O-oxygen stopcock which becomes available in 1897.
1893	Hewitt's anesthesia apparatus uses cylinders for nitrous oxide and O ₂ .
1902	Drager develops a drip-feed vaporizer.
1903	Dragerwerk describes the first breathing system with CO ₂ absorbent.
1906	Heidbrink develops an O ₂ -N ₂ O anesthesia machine.
1909	Kuppers develops the rotameter.
1910	Neu uses the rotameter in anesthesia
1910	SS White anesthesia machine has yokes for 4 cylinders but does not estimate gas concentration or flow.
1912	Boothby develops the bubble bottle flowmeter.
1913	Heidbrink develops the disc flowmeter.
1914	The Foregger Company builds the Gwathmey apparatus.
1916	Dennis Jackson describes a breathing system that absorbs CO ₂ using an alkali solution.
1923	Ralph Waters introduces to-and-fro rebreathing systems with CO ₂ absorption.
1926	Heidbrink offers the first mass-produced anesthesia machine, the Model A.
1926	Dragerwerk develops the circle rebreathing system.
Late 1920s	Foregger develops the water depression flowmeter.
1930	Coxeter dry bobbin flowmeter is developed.
1934	Connell double ball flowmeter is developed.
1950	Rotameters are introduced into US anesthesia machines.
1952	Lucien Morris invents the Copper Kettle vaporizer.
1954	Mapleson categorizes non-rebreathing anesthesia circuits.
1957	Fluotec vaporizer is released.
1978	The Boston Anesthesia System is described.

workstation". These workstations were designed to solve some problems by integration so that all modalities were controlled and displayed consistently and in one place, with alarms coordinated and prioritized. The whole setup could be purchased from and serviced by a single manufacturer.

And what of the future? It seems likely that the anesthesia workstation will someday be part of an information network for the entire healthcare facility. Other tasks, including anesthesia recordkeeping, will increasingly become automated.

Reprise

In the beginning, anesthetists delivered ether and chloroform from various devices ranging from handkerchiefs to inhalers, while nitrous oxide was inhaled from a bladder (see

Table 52.1). The inhalers underwent improvements in their control over the delivered anesthetic concentration. Today's vaporizers accurately deliver the anesthetic concentration dialed by the anesthesia provider at any fresh gas flow rate and at any temperature, an achievement attained by the mid-twentieth century. The use of nitrous oxide to complement the action of the potent inhaled anesthetics was delayed for several decades after the discovery of anesthesia in 1846, until a means to efficiently store it and combine it with oxygen (also requiring an effective means of storage) were developed. The needed technology was applied in the latter part of the nineteenth century, and was combined with gas flow measurement to give birth to the anesthetic machine. Gas flow measurement was first accomplished using a water sight flowmeter where bubbles indicated the gas flow. Water depression and dry bobbin flowmeters were replaced by the

rotameter. Electronic flow controls replaced rotameters in the twenty-first century.

The machines supplied the anesthetic mixture, but a breathing system was needed for the interface between the machine and the patient. Many early breathing systems were non-rebreathing devices (e.g., open drop delivery of ether or chloroform). Most mask inhalers relied on rebreathing, some to a potentially dangerous level. All these devices released the exhaled gases into the operating room. With the need to minimize delivery of expensive or explosive anesthetics, in the first half of the twentieth century, anesthesia providers turned to rebreathing systems with carbon dioxide absorption—except for anesthetics such as trichloroethylene where the potential for production of phosgene from the reaction of absorbent with trichloroethylene discouraged the use of such absorption. To-and-fro systems competed with circle systems in the first half of the twentieth century, with circle systems winning out. Carbon dioxide absorbents developed in ways that decreased the likelihood of degradation of potent inhaled anesthetics. Other components of the circle system (the corrugated tubing, valves, and reservoir bag) evolved in ways that minimized resistance to gas flow, and unwieldiness. In the latter portion of the twentieth century, concerns regarding the health implications to operating room personnel of breathing exhaled anesthetics led to the scavenging of excess gases.

The Development of the Copper Kettle with Comments on Vaporizers that Preceded and Followed

53

Lucien E. Morris and Donald C. Morris

Summary

Chance and personal interest led me (LEM) sequentially to chemistry, medicine (graduating in 1943), anesthesia, and Ralph Waters who offered me a residency. World War II intervened, and being drafted into the US Army delayed the residency. I managed to practice anesthesia despite a limited knowledge of the art, in 1944 becoming chief of the anesthesia and operating room section at the US Army 103rd General Hospital in England.

In 1946, I began residency, working regularly with Waters in the operating room. In my second year, I participated in the ongoing 1947 departmental study of chloroform as though it were a brand new anesthetic agent. The poor control over chloroform vapor concentration frustrated me, and I foolishly publically lamented that “anyone ought to be able to make a better vaporizer than this”. Waters persuaded me to try.

I applied principles John Snow used 100 years earlier: adequate anesthetic vaporization and control over vapor pressure. I added the goals of delivery of a known concentration of anesthetic at a measured inflow rate. To achieve these ends I controlled the liquid anesthetic temperature by housing it in a copper sump (reservoir) and delivered two precisely known flows – one to the sump and the other bypassing the sump. Flow through the sump passed through a sintered bubbler, ensuring complete vapor equilibration with the flow. Knowing the liquid anesthetic temperatures and the two flows allowed a precise calculation of the anesthetic concentration delivered.

The Foregger Company manufactured the prototype of the Copper Kettle, delivering the first version late in the summer of 1948. The first satisfactory commercial model of the vaporizer appeared in late 1951. It was described in *Anesthesiology* in 1952 and now resides in the Guedel Memorial Anesthesia Center in San Francisco.

The Copper Kettle could be used with any volatile anesthetic, and so it was used for ether and then halothane and enflurane anesthesia. Imitations of the Copper Kettle were made in the US, Japan, South America, and the United Kingdom, and motivated development of variable by-pass, Tec-type vaporizers in the mid-1950s. The principles of operation were the same as those for the Copper Kettle. All had two flows through the vaporizer, the by-pass flow and the flow through the sump containing the liquid anesthetic. Over the next decade or two, these vaporizers replaced the Copper Kettle because they were simpler to use, and required no calculations. They flattered the Copper Kettle with their imitation.

Lucien Morris lived from November 30, 1914 to November 15, 2011. By the time he died, he had created and completed this essay with the help of his son and co-author, Donald Morris. Lucien was effectively blind from macular degeneration in his last years, and much of the story was told from memory. It is a lovely story, a personal story of an invention that helped advance anesthesia from art to science. It also paints a picture of part of anesthesia in the US at mid-century.

The Story

My increasing dissatisfaction with existing equipment, an interest in chemistry and physics, and a personal challenge led to the creation of what became the Copper Kettle vaporizer. How did it begin? I long had an affection for chemistry and physics, an affection that may have attracted me to anesthesia and certainly influenced my invention of the Copper Kettle. I fondly remember spending time as a child in the laboratory with my father, who was the professor and head of the Department of Biochemistry at Western Reserve University. After graduating in 1936 from Oberlin College with a bachelor's degree in chemistry, I enrolled as a graduate student at Western Reserve University in biochemistry,

715

intending to teach biochemistry to medical students. Because I thought I might better understand what medical students needed to know if I saw biochemistry through their eyes, I enrolled into the medical college, continuing as a laboratory assistant in the Biochemistry Department until the beginning of my senior year. I graduated as an MD in February 1943.

My internship at Grasslands Hospital, Westchester County, New York provided my first exposure to anesthesia, a one-on-one tutoring that in hindsight led to an appreciation of how my basic science training would support my future interests in anesthesia. Not yet realizing that I was destined to become an anesthesiologist, I applied for a residency in women's diseases, an area of study that I felt had been neglected during my internship. My letters of inquiry evoked a single response from a small private hospital in Madison, Wisconsin. En route to Madison, I learned that all the house officers for that hospital had been called into active military duty and the post of being the only resident was offered to me. I accepted it because I felt that as the sole resident, I might choose my opportunities based on what interested me.

After reporting for duty in Madison, and while exploring the hospital, I met a surgeon who asked if I had any experience with anesthesia. When I said I had some experience as an intern, he explained that all nurse anesthetists were busy and requested that I provide "just a touch of Pentothal for a short case". Wanting to be helpful, I unwisely acquiesced. Because the three CRNA's were using all available machines, I hurried to find an intravenous drip, suction equipment, an oropharyngeal airway, an oxygen tank fitted with a flow meter and a bag and mask. Finding these essentials in unfamiliar surroundings took about fifteen minutes. The displeased surgeon berated me for the delay. The "short case" lasted nearly four hours, compounding my and his unease. I managed to keep the patient quiescent with a total of three and a half grams of thiopental. Later that evening, after listening to my grumbling about the case, an extern, a medical student from the University of Wisconsin, suggested, "If you're that interested in anesthesia why don't you go and see Dr. Waters" (1883–1979)? Perceiving my ignorance about Dr. Waters, he told me about the excellent residency program in anesthesia at Wisconsin, and why students held Prof. Waters in high regard.

Shortly thereafter, I received notice to report for active military duty. I called Dr. Waters and requested an urgent interview. He responded quickly, graciously inviting me to his home that evening. After an hour and a half interview we agreed that if I survived the war, I would return as his resident for advanced training in clinical anesthesia.

A week later I was in the Army. Following a few weeks of indoctrination, those of us who had received a war-truncated nine month internship were ordered to an army general hospital in upper New York State where we were to spend two

weeks each on surgery and medicine, and a third two weeks on an elective option. I asked to have an anesthetic elective for the first two week stint, and then asked the chief of surgery to have the second two weeks on anesthesia instead of surgery. After obtaining his agreement, I presented the chief of medicine with a similar request, which was also granted. I suspect that these men complied because they then had one less naïve transient to keep out of trouble. Although the anesthesiologist in charge taught poorly and lacked enthusiasm, I was delighted to have six weeks experience in anesthesia, and grateful to learn how to use a Heidbrink machine to give a satisfactory GOE [gas (nitrous oxide)-oxygen-ether] anesthesia. My next assignment was to O'Halloran General Hospital on Staten Island where I learned a variety of anesthetic blocks. After two and a half weeks, I joined the 103rd General Hospital, in preparation for deployment to England.

On arrival in England, all doctors were interviewed by Lt. Col. Morton. Because another Morton first publically demonstrated ether anesthesia, I took it as a favorable sign, saluting and saying "Lt. Morris reporting, Sir". He looked up, seemingly startled and said, "Lucien Morris is it?" I said, "Yes sir". I felt certain he had started to say, "We've been looking for you", but the rest of the interview was unremarkable. The next day I was interviewed by a full colonel, William S. Middleton, who probed my background and experience, ending with a discussion of mutual friends and acquaintances in medicine. I later learned he was the Dean of the Medical School at the University of Wisconsin – on military leave of absence. The next day my name was posted, indicating my assignment as chief of the anesthesia and operating room section at the 103rd General Hospital.

From the beginning, the 103rd General Hospital received soldiers injured in the European Theatre. In eight and a half months in 1944–45, we provided nearly 5,000 anesthetics. I personally administered more than 700 anesthetics and, in addition, supervised and assisted a staff of nurse anesthetists and other physicians who dealt with the remainder. Although relatively few cases required tracheal intubation, we did enough that the team and I began to feel reasonably confident in the use of the Guedel laryngoscope. No deaths could be either directly or remotely related to the administration of anesthesia. This reflected the health and youth of our patient population with war wounds of the extremities. Patients with life threatening injuries of head, thorax, or abdomen were sent elsewhere.

With the end of the European conflict and then VJ Day (14 August 1945), I was redeployed onto home territory. The final months of my more than two and one-half years of active military service were spread among assignments to several small army hospitals in the eastern and southeastern US.

Returning to Madison in late August 1946 to begin the residency program, I worked with Dr. Waters in the operating room on a daily basis, quickly learning about the

Fig. 53.1 Dr. Ralph Waters at age 65 in 1948 from the same group picture that included Lucien Morris (Fig. 53.2). (From the personal collection of the author)

pharmacological and psychological preparation of the patient. Dr. Waters routinely gave an amnesic drug as part of his pre-medication routine, because he believed it facilitated the use of less anesthesia and diminished patient recollection of problems with the anesthetic induction. Dr. Waters would have a friendly conversation with the patient as the patient moved to the operating table. The conversation always indicated Dr. Waters' concern for the patient's well being and often included a suggestion that the patient make a conscious effort to relax. He used the positioning of the blood pressure cuff as the signal that this was a part of the routine. A pillow under the patient's head had another purpose: it helped to support the to-and-fro carbon dioxide absorption canister (see Figs. 52.10 and 57.1) [9]. Part of Dr. Waters' conversation was intended to distract the patient, and part assure them that he was their advocate and would look after their well being during anesthesia. During the surgical procedure, Dr. Waters' attention to patient well-being included tracking pulse, blood pressure and urinary output. Throughout his esteemed career, Dr. Waters advocated teaching by example, continuing this daily pattern until he retired in 1948 on the day he turned 65 (Fig. 53.1).

Fig. 53.2 A young Lucien Morris from a group photograph of his residency mates and the faculty at the University of Wisconsin. (From the personal collection of the author)

In my second year at Madison (Fig. 53.2), I participated in the ongoing departmental study of chloroform, which was subjected to scrutiny as though it were a brand new anesthetic agent [1]. I worked closely with Dr. Waters on the chloroform cases, becoming increasingly frustrated by the poor control over chloroform vapor concentration, and lamenting in the operating room that "anyone ought to be able to make a better vaporizer than this". Several weeks later, while in Florida, Dr. Waters sent a postcard to the staff and residents with a single question: "Has Morris made a new vaporizer yet?" With that encouragement, I set out to solve the problem.

Though not known by me at the start of this quest, John Snow (1813–1858) had noted the importance of several principles that I eventually applied. He observed that there had to be an anesthetic surface area sufficient to ensure equilibrium of anesthetic with the air passing through it. He knew that temperature affected vaporization and to stabilize temperature he made his vaporizer of copper and surrounded it with a water jacket (water because it has a great capacity to hold heat) (see Fig. 52.2). But his and the contemporaneous vaporizer developed by Joseph Thomas Clover (1825–1882) were "non-rebreathing" systems that lacked the economy needed in modern vaporizers [2, 3]. Other vaporizers developed in the last half of the nineteenth century had one

Fig. 53.3 The Harcourt vaporizer was designed to produce a known delivered concentration of chloroform. Two glass bulbs, probably long since broken, were attached to the two arms. The vaporizer compensated for the effect of the temperature of the chloroform on the concentration produced. (Courtesy of the Wood Library-Museum of Anesthesiology, Park Ridge, IL)

or more deficiencies. Vernon Harcourt (1834–1919) for example, built an accurate chloroform vaporizer that was easily broken and its glass components did not lend themselves to temperature stability (Fig. 53.3).

In the first half of the twentieth century, volatile anesthetic concentrations were often provided to patients from gauze masks onto which the liquid anesthetic was dropped. There was no way to estimate the anesthetic concentration breathed by the patient. Alternatively, anesthetic concentrations were produced by anesthetic machines with metered gas flows to which anesthetic vapor was added. In these machines, vapor was added by diverting a coarsely variable portion of the total flow of gases breathed and rebreathed by the patient over or through liquid anesthetic contained in an "in-circuit" vaporizer. These diverted gases were returned to the mixture of fresh and rebreathed gas, ultimately delivered to the patient. Vapor concentration and anesthetic effect could not be predicted, and could produce excessive or inadequate

concentrations. The Boyle's vaporizer (bottle), invented by Henry Boyle (1875–1941), is an example of such a vaporizer. The glass with which it was made insulated the liquid anesthetic which thus would cool (although a water jacket surrounded the glass and limited the cooling). It provided a limited anesthetic surface area, and the control for the diversion of gases through the vaporizer was qualitative at best, indicating administration of more or less anesthetic, but not how much more or how much less. Other vaporizers, including one built by Victor Goldman (1903–1994), had some modern characteristics, but like many previous devices, they were usually designed for nonbreathing use and did not provide for the quantitative delivery of anesthetic. Generations of anesthetists learned to cope with these deficiencies. I wanted something better.

In retrospect the desirability of producing precisely known concentrations of vapor for addition to the respired gas mixture is clear. My laboratory notebook contained several designs to achieve that end, but they all contained one notion – a separate measured flow of carrier gas, all of which bubbled through the vaporizer. In disguise, this principle continues to be applied in vaporizers used today (see below), long after the demise of the Copper Kettle. Oxygen was chosen as the carrier gas so that if the oxygen supply failed the addition of anesthetic vapor would cease (Fig. 53.4).

The new vaporizer had two important additional components. First, to provide the heat necessary for vaporization, and thereby prevent undue chilling of the anesthetic, I replaced the nearly ubiquitous glass bottle of previous decades with a copper container (Figs. 53.4 and 53.5). Copper was used because of its considerable capacity to conduct heat. I further increased temperature stability by attaching the copper container to a copper tabletop. Secondly, the metered gas was directed through a sintered bronze bubbler (see POREX in Fig. 53.4) at the bottom of the copper container with a resulting dispersion into a multitude of fine bubbles. This provided an enormous combined surface area, a large gas-liquid interface, one providing rapid saturation of the bubbling gas with anesthetic.

The output of this vaporizer, the Copper Kettle, was added to an independent, precisely metered flow of other gases such as oxygen with or without nitrous oxide. Thus the entire system delivered three gases to the anesthetic circuit from which the patient breathed. First, there was the measured flow of fresh gas (A) directed to the Copper Kettle. Second, there was the vaporized anesthetic gas (B) added to A. Third, there was the independent precisely metered flow of other fresh gases (C) that had bypassed the vaporizer. A and B were added to C. The fractional concentration of anesthetic could then be calculated as $B/(A+B+C)$. If one wanted percent, one multiplied the fractional concentration by 100.

But how to calculate B, the volume of entrained vapor per unit of carrier gas? B depended upon the saturated

Fig. 53.4 The photograph of an early Copper Kettle on the left is from the ASA Newsletter 62:1998. The schematic on the right shows a precisely known flow of oxygen that enters through a diffuser leading to a porex filter that caused the gas to break into small bubbles, assuring that a maximum concentration of anesthetic was achieved in the gas, which then passed through an outflow tube, ultimately to be mixed with a second precisely known gas flow. Note the less safe filling funnel at the top of the vaporizer, a position that would permit the careless anesthetist to overfill the vaporizer and allow liquid anesthetic to enter the carrier gas stream, thereby potentially producing a lethal anesthetic concentration. Contrast this with the vaporizer shown in Fig. 53.7. (From the personal collection of the author)

Fig. 53.5 This photograph shows the first commercial Copper Kettle that was made by the Foregger Company. The Copper Kettle placement at the front left of the tabletop (itself to be made of copper to increase the heat sink for and thus temperature stability of the anesthetic) was changed in later models to the rear of the tabletop. The panel at the rear of the tabletop consisted of the two flowmeters (plus other flowmeters) needed in the design of the Copper Kettle. (From the ASA Newsletter, 62:1998)

vapor pressure of anesthetic at the observed temperature (temperature in the Copper Kettle was measured separately). Each anesthetic has its own characteristic vapor pressure-temperature curve, and this had to be applied to accurately calculate the delivered concentration. For example, suppose isoflurane had a saturated pressure of 250 mm Hg and the total ambient pressure was 750 mm Hg, then the effluent concentration would be 250/750 or 1/3rd of an atmo-

sphere. That is, every third molecule issuing from the vaporizer would be isoflurane. For 100 ml of metered carrier gas flowing into the vaporizer, 50 ml of isoflurane plus the 100 ml of metered gas would emerge (i.e., the output would equal $50/(100+50)$). This highly concentrated output of 33% is roughly thirty times an appropriate anesthetic concentration. Such a concentrated output must be properly diluted by the other metered gases (the “C” gases, above) in the total flow offered to the patient.

The Foregger Company, New York, made the first apparatus that included many of the design principles of this new vaporizing system. They delivered it to us in the late summer of 1948 (Fig. 53.5). We chose Foregger because they made their staff and facilities available for prototype manufacturing. This prototype now resides in the Wood Library-Museum in Park Ridge, Illinois. Although it had the separate metered vaporizing circuit and the copper container for anesthetic liquid, it did not meet all our criteria, specifically omitting certain safety features such as prevention of vaporizer overfilling or pressurization. However, it allowed us to gain clinical experience and pursue further laboratory studies. Persuading the manufacturer to incorporate all the design features of this new apparatus was not easy. Many letters of explanation and several vigorous face-to-face discussions with the owner, Richard von Foregger, Ph.D. (Fig. 53.6), produced a grudging agreement to include all of the features of my design. I received the first satisfactory commercial model of the Copper Kettle vaporizer (Fig. 53.5) in late 1951. The apparatus was described in *Anesthesiology* in 1952 [4], and now resides in the Guedel Memorial Anesthesia Center in San Francisco.

Fig. 53.6 Richard von Foregger in his office. (From an internet tribute for Richard von Foregger, Ph.D., 1872–1960)

Further clinical trials and laboratory studies resulted in additional modifications motivated by safety considerations, most notably a side arm funnel (Fig. 53.7) for filling the liquid container (to prevent over filling), and a double cam valve for the positive exclusion of both the outflow and inflow of the vaporizing chamber. This valve precluded entrainment of vapor or build up of pressure in the vaporizer – which otherwise might cause a surge in vapor output after an oxygen flush.

A need for better control over *chloroform* vapor delivery motivated the design of this innovative vaporizer. But why stop there? This versatile precision equipment could deliver any volatile anesthetic that was liquid at room temperature. It was soon applied to administration of diethyl ether. The ability to smoothly and gradually increase ether vapor concentrations sped inductions and decreased patient discomfort that sometimes accompanied induction of anesthesia with ether. It also became evident that it was easy to overdose a patient with ether: “Good old safe ether” was less safe when ether was improperly administered from the Copper Kettle. Concern regarding the ease of over-dosage with misuse caused us to advise the use of the Copper Kettle primarily in high flow and semi-closed systems. It also seemed best to limit its use to spontaneously breathing patients (that is, without the help of a ventilator or manual ventilation) and to carefully adjust the dosage in accordance with patient response and surgical needs.

Halothane, introduced in the late 1950s, rapidly replaced ether as the anesthetic of choice. Again the Copper Kettle was widely used for its administration – and for administration of other liquid anesthetic agents as well.

Fig. 53.7 In this picture of the revised Copper Kettle, the opening used to fill the vaporizer with anesthetic is placed low on the side (right side in this picture) of the vaporizer, precluding overfilling of the vaporizer. (Picture from the ASA Newsletter 62:1998)

Several reports [5–7] following the original publication [4], enlarged our understanding of the concepts and underlying principles embodied in the design of this versatile vaporizer as a precision tool for the administration of anesthetic vapors. The Copper Kettle rapidly became popular and remained the preferred vaporizer in many US teaching hospitals for many years. The Foregger Company developed several models incorporating the principles of the Copper Kettle, but after the death of Richard von Foregger in 1960 [8], the company made some inappropriate modifications, such as a multiple selection anesthetic turntable, likely intended to simplify agent selection, without regard for potential human error of unknowingly mixing anesthetic agents. Such decisions may have been indicative of problems in management. The company was sold in 1968 and went out of business in 1984 [8].

Imitations of the Copper Kettle were made in the US (especially the Vernitrol® vaporizer), Japan, South America, and the United Kingdom. Most of these ignored one or more of the underlying principles that were part of the original

design. In England for instance, a so-called copy utilized the separate carrier gas flow, but used a glass bottle rather than a copper container. As a result, some users never gained a full appreciation of the benefits of the Copper Kettle.

Introduction of the Copper Kettle motivated commercial competition, mostly agent-specific, temperature- and flow-compensated direct reading percentage vaporizers (i.e., variable by-pass, Tec-type vaporizers). The earliest variable by-pass vaporizers were often faulty and imprecise, and were originally intended for use with high flow systems, precluding the application of economical low flow and closed absorption techniques. Compounding the lesser economy, these vaporizers were intended for use with a specific anesthetic rather than the general use possible with the Copper Kettle. However, they had one (perceived) advantage over the Copper Kettle. The anesthetist did not need to calculate and recalculate the concentration of anesthetic obtained at the initiation of anesthesia, or after changes in inflow rate or dialed concentration. Life was simpler, and this fact contributed to their now universal adoption. In the process, we have lost more than the flexibility and economy of the Copper Kettle. The need to calculate the concentration of anesthetic educated a generation of anesthetists concerning the physics underlying anesthetic delivery—a great loss.

We should not leave this history without noting that variable by-pass vaporizers are, in fact, imitations of the Copper Kettle. Like the Copper Kettle, variable by-pass vaporizers have two flows through the vaporizer, although seemingly there is but one: The by-pass flow and the flow through the sump (reservoir) containing the liquid anesthetic, each, as with the Copper Kettle, metered precisely. As with the Copper Kettle, the variable-by-pass vaporizer ensures complete equilibrium of the gas passing through the sump. Finally, as with the Copper Kettle, the variable by-pass vaporizer accounts for the temperature of the anesthetic and the total flow delivered. These marvelous devices have now been perfected to eliminate the inadequacies of earlier models. They flatter the Copper Kettle with their imitation.

And what about the revival of chloroform, a revival that motivated the invention of the Copper Kettle? The Copper Kettle allowed control over the delivery of chloroform that was not possible with previous approaches. But that control did not alter the inherent toxicity of chloroform. Still, we have chloroform to thank for the invention, without which the anesthetic community would be the poorer.

The Copper Kettle proved to be a versatile tool for administration of all anesthetic vapors, and was in general use in the US for about twenty-five years. It went out of favor, in part, because of the development of variable bypass vaporizers that supplied an easy alternative to the requirement that the anesthetist calculate the delivered concentration. It also may have gone out of favor, in part because of ill-advised modifications made by the manufacturer, and in part because of misuse and lack of appreciation of the dangers of over-dosage. *Just as with a jet airplane or car, the best safety device of any potentially harmful equipment is the knowledge and full attention of the operator!* In contrast to variable by-pass (direct reading percentage) vaporizers which may encourage “cookbook” administration of anesthesia, the Copper Kettle encouraged users to think in terms of patient response, partial pressures and volume of vapor in the vaporizer output, which (when used in a closed absorption system) leads to a clearer understanding of uptake of anesthetics in the patient; important points for anesthetists and patient care even today.

Summary

For a century, gauze masks served as the vehicle for vaporizing ether and chloroform. The anesthetist controlled anesthesia by regulating the drops of anesthetic applied to the gauze. Solid masks (leather, metal, rubber, and modern disposable plastic masks) fitted to the face allowed a more controlled delivery of anesthetic from vaporizers and gas flowmeters.

Ventilation and anesthetic delivery require an unobstructed airway. In 1873, Heiberg suggested jaw thrust, and in 1880, Howard added head tilt and extension. Artificial airways, tubes introduced through the nose (Faure 1859) or mouth (Hewitt 1908) replaced tongue forceps that might draw the tongue forward but also often damaged the tongue. Guedel and Waters produced the modern oropharyngeal airway in the 1930s, and Shipway introduced a cuffed oropharyngeal airway in 1935, predating Brain's 1983 laryngeal mask airway.

Tracheal intubation provided a more secure airway. In 1796, Herholdt and Rafn used blind digitally-guided tracheal intubation to resuscitate drowning victims. Babbington viewed the glottis in 1829 by indirect laryngoscopy. Macewen pioneered blind tracheal intubation for anesthetic delivery in 1878, and in 1882, O'Dwyer used a tube to relieve obstruction from diphtheria. Kirstein reported laryngoscopy in 1895 with the "autoscope", used by Killian in 1897 to extract a foreign body from a bronchus. Jackson invented a direct laryngoscope in 1910. Miller and Macintosh described their blades for viewing the larynx by direct and indirect elevation of the epiglottis in the 1940s. Indirect laryngoscopy returned as an aid to intubation in 1980, with Bullard's rigid fiberoptic laryngoscope. Subsequently, advances in fiberoptic and video technology applied to laryngoscopes and bronchoscopy improved portability and ease of use.

Tracheal intubation began with rigid, then flexible, metal tubes. In 1898, van Stockum fitted his tube with an inflatable cuff. Reports of cuffed tracheal tubes appeared over the next three decades. In 1919, Magill and Rowbotham inserted a narrow rubber tube into the trachea for insufflation, later adding an exit tube. Flagg (1927) and Magill (1938) concluded that one wide-bore tube should work equally well. Magill made his tube from mineralized red rubber tubing. Polyvinyl chloride tubes were introduced in 1964.

Early thoracic surgeons operated on moving lungs. In 1931, Waters and Gale solved this problem by ventilating only the non-operated lung. Magill suggested the bronchial blocker in 1936. Carlens' invented the double-lumen tube in 1949 for bronchspirometry. It was later used in anesthetized patients.

In 1984, the Cormack-Lehane Laryngoscopy Grading System provided the first systematic approach to prediction of difficult intubation. Mallampati suggested an alternative the following year.

Introduction

Egyptian tablets from 3600 BCE (before the common era—equivalent to BC) describe tracheostomy, a surgical procedure which subsequently fell into and out of popularity

[1–3]. Avicenna (also known as Ibn Sīnā), an Arabian physician, described tracheal intubation or an oropharyngeal airway in his book *Liber Canonis*: "when necessary, a cannula of gold, silver or suitable material is advanced down the throat to support inspiration." [3–5] Airway management attracted increasing interest after the 1846 discovery of anesthesia. A diverse assortment of physicians, priests, engineers, ministers and even musicians, made subsequent inventions and discoveries in airway management [1]. The use of the neuromuscular blocking drug, curare, to produce relaxation changed anesthetic delivery and launched further developments in airway management [6].

Tracheostomy

Currently accepted as the last line of airway defense, a surgically obtained airway—tracheostomy or cricothyrotomy—is the oldest form of airway management. It remains the final pathway in “cannot intubate-cannot ventilate” circumstances [7–9].

Following the above-noted 3600 BCE Egyptian tablets, 2000 BCE Hindu scriptures mention tracheostomy, and around 100 BCE, Asclepiades is said to have performed a non-emergency tracheostomy [10–12]. Near to 100 CE, the Greek surgeon, Antyllus suggested bypassing upper airway obstruction by transverse tracheostomy. In 160 CE, the great Greek philosopher, Galen, described a technique similar to today’s vertical tracheotomies [2, 3, 10], finding that “if you take a dead animal and blow air through its larynx (through a reed) you will fill its bronchi and watch its lungs attain the greatest dimensions.” [3, 11]

In 1543, 28-year-old Andreas Vesalius published *de humani corporis Fabrica*, a 7-volume book, providing anatomic descriptions of the human body, including a detailed depiction of how to perform a tracheostomy in an animal. Because performing autopsies was considered scandalous, his dissections were performed in secrecy. Ironically, his demonstration of ventilation on the fresh cadaver of a Spanish nobleman led to Vesalius’ death. Allegedly, while performing the tracheostomy and artificial ventilation, the nobleman’s heart began to beat, outraging the general and medical community. Vesalius was exiled and while escaping, his boat capsized and he drowned [4, 5, 11, 13].

In 1546, Antonio Brasavola, an Italian physician, described the first successful use of a tracheostomy to bypass tonsillar obstruction in a human [5, 10]. In the early 1600s, Italian anatomist, Fabricius of Aquapendent, stated that few surgical procedures could so quickly revive a person as a tracheostomy [5, 10]. No evidence of regular use, however, appeared, and a 2001 review found published descriptions of only 50 tracheostomies before 1800 [3].

An early 1800s epidemic of diphtheria prompted the performance of tracheostomies, led by French internist, Armand Trousseau [5, 11, 13]. Desperate to save lives, Trousseau personally conducted more than 200 tracheostomies in afflicted children by 1833 [2, 5, 11]. Unfortunately, his method often produced tracheal stenosis which had a 50% mortality rate. High perhaps, but better than the nearly 100% mortality from diphtheria-induced suffocation [13, 14].

The use of a tracheostomy to facilitate anesthetic delivery began soon after the discovery of anesthesia. In 1853, John Snow administered chloroform to rabbits through a tracheostomy tube [4, 5]. In 1871, Friedrich Trendelenburg used this technique on humans, solving the problem of aspiration with his cuffed tracheostomy tube and funnel apparatus (Fig. 54.1) [4, 5, 11].

Fig. 54.1 Trendelenburg apparatus. (Courtesy of American Society of Anesthesiologists, ASA Newsletter Vol 72, Sep 2008, p. 9)

In 1909, Chevalier Jackson advanced the performance of tracheostomy by describing what are now modern techniques and principles (optimizing airway control before surgery; employing local anesthesia; using a well-designed tube; and applying meticulous surgical technique and post-operative care). These principles decreased mortality to 3% and increased the acceptance of the procedure [10, 14, 15].

Cricothyrotomy

In 1805, French surgeon and anatomist Vicq d’Azyr described cricothyrotomy [16]. Initially ignored, these “high tracheostomies” increased in popularity in parallel with tracheostomies. However, concerned about the associated risk of subglottic stenosis, Chevalier Jackson decried

cricothyrotomy. His objections hindered the performance of cricothyrotomy for over half a century [13, 14, 17].

In 1976, Colorado cardiothoracic surgeons Charles Brantigan and John Grow, Sr. published results of cricothyrotomies in 655 patients, with no incidence of chronic subglottic stenosis. Published complication rates of traditional tracheostomy exceeded the overall complication rate of 6.1%. Brantigan and Grow concluded that cricothyrotomy was faster, easier, and less likely to bleed [16]. Today, although the use of either tracheostomy or cricothyrotomy has decreased, they remain the preferred techniques when all other approaches have failed [7–9].

Anesthesia Facemasks and Upper Airway Obstruction

For more than a century, the facemask provided the primary interface to the anesthetic system for spontaneously breathing patients, and for most of those receiving positive pressure ventilation. After the 1950s, tracheal tubes increasingly displaced the facemask. Ventilation via a facemask remains an essential component of all difficult airway algorithms [7–9]. Modern transparent, high-volume, low pressure disposable plastic facemasks minimize dead space, maximize seal, and allow prompt recognition of regurgitation—as the ideal facemask should [18–20].

The facemasks created soon after the discovery of anesthesia took two forms. One provided a gauze surface (sometimes simply a handkerchief) onto which ether or chloroform was dripped or poured, and through which the patient might breathe, acquiring anesthetic in the process. The gauze might be supported by a wire frame, such as that devised by Thomas Skinner, a Scottish obstetrician [21]. These devices evolved into many variations, the most popular being the Yankauer and Schimmelbusch masks. Facemasks made of gauze had the advantages of simplicity and minimal cost, but the operating room became contaminated with anesthetic vapor (wasting anesthetic in the process) and positive pressure ventilation was not possible.

Skinner's reason for designing the wire frame mask was truly advanced for his time. Although the antisepsis debate developed eight years later, Skinner felt that facepieces preceding his design were “disgusting”. Typically, a mask would be used and reused, without cleaning, without considering whether it had been applied to a patient with a possibly contagious infection before applying it to the next patient. Skinner's mask came with multiple flannel cloth coverings that could easily be replaced allowing each patient to have a clean mask [22, 23].

The second form of facemask, like that devised by Snow, might be recognized as the forerunner of the modern mask. It was made with harder material—leather or leather edged

metal. In the latter part of the nineteenth century, most masks (often in the form of “inhalers”) were made of metal, sometimes with a rubber rim. Masks in the first half of the twentieth century were made of rubber, softer than leather or metal, but far harder than today's masks.

In the late 1950s, pediatric facemasks were miniature versions of adult masks. Because an infant's face differs from an adult's, these masks provided a poor seal and imposed a deadspace that might equal an infant's tidal exchange. Anesthesiologist Leslie Rendell-Baker and dental student Donald Soucek, (both from Western Reserve University) designed a better facemask from plaster moulds of infants' faces. They eliminated the cuffed rim and added a partitioned adapter that further minimized deadspace. Their 1961 result produced the still popular RBS facemask for children ≤ 5 years old [24, 25].

Adequate ventilation via facemask requires both a good seal and an unobstructed airway [18, 19]. In the late 1800s, Joseph Clover, Jacob Heiberg and Johannes Von Esmarch each recommended jaw thrust to relieve obstruction [20, 26, 27]. In 1894, surgeon Theodor Kocher advocated jaw thrust and chin lift for all anesthetized patients [28]. Jaw thrust became known as Esmarch's maneuver although it was first described by Heiberg [26, 27]. In 1880, Benjamin Howard found that head tilt and neck extension opened the airway by lifting the epiglottis and tongue [27]. In the 1950s and 1960s, radiologic studies documented that chin lift, head tilt, and jaw thrust opened the airway [18, 20].

Position change was used to resolve some forms of upper airway obstruction. Snow argued that the recumbent position permitted surgical debris to pool in the back of the throat where it might pass down the esophagus—never mind that it might also enter the glottis. If the anesthesiologist heard gurgling sounds, the patient's head should be tilted forward or sideways to empty accumulated debris [4, 29, 30]. British anesthetist Alexander Wilson tied his patients to a rocking chair for surgeries of the tongue, thereby allowing an array of positions: reclined for induction; seated for surgery; and, body/head tilted forward to clear the pharynx of debris [29, 30]. James Murphy described an 1894 Parisian patient position—supine with his head hanging over the end of the operating table, using gravity to protect the airway against aspiration. In 1904, operating tables were fitted with special headrests to simulate Murphy's position [30]. Trendelenburg's downward tilt was similarly used to drain debris from the airway [31].

Devices Used to Manage Upper Airway Obstruction

Tongue Forceps

In an 1856 letter describing “never before pointed out impediments of respiration,” Marshall Hall observed that

Fig. 54.2 Various tongue forceps were devised to allow the user to pull the subject's tongue forward, sometimes damaging tongue and teeth in the process. (Courtesy of Rod N. Westhorpe and the Geoffrey Kaye Museum of Anaesthetic History)

glottic obstruction sometimes occurred in supine patients. He believed that relaxation of the tongue caused the epiglottis to block the glottis [26]. In seeming support of Hall's suggestion in 1880, Benjamin Howard found that traction on the tongue to displace it from the posterior pharyngeal wall could relieve obstruction (actually implying that the tongue and not the epiglottis was the problem) [27].

Accordingly, tongue forceps were invented (Fig. 54.2). But in 1874, Jacob Heiberg gave a frightful image of forceps-based management of airway obstruction. Their use broke teeth and injured the tongue. Injury could impair speaking and/or swallowing and cause prolonged pain [26]. Despite the English Suspended Animation Committee's 1879 objection to these devices—recommending instead Esmarch's maneuver—tongue forceps continued in use into the 1930s [26, 32].

Oropharyngeal and Nasopharyngeal Airways

An oropharyngeal or nasopharyngeal airway may be used to assist in opening the upper airway [18, 19]. In 1859, Faure of Paris inserted a long rubber tube through the nares, a primitive nasopharyngeal airway, to create a passage for chloroform delivery [33]. Similarly, Joseph Clover in 1881 connected his chloroform/nitrous oxide bag to an India-rubber nasal tube to deliver anesthesia during jaw surgery [32–34]. In 1913, Karl Connell, a Columbia University surgeon,

Fig. 54.3 Hewitt oropharyngeal airway, original straight version on left. (Courtesy of Rod N. Westhorpe and the Geoffrey Kaye Museum of Anaesthetic History)

described anesthetic delivery through either a single or double nasopharyngeal airway [32, 35].

Frederic Hewitt's classic 1890 summary noted the frequency and danger of upper airway obstruction. In 1908, dissatisfied with the use of tongue forceps and acknowledging that Esmarch's maneuver sometimes failed, he described the first oropharyngeal airway, the Hewitt Airway (Fig. 54.3). The tube was less than 8 cm long, ideally connecting the oral opening to the hypopharynx [27, 30, 36]. Within a year, a longer curved version replaced the first, straight model. The Hewitt Airway anticipated many subsequent oropharyngeal airway designs [4, 27, 32].

Improvements and increased use of the oropharyngeal airway followed World War I [32]. In 1930, Ralph Waters, the first Chairman of an Anesthesiology department in the US (University of Wisconsin), designed an airway made of metal, further differing from Hewitt's design by being oval in shape and later including a side tube for insufflation [34, 37, 38].

Although Arthur Guedel and Waters never worked at the same institution, they corresponded and collaborated on research projects [39, 40]. Guedel, at the University of Southern California, believed that steel oropharyngeal airways caused oral trauma [38–40], and that it could be better contoured to fit the shape of the pharynx [32, 40]. Thus he

made his airway of rubber, sufficiently soft to be flexible and perhaps less traumatic, yet rigid enough to maintain a patent airway. It included a metal piece at the level of the incisors as a bite block [39, 40]. A wide rubber flange at the oral opening prevented over insertion and allowed easy retrieval [40]. Guedel wrote to Waters “As I use the rubber airway more and more, I am growing to like its action better and even as well as or better than the metal (Waters) airway. I am proud of the idea...” [40]

Resident Robert Berman had an incident with a Guedel Oral Airway which resulted in a new oropharyngeal airway [41]. He had placed a Guedel Airway in a shirt pocket that also contained safety pins (safety pins were often used to puncture the lead tops of containers of ether; they formed a wick that facilitated the controlled delivery of ether). After using the oropharyngeal airway during induction, he performed laryngoscopy and noticed a safety pin in the posterior pharynx. The opacity of the black rubber had hidden the presence of the safety pin, which had been dislodged by the force of ventilation [41]. Berman discussed the problem with his neighbor, Meyer Moch, a plastic fabricator. Excited by the problem and seeing a solution, Moch and Berman retired to Moch’s basement where they softened butyrate tubing, formed it into the shape of an airway, and sanded it smooth. Since Moch lacked pharyngeal reflexes, they immediately tested its fitting and function on him [41]. In 1951, Berman and Moch officially introduced the airway. The final version differed from Guedel’s in having no closed tube that might trap foreign bodies. Instead, it had a central longitudinal strut with upper and lower flanges [41, 42]. See Fig. 54.4 for a view of the different types of oropharyngeal airways.

While these oropharyngeal airways could overcome upper airway obstruction, their use did not preclude aspiration. Without tracheal intubation, packing with gauze, sponges, or repositioning of the patient was used to manage this complication. Such management was imperfect and gauze and sponges could be swallowed or inhaled. An alternative solution was required [43]. Just before retiring in 1935, Francis Shipway, anesthetist to King George V, designed the Shipway Oropharyngeal Airway (Fig. 54.5). The Shipway Airway added an inflatable cuff to the Hewitt Airway. It was specifically designed to prevent aspiration of blood during intranasal surgery [30, 43, 44]. A special fitting permitted the connection of the Shipway Airway directly to an anesthetic circuit [30, 43, 44].

In 1937, Canadian Beverly Leech invented the Leech Pharyngeal Bulb Gasway. A solid rubber bulbous plug with a hollow core surrounded the distal end of this metal oropharyngeal airway, the assembly fitting closely to the pharyngeal tissues to provide an airtight seal [32, 44–46]. While not an inflatable cuff, the plug served a similar function and is often called a “cuffed device”. Its design was based on studies of pharyngeal anatomy [30, 32, 45]. Used to deliver

closed circuit cyclopropane anesthesia, it remained popular until tracheal intubation rendered it obsolete in the mid-1950s [45].

In 1991, Robert Greenberg, at John Hopkins developed the Cuffed Oropharyngeal Airway, a Guedel oral airway which included an inflatable cuff and a 15 mm connector for attaching to an anesthesia circuit. The cuffed oropharyngeal airway was prone to dislodgement when the cuff was inflated [45]. Removal with its cuff inflated helped prevent aspiration of blood or secretions.

Cuffed oropharyngeal airways were an important part of airway management history, serving as an inspiration for future supra-laryngeal airways [18, 43, 44], but interest in these airways was not sustained. They gave way to tracheal intubation and supralaryngeal airways.

Supralaryngeal Airway Devices

Before the 1980s, ventilation via a facemask supplied the primary alternative for tracheal intubation. However, ventilation via a facemask did not preclude aspiration of gastric contents. Securing an airtight seal could also be difficult [4, 47, 48]. After 1981, progress in supralaryngeal airway devices increasingly overcame these shortcomings.

Determined to develop an airway minimizing the limitations of facemask-assisted ventilation, British anesthetist Archie Brain invented a device connecting the natural airway to an artificial airway that did not require insertion equipment, and did not demand the use of muscle relaxants [4, 34, 47, 48]. Brain noticed that the shapes of plaster casts of a cadaver's pharynx resembled the Goldman nasal masks used in dental anesthesia. Brain created his first laryngeal mask airway (LMA) by attaching a Goldman nasal mask to a diagonally cut end of a 10 mm Portex tracheal tube, joining them with acrylic adhesive [47–49]. In the summer of 1981, Brain blindly inserted the LMA prototype in a patient undergoing a routine hernia repair under halothane anesthesia, achieving a clear airway that allowed positive pressure ventilation [48, 49]. Success! A pilot study in 23 patients undergoing various operations, including gynecological laparoscopic procedures requiring positive pressure ventilation, showed that the device could supply a patent protected airway without requiring muscle relaxants to facilitate placement. Published in the British Journal of Anaesthesia in 1983, the results received surprisingly little attention from the medical or manufacturing community [47–50]. Undeterred, Brain soon filed a dozen patents [4, 47].

Despite the lack of commercial interest, Brain continued to modify his invention, experimenting with diverse materials before settling on silicone for the LMA-Classic (cLMA) [47, 48]. So strange were some designs that several early prototypes were mistaken for exotic rubber condoms by members of the cleaning staff at Brain's laboratory in

Newham General Hospital [47]. Over the next seven years, Brain produced hundreds of prototypes testing them in approximately 7,000 patients [47–49].

The large number of prototypes and long development process reflected Brain's quest to balance ease of use, efficacy and safety [48, 49]. While one modification improved one aspect of the LMA, it might sacrifice another [48, 49]. For example, increasing surface mucosal contact with the cuff provided greater seal pressure but caused ischemia of the tongue. Also, the use of an insertion device eased placement, but increased the risk of trauma. With clinically acceptable seal pressures of 20 cm H₂O, the cLMA became commercially available in 1988 [49, 51, 52]. Following a demonstration of the new device, Colin Alexander, a British anesthetist and chair at the Royal East Sussex Hospital, acquired the cLMA for his hospital and published his experiences in a letter to *Anaesthesia* [47, 49]. Within 2 years, the LMA was available in every hospital in the UK [34, 48]. It was marketed in Australia and New Zealand in 1989. Ronald Katz at UCLA received a prototype LMA in 1985. He quickly wrote of his experiences, sparking interest in the US [49]. The cLMA had been used in more than 2 million cases when approved by the FDA in 1991 [48, 49]. Commercial release of the LMA in the US occurred in 1992.

British anesthetist, John Nunn, assisted Brain in marketing the cLMA in the UK [47, 48]. US anesthesiologists Jonathan Benumof, Paul White and Andranik Ovassapian paved the way for North American recognition. White and his team demonstrated that the cLMA was a useful airway device for routine anesthetic cases. Ovassapian and Benumof tested its use for "cannot intubate, cannot ventilate" patients. They argued that the cLMA provided a "second-last-ditch" effort for cases of failed intubation when a surgical airway was the only other remaining option [48]. With their influence, the LMA was added to the ASA Difficult Airway Algorithm in 1993, with an expanded role in the 1996 and 2003 algorithms [7–9, 51, 53]. It is currently listed in difficult airway algorithms throughout the world [9]. The American Heart Association's 2000 Guidelines for CPR and Emergency Medicine Cardiovascular Care incorporated the disposable LMA-Unique (uLMA) as an essential airway rescue device [52]. Development of the LMA has been touted as one of the greatest advancements in anesthesia since the advent of the tracheal tube. It has changed airway management in emergency, critical care, and ambulatory medicine, as well as anesthesia. For his efforts, Brain received numerous awards and accolades [4, 47, 48].

Brain revolutionized the use of the supralaryngeal airway, but he was not the first to conceive of the idea [4, 48, 49]. Oropharyngeal airways (1908) and the Fell-O'Dwyer apparatus (1882) took advantage of placing the tip of an artificial airway into the pharynx rather than the trachea. Some argue that the Leech Gasway (1937) was father to all supralaryngeal airway devices, including the LMA [2, 4, 34]. Brain's

device differed in a crucial attribute—its approach to sealing the airway. While the LMA used a soft inflatable “mask over the larynx” whose tip is positioned in the esophagus, at least one previous device surrounded the tube at the glottic opening with a solid plug [2, 4, 34].

While some supralaryngeal airway devices were similar to Brain’s LMA design, others resembled a tracheal tube that enabled pulmonary ventilation without passing through the vocal cords. In 1968, Don Michael developed the first of such devices, the Esophageal Obturator Airway. It had a distal balloon blocking the esophagus and sixteen holes for ventilation between this and a proximal balloon. Difficulties arose in using the Esophageal Obturator Airway and comparative studies with tracheal tubes revealed no advantages, thus the device disappeared [34, 54, 55].

Austrian internist, Michael Frass, with Reinhard Frenzer and Jonas Zahler envisioned a need for an airway device that could ventilate the lungs regardless of whether the device entered the glottis or esophagus. In 1987, they invented the Esophageal Tracheal Combitube (Fig. 54.6), a device with two lumens separated at the proximal end, allowing attachment of the airway circuit to either [52, 54–56]. The esophageal lumen is closed at the tip and has eight perforations between a proximal and a distal cuff. The alternative lumen, the tracheal lumen, is open at the end and when placed in the glottis, functions essentially as a tracheal tube. Thus, regardless of where the device is positioned, the Esophageal Tracheal Combitube provides a patent airway. No time is lost to repositioning, making it particularly useful in prehospital and emergency care settings, where time may be crucial [52, 54–56].

Developed in 2003, the EasyTube was functionally the same as the Esophageal Tracheal Combitube but had a smaller tip and the pharyngeal cuff had a lower volume. The redesigned pharyngeal aperture allowed for easier passage of a flexible fiberoptic bronchoscope, gum elastic bougie or tracheal suction catheter and uses polyvinyl chloride in the large oropharyngeal cuff [34, 52, 56]. Both devices are included in guidelines for difficult airway management and emergency resuscitation throughout the world [9].

Similar in appearance to the Esophageal Tracheal Combitube, the King Laryngeal Tube (King LT) is a supralaryngeal airway device introduced in Europe in 1999 by VBM Medizintechnik. Redesigned by King Systems, it received FDA approval in 2003 [56]. It differs slightly from other supralaryngeal airways in that it consists of a reusable, dual-cuffed single-lumen tube with a blind distal tip. Two anterior ventilation outlets between the low-pressure distal (esophageal) and proximal (oropharyngeal) cuffs allow the device to function as a supralaryngeal airway. Unlike the Esophageal Tracheal Combitube or EasyTube, both cuffs are inflated through a single valve [52, 55, 56]. The King LT can be used during both positive pressure ventilation and spontaneous ventilation. The King LTS (reusable) and King LTS-D (disposable)

devices released in 2003 added an opening in their distal tip for esophageal access. Like the pLMA, the King LTS and LTS-D allow for passage of a gastric tube. The King LT family of devices has gained popularity in emergency medicine and prehospital care settings [52, 55, 56].

Laryngoscopy, Laryngoscopes, and Tracheal Tubes

Initial visualization of the larynx occurred outside the operating room, and was prompted by curiosity concerning

voice production. In 1829, Benjamin Babington, a British physician, used sunlight reflected off a hand mirror and a small mirror attached to the end of a spatula to view the vocal cords in action. A colleague called Babington's device a "laryngoscope" while Babington called it a glottiscope. He reported his findings to a disbelieving Hunterian Society, his peers certain that the vocal cords could not be seen in a living person [57, 58].

A quarter century later, Manuel Garcia, a famous singing teacher at the Royal Academy of Music in London, wanted to see his own vocal cords. Benefiting from naturally obtunded gag reflexes, Garcia performed laryngoscopy of his active vocal cords using a dental mirror positioned in his oropharynx and a hand mirror to simultaneously reflect light and visualize the image in the dental mirror. He meticulously documented observations of his vocalization and that of others, and in 1855, presented his results to the Royal Society. This time, indirect laryngoscopy was met with interest [33, 58–60].

After witnessing Garcia's demonstration, Austrian neurologist, Ludwig Turck, began using laryngeal mirrors in his hospital practice. Attaining indirect laryngoscopy was cumbersome, often requiring cooperative patients to assist with a self-applied tongue depressor and/or forceps, while Turck positioned the mirrors. Turck claimed to see the mucosal surface of the posterior tracheal wall, the bifurcation of the trachea and even the first six circular cartilages of the bronchi in optimal cases. His colleagues considered these assertions exaggerated [33, 58–60]. Hungarian physiologist and physician, Johann Czermak, expanded the studies of indirect laryngoscopy, popularizing the technique. His work introduced laryngoscopy as a new branch of surgery [58–60].

Tracheal Intubation

Indirect laryngoscopy allowed a view of the glottis but did not immediately lead to tracheal intubation. After Avicenna, tracheal intubation was mostly performed to aid in the resuscitation of drowning victims and to treat patients with diphtheria. In 1796, Herholdt and Rafn described blind digitally assisted tracheal intubation to resuscitate drowning victims, their work receiving little notice until the mid-1980s [61]. In 1788, the British physician, Charles Kite, described a metal orotracheal tube bent like a male urethral catheter, passed blindly through the glottis, and then connected to a bellows [4, 62, 63]. Encouragement by European and British medical societies in the late 18th century prompted development of new airway devices for artificial ventilation. These were widely distributed, primarily for use in victims of drowning. However, experiments performed by Jean Leroy d'Etoilles in the late 1820s, revealed the danger of developing a tension pneumothorax from forced inflation of the lungs caused by the use of the bellows in the resuscitation of drowned victims.

Although Leroy modified the bellows to be safer, the Royal Humane Society retracted their support of artificial ventilation, temporarily delaying the advancement of airway management and the use of positive pressure ventilation [11, 64].

Scottish surgeon William Macewen pioneered elective tracheal intubation for anesthetic delivery [60, 65–67]. In 1878, he practiced blind digitally assisted orotracheal and nasotracheal intubation on cadavers. He abandoned nasotracheal intubation as impractical, probably because of the size and stiffness of his metal tubes [33, 60, 66]. He hoped to deliver anesthetic without contaminating the surgical field and to protect the lungs from aspiration without performing a tracheostomy. Orotracheal intubation would also resolve the conflict between surgeon and anesthesiologist for access to the mouth and airway [1, 33, 61, 66]. He used his index finger to depress the epiglottis and guide a rigid, curved brass tracheal tube of his design [1, 61, 68] over his finger and into the larynx [33]. In July 1878, he performed his first tracheal intubation in a patient undergoing removal of an epithelioma of the tongue, right anterior pillar of fauces and posterior pharyngeal wall [33, 60, 68]. Topical anesthesia awaited discovery, and Macewen practiced several awake tracheal intubations in the unanesthetized patient before the day of surgery [33, 61, 66, 68]. Other than bouts of coughing both during and immediately after placement of the tracheal tube, the patient tolerated the intubation, and Macewen proceeded with anesthesia [33, 60]. With sponges packed into the pharynx to prevent aspiration, the extensive surgical procedure, including sawing through the lower jaw, concluded successfully [1, 33, 60, 66]. The patient maintained spontaneous ventilation and showed no signs of pain [60]. As did others, Macewen advocated viewing the glottis via indirect laryngoscopy to determine oropharyngeal pathology before performing intubation.

Between 1878 and 1880, Macewen described two additional successful tracheal intubations for glottic obstruction [60, 66, 68]. His fourth patient, the second scheduled for anesthesia and surgery following tracheal intubation, resulted in a fatality [33, 60, 68]. Like the first case, the patient had an epithelioma of the tongue—but also had bronchitis [60]. Although Macewen successfully practiced awake intubations in the patient before the day of surgery, on the day of surgery the patient pulled out the tube and pleaded for its placement after induction with chloroform [60, 66, 68]. The patient struggled with induction, and once achieved, Macewen inserted the tube [60, 66]. Within minutes, the radial pulse and spontaneous ventilation ceased [36, 60, 66]. An autopsy revealed cerebral hemorrhage, probably stress-related [36, 66]. This was the last tracheal intubation reported by Macewen [33, 60, 66, 68].

Joseph O'Dwyer, a physician at the Foundling Hospital in New York, found the mortality from diphtheria to be unacceptable. He studied autopsies to define alternatives to tracheostomy [2, 60, 69], and from these investigations

developed the O'Dwyer endolaryngeal tubes. He first used these clinically in 1882 and by 1885 had perfected his skills and tubes. The metal tubes came as a set in a range of sizes and featured a collar, designed to rest within the pharynx against the false vocal cords, to prevent the tube from advancing down the trachea [1, 68]. O'Dwyer is credited with publicizing tracheal (actually endolaryngeal) intubation, albeit not for anesthetic purposes [4, 60].

In 1885, a young woman with known laryngeal stenosis, approached O'Dwyer requesting an alternative to tracheostomy. O'Dwyer accommodated her request, by inserting one of his tubes. Similar cases followed [33]. In 1887, the New York physician George Fell modified his breathing apparatus supplying positive pressure ventilation using a bellows and mask, by attaching it to a tracheotomy tube. Fell's apparatus was specifically used to treat narcotic overdose. Learning of Fell's modifications, O'Dwyer altered his tube to permit controlled ventilation with Fell's device, hence the Fell-O'Dwyer Apparatus [1, 4, 68]. (Fig. 54.7) Theodore Tuffier, a French surgeon, and Rudolph Matas, a Texas and Louisiana surgeon, made further modifications for positive pressure ventilation during intrathoracic surgery [1, 33, 68].

In 1893, Karl Maydl, Professor of Surgery at the University of Prague, suggested that intubation of the larynx, and packing gauze around the glottic opening would prevent aspiration of blood [33, 66]. Although Macewen had advocated this technique, little was known of Macewen's work [33]. Maydl knew however, of O'Dwyer's work and adopted O'Dwyer's intubation techniques for otorhinolaryngological surgical procedures [1, 33, 66].

In 1896, German surgeon Franz Kuhn found that rigidity of existing tracheal tubes was limiting [68, 70]. Using coiled metal similar to that found in spouts of old gasoline cans, he made a tracheal tube that was flexible, yet resisted compression [36, 68, 70]. Like Macewen, Kuhn performed blind, digitally-assisted awake tracheal intubation with the aid of a rigid curved introducer [60, 68, 70]. His method was easier than Macewen's because topical anesthesia with cocaine had been discovered. Topical anesthesia allowed great advances in nasotracheal intubation after World War I [1, 66, 70].

Kuhn surrounded his tracheal tube with a supralaryngeal flange to prevent over-insertion [60, 66, 68]. Kuhn acknowledged the existence of tracheal tube cuffs but preferred to pack the larynx with oil-soaked gauze [30, 36, 60, 68] which also helped secure the tube in place [60]. Kuhn pioneered suctioning of tracheal blood and secretions [68, 71]. Most tubes at this time were narrow and were used for insufflation (blowing air plus ether or chloroform vapor into the trachea). He preferred larger tubes because they allowed bidirectional respiration. During World War II, English prisoners of war found Kuhn's technique and tracheal tubes beneficial. One

Fig. 54.7 Modified O'Dwyer's tubes intended for insertion into the larynx. Combined with Fell's foot bellows and air hose, they comprised the Fell-O'Dwyer apparatus. (Courtesy of Science Museum London/ Science and Society Picture Library, London, England)

advantage touted for this technique was that batteries which were in short supply were not required [30, 60].

In 1902, Kuhn pioneered nasotracheal intubation in living patients [66, 69, 72]. He argued that the anatomy of the nasal route provided a more direct approach to the glottic opening [66], prevented the tracheal tube from being bitten, and left the mouth unoccupied [66, 68]. However, he ultimately viewed orotracheal intubation as better suited to his patients' needs, probably because the metallic composition of his tubes might traumatize the nasal mucosa despite its flexibility [66].

Before 1900, placement of a tracheal tube usually required a blind digitally assisted orotracheal intubation, a difficult maneuver requiring extensive practice and involving significant risk to the intubator whose finger might be bitten and become infected [2, 36]. Widespread use of blind nasotracheal intubation awaited development of soft flexible tracheal tubes. The introduction of direct laryngoscopy during the 1910s overcame these limitations.

Fig. 54.8 Alfred Kirstein's "Autoscope". (From [73])

Laryngoscopy

Direct laryngoscopy originated with Alfred Kirstein's 1895 article describing his "autoscope" (Fig. 54.8) [58, 73, 74]. A colleague's accidental placement of an esophagoscope into the trachea sparked Kirstein's interest. Initially, he directly visualized the larynx by shortening an esophagoscope and attaching an electric lamp to the handle, deflecting light down the lumen by a prism taken from Caspar's electroscope. The enclosed "O" shape of this original autoscope limited the view of the glottis, leading to a redesigned blade with an open crescent shape and an improved distal width and thickness for direct or indirect positioning of the epiglottis [33, 59, 68]. Notwithstanding this work, Kirstein never performed tracheal intubation or bronchoscopy. But in 1897, his student, Gustav Killian, used the autoscope to extract a foreign body from a patient's bronchus. This case and his subsequent work made Killian the "father of bronchoscopy." [59]

By 1910, Chevalier Jackson had invented a U-Shaped direct laryngoscope (Fig. 54.9) for examining the esophagus and airway. He became renowned for his ability to remove foreign bodies from the airway, and patients came from all over the world to obtain his services—often performed at little to no cost to the patient. In 1912, Charles Elsberg used the Jackson laryngoscope for tracheal intubation and insufflation. This prompted Jackson to publish a paper advocating examining vocal cords for pathology before intubation and ascertaining the proper size of tube to be used. His work furthered the popularity that laryngoscopy gained over the succeeding decades [15, 75, 76].

Fig. 54.9 Chevalier Jackson's U-shaped laryngoscope. (Courtesy of Sheffield Teaching Hospitals NHS Trust Dept of Anaesthesia, Sheffield, UK)

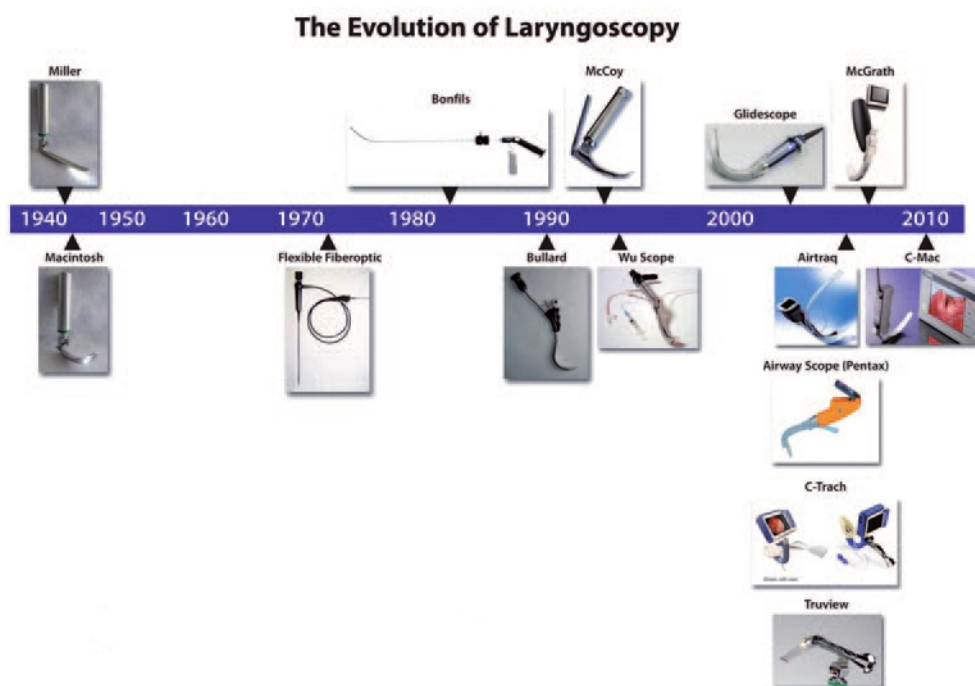

Appreciating the benefits of illumination, Jackson added a light bulb to the distal end of the blade. Cords from a large dry cell battery powered the light, which, however, added the risk of an explosion if a short circuit caused a spark in the presence of ether. Nonetheless, this Jackson laryngoscope gained great popularity over the next three decades [1, 59, 60, 68]. New York anesthesiologist, Henry Janeway, solved the sparking problem in 1913 with a laryngoscope powered by batteries located in the handle, but his laryngoscope never achieved the popularity of Jackson's [60, 68].

Laryngoscope blades remained largely unchanged until Robert Miller and Robert Macintosh described their inventions for direct and indirect elevation of the epiglottis in the 1940s. Blades did evolve (Fig. 54.10). Straight blades are traditionally called Miller-type blades, but the straight blades devised by Magill, Flagg and Guedel all predate Miller's [59]. Miller introduced his modification in 1941. In 1943, Macintosh developed a curved blade which when placed into the angle made by the epiglottis and the base of the tongue indirectly lifted the epiglottis, potentially reducing the risk of trauma. Macintosh contended that the blade could be used at a lighter level of anesthesia (perhaps because it caused less stimulation of the epiglottis.).

It became apparent that patient position affected the ease of tracheal intubation. Initially, patients assumed the sitting position, useful in awake patients but problematic in anesthetized patients. In 1913, Jackson advocated the "classical position" placing the patient supine on a flat surface with the head and neck fully extended. In 1933, he amended this to have patients "sniffing the air" (aka, "sniffing position"): head extended with the neck flexed, accomplished by placing a 10 cm thick pillow underneath the head [59].

In 1944, British anesthetist Freda Bannister and British otolaryngologist Ronald MacBeth proposed a theory of best position for visualisation of the larynx, defined by three longitudinal axes: the oral, pharyngeal and laryngeal axes. From

Fig. 54.10 Evolution of laryngoscopy. (From *Anesthesia & Analgesia*, April 2010 journal cover, with permission)

radiographic studies they confirmed Jackson's conclusion that the sniffing position created the ideal position by aligning these axes [59]. In 1964, Frederic Adnet and colleagues reviewed the original radiographs, and obtained new images, concluding that the classical position produces optimal positioning [59]. This debate continues.

While the art of direct laryngoscopy blossomed, major advancements were also made in the techniques and tubes used for nasotracheal intubation. In 1919, British anesthetist Ivan Magill, and his colleague Edgar Rowbotham, an anesthetist in the Royal Army Medical Corps, were stationed at the Queen's Hospital for Facial and Jaw Injuries. They managed patients undergoing prolonged surgeries requiring a secure airway that did not obstruct surgical access [1, 36, 72, 77]. Anesthesia for these patients had been ether in oil administered rectally. Beyond the drawbacks of prolonged induction and emergence plus minimal control over the depth of anesthesia, this approach left the airway unprotected [1, 68, 78].

Insufflation offered a better solution. A narrow tube was inserted via the mouth or nose through the glottic opening. Anesthetic vapor delivered via this tube was inspired, and, escaped around the tube [4, 68, 77]. The surgeons appreciated the more secure airway and greater control over anesthesia, but were not enthralled with vapor-laden air blown into their faces or blood occasionally sprayed from the surgical site [68, 77, 78]. However this technique required that the insufflated air freely escape to avoid a fatal pneumothorax. The means to assure such an escape while also diverting the

excess became apparent in 1922. A facial deformity prevented air from properly escaping, leading Magill and Rowbotham to pass a second tube through the nose into the trachea parallel to the first one. The benefit of this "exhaust" tube was immediately obvious [77].

Magill and Rowbotham adopted this two-tube intubation system for routine cases using either another insufflation catheter or Silk's wide-bore rubber pharyngeal tube [67, 71, 77]. This second, exit tube allowed the surgeons to pack the pharynx with gauze to protect against aspiration [1, 4, 66]. Magill and Rowbotham learned that placing the semi-rigid insufflation catheters in hot water softened them, decreasing nasal trauma during insertion [66, 68, 72]. Nasotracheal intubation became standard practice.

In New York, Paluel Flagg learned of Magill's and Rowbotham's two-tube system and concluded that one wide-bore tube should work equally well. The result was Flagg's tracheal tube: a single, wide-bore tube useful for either orotracheal or nasotracheal intubation [78]. Unaware of Flagg's work, Magill reached a similar conclusion in 1928. Magill sought a tube allowing for bidirectional airflow and rigid enough to hold the curve necessary for nasotracheal intubation without traumatizing nasal tissues [68, 72, 77]. The solution came to him in a local hardware store selling rubber gas tubing [72]. The natural curve in the tubing formed by their storage in coils was ideal for passage through the nose [67, 71, 72]. He customized the length of each tube to each patient—twice the distance from the tip of the earlobe to the tip of the nose. He beveled the tip, lubricated its

surface with paraffin wax and smoothed it with emery sandpaper [67, 72, 77]. It took him several years to secure a company to manufacture stiffer mineralized rubber tubes to his specifications [77]. Between 1928 and 1932, his method of tracheal anesthesia, coinciding with his introduction of the “Magill circuit” (later known as the Mapleson A breathing system), gradually replaced insufflation [66, 71, 77].

Magill and Rowbotham perfected their technique for blind nasotracheal intubation. They rediscovered the advantages of airway cocaine, which allowed tracheal intubation with the patient awake or lightly sedated [68, 72, 77]. As they practiced their skills, they noticed that as it left the nasopharynx, the tracheal tube naturally entered the trachea [68, 72, 77, 78]. To deal with circumstances when this failed, Magill designed curved forceps (aka Magill forceps) used to guide the tracheal tube tip into the glottis, facilitated if necessary by laryngoscopy [60, 66, 77]. Because blind awake nasotracheal intubation required frequent use and practice to perform well, the technique initially met resistance. Acceptance gradually increased in the 1930s [36, 60, 77]. Until the 1980s, blind nasotracheal intubation was an essential skill needed to circumvent difficult or contraindicated laryngoscopy, but the advent of fiberoptic endoscopy eliminated this need.

In the 1940s, Francis Murphy, Chief Anesthesiologist at the University of California San Francisco, designed tubes with a rounded tip to prevent the tip from catching on the vocal cords, as bevel-tipped tubes often did. In addition, the rounded tip had one or two small side holes, referred to as Murphy eyes, which allowed continued ventilation if the distal opening abutted the tracheal or bronchial wall. The famous Murphy eye exists in the design of many later tracheal tubes [36, 79].

Cuffed Tracheal Tubes

Maydl protected against aspiration of surgical debris and/or gastric contents by surrounding the orotracheal tube with oil-soaked gauze as it passed through the oropharynx. In 1893, Austrian physician Victor Eisenmenger added an inflatable cuff, like the one used with Trendelenburg’s tracheostomy tubes, to his curved tracheal tube made of hard rubber [1, 4, 33, 66]. In 1898, Dutch physician WJ van Stockum, aware of both Maydl’s and Eisenmenger’s work, constructed a wide-bore tracheal tube fitted with an inflatable cuff. He combined both techniques, packing the airway with a collar of sponges above an inflated cuff [33, 66]. Over the next three decades, reports of cuffed tracheal tubes would appear and disappear, but had little practical impact, perhaps because of the lack of a significant market.

Fig. 54.11 “Airway” the subject of the Dunked Dog Experiment. (Courtesy of Guedel Memorial Center, San Francisco, CA)

In the early 1900s, approximately 100 physicians regularly practiced anesthesia in the US [68]. Only otolaryngologists performed intubations, usually for emergency purposes [68]. Not until the 1930s, when the work of Guedel and Waters became known, did the use of cuffed tracheal tubes become common as pathways for anesthetic delivery. Anesthesia needed to emerge as a specialty chosen by increasing numbers of physicians.

Guedel made his first cuffs by gluing the fingers of surgical gloves, and later condoms, to the outer wall of a tracheal tube [39, 68]. He experimented with position: the cuff above, below and at the level of the vocal cords, concluding that just below the cords provided the best seal of the airway and allowed access to fluid that might accumulate above the cuff [39, 68]. The design for the cuff, however, eluded him until Waters recommended a detachable cuff made of two layers of soft rubber cemented together at the edge, allowing it to easily slip over the end of the tracheal tube. And a detachable cuff could be replaced if it malfunctioned [67, 68].

By 1928, Guedel and Waters became satisfied with their cuff and began exhibiting its use. Initially, Guedel demonstrated its effectiveness and safety by filling an anesthetized patient’s oropharyngeal cavity with water following intubation and cuff inflation. He would remove the water with suction before extubation. Unfortunately, during the second demonstration, his assistant neglected to apply suction, and the patient experienced bronchospasm from inhaling the water [39, 40, 68].

Guedel subsequently performed experiments on his dog, “Airway”. He anesthetized and intubated Airway’s trachea, connected the tracheal tube to a Waters carbon dioxide absorption canister and rebreathing bag, and placed Airway under water in an aquarium. He performed the first public “dunked dog” experiment (Fig. 54.11) in 1928, at the Indiana University School of Medicine. Airway was submerged for

an hour. He was then removed from the tank and allowed to awaken. He showed that he was unharmed by shaking-off on the audience. He then pranced out of the room for an afternoon nap. This “dunked dog” experiment became a popular display that introduced carbon dioxide absorption and cuffed tracheal tubes into clinical practice [36, 39, 40, 60, 68]. After retiring from show business, Airway happily lived out his life at the Waters’ family home [39].

While tracheal intubation protected patients’ lungs from aspiration once the cuffed tracheal tube was placed, they were at risk prior to intubation. To reduce this, in 1961, British anesthetist Brian Sellick, suggested applying pressure to the cricoid cartilage during induction [63, 80]. This “Sellick maneuver” (or simply cricoid pressure) was not original to Sellick. In the eighteenth century, Charles Kite and James Curry suggested the application of cricoid pressure to prevent air from entering the stomach of drowning victims during their resuscitation. In contrast, Sellick hoped to prevent the gastric contents from entering the lungs [63].

By the time Sellick had developed this maneuver, it had already been recognized that aspiration of acidic gastric contents had disastrous consequences, particularly in obstetric patients and non-fasting patients requiring emergency surgery [63]. Correctly applied, Sellick’s maneuver obliterated the esophageal lumen and prevented ejection of stomach contents [63, 80]. Sellick warned against performing his maneuver in an actively vomiting patient because the resulting high pressures in the esophagus might rupture the esophagus [80]. With this caveat, “Sellick’s maneuver” was quickly adopted internationally [63]. Although the effectiveness of cricoid pressure is currently debated, it has continued as standard practice for over 50 years in the performance of rapid sequence or modified rapid sequence induction of general anesthesia.

The limited supply of rubber during World War II prompted the evolution from reusable rubber tracheal tubes to disposable plastic tubes. In 1940, Sydney Leader, a London dental surgeon, started the company, Portland Plastics, later Portex. He sought to replace the ceramic and glass used in medical and dental equipment with plastic. He began producing plastics, such as polyvinyl chloride, polyethylene and acrylic as substitutes for the natural rubber and shellacs used in dentures, artificial eyes and flexible dental tubing [67, 71].

Working with Major HL Thornton of the Royal Army Medical Corps, Leader substituted disposable polyvinyl chloride for rubber tracheal tubes, publishing reports on the first clinical trials in 1944 [71]. Initially, Leader supplied lengths of polyvinyl chloride tubing which anesthesiologists customized for each patient. Eventually, Portex marketed tubes with predetermined specifications [71]. Polyvinyl chloride tubes quickly replaced rubber tubes because polyvinyl chloride tubes were less apt to kink (occlude) when bent to acute angles; and polyvinyl chloride softened as it

warmed to body temperature, molding to the shape of the airway, thereby reducing pressure on laryngeal and tracheal tissues [67, 71].

An American, David Sheridan, contributed to the evolution of disposable tracheal tubes because of his concern that cross-contamination increased the risk of infection. Sheridan had to learn how to extrude plastic, which he originally did in his home. He pioneered the addition of centimeter markings on the tube to assist in determining the insertion depth. This decreased the risks of both accidental bronchial intubation and inadvertent extubation [68].

Advancements in disposable tracheal tubes continued with the introduction of the polyvinyl chloride cuff in 1964. The original version copied the less than ideal thickness and spherical shape found with older rubber cuffs [67, 71, 81]. Around the same time, polyvinyl chloride was shown to allow prolonged intubation with minimal injury to airway tissues. Tissue injury still occurred due to high intracuff pressures leading to the introduction of high-volume, low-pressure cuffs by Niels Lomholt in 1967 [71]. In 1969, Benny Geffin and Henning Pontopiddan found that pre-stretching the standard polyvinyl chloride cuff in boiling water produced a thinner cuff that better adapted to airway contours and decreased injury to tracheal tissue. By 1973, the cuff became more oblong, larger in diameter and decreased in thickness [67, 71].

Although these modifications decreased the incidence of tissue damage, injury still occurred during prolonged intubation. In 1975, British anesthetists Brian Crawley and David Cross, sought techniques that further reduced tracheal tissue damage yet maintained protection against aspiration. They introduced the concept of minimal intracuff pressure [67, 71]. The 1977 research of U Nordin found that intracuff pressures exceeding 40 cm H₂O caused tissue damage. By 1984, this value was reduced to 30 cm H₂O [71].

In the 1950s and 1960s, the ventilation paradigm for delivery of general anesthesia switched from spontaneous ventilation via a mask, to positive pressure ventilation via a tracheal tube [20, 65]. This was an essential development for the advancement of thoracic surgery and the associated need for one-lung ventilation [65].

When intrathoracic surgery began, no provision existed to prevent potentially lethal lung collapse. Although drowned victims had long benefited from artificial respiration with bellows, thoracic surgery was performed with the patient spontaneously breathing. Surgical speed and dexterity favored survival, but if the surgery could not be completed before the lung(s) collapsed, the patient died [64]. Much of the apprehension in using artificial respiration throughout the medical community, including use in thoracic surgery, came from the adverse reports of Leroy d’Etoilles regarding the risk of pneumothorax [64]. Consequently, surgeons accepted costly and/or inconvenient solutions [82].

To preclude lung collapse, in 1896, Ernst Sauerbruch, a German thoracic surgeon, developed the Sauerbruch Box, a negative-pressure chamber housing the body of the patient, as well as the surgical team. The head of the patient and the anesthesiologist remained outside the box at normal atmospheric pressure. This was considered a great feat for intrathoracic surgery. Surgeons using the Sauerbruch Box could take more time to carefully perform surgery, dramatically decreasing the overall mortality rate [36, 64, 82].

Sauerbruch's colleague, Ludolf Brauer, developed a positive pressure chamber to maintain lung expansion. Brauer placed just the patient's head into a box and pumped in pressurized oxygen and chloroform from a Roth-Drager apparatus. Of course, with the chest open the patient could not breathe, so the delivery of anesthetic was irrelevant. Clinically, the results were the same as with Sauerbruch's box, but using positive pressure added advantages of smallness and greater portability [64].

The inconvenience of these devices ultimately caused surgeons and anesthesiologists to return to tracheal intubation. This cheaper, convenient solution initially was used to insufflate gases and later used to produce positive pressure controlled ventilation. Franz Kuhn of Germany, Rudolph Matas and FW Parham of the US, and Theodore Tuffier of France pioneered this evolution. Kuhn, Tuffier and Matas modified the Fell-O'Dwyer apparatus to provide tracheal anesthesia for patients undergoing thoracic surgery. The pharynx was packed to form an air-tight seal, and the tracheal (actually endolaryngeal) tube was connected to a bellows providing positive pressure ventilation [4, 33, 66, 82].

In 1899, Matas experimented with the modified Fell-O'Dwyer apparatus in animals paralyzed with curare [1, 83]. In fact, Matas believed O'Dwyer's intubation system was so ingenious, he wrote "O'Dwyer's resurrection of...intubation and his magical transformation of the bloody and tragic picture of tracheotomy in diphtheria into a simple, painless, and bloodless bit of technical jugglery by his perfected method of intubation has practically closed for all time one of the most conspicuous chapters in the history of surgery." [64] Matas believed "The procedure that promises the most benefit in preventing pulmonary collapse in operations of the chest is the artificial inflation of the lung and the rhythmical maintenance of artificial respiration by a tube in the glottis directly connected with a bellow." [64] Matas' colleague, Frederick Parham, applied Matas' work to humans and reported on a comparison of two patients for the removal of intrathoracic tumors, one anesthetized via open drop ether versus a second where anesthesia was delivered via the Fell-O'Dwyer apparatus. In the first case, the lungs collapsed and the patient nearly died. In the second case, the open drop technique was initially used, but Parham then intubated the trachea using a modified Fell-O'Dwyer apparatus. Surgery

proceeded with greater ease than in the first case [1, 83]. Despite this, it would take almost 30 years for Matas' work to enter clinical practice [64].

Providing controlled positive pressure ventilation required the thoracic surgeon to operate on moving (ventilated) lungs. In 1931, Waters and Joseph Gale accidentally placed a standard tracheal tube into the right main bronchus. They immediately recognized that such placement offered the benefit of one-lung ventilation [4, 68, 82]. Learning of his friend's "misadventure", Guedel proposed the construction of a double-cuffed, elongated tracheal tube to isolate the ventilation of the right and left lungs. Emory Rovenstine later put the idea into practice [4, 68, 82].

Magill moved from facial to thoracic anesthesia, in 1936 describing insertion of a cuffed catheter into the bronchus of the operated side. Inflation of the cuff would close off the main bronchus, allowing tracheal anesthesia to and suctioning of the other lung. Thus was born the bronchial blocker. He preferred this method of one-lung ventilation because it could be extended to cordon off just the lower lobe for lobectomies [36, 77, 78, 82].

Now consider the invention of the double-lumen tracheal tube, two long D-shaped tracheal tubes fused together. One of the D-shaped tracheal tubes extends into a main bronchus and has a cuff that fits in the bronchus, allowing ventilation of the lung served by that bronchus. The opening of the second D-shaped tracheal tube ends (if the tube is placed properly) in the trachea, just above the carina. A cuff just proximal to this opening surrounds both D-shaped tracheal tubes just as would a cuff on an ordinary tracheal tube. This array allows ventilation to be limited to one lung or both [81]. In 1949, Eric Carlens, a Swedish physiologist, designed the first double-lumen tube for use in bronchspirometry [36, 82]. By 1950, he and Bjork had modified the tube specifically for use in anesthetized patients undergoing intrathoracic surgery [68, 82, 84]. His tube included a hook designed to sit on the carina to ensure proper placement, stabilize the tube, and prevent dislodgement during patient movement [81, 82, 84]. In 1962, Frank Robertshaw designed the double-lumen tracheal tube commonly used today, differing from Carlens' tube by removal of the carinal hook [36, 69, 82]. Special versions of both tubes have been developed for positioning in the right main bronchus to prevent occlusion of the right upper lobe bronchus [81].

In 1982, Hiroshi Inoue invented the Univent Tube, a tracheal tube providing a separate catheter passing via the main lumen into the bronchus to be blocked. The separate catheter had a cuff for bronchial blockade and a channel that permitted suction or high-frequency jet ventilation [81, 82].

Like thoracic surgery, otorhinolaryngeal surgery, surgery involving the mouth or nose, can pose special challenges. The standard tracheal tube may impair the surgeon's view. To solve this problem, British anesthetist, Alsop devel-

oped the right angled “Oxford” tube in 1955. Sylvia Duckworth published the experience with 18,000 cases in 1962 [83]. Improving on these rigid rubber tubes, Utah pediatric anesthesiologists, Wallace Ring, John Adair and Richard Elwin invented RAE tubes, pre-shaped tracheal tubes bent to hug the chin or nose. They performed 10,000 intubations with their prototype before publishing their results in 1975 [81, 85]. Since the introduction of plastic in the early 1960s, more diverse airways and tracheal tubes have been invented and produced than can be discussed here [81].

As tracheal intubation became the standard of care for most surgeries, a problem arose; not all patient’s tracheas could be successfully intubated using direct laryngoscopy. For such patients, a tracheostomy was often their only option. In 1960, New York surgeons Frank Butler and Anchise Cirilo, suggested an alternative technique, retrograde intubation [86–88]. In 1963, D Waters, a British anesthetist at the University of Ibadan in Nigeria, performed retrograde intubation in a patient with “cancrum oris” (gangrenous condition of the oral cavity). Through a Tuohy epidural needle passed through the cricothyroid membrane, he threaded an epidural catheter back into the nasopharynx. Waters retrieved the catheter from the nasopharynx and used it as a guide for delivering the tracheal tube through the nose into the trachea [87, 88].

The invasiveness and potential complications from puncturing the cricothyroid membrane limited the popularity of retrograde tracheal intubation [87, 88]. By the mid-1990s, studies showed that retrograde intubation was an easy and reliable technique; however, only approximately 500 cases had been reported, over half in cadavers [87]. Despite its infrequent use, retrograde intubation was incorporated into the ASA Difficult Airway Algorithm in 1993 [8, 34, 88]. In 1990, with the assistance of Antonio Sanchez, a California anesthesiologist, Cook Critical Care developed a preassembled kit for retrograde intubation [88, 89]. It has been successfully used in human patients, and was adapted for use in a llama when Sanchez consulted at the San Diego Zoo [90].

Intubating Stylets

As mentioned previously, the intubating stylet, or gum elastic bougie, provided another tool for guiding the tracheal tube into the glottic opening. The Portex Venn Tracheal Tube Introducer, previously known as the Eschmann Endotracheal Tube Introducer, is commonly referred to as a gum elastic bougie—a misnomer, as it is neither made of gum elastic nor used as a bougie (a dilator). In 1973, Paul Venn, a British anesthetist and advisor to the original Eschmann company, developed the tracheal tube introducer. Venn was inspired by Robert Macintosh’s 1949 report of tracheal intubation using a real gum elastic bougie, a urinary catheter made of

gum elastic and originally intended for dilating urethral strictures [91–93]. Several other intubating guides/stylets act like the Portex Venn Tracheal Tube Introducer, but are made of different materials and have different features. Most of these guides and stylets are disposable, including the present Portex Venn Tracheal Tube Introducer.

Macintosh did not invent the intubating stylet. O’Dwyer, Kuhn and Maydl used curved metal stylets around a hundred years ago [33, 68, 69]. During World War I, Rowbotham designed a “guiding rod” to facilitate nasotracheal intubation [36, 68, 69]. In 1941, Murphy used a metal stylet to keep tracheal tubes rigid while intubating under direct laryngoscopy [79]. The malleable stylet continues to be a part of routine tracheal intubation and is an essential adjunct to many alternative intubating devices.

In 1957, Macintosh and his colleague, Harry Richards, described the lighted tracheal tube introducer, a device they used to assist tracheal tube placement during direct laryngoscopy [93]. However, they did not describe the technique of trans-illumination. This fell to Hideo Yamamura and colleagues, who in 1959 described trans-illumination (the transmission of a bright light from the tip of a catheter, visible through the skin of the neck, thus indicating the location of the catheter tip) during nasotracheal intubation.⁹³ Since then, lighted stylets or “lightwands” have been used to assist blind intubation during difficult and routine airway management [89, 93].

Lighted stylets for trans-illumination increased in popularity after 1977, when British anesthetist CA Foster had a special trans-illuminating fiberoptic bundle designed to facilitate tracheal intubation in a young child with trismus [93, 94]. (In 1978, M Ducrow used a flexible surgical light, the Flexi-lum, to achieve the same result. After achieving trans-illumination with the lighted stylet, Ducrow passed a guide (two plastic suction catheters connected end to end) into the trachea followed by passage of the tracheal tube over the guide. It was not until a year later that it was noted that the Flexi-lum could be placed inside the tracheal tube, thus acting as a guide for the tube. The Flexi-lum became the first commercial lightwand [93–95]. In 1986, the Flexi-lum evolved into the Tube-stat which included a sleeve surrounding the bulb designed to prevent bulb loss/detachment. Although originally limited to use in children, a longer, more flexible version was developed for adult nasotracheal intubation [93–95].

Despite growing interest in these devices, limitations, such as diminished light intensity, short length, and absence of a connector to secure the tube, became apparent [93]. Released in 1995 for blind intubation, the Trachlight was designed to overcome limitations of the previous devices. It consisted of two pieces, a reusable handle with an internal light source and a disposable, retractable stylet providing rigidity during insertion but flexibility during withdrawal [93–95]. Several other lighted stylets have since been introduced and removed

from clinical practice [94]. However, limited transmission of light especially in obese patients with thick necks remains as a limitation of the technique.

In 1969, Peter Murphy, a British anesthetist, introduced the optical stylet, a flexible fiberoptic choledochoscope that he used to aid in nasotracheal intubation of a patient with Still's disease [59, 96]. Optical stylets further evolved in 1979 when George Berci and Ronald Katz, published the use of a straight endoscope as a tracheal tube stylet that featured a proximal viewing element and a sliding tracheal tube adapter with a Luer-lock inlet through which oxygen or air could be insufflated [59, 96]. This publication coined the term "optical stylet" [96].

Fiberoptic Devices

Flexible fiberoptic intubation continued the evolution of advances in airway management, particularly for viewing the airway and introducing tubes into the airway. Bronchoscopy dates to 1887, when Gustav Killian devised a rigid bronchoscope to extract a foreign object from the respiratory tract of a farmer. In 1904, his student, Chevalier Jackson, added a distal tungsten light bulb and suction channel [97]. John Baird, a Scottish electrical engineer and pioneer of fiberoptics, television and radar technology, conceived of fiberoptic bronchoscopy in the late 1920s. His patented idea used hollow, thin, flexible, glass rods bundled together in a honeycomb-type collection that transmitted images by internal reflection down their entire length. Not requiring a lens or mirror, fiberoptic devices could be much smaller than their predecessors [98]. In 1954, fiberoptic technology made its way into the medical field, when Basil Hirschowitz, a Michigan gastroenterologist, developed the first fiberoptic endoscope [4, 98].

Shigo Ikeda, a Japanese thoracic surgeon and "father" of fiberoptic bronchoscopy proposed the concept of using fiberoptic technology for flexible bronchoscopy, to the Machida Endoscope Company in 1964, and then the Olympus Company in 1965 [99, 100]. Based on Ikeda's recommendations, Machida Endoscope developed the first prototype of the flexible fiberoptic bronchoscope in 1966. It was initially used in conjunction with a rigid bronchoscope [5, 100]. One month later, Olympus developed its own flexible fiberoptic bronchoscope, a stand-alone device that included a maneuverable working channel allowing the use of cytology brushes. Ikeda described his work at the International Congress on Diseases of the Chest in 1966, and reported on his new flexible fiberoptic bronchoscope in 1971 [100, 101].

In 1972, a flexible fiberoptic bronchoscope was used for nasotracheal intubation in a patient in whom rheumatoid arthritis had precluded orotracheal intubation [102]. In 1972, California anesthesiologist Claire Stiles and colleagues published a report of the first 100 cases using flexible fiberoptic

bronchoscopy for tracheal intubation, demonstrating that intubation could be performed in less than 60 seconds, making it a viable option for difficult intubations [103]. The use of flexible fiberoptic bronchoscopy expanded to include the confirmation of tracheal tube positioning, [104] placement of left-sided and right-sided double-lumen bronchial tubes, [105, 106] and evaluation of the upper and lower airway. Andranik Ovassapian was a pioneer in teaching the proper use of flexible fiberoptic bronchoscopy, especially for awake tracheal intubation, creating workshops for training and simulation that were critical in accomplishing its universal acceptance [51, 107].

Specialized oropharyngeal airways were developed to offer all the benefits and simplicity of the traditional oropharyngeal airway during flexible fiberoptic intubation [108, 109]. They protected the flexible fiberoptic bronchoscope from physical damage from teeth, offered a clear passageway for the flexible fiberoptic bronchoscope, and aligned the tracheal tube with the glottic opening [34, 108, 109].

Transtracheal Ventilation

In the rare patient, after induction of anesthesia, adequate airway and ventilation cannot be established. Time is needed to allow the patient to awaken and recover their airway control. If supraglottic airway devices, such as the LMA, are inappropriate or unsuccessful, the anesthesiologist has two options—surgical/percutaneous airway or the less invasive transtracheal jet ventilation [34].

Robert Hooke in 1667 and Meltzer and Auer in 1909 demonstrated transtracheal ventilation of paralyzed dogs [66, 110]. Ohio anesthesiologist Jay Jacoby and colleagues revisited the idea in 1951, examining the safety and efficacy of oxygen insufflation through a 13 gauge transtracheal needle in dogs [110]. In 1956, Jacoby and colleagues performed transtracheal resuscitation in an anesthetized patient with complete respiratory obstruction [111]. Oxygen insufflated via a cricothyrotomy catheter provided adequate oxygenation but caused carbon dioxide retention. In 1971, Spoerel and coworkers introduced the concept of intermittent jet ventilation via a percutaneous transtracheal catheter in adults undergoing general anesthesia [112]. Jonathan Benumof, became a strong advocate of transtracheal jet ventilation as a life-saving technique. His 1989 review encouraged all US hospitals to stock the jet ventilation equipment needed for the unexpected "cannot intubate, cannot ventilate" scenario, including how to accomplish emergency jet ventilation when appropriate kits were unavailable [113]. He ensured inclusion of transtracheal jet ventilation in the ASA Difficult Airway Algorithm [7–9].

Airway Exchange Catheters

Placement of a tracheal tube, especially a cuffed tracheal tube, secures the airway. What should be done if the tracheal tube requires exchange in the patient whose trachea was difficult to intubate? This issue led to invention of airway exchange catheters.

In 1978, Brendan Finucan and Hilton Kupshik at Emory University in Georgia performed a blind awake nasal intubation in a patient with an unstable cervical fracture. After beginning anesthesia, they discovered a significant cuff leak requiring tracheal reintubation. Having just placed a Sorenson central venous pressure catheter, they had the outer protective sheath in which the catheter was packaged. It was long and narrow and fitted inside the faulty tracheal tube. They inserted the sheath deeply within the tracheal tube; withdrew the tracheal tube; and slid a new tracheal tube over the sheath, down the nose, and into the trachea, the sheath guiding the way. Voila! The first airway exchange catheter [114].

In 1980, Sukumar Desai and Vladimir Fencl, at the Peter Bent Brigham Hospital in Massachusetts, used a flexible fiberoptic bronchoscope to guide the exchange of faulty tracheal tubes. Because of the limited length of the flexible fiberoptic bronchoscope, such an exchange required cutting the replacement and original tracheal tubes to the shortest length possible, [115] a less than ideal solution.

In 1987, Irving Mizus invented a catheter specifically for the purpose of exchanging tracheal tubes, the Mizus Endotracheal Tube Replacement Obturator (METTRO). The METTRO was a long, polyethylene, solid core, bougie that had distance markings and a flexible tip. The use of the METTRO did not necessitate the use of a cut tracheal tube and the anesthesiologist knew exactly how deeply it had been inserted. Other uses for the METTRO (which applied to all airway exchange catheters) included the removal of a tracheal tube during a tracheostomy procedure, and tentative extubation of patients who might need reintubation [116].

But the METTRO was not hollow, precluding the use of insufflation or jet ventilation. Development of the hollow Cook Airway Exchange Catheter in 1990 by Cook Critical Care solved this problem. An adapter allowed the catheter to be attached to an Ambu bag or airway circuit [90].

Advances in technology prompted new requirements for exchanging airways. While the Cook airway exchange catheter was hollow, its long and narrow lumen precluded passage of a flexible fiberoptic bronchoscope. The desire to use flexible fiberoptic bronchoscopy in exchanging a supralaryngeal airway for a tracheal tube, prompted the development of a new airway exchange catheter device by Peter Charters, a British anesthetist at Aintree Hospital. Introduced into clinical practice in 1997, the Aintree Intubation Catheter allowed enough exposure of the distal fiberoptic bronchoscope for

the operator to steer the tip into the glottis and trachea. Beyond acting as an airway exchange catheter, it could be used as a tracheal tube introducer, or applied to facilitate extubation [90, 117, 118].

Indirect Laryngoscopes

Indirect rigid laryngoscopy using mirrors and prisms figured in the initial efforts to view the larynx but gave way to less cumbersome approaches that used direct laryngoscopy. New technology restored indirect laryngoscopy as an aid to intubation. Modern indirect rigid laryngoscopes enable a view of the laryngeal inlet through fiberoptic bundles or other optical aids such as mirrors and prisms packaged into a single unit and easily operated by one person. Their advantage is the reduction of anatomic stress needed for direct laryngoscopy; they enable vision “around the corner” of the tongue.

In 1980, Georgia anesthesiologist Roger Bullard designed the first indirect rigid fiberoptic laryngoscope introduced into anesthetic practice. A rigid L-shaped blade incorporating fiberoptic bundles transmitted an image to an eye piece. The most recent version, the Bullard Elite Laryngoscope, can be used with a conventional laryngoscope handle, and the eye piece can accept a video camera attachment [19, 34, 59, 89].

Two historically important, now extinct, indirect fiberoptic rigid laryngoscopes were the 1994 Wu Scope and the 1996 Upsher Scope [34, 59]. Although neither the Wu-Scope or the Upsher scope gained widespread use, they represented devices used during the transition between the Bullard rigid laryngoscope and the soon to arrive videolaryngoscopes in the early 2000s. In 2006, King Systems Corporation developed the Airtraq, an indirect rigid laryngoscope that provided a view of the glottis without requiring alignment of the 3 axes. Unlike indirect rigid fiberoptic laryngoscopes, images were transmitted to a proximal viewfinder by lenses and prisms. Versions of the Airtraq also provided for nasotracheal intubation and double lumen tube placement. A snap-on video system allowed viewing on an external screen [34, 89, 119].

Videolaryngoscopy

Video imaging during bronchoscopy began immediately before World War II when British surgeon John McGibbon obtained photographs and a video of the epiglottis, carina, and trachea using a rigid bronchoscope fitted with a camera lens [120]. Flexible fiberoptic bronchoscopy added external cameras to record the view or to allow visualization on external monitors. In the late 1980s, the charge coupled device (CCD) video microchip became available, placing video technology inside the scope. This costly device required

bulky cables [34, 51]. In 1987, Ikeda worked with the Asahi Corporation to develop the prototype of the flexible video endoscope, thereby revolutionizing the bronchoscope [100]. Pentax, then Olympus and Machida-Toshiba made the first commercial video endoscopes. Otolaryngologists and pulmonologists quickly adopted these devices, but their use by anesthesiologists for tracheal intubation lagged, eventually becoming popular at the end of the 1990s.

Around 2006, mobile phone technology required a smaller and less expensive CMOS camera chip. Video endoscopes and laryngoscopes soon incorporated this new technology, which offered better image resolution [34, 121]. Placing the chip within the device also decreased weight and reduced the number of cables extending from the device, or permitted the incorporation of the monitor into the device itself.

In 2009, Olympus introduced this built-in video monitor into the portable Olympus MAF Flexible Endoscope with a built-in, long-life, white LED light source and a 2.5 inch color LCD display monitor incorporated into the proximal end of the scope, replacing the eyepiece. A rechargeable lithium battery could power the MAF endoscope for 60 minutes [122].

Flexible fiberoptic bronchoscopes and video endoscopes require time-consuming and potentially costly disinfection [123]. To solve this problem, Vision Science developed the BRS-5000 Video Bronchoscope with EndoSheath Technology, a single-use, disposable, sterile sheath that isolates the scope from the patient. With replacement of the sheath, the BRS-5000 is immediately ready for re-use [123].

A disposable, flexible, video endoscope provided another solution to the problem of endoscope disinfection. In 2007, the Ambu engineering team sought the world-wide assistance of airway experts to develop the aScope, a disposable video endoscope with a flexible, steerable tip plus the expected refinements for high resolution viewing and recording. The aScope became available in 2009 [121, 123].

Video Laryngoscopes

Application of advances in video technology to laryngoscopes provided improved views of the glottis and an enlarged image of the tracheal tube as it passed through the glottic opening. The video laryngoscope consists of a traditional laryngoscope design with a miniature video camera or fiberoptic bundle embedded within the blade to capture an image of the laryngeal inlet. The image is transmitted to a monitor mounted either on the handle or separately [59, 119, 124, 125].

Around 1999, George Berci, a California surgeon and a pioneer in endoscopic surgery; John Pacey, a Canadian surgeon; Markus Weiss, a Swiss anesthesiologist; and Jon Berall, a US military Internist, independently produced distinctive video laryngoscopy systems. Weiss invented the Angulated Video Intubating Laryngoscope, primarily for use in children. Although Weiss wrote the first paper on video la-

ryngoscopy in 2001, his device never became commercially available in the US [126].

Pacey invented the first commercially available video laryngoscope, introduced into clinical practice in 2001. After observing a tediously difficult intubation by two highly skilled anesthesiologists, Pacey realized that the video technology that had revolutionized minimally invasive surgery might be applied to facilitate intubation [127]. His idea spawned the GlideScope, a single-piece handle and blade made from medical-grade plastic. A video camera with an LED and antifogging mechanism was mounted at the distal end of the blade. The captured image was transmitted to a color LCD monitor [34, 59, 128]. Many versions of the GlideScope appeared subsequently, as did a special stylet, the GlideRite[®] Auto Stylet, with a pre-curved shape that matched the angle of the Glidescope blades [59, 128]. Studies comparing the GlideScope systems with traditional direct laryngoscopy, confirmed the usefulness of the GlideScope, especially in patients with a potentially difficult airway [59, 128, 129].

Berci, with anesthesiologist Marshal Kaplan, invented the most diverse of the initial video laryngoscopy systems, the Berci-Kaplan DCI Video Laryngoscope (DCI; direct coupler interface). In 1999, Berci and Kaplan made the first direct coupler interface prototype. It allowed a limited tubular view similar to that seen during direct laryngoscopy. In 2000, a second prototype incorporated a panoramic view that improved visualization. The final version appeared in clinical practice in 2003, as a hybrid device using fiberoptic bundles in a channel of the laryngoscope blade, to deliver an image to a camera located in the handle.

The advantage of the initial direct coupler interface over other video laryngoscopes, was that it used traditionally shaped blades and allowed direct or indirect viewing of the larynx. Several makers of video laryngoscopes, such as the GlideScope Direct recognized these advantages and incorporated them into their own devices [119, 125].

A 2009 version of this system, the CMAC video laryngoscope, had an integrated video camera in the blade, and like its predecessor, provided a wide viewing arc. Data are delivered by cable to an accompanying battery-powered, portable, 7 inch monitor with the usual options for recording images [59, 119, 125]. Studies indicated the ease of use and versatility of the direct coupler interface and CMAC systems, especially as aids for teaching tracheal intubation [130, 131].

Berall invented the last of the original video laryngoscopes, the Coopdech C-Scope Video Laryngoscope, available in Europe and Japan since 2005. The handle of the laryngoscope contained the 3.5 inch LCD video monitor, included a high-intensity white LED light source, and was powered by a rechargeable lithium ion battery. The C-Scope could be fitted with disposable plastic blade covers to minimize cross-contamination [132].

Airway Assessment Techniques

In the 1960s and 1970s, Ronald Cormack and John Lehane found that anesthetic deaths due to aspiration were often associated with a failure to perform tracheal intubation. They offered two key conclusions: 1) although specific diseases might predispose to difficult intubation, difficulty was also seen in apparently normal/healthy individuals; and 2) if difficulty was not always predictable, then anesthesiologists must learn how to master the art of difficult intubation. This research produced the 1984 Cormack-Lehane Laryngoscopy Grading System. The system divided the view during laryngoscopy into four grades defined by how much of the vocal cords and surrounding tissue were visible, 1-to-4 indicating minimal to maximal view of the larynx [83, 133]. The concept received immediate international acceptance.

Seshagiri Mallampati, at Harvard Medical School, suggested an alternative Grading System. In 1983, he published a letter describing an unexpectedly difficult intubation in a female whose mouth could be opened widely but whose tongue obstructed the view of her faucial pillars and uvula, leaving only her soft palate visible. Subsequently, he asked his patients to open their mouths and stick out their tongues. He found that the resulting view correlated with the difficulty of intubation. In 1985, he published the results of his study of 210 patients. The original Mallampati scoring system had three classes that ascended with decreasing visualization of the faucial pillars, soft palate, and uvula and correlated inversely with the ease of intubation [134]. Samsoon and Young added a fourth class (more difficult intubation) where the soft palate was not visible [134, 135]. A fifth (but easier intubation) class was suggested for patients whose epiglottis could be seen [136].

Conclusion

While anesthesia began in the mid-1800s, the history of airway management is as old as medicine itself. Surgical airway management dates back to 3600 BCE. Major contributions to the many techniques and devices for airway management came from dentists, priests, engineers, musicians—and physicians.

Discoveries evolved concurrently in multiple parts of the world, but early limitations in communication invited controversy in claims of priority. Ideas might be invented and reinvented. While tracheostomies date to 3600 BCE, they were repeatedly rediscovered, finally becoming popular in the 1900s. Although tracheal intubation was first described in the 1 century, it was rarely, if ever performed in humans until the 1700s, and not for airway management during surgery until the late 1800s. It did not become popular until the early 1900s. With the invention of the LMA in the 1980s, the

most recent addition to airway management, the supralaryngeal airway was born, but the idea was formed long before with the concept of the oropharyngeal airway and the Fell-O'Dwyer apparatus, both of which are positioned either at, or above, the vocal cords.

Modern anesthesia owes a great deal to these past inventors, for their contributions to the many airway devices and techniques mentioned throughout this chapter. Their inquisitive nature and skills of observations revolutionized how and what surgeries could be performed. Future inventors will only further their progress.

John W. Severinghaus

Summary

Before 1950, anesthetists assessed adequacy of ventilation by watching or rarely measuring gas volume exchange or chest movements. About 1950, infrared (IR) light absorption by CO₂ was used to continuously measure expired CO₂, a first real monitor of respiration. It was dubbed capnometry, and remains the basis of all respiratory gas monitors. Gaseous oxygen was first monitored in anesthetic circuits using a polarographic oxygen electrode, made available about 1960. Mass spectrometers that could continuously measure O₂, CO₂, N₂O and anesthetic gases were rarely used until 1975 when methods were introduced to use one mass spectrometer to sequentially measure gases sampled through long catheters from many patients. In the late 1980s, infra red detectors of CO₂ and anesthetic vapors were combined with polarographic O₂ electrodes to make the modern operating room gas monitoring devices.

Blood gas analysis never became a continuous monitoring procedure except in cardio-pulmonary by-pass oxygenators. Invention in 1954 of a blood CO₂ electrode and in 1956 of a blood O₂ electrode led to rapid, if not continuous, blood PO₂, PCO₂ and pH analysis, introduced in 1958 and soon made available in most operating, recovery and other critical care areas.

Transcutaneous estimation of blood PO₂ and PCO₂ was developed in the early 1970s to protect premature infants from either too much or too little oxygen. It played little role in anesthesia monitoring.

Oximetry was occasionally used in anesthesia after World War II, but only became widely used following the development of pulse oximetry about 1985, 10 years after its serendipitous invention in Japan.

Anesthesia Monitoring Before Polio and Transistors

During the first century of anesthesia, the only variables that anesthetists monitored routinely were chest movements, skin color and pulse. S Riva Rocci (1863–1937) invented blood pressure measurement using an inflatable cuff in 1896. In 1905 N Korotkoff (1874–1920) reported that the arterial sounds heard through a stethoscope placed over the brachial artery during occlusion and release of pressure in a cuff surrounding the arm could be used to measure diastolic as well as arterial pressure. Harvey Cushing applied these in his newly invented anesthetic record in the early 1900s.

Monitoring was still minimal in 1927, when academic anesthesia training began in Madison, Wisconsin under Ralph Waters (1883–1979), the world's first academic anesthesia department chair. In 1950, Stuart Cullen (1909–1979), Professor of Anesthesia at the University of Iowa, taught inhalational anesthesia methods at the WHO training course for

3rd world physicians in Copenhagen (Fig. 55.1). Watched by Waters and 4 young Danish anesthetists (each a future department chair), the only monitors to be seen were Cullen's finger on the pulse and his view of the motion of the rebreathing bag. Pupil size was used to gauge the depth of ether anesthesia, the legacy of Arthur Guedel (1883–1956). At the time, mortality primarily due to anesthesia in the US was 3.7–11.7 per 10,000 anesthetics [1, 2].

In the 1950s, ether and cyclopropane flammability precluded the use of most electrical apparatus near the patient. Operating rooms in the US and elsewhere had conductive floors, and anesthesia machines had chains or wires touching the floor to discharge static charges. To avoid explosions, ECG monitoring required construction of a pressurized cathode ray tube electrocardiograph in a bullet-like cylinder, supplied with a bicycle tire pump to sustain its internal pressure. Low voltage thermistors in flexible catheters were used to monitor rectal or esophageal temperature in the early days of hypothermic anesthesia for cardiac and neurosurgery. Non-electrical ventilatory volume monitors became incorporated in some new anesthesia machines, particularly if artificial ventilators were used.

Introduction of the transistor in 1954 removed the danger of sparks and permitted low voltage amplifying devices to

be used, thus initiating the modern use of monitoring. The introduction of curare and other muscle relaxants, the poliomyelitis epidemics of the 1950s, positive pressure ventilators, cardio-pulmonary bypass, and of course, the fatality rate, stimulated development of monitoring devices.

Airway Monitoring of Respiratory and Anesthetic Gases

Capnometry

John Tyndall (1820–1893) Professor of Natural Philosophy at the Royal Institution, was the first to discover and report that CO_2 gas absorbs infra red light [3]. He built a device to measure this absorption. August Pfund (1879–1949) developed an analyser in 1939, to measure concentrations of carbon dioxide and carbon monoxide [4]. Radiation from a heated nickel chrome wire was directed through a sample cell into a detector cell containing a 3% carbon dioxide

Fig. 55.2 Luft CO_2 detector principle was used in Beckman infrared CO_2 analyzers for research and operating room use, 1950. (Courtesy of the author's collection.)

mixture, where the temperature was measured. The presence of carbon dioxide in the sample cell caused less radiation to reach the detector cell resulting in a smaller rise in temperature.

Karl Luft (1909–1999) deserves the credit for developing the modern infrared capnograph. Working with the German BASF company in 1937, he invented a clever principle to detect the infra-red (IR) light passing through an unknown gas sample [5]. His “Luft cell” incorporated two IR light sources, one beam directed through a reference cell, the other through a sample cell filled with a stream of the unknown gas (Fig. 55.2). The IR light beams then entered a two-chambered detector cell, each containing 3% CO_2 . The relative heating induced by the incoming IR light beams moved a membrane separating the two chambers. An electrical capacitance sensor detected the membrane motion. The IR beams were “chopped” by a rotating shutter, providing an AC signal proportional to the decrease in IR light entering the detector on the sample side.

Shortage of components before and during World War II limited the manufacture of Luft cells to several hundred. Some were used for environmental monitoring in submarines. Others, stored in salt mines, were confiscated and removed to the US and England after the war. The Germans also telescopically tracked their buzz-bombs by the CO_2 absorption of IR light from the exhaust of the bomb.

In the 1950s, an infra-red respiratory CO_2 analyzer was designed by Max Liston (1924–2004) using German patents confiscated at the end of WWII. He was guided and encouraged by James Elam (1918–1995) and associates to apply it to operating room monitoring [6]. The Beckman Co.

marketed the capnograph. Like the ECG bullet, its cast aluminum “head” near the airway was pressurized. The unpressurized capnograph amplifier control was supposed to be mounted at least 6 ft above the OR floor, a rule that assumed leaking explosive agents were heavier than air thus settling at a lower level.

The device was widely used for research but little used for patient safety monitoring. In the 1960s, the Beckman LB-1 capnometer was modified to analyze N_2O , ether, halothane or other anesthetics, for research (only one gas per instrument) [7].

Multi-Patient Anesthetic Mass Spectrometry

Francis Aston (1877–1945), a student of Joseph (JJ) Thomson (1856–1940) at the Cavendish Laboratory at Cambridge, devised the first mass spectrometer to separate isotopes of elements in 1919. Aston was awarded the Nobel Prize in Chemistry in 1922 for his discovery. A mass spectrometer ionized substances (in a vacuum) and accelerated a beam of charged particles (elements or compounds). The beam passed through a magnetic field to bend and separate heavier from lighter particles, each weight being collected in separate metal cups from which the ion current was measured. For respiratory gas studies, an extremely small leak continuously admitted a stream of sample gas into the ionizer, providing continuous concentration information.

In the late 1950s, in order to continuously monitor many artificially ventilated ICU patients (particularly polio victims suffering from long term paralysis), several institutions used a single centrally located respiratory mass spectrometer connected through long sampling catheters to the airways to provide sequential and frequent analysis of inspired and end tidal PCO_2 [8]. The data were typically displayed on the central nursing desk. N Davies and D Denison [9] investigated the performance of long sampling catheters, and concluded that they introduced no important errors.

Mass spectrometers could also analyze inhalational anesthetics, but were too expensive and too difficult to maintain for continuous use in each operating room. However, the monitoring cost per patient could be reduced significantly by using one mass spectrometer for many patients, as in the ICU systems. In the mid 1970s at UCSF, Gerald Ozanne (1941-), Bill Young (1954-) and I installed a single mass spectrometer to sequentially sample airway gases from each patient in the 10 room OR suite of Moffitt Hospital [10]. Long nylon catheters were installed thru the OR ceilings. Young, a recent Oberlin college graduate with talents in both physical chemistry and computer programming, enthusiastically took on the design and programming tasks. We found that patient airway gases could be continuously and slowly sampled from each patient through 30 m long catheters, accurately storing in the catheters about 20 sec of data. When a catheter

Fig. 55.3 Mass spectrometer anesthetic and respiratory gas analysis operating room display screen in Moffitt Hospital with author, 1978. (Courtesy of the author’s collection.)

was switched to the mass spectrometer inlet, gas stored in the catheter was drawn into the mass spectrometer within 6 sec by a lower pressure. The inspired and end tidal concentrations of respiratory gases and the anesthetic vapor were reported on a display in each OR about once per minute (Fig. 55.3). In each OR, by default, the display was a time plot of 30 min of end tidal PCO_2 and halothane %, and a table of current values of all sampled end-tidal gases. The mass spectrometer terminal in each operating room became a communication system before the Web. It permitted Bill Young to monitor each operating room after he moved to New York. He called me one day, worried about operating room 5. I called the attending anesthesiologist and said, “New York wants to know why your patient in room 5 has a PCO_2 of 80.”

Anesthetists at UCSF became dependent on (addicted to) this device. So did researchers. A couple of things flowed from this dependence. One was a demand for such analysis by other institutions. At one point, several hundred of these multiplexed multi-OR systems were in use at institutions, mostly in the U.S. The second was that the device needed

competent technician care and was susceptible to occasional breakdown, affecting all the operating rooms. Not good for anesthetists addicted to minute by minute analyses of anesthetic concentrations. This stimulated various manufacturers to develop cheaper stand-alone respiratory gas monitors, using the infrared principle already described.

Infrared Analyzers

The absorption spectrum of each anesthetic vapor is unique, especially in the far IR band from 8–9 μm wavelength. The technology for inhaled anesthetic analysis was slowly improved, primarily by the Datex Co, until mixtures of several halogenated vapor anesthetics, CO_2 and N_2O could be successfully analyzed with a single Luft type IR detector cell, including correcting for overlap of the IR absorption peaks [11]. With the addition of an internal polarographic O_2 electrode, end-tidal gas monitoring in every operating room became widely employed. These monitors were less expensive to maintain than the mass spectrometer systems, a failing unit could rapidly be replaced, and only affected one OR. By 1995, multiplexed mass spectrometers had been replaced by stand-alone infra-red gas analyzers [12].

Blood Gas Analysis

Gas Bubble Analysis

In 1801, John Dalton (1766–1844), the Quaker English chemist, meteorologist and physicist, observed that the total pressure exerted by a mixture of gases is the sum of the “partial pressures” of each component gas. In 1803, he described the role of partial pressure in absorption of gases by water and other liquids. The concept of partial pressures gradually stimulated interest in measuring the partial pressures of oxygen (PO_2) and carbon dioxide (PCO_2) in blood in the late nineteenth century. In 1872, Eduard Pflüger (1829–1910) in Bonn equilibrated a small gas bubble with a large volume of blood at body temperature, and then analyzed the O_2 and CO_2 in the bubble using volume loss by chemical absorption [13]. Bubble analysis was developed into a clinical and laboratory method in 1945 by Richard Riley (1911–2001) [14]. He used a specially adapted syringe with a capillary attached, that had been invented by FJW (Jack) Roughton (1899–1972) and Per Scholander (1905–1980) during World War II [15]. Riley’s method worked reasonably well for PCO_2 , but poorly for PO_2 , especially for blood nearly saturated with oxygen.

Acid Base Balance and Carbon Dioxide

Even before Robert Boyle’s time in the 1660s, fermentation and respiration were recognized as producing “fixed

air” or “gas”, early names for CO_2 . The alchemists had used acids and bases in the middle ages, and in Paris, Hilaire-Martin Rouelle (1718–1779) discovered the alkalinity of blood, using titration and color indicators. In 1831, William O’Shaughnessy (1809–1889), an Irish physician working in India, showed that the major pathologic effect of cholera was loss of blood “free alkali” [16]. In 1877, Friedrich Walter (1850–?) established the relationship between the carbon dioxide content of blood and its alkalinity in his 1877 thesis, while studying in Strasbourg under fellow Latvian, Oswald Schmiedeberg (1838–1921) [17]. Walter’s finding made it possible to measure a patient’s abnormality of alkalinity (now called metabolic acid-base balance) by analyzing blood carbon dioxide content.

Methods Underlying Blood Gas and Acid Base Analysis

The electrodes now used for rapid analysis of oxygen, CO_2 and pH, and all the derived acid-base balance data, come from the science of physical (electro) chemistry, born in the 1880s by two discoveries; ionization and osmotic pressure theory.

Ionic Theory and the Hydrogen Ion

Jacobus van’t Hoff (1852–1911) initiated the development of electrochemical theory in 1889, by discovering that the long known gas laws applied to osmotic pressure [18]. The concept of ionization of salts into cations and anions, although first suggested by Michael Faraday (1791–1867) in 1830, was thought to be imaginary until 1887, when Svante Arrhenius (1859–1927) in Uppsala published a thesis proving, by measuring solution conductivity, that some salts dissociated as their concentration was reduced [19]. His discovery was the first to link acid strength to the hydrogen ion concentration. It stimulated Wilhelm Ostwald (1853–1932) to make the first electrometric measurement of H^+ ions by the potential on a platinum electrode in solutions saturated with hydrogen gas [20]. By combining the van’t Hoff osmotic theory with the new ionic theory, Ostwald’s student, Walter Nernst (1864–1941), discovered the energetic equivalence of Faraday’s constant, F , to the gas laws, thereby mathematically linking electrometric ion activity to the behavior of gases [21]. For these discoveries, Nobel prizes in chemistry were awarded to van’t Hoff (1901), Arrhenius (1903), Ostwald (1909), and Nernst (1920).

Introduction of pH for Hydrogen Ion Activity

Søren Sørensen [22] (1868–1939) proposed the term pH, the negative logarithm of H^+ concentration, as a simplification. The pH terminology quickly came to be used more than nanomoles of hydrogen ion concentration because the behavior of a substance in a chemical system is proportional to its energy (chemical potential), a logarithmic function of the

activity (or concentration) of the substance. A pH electrode responds to the chemical potential of H^+ , and thus the instrument provides a precise and readily obtained measurement of the chemical behavior of H^+ .

Development of the Glass pH Electrode

In 1906, Max Cremer (1865–1935) discovered an electrical potential across thin glass membranes, proportional to the acid concentration difference on each side, implying that the glass is actually permeable to H^+ ions [23]. By 1909, glass H^+ ion (pH) electrodes had been constructed [24]. In London in 1925, Phyllis Kerridge built the first blood pH electrode designed to prevent CO_2 escape from the sample [25]. Corning Glass marketed the first precise pH glass capillary electrode in 1932, and it was still the best when I started a blood gas laboratory at NIH in 1953 [26].

Buffers: The Relationships of Bicarbonate, Hydrogen Ion and Carbonic Acid

In 1907, the remarkable ability of blood to neutralize large amounts of acid, led Lawrence Henderson (1878–1942), then an instructor in biochemistry at Harvard University, to investigate the relationship of bicarbonate to dissolved carbon dioxide gas, and how they acted as buffers of fixed acids [27]. It was his insight that helped chemists and physiologists realize that when acids are added to blood, the hydrogen ions react with blood bicarbonate, generating CO_2 gas that is then excreted by the lungs, almost eliminating the increased acidity. The computer equations in all modern blood gas analyzers derive from Henderson [28] who rewrote the laws of mass action for weak acids and their salts, in the case of carbonic acid as: $k = [H^+][HCO_3^-]/[H_2CO_3]$. In 1917, Karl Hasselbalch (1874–1962) converted Henderson's equation to log form, the Henderson-Hasselbalch equation, $pH = pK' + \log[HCO_3^-/(S \cdot PCO_2)]$ [29].

Until the mid 1950s, PCO_2 was computed from this equation by measuring the blood pH and plasma CO_2 content using the manometric apparatus developed by Donald van Slyke (1883–1971), head of the laboratory at the Rockefeller Institute in New York [30].

The World Wide 1952 Polio Epidemic Leads to Blood Gas Analysis

Severinghaus' Memories of Ibsen, Astrup and the Polio Epidemic

I was invited by Bjørn Ibsen (1915–2007; Fig. 55.4) to dine in his apartment with his wife, shortly after arrival for my first sabbatical in Copenhagen, in 1964–5. I was there to

Fig. 55.4 Bjørn Ibsen, creator and director of world's first intensive care unit during the 1950's polio epidemic in Copenhagen. (Courtesy of the author's collection.)

study the possible active transport of something, presumably HCO_3^- , across the blood brain barrier to account for the rapid reduction in CSF HCO_3^- and relatively constant, slightly increased pH found during altitude acclimatization. I had met Poul Astrup (1915–2000; Fig. 55.5) in London in December, 1958, at the Ciba Symposium on blood gas analysis organized by John Nunn (1923-). I collaborated with Astrup and Ole Siggaard Andersen (1932-) on acid base problems, and taught 3rd world WHO anesthesia students in an ongoing program, mostly taught by well trained Danish anesthesiologists (Fig. 55.6).

A vicious polio epidemic struck Copenhagen in 1952–3. Hundreds of people, especially the young, were sent for isolation to the communicable disease Blegdams hospital just across Tagensvej from Rigshospitalet. The director, Professor HCA Lassen, was overwhelmed. He and his associate Mogens Bjørneboe had not understood the cause of many deaths. High CO_2 concentrations in blood samples led him to assume that the patients were somehow developing a metabolic alkalosis.

Fig. 55.5 Poul Astrup, who invented a new method to analyze blood PCO_2 in response to the need to control artificial ventilation during the polio epidemic. (Courtesy of the author's collection.)

After a suggestion from Bjerneboe, Lassen asked Ibsen, a young anesthesiologist (who had trained at the Massachusetts General Hospital) at Rigshospitalet to help. Ibsen, looking at the blood studies, that did not include pH, realized that the diagnosis was not metabolic alkalosis but hypoventilation, with CO_2 retention and resulting severe hypoxia [31]. Blegdam hospital had only one iron lung and some almost useless cuirass ventilators. Ibsen initiated ventilation in a 12-year-old girl (Fig. 55.7), at first by an anesthesia bag and mask, then later ventilation powered by hand via a tracheotomy. She survived.

Ibsen was not sure how much ventilation the patients needed. He asked Poul Astrup for help by determining what the arterial PCO_2 was in some of the patients in order to guide adjustments needed to maintain PCO_2 at the normal level of 5% (or 40 mm Hg). Astrup was a young clinical chemist in charge of the laboratory at Rigshospitalet. He had no routine way of measuring PCO_2 but knew the method: Measure arterial pH, and measure plasma or serum CO_2 content using a Van Slyke manometric analyser. Compute PCO_2 by the Henderson-Hasselbalch equation, formalized in Copenhagen 35 years earlier by Hasselbalch.

Fig. 55.6 Ole Siggaard Andersen, student of Astrup, developer of acid-base apparatus, theory and Base Excess and Standard Base Excess definitions and terms. (Courtesy of the author's collection.)

Fig. 55.7 A smiling 12 year-old polio patient ventilated via a tracheostomy by a medical student. (Courtesy of the author's collection.)

Astrup knew that the pH of blood must be measured at body temperature. No temperature controlled pH meters were available so Astrup took his lab pH meter into his 37°C culture room, and waited while the meter and the blood sample warmed. He soon became involved in speeding up the analysis of large numbers of samples, doing arterial punctures, transporting the warm blood, in a syringe wrapped in a blanket, to his culture room, computing PCO_2 and sending

the result to help the student adjust the ventilation toward a more normal level.

Astrup sought a better method of measuring PCO_2 . His solution became known as the “equilibration method”. He modified one of Hasselbalch’s ideas: Measuring “reduced pH” after equilibration of a blood sample to 40 mm Hg PCO_2 . Astrup modified Van Slyke’s graph showing the linear relationship of $\log \text{PCO}_2$ to pH after equilibration of blood with differing PCO_2 gases [32]. Displacement of this straight line by added acid or base permitted Astrup, and his student and associate Ole Siggaard Andersen (1932-), to estimate not only PCO_2 but also the acid-base abnormality of the blood, later named base excess.

Astrup and Svend Schroeder of the Radiometer Co. designed and built an apparatus to measure pH at 37°C before and after equilibration with gases of known CO_2 content. Over the next decade, it was modified by Siggaard Andersen [33], improved, marketed by Radiometer, and widely used as the “Astrup Apparatus” (Fig. 55.8). The Stow-Severinghaus PCO_2 electrode gradually made it obsolete.

Acid-Base Nomenclature

The term base excess (BE) was originally introduced to define blood metabolic (non-respiratory) acid base balance [34]. Some clinicians rejected BE because it changed with altered PCO_2 as plasma bicarbonate equilibrated readily with all the body’s extracellular fluid (ECF), about 3 times the blood volume. To obtain an index independent of acute changes in PCO_2 , in 1966, Siggaard Andersen introduced a modified index termed Standard Base Excess (SBE) and published a modified Van Slyke equation to compute SBE now used in most blood gas analyzers [35]. SBE is nearly independent of acute changes in PCO_2 , and applies to the ECF of the entire body by assuming a total ECF hemoglobin concentration of 5 g/dl.

The CO_2 Electrode

A CO_2 electrode was first described by physiologists Robert Gesell (1886–1954) and Daniel McGinty at the University of Michigan in 1926, for use in expired air, but not in blood [36]. It used the effect of CO_2 on the pH of a film of peritoneal membrane, wet with a salt solution, and wrapped over an antimony pH electrode.

In Columbus, Ohio, a physical chemist, Richard Stow (1916-), in the department of Physical Medicine, Ohio State University, (Fig. 55.9), needed to measure blood PCO_2 to guide the setting of mechanical ventilators in the care of polio patients in 1951–3. In the library, he found several Macy reports about ion-specific electrodes. They triggered an idea. He knew that carbon dioxide permeated rubber freely and

Fig. 55.8 Blood gas analyzer using the Astrup equilibration method for PCO_2 , with micro-capillary pH electrode and equilibrators designed by Siggaard Andersen, and the Clark electrode for PO_2 analysis. “S”: sampling tip on hand-held pH electrode, also used to connect pH sample to KCl reference electrode. (Radiometer Co, Copenhagen, ~1960). (Courtesy of the author’s collection.)

Fig. 55.9 Richard Stow, the inventor of a blood PCO_2 electrode. (Courtesy of the author’s collection.)

that it acidified water. He conceived of an electrode for measuring PCO_2 using a latex film to separate a blood sample from a glass pH electrode wet with distilled water. Being an expert glass blower, he constructed his own combined

Fig. 55.10 Stow's combined glass pH and reference electrode. (Courtesy of the author's collection.)

glass pH and reference electrode (Fig. 55.10). He immediately confirmed that the pH electrode potential increased in response to increasing PCO_2 in either gas or liquid. As he expected, pH was a logarithmic function of PCO_2 .

In August 1954, Stow reported his design at the fall meeting of the American Physiologic Society in Madison, Wisconsin [37]. He had been unable to prevent significant drift, and therefore concluded that his electrode probably could not be useful. During the question period after his talk, I asked Stow whether he had considered adding bicarbonate to the distilled water electrolyte. He said he had assumed that bicarbonate was a buffer that would prevent any change of pH when PCO_2 varied. I realized that, despite his doctorate in physical chemistry, Stow clearly did not grasp the differences between fixed and volatile buffering systems. We agreed that I would construct and investigate a CO_2 electrode with a bicarbonate electrolyte [38].

A few days later, using a Stow type pH and reference electrode, I found that a 25 mM sodium bicarbonate electrolyte solution stabilized the pH signal and doubled the PCO_2 sensitivity such that a 10 fold change in PCO_2 altered pH by almost 1 pH unit. A spacer of cellophane was needed to hold a wet film between the non-conductive rubber membrane, and the pH glass surface (Fig. 55.11). In 1959, Forrest Bird (1921-), inventor of a popular ventilator, arranged for his firm, the National Welding Co, to make my CO_2 electrodes commercially available. The unpatented design concept was soon copied and marketed by Beckman, Radiometer, Instrumentation Labs and several other firms in the US, Europe and Japan.

The Polarographic Oxygen Electrode

The method now called polarography originated in Nernst's laboratory in Göttingen, Germany. Nernst suggested to his assistant Heinrich Danneel (1867–1942), that he investigate the properties of single noble metal electrodes (gold,

Fig. 55.11 First working PCO_2 electrode, stabilized and made practical by author, 1954. (Courtesy of the author's collection.)

platinum) in solutions, by using large and non-polarizable reference electrodes to maintain a constant and known solution potential. Danneel soon noted that oxygen in the solution interfered with measurements whenever the test metal was cathodic (negative). In studying this, he showed that the reaction of oxygen with a negatively charged metal (cathode) was approximately a linear function of the oxygen pressure in the solution [39]. Danneel's work was soon forgotten because the noble metal surface was easily contaminated or 'poisoned' by organic substances but his work had identified the basis of the polarographic oxygen electrode.

Jaroslav Heyrovsky (1890–1967), in Prague, avoided 'poisoning' by using polarized mercury in a continuously refreshed droplet surface exiting a tiny capillary. Heyrovsky coined the name "polarography" to describe his automatic recording apparatus for plotting the relationship between applied voltage and resulting current, the polarogram [40]. After removing all the O_2 , Heyrovsky found that this device could be used for measuring the concentrations of very small quantities of the most diverse substances. Heyrovsky was awarded the Nobel Prize in chemistry in 1959 for his discovery of the then widely used polarographic analysis.

J Percy Baumberger (1892–1973) at Stanford, first applied the dropping mercury polarographic method for blood oxygen measurements in 1938 [41], in order to study the oxygen dissociation curve of the blood of insects, his scientific interest. Henry K. Beecher (1904–1976), as a young researcher in anesthesia at Harvard, devised a dropping mercury apparatus to measure PO_2 in plasma separated from blood [42].

The Membrane Covered Polarographic Oxygen Electrode

The solution to the problem of measurement of PO_2 in blood and other liquids is attributed to Leland Clark (1918–2005), a biochemist, physiologist and inventor (Fig. 55.12), working at the Fels Research Institute of Antioch College, Ohio. While investigating enzyme and steroid chemistry in perfused

Fig. 55.12 Leland Clark, inventor of the membrane covered polarographic oxygen electrode. (Courtesy of the author's collection.)

liver, he used Heyrovsky's dropping mercury polarography, becoming aware that oxygen had to be removed because it reacted first with a negatively charged cathode. In order to perfuse a liver with oxygenated blood for testosterone studies, he built a bubble oxygenator. He discovered that silicone covered glass wool was effective in breaking the foam created by bubbles. The oxygenator was so successful that Clark and Frank Gollan (1909–1988) built a whole animal cardiac bypass apparatus [43] and demonstrated its use in animals. In collaboration with surgeons in 1950, they developed one of the first successful clinical oxygenators. Their paper, submitted to *Science*, was initially rejected because they had not measured the blood oxygen levels before and after oxygenation. In response, Clark covered a polarographic platinum oxygen electrode with cellophane to avoid cathode poisoning by blood protein. He obtained sufficient data to satisfy the *Science* editors but found that the electrode was incapable of accurate oxygen analysis because the permeable cellophane resulted in very high cathode oxygen consumption [44].

Clark's Aha Moment

In October, 1954, Clark suddenly realized that he could combine a platinum cathode with a silver reference wire coated with silver chloride in a self contained electrode,

Fig. 55.13 Clark's oxygen electrode, 1956. (Courtesy of the author's collection.)

avoiding having the reference electrode in the blood sample. This made possible the use of an electrically non-conducting and much less permeable polyethylene membrane over the tip. He promptly wrote a patent application and sold it to the Beckman Co. The Yellow Springs Instrument Co. made these electrodes, using Clark's design of a 2 mm diameter platinum disk cathode sealed in the tip of glass. He submitted an abstract describing his new electrode to the Society for Artificial Organs that he had just founded. Its first meeting was held at the Federation meetings in Atlantic City on April 18, 1956 [45]. By chance, I had invited Clark and some 30 other respiratory physiologists who had been trying to measure blood PO_2 to an ad-hoc meeting at FASEB on the same day. Before our meeting began, Clark pulled his electrode out of his pocket for us to inspect (Fig. 55.13). Our meeting adjourned, each of us realizing that Clark had solved the problem of measuring blood PO_2 . Clark's electrode was immediately in demand, and impacted the subsequent scientific careers of dozens of physiologists.

Clark's invention was the historic turning point in blood gas analysis and all of respiratory physiology. It has been applied in anesthesia, aviation, transcutaneous blood gas analysis, blood oxygen content determination, cell metabolism, and in food, sewage, wine, and various other industrial applications.

Applying Clark's Electrode to Blood Gas Analysis

The Clark electrode had to be calibrated with blood equilibrated at 37°C with a known gas PO_2 , and read in a cuvette with a stirring paddle. In 1957, I built a thermostat water bath for the CO_2 electrode and the Clark O_2 electrode [46]. This first blood gas analyzer was exhibited at the 1957 ASA annual meeting, and at the Atlantic City FASEB spring meeting in 1958 (Fig. 55.14). The need for stirring blood was eliminated by reducing the diameter of the platinum cathode from 2 mm to 10 microns in commercial versions of Clark's

Fig. 55.14 First 2-function blood gas apparatus for PCO_2 and PO_2 analysis by author, 1957. (Courtesy of the author's collection.)

Fig. 55.15 First 3-function blood gas apparatus, with added pH electrode, by author, 1958. (Courtesy of the author's collection.)

electrode. This reduced the O_2 consumption from samples to about 2% difference between stirred and unstirred blood. In 1958, I added a pH electrode, the first three-function blood gas apparatus (Fig. 55.15) [47].

Transcutaneous (tc) Blood Gas Analysis

Transcutaneous PO_2

In the early 1960s, when airway positive pressure ventilation with oxygen was introduced to save very premature infants, many of the saved infants became blind. This blindness was originally termed RLF (retrolental fibroplasia) but now ROP (retinopathy of prematurity). It created an urgent need for continuous non-invasive monitoring of premature infant

blood oxygen [48]. Physiologists studying skin respiration had shown that human skin breathes, taking up oxygen and giving off CO_2 to the air. If skin is covered (as by a flat unheated PO_2 electrode) the surface PO_2 decreases to zero in a few minutes. However, in 1951, Baumberger and Goodfriend showed that if skin blood flow is greatly increased by the highest tolerable heat, the surface PO_2 increases to approximate PaO_2 (arterial blood) [48].

Within a year after Clark announced his invention of the membrane covered platinum polarographic electrode, studies with polarographic electrodes confirmed the Baumberger report [49]. In Marburg, Germany, Dietrich Lübbers (1917–2005) and students vaso-dilated the skin under an oxygen electrode by heating the electrode to 43–45 °C [50]. The resulting “transcutaneous” PtcO_2 was remarkably similar to arterial blood PO_2 in infants [51, 52]. Transcutaneous oxygen monitoring was soon made commercially available by many firms and used in other clinical and critical care situations. It was also useful although less accurate in older children and adults, especially at high PO_2 [53].

Transcutaneous PCO_2

The success of transcutaneous measurement of oxygen led to the design and testing of electrodes to measure PtcCO_2 by Beran et al. [54, 55], Huch et al. [56], and me [57]. Interestingly, we found that PO_2 and PCO_2 electrodes could be combined, sharing the same electrolyte and reference electrode because the very small O_2 current had no effect on the pH at the CO_2 electrode surface [58, 59].

Combined Earlobe SpO_2 and PtcCO_2

In 2002, Eberhard et al. developed a surprisingly small and light-weight earlobe probe containing both a pulse oximeter and a heated transcutaneous PtcCO_2 electrode, cleverly dubbed TOSCA (Transcutaneous Oxygen Saturation and CO_2 Analyzer) [60]. The heating of the skin, needed for PtcCO_2 , improved the pulse signal strength and speed of response of the pulse oximeter.

Oximetry

Before 1950, physicians estimated adequacy of oxygenation by looking for cyanosis. In good light and with adequate hemoglobin concentration, a keen observer could detect cyanosis at desaturations exceeding 15% of the hemoglobin [61]. More accurate measures were clearly needed.

Optical Physics Underlying Oximetry

In 1860, Robert Bunsen (1811–1899), professor of chemistry at Heidelberg, and his colleague Gustav Kirchhoff (1824–1887), professor of physics, invented the spectroscope [62]. They showed that each element, when in a flame, gives off

its own specific, identifying wavelengths of light that they called the emission spectrum.

The observation that light influenced electricity is attributed to Alexandre Becquerel (1820–1891), who showed in 1839 that the potential between two electrodes in a solution was altered when one electrode was illuminated. This was the forerunner of the photocell.

In 1760, Johann Lambert (1728–1777) described the relationship of the absorption of light to the amount of absorbent. August Beer (1825–1863) further investigated the relationship in colored flowing solutions in 1852, and from these studies came the Lambert-Beer law: The transmission of light is a logarithmic function of the density or concentration of the absorbent, since each absorbing molecule absorbs an equal fraction of a particular wavelength of the incident light [63, 64].

George Stokes (1819–1903) discovered that the colored substance in blood was the carrier of oxygen [65]. Felix Hoppe-Seyler (1825–1895), professor of applied chemistry in Tübingen and the founder of physiological chemistry in Germany, crystallized the blood pigment and coined the term hemoglobin in 1864. He proved that hemoglobin caused the absorption of green and blue light from the solar spectrum, the “Soret band,” and that this absorption changed when he shook the solution with air. He then showed that oxygen and hemoglobin formed a loose, dissociable compound that he called oxyhemoglobin [66].

Hemoglobin’s strongest absorption bands are in the blue-green region, so opaque that blood must be diluted to measure optical density, and this changes the oxygen saturation. Optical density is less in the red band from 600 to 750 nm where reduction increases density. In the infrared region, at 805 nm, no change in light absorption occurs with oxygenation, and is called the isobestic point. At greater wavelengths, oxyhemoglobin absorbs more infrared light than that absorbed by reduced hemoglobin.

Origins of In Vivo Oximetry

In 1876, using Bunsen and Kirchhoff’s spectrometer, Karl von Vierordt (1818–1884) studied the spectrum of light transmitted through hemoglobin and oxyhemoglobin in solutions and in tissues (his hand) [67]. He found that after stopping circulation in the hand using a tourniquet, the two bands of oxyhemoglobin disappeared and the band of deoxygenated hemoglobin appeared. He measured the hand’s oxygen consumption by timing this change in transmitted light. His methods were not used again for 55 years.

In 1931, Ludwig Nicolai (1904–?) initiated the quantitative spectrophotometric investigation of light transmitted through human skin in an effort to understand the dynamics of tissue oxygen consumption [68]. By occluding the circulation, he measured the rate of decay of oxyhemoglobin, and the increase in reduced hemoglobin.

In 1934, Nicolai’s associate, K Kramer reported the first precise measurements of oxygen saturation in cuvettes through which blood flowed [69]. He confirmed that the Lambert-Beer law was precisely correct in hemoglobin solutions, and approximately correct in whole blood in cuvettes. In 1935, Kramer continuously recorded the oxygen saturation of blood flowing through unopened vessels in animals [70]. These oxygen saturation measurements had an accuracy of $\pm 1\%$ compared with Van Slyke analyses.

In 1935 in Leipzig, Karl Matthes (1905–1962), constructed the first device to continuously measure the saturation of human blood in vivo by transillumination of the ear or other tissue, based on Nicolai’s prior studies [71]. He and Franz Gross were the first to use two spectral regions, one not affected by oxygen, to compensate for changes in tissue thickness, blood content, light intensity, and other variables [72, 73]. They first used blue-green light, following Nicolai’s lead, but later switched to infrared. In 1939, they described the first red and infrared ear oxygen saturation meter [74].

In 1940, J Squire at University College Hospital in London, built an oxygen saturation meter for use on the web of the hand [75]. Squire measured the light transmission while compressing the tissue to squeeze out the blood, and again after restoring blood flow. This was a first step toward the absolute reading oximeter. Squire was the first to suggest that the changes of light transmission caused by return of blood should permit an absolute calibration.

Development of oximetry in the US and Britain was stimulated by the needs of World War II fighter aircraft, most of which lacked pressurized cabins but carried O₂ and masks. In 1941, Glen Millikan developed a lightweight ear oxygen meter for which he coined the term oximeter (Fig. 55.16) [76]. However, because measurement was with a motion sensitive galvanometer, his oximeter could not be used in aviation. The earliest studies on the effect of the depth of anesthesia on the electroencephalogram used Millikan’s oximeter in a positive pressure chamber, in subjects receiving nitrous oxide anesthesia [77].

Calibration Problems

For calibration, the Millikan oximeter was initially set to read 100%, while the subject breathed oxygen, but it was not calibrated at low saturation. Earl Wood (1912–2009) (Fig. 55.17) at the Mayo Clinic needed oxygen saturation measurements during human centrifuge studies. He knew that in vitro studies had shown that the ratio of the red and IR optical densities of hemoglobin solutions was a unique function of saturation, and he knew of Squire’s use of pneumatic tissue compression. He and J Geraci modified Millikan’s earpiece, improving the infrared filter and adding an inflatable balloon with which the ear could be made bloodless [78]. Wood recorded the changes of the ear optical density at

Fig. 55.16 Milliken's ear oximeter, 1941. (Courtesy of the author's collection.)

Fig. 55.17 Earl Wood, inventor of oximeter calibration by ear tissue pneumatic compression, a key to the later discovery of pulse oximetry. (Courtesy of the author's collection.)

the two wavelengths when blood was readmitted to the ear, using the resulting 4 values to compute oxygen saturation.

By 1950, Wood's group had reported use of the new oximeter in newborns, in thoracic surgical operations, in cardiac diagnostic procedures, in exercise testing of congenital heart defects, in the human centrifuge and in catheterization (with the cuvette oximeter) [79, 80]. Wood's calibration method failed because the barrier layer photocells were non-uniform in spectral sensitivity, and variable with time, the light was too unsteady and the galvanometer resistance caused photocell output voltage to change with signal. But Wood's insight was crucial to the later discovery by Aoyagi of the pulse oximeter.

Ear Oximetry

R Shaw, a surgeon, engineer and inventor in San Francisco, in 1963–4, invented an ear oximeter using eight-wavelengths to avoid the need for calibration. It successfully tracked SaO_2 to within 1% over the range from 100% down at least to 50%. Because of its large earpiece and great expense (Hewlett Packard, >\$ 12,000), it was seldom used for clinical monitoring but was used in physiological research and in cardiac catheterization and pulmonary function laboratories.

Pulse Oximetry

The concept of pulse oximetry may be considered a development of the technique of Squire and Wood. Each had compressed the tissue pneumatically at the beginning of measurement to set the bloodless density for both wavelengths. When blood was readmitted, one could assume that all the light absorption was produced by blood, thereby eliminating tissue pigments and thickness as factors. Wood used the ratio of ratios of the changes in light at the two wavelengths, to compute saturation of the readmitted arterial blood.

Discovery of Pulse Oximetry

The realization that the arterial pulsatile light variation could be used to measure arterial oxygen saturation first occurred to Japanese physiological bioengineer Takuo Aoyagi (Fig. 55.18) [81]. Aoyagi was born on 14 February 1936, in Niigata Prefecture, Japan, and graduated in 1958 from the Faculty of Engineering at Niigata University with a degree in electrical engineering. While working on dye dilution technology at the Shimadzu Corp, he was stimulated by a summer course, "Classical Physiology with Modern Instrumentation," taught at Baylor University, Waco, Texas, by H Hoff and L Geddes. This led him, in February 1971, to join the Research Division of Nihon Kohden Corporation. He tried to use an earpiece densitometer for the measurement of cardiac output by dye dilution to avoid arterial blood sampling. The light signal transmitted through the ear contained pulsatile variations that prevented accurate extrapolation during washout. The effort to eliminate these artifacts led Aoyagi to the possibility of using them to measure oxygen saturation,

Fig. 55.18 Takuo Aoyagi, inventor of pulse oximetry, 1971. (Courtesy of the author's collection.)

a classic example of the adage that “one man’s noise is another man’s signal”. In 1971, Aoyagi suddenly realized that the pulse-induced variation in detected red and infrared light was equivalent to Wood’s use of the pneumatic cuff to induce the change of ear blood volume, and thereby obtain the 4 data points used to directly compute oxygen saturation by the ratio of ratios. Aoyagi’s insight made pulse oximetry possible.

Aoyagi tested various wavelengths and methods of implementing the device. He selected the 630-nm wavelength, at which red light transmission was most sensitive to saturation, and he balanced this against a 900-nm infrared wavelength, which is not absorbed by dye. The maximum density of the dye occurs at 805 nm, the isobestic point of hemoglobin and oxyhemoglobin absorption (i.e., the point of equal absorptions). Wood and other workers had chosen 805 nm as the optimal oxygen-insensitive wavelength to balance the 650-nm oxygen-sensing red light for oximetry, and 805 nm would have been useful as the third wavelength in an earpiece designed for recording both dye dilution curves and oxygen saturation. However, Aoyagi had seen oxygen sensitivity without using the usual oximeter red wavelengths around 650 nm. He had compared light at 805 and 900 nm. Thus the 900-nm light was found to be sensitive to oxygen.

Its response proved to be opposite in direction to the effect of oxygen in the red wavelengths; that is, desaturation increased the infrared light transmission of blood but decreased the red light transmission. Thus the now universal choice of infrared light in pulse oximetry arose fortuitously from Aoyagi’s work with dye dilution.

On April 26, 1974, Aoyagi presented “Improvement of the Earpiece Oximeter,” to the Japanese Society of Medical Electronics and Biological Engineering, representing the development team of Aoyagi, M Kishi, K Yamaguchi, and S Watanabe.

In early 1973, S Nakajima, a surgeon working at the Sapporo Minami National Sanatorium, heard about Aoyagi’s idea from Aoyagi’s supervisor, Y Sugiyama. Nakajima ordered the as-yet-undeveloped apparatus from Nihon Kohden. In September 1973, Nakajima tested Aoyagi’s prototype pulse oximeter in Sapporo. Nakajima and his associates used a revised instrument in February 1974, and their initial publication included the developers as authors [82]. Aoyagi and his associates delivered the first commercial instrument, the OLV-5100, to Nakajima on 13 March 1974. It used an earpiece with incandescent light, filters, and photocells like those of Millikan’s 1940 oximeter.

However, Nihon Kohden did not continue to develop or market this instrument and made no effort to patent it abroad. Aoyagi was transferred to a post as assistant manager in the patient monitoring division of Nihon Kohden in September 1975, and the research and development of the pulse oximeter was assigned to another worker. Finally, in September 1985 Aoyagi was permitted to resume research and development of his pulse spectrophotometer, a dye dilution method to measure cardiac output, plasma volume and liver blood flow.

In the late 1970s, the Minolta Co in Japan marketed the Oximet MET-1471, a version of Aoyagi’s pulse oximeter, and it was tested in the US where several groups began developmental work using Aoyagi’s idea. However, few foresaw its value during anesthesia, intensive care, and other emerging venues, probably because conventional oximetry had never been convenient or inexpensive enough for these uses.

Michael Hickey, Scott Wilber, and Bill Moe founded Biox Technology in 1979. Chief engineer-scientist Wilbur introduced and patented the use of red and infrared light emitting diodes (LED’s) and “normalization circuitry”. Biox marketed the first pulse oximeters in the US in 1980, mainly for respiratory therapy, but soon noted that anesthesiologists were using them in the operating room. Ohmeda Corporation soon purchased Biox and marketed the Ohmeda-Biox 3700. Stanford University anesthesiologist William New was among the first to recognize the tremendous need for pulse oximetry. In 1981 with Jack Lloyd and Jim Corenham, he founded Nellcor. Their first pulse oximeter was marketed in 1983 [83]. Fortunately, light-emitting diodes provided the wavelengths permitting the construction of small finger or ear probes. Furthermore these diodes could turn on and off

at high frequencies, enabling the device to use a single photocell sensitive to both wavelengths by turning on one light at a time. A further advantage was that ambient light, being continuous, was not sensed and amplified by the gated AC amplifiers detecting current pulses from the photocell. Technological developments occurred at critical times for pulse oximetry and account for some of its growth.

Role of Pulse Oximetry in Patient Safety

Pulse oximetry is arguably the most important technological advance ever made in monitoring the well-being and safety of patients during anesthesia, recovery, and critical care. Its simplicity, portability, low cost and permanent calibration made its use nearly universal in patients having potentially impaired gas exchange. Physicians now monitor and control oxygen saturation (SpO₂), rather than PO₂.

The more than 10 fold reduction in deaths attributed to anesthesia in the US since 1980 coincided with the widespread use of pulse oximetry. In an effort to link these events, a Danish Anesthesia group initiated multi-institutional double blind studies of anesthesia in which the anesthesiologist was unaware of the pulse oximeter readings in half the patients [84]. Four groups have repeated this for a total of 23,000 study patients. None of these studies revealed a beneficial role of pulse oximetry!

No conclusive explanation has been offered for this anomaly. Perhaps even a brief experience with a pulse oximeter and the resulting better understanding of the importance of cardio-respiratory physiology provoked anesthesiologists to pay more careful attention to their patients. And in all these double blind studies the anesthesiologists were aware that they were involved in a study.

Keith Sykes

Summary

In 1543, Vesalius found that lung collapse resulting from opening the chest soon caused the heart to stop, but Hooke showed in 1667, that blowing air down the windpipe and out through punctures in the lungs sustained life. In 1744, Tossach reported saving a suffocated miner with expired air (mouth-to-mouth) resuscitation (EAR).

Between the 1850s and the 1940s there were over 70 descriptions of diverse, rarely successful manual methods of artificial ventilation. A few methods were effective, including the Swedish Holger Nielson technique (external chest compression and expansion) that came to be recommended. In 1954, Elam showed that individuals taught to maintain an open airway in a patient without a tracheal tube could maintain normal levels of oxygen and carbon dioxide with EAR. In 1958–9, Safar showed that lay personnel could open the airway by thrusting the jaw forwards and tilting the head backwards. Rescue organizations slowly adopted the new techniques.

In 1876, Woillez described a chamber that enclosed the body below the neck and enabled the lungs to be inflated by intermittent manual reduction of the pressure surrounding the chest. In 1929, Drinker and McKann produced a mechanical version. Over the next 30 years, these “iron lungs” saved many lives, but cost limited their availability and they restricted access to the patient.

In the severe polio epidemic in the UK in 1938 there were too few iron lungs to treat patients with respiratory paralysis. On the advice of Macintosh (Professor of Anaesthetics at Oxford), Lord Nuffield, owner of the Morris car factory, offered to provide a tank ventilator for every Commonwealth hospital. Australian, Ted Both, designer of a simple wooden version of the Drinker “iron lung”, volunteered his design. The Morris factory built 1,750 Both ventilators by 1947.

Disadvantages of the iron lung led to its replacement by intermittent positive pressure ventilation (IPPV). In 1887, Fell used IPPV from a bellows via a tracheostomy to inflate the lungs. Later he substituted a facemask for the tracheostomy. In 1904, German surgeon Sauerbruch maintained lung inflation (but not ventilation) by enclosing the patient’s body and the operating team within a giant chamber having a negative pressure of 5 cm of water, the patient’s head protruding from the chamber. In 1907, Dräger produced the Pulmotor, a compressed gas powered ventilator designed for rescuing miners. Between 1906 and 1910, Green and Janeway demonstrated the advantages of controlled (as opposed to assisted) ventilation but prematurely discontinued their groundbreaking work. For the next 20 years, surgeons used the technique of insufflation introduced by Meltzer and Auer in 1909.

In 1916, Giertz reported in Swedish the advantages of IPPV. In 1934, Anderson, Frenckner and Crafoord, described the Spiropulsator ventilator, making Giertz’ work known outside Sweden. Blease, in England, produced a prototype mechanical ventilator in 1947, and a commercial model in 1950. Other events promoted the use of ventilators, including the 1942 introduction of neuromuscular blocking drugs, the expansion of thoracic surgery, and the use of cardio-pulmonary bypass machines in the 1950s.

Introduction

In this and the next chapter, we trace the development of methods of artificially ventilating the lungs. This chapter examines how various methods for resuscitating the apparently dead eventually led to the 1960s introduction of the ABCs

of resuscitation—Airway, Breathing and Cardiac compression. We then deal with the development of tank ventilators or “iron lungs”, large machines that create sub-atmospheric pressures around the chest to inflate the lungs in patients with poliomyelitis. The final section describes the development of controlled ventilation and the use of intermittent positive pressure ventilation for thoracic and other types of surgery.

In the next chapter the remarkable story of how the 1952 epidemic of poliomyelitis in Copenhagen initially overwhelmed the medical facilities is told along with how the

anaesthetist, Bjørn Ibsen, saved the day by applying methods of airway care and artificial ventilation used during anaesthesia. The realization that these techniques could save lives led to the development of critical care as we know it today.

Artificial Ventilation

Two methods may be used to artificially expand the lungs. One applies positive pressure to the airway (intermittent positive pressure ventilation, or IPPV), and the second creates a sub-atmospheric or “negative” pressure around the chest (intermittent negative pressure ventilation or INPV). Both techniques rely on the natural elasticity of the lungs to produce expiration.

Intermittent Positive Pressure Ventilation

Mouth-to-mouth respiration (now called expired air resuscitation or EAR) provides a simple and effective way to restore ventilation in apnoeic subjects. The technique may have been practised in biblical times (11 Kings 4, v.34–5) and was later used by midwives to resuscitate newborn babies [1]. The carbon dioxide and decreased oxygen in the rescuer’s breath do not compromise the effectiveness of the technique. It requires no apparatus and can be applied immediately, preventing the brain damage occurring with oxygen deprivation exceeding 2–3 min. But it is sometimes difficult to maintain a clear airway and rescuers may not like either kissing a potential corpse, or a live but possibly infected person!

A negative intrapleural pressure of 5 to 10 cm of water normally holds the lung against the inside of the chest wall, but if the chest is opened, air rushes in and the lungs collapse, ultimately looking like liver. In 1543, Andreas Vesalius, the great Italian anatomist, opened the chest of a live animal, observing that when the lungs collapsed, the heart would beat irregularly and eventually stop. In his famous work *De humanis corporis fabrica (On the fabric of the body)* [2] he wrote:

“That life may in a manner of speaking be restored to the animal, an opening must be attempted in the trunk of the trachea, into which a tube of reed or cane should be put; you will then blow into this, so that the lung may rise again and the animal take in air. Indeed with a slight breath in the case of the living animal, the lung will swell to the full extent of the thoracic cavity, and the heart will become strong and exhibit a wondrous variety of motions”.

Robert Hooke, (a polymath who designed and performed experiments for meetings of the Royal Society in London, and who helped Christopher Wren redesign London after the Great Fire of 1666), repeated the experiments of Vesalius in 1664. In 1667, he performed an extraordinary sequel: he opened a dog’s chest and held the lungs inflated by blowing air down the windpipe and out through holes drilled in the lungs. The animal stayed alive, even though the lungs were still. However, when Hooke stopped the airflow, the lungs collapsed and the heart faltered, only to recover when the flow of air was restored. Anaesthesia had not been invented, and these horrific experiments were performed in a conscious animal. The suffering of the animal so upset Hooke that he vowed never to repeat the experiment. The result however, was of great importance, unquestionably demonstrating that the gases entering and leaving the lungs, and not the movement of the lungs (as had previously been thought) sustained life.

Because 18th century life expectancy was low, deaths from cardiovascular disease were uncommon. Infections, accidents, drowning and smoke inhalation caused most deaths. In 1744, a Scottish physician, William Tossach, described his 1732 resuscitation of a suffocated miner with mouth-to-mouth ventilation [1]. Although mouth-to-mouth ventilation persisted in midwifery, the public did not adopt it.

The many canals in Amsterdam made drowning a particular problem, and in 1767, some citizens formed a Society for the Resuscitation of the Apparently Drowned. Similar societies were formed in Venice and Milan in 1768, Paris in 1771 and London in 1774. Some bizarre treatments were suggested (e.g. insufflation of tobacco smoke into the rectum). The Amsterdam Society recommended using a fireside bellows to provide artificial respiration, and the English surgeon John Hunter investigated the use of a double bellows to produce inspiration and expiration [3]. Although many rescuers attempted to use a bellows (Fig. 56.1), it proved difficult to provide an airtight connection with the lungs. Diverse tubes

were designed to join the bellows to the nose or windpipe, but only the highly skilled could use them effectively. Successful resuscitations were reported, but there was considerable doubt about the efficacy of the technique. In 1827 and 1828, J Leroy in Paris, showed that over-inflation with a bellows could damage the lungs, and the use of a bellows soon ceased [4].

Manual Methods of Artificial Ventilation

From the 1850s to the 1940s, more than 70 different manual methods of artificial ventilation were described. These expanded the lungs by lifting the upper limbs, thus stretching the muscles attached to the chest wall. Compressing the thorax or abdomen then caused deflation. Although rarely successful, these techniques became sacrosanct. Attempts to introduce EAR to police and rescue organisations in the early 1960s met enormous opposition, despite demonstrating superior results. Surprisingly, some opposition came from distinguished scientists.

Between 1930–1950, several investigators compared the effectiveness of various manual techniques in apnoeic subjects, including those with drug overdose and anaesthesia, and even in warm corpses without rigor mortis [5]. These studies demonstrated that some manual methods were effective and The Council on Physical Medicine and Rehabilitation then recommended adoption of the Swedish Holger Nielson technique [6]. This seemed to be the last word, but nothing in science stays still.

Expired Air Resuscitation (EAR) Returns

In all these studies, a tracheal tube maintained the airway, permitting direct measurement of the volume of air moved. But, as James Elam (Fig. 56.2) an anaesthesiologist from Buffalo observed, tracheal intubation invalidated the results [7]. Why? Because with loss of consciousness, the tongue falls back obstructing the airway while the tube prevents the obstruction! Elam then showed that EAR performed by individuals taught to maintain a clear airway without a tracheal tube, could provide normal levels of oxygen and carbon dioxide in an apnoeic victim for prolonged periods [8, 9].

In 1954, Elam met Baltimore anaesthesiologist Peter Safar at a mid-west meeting. Safar gave Elam a lift back to Baltimore. During the journey, Elam persuaded Safar to join the crusade to convince the establishment that EAR provided optimum rescue ventilation for apnoeic subjects. The key to success was Safar's demonstration that the tongue obstructed the airway in the unconscious patient, and that thrusting the jaw forwards and tilting the head backwards,

Fig. 56.2 James O Elam (1918–1995), the innovative but controversial anaesthesiologist from Buffalo who had a contract with the US Army to study methods of resuscitating victims of nerve gas poisoning, and who subsequently led the campaign to re-instate expired air resuscitation. (From [7])

a technique that anaesthesiologists use routinely, opened the airway [10]. Safar next conducted several daring studies on anaesthetized-paralysed human volunteers who were not intubated, demonstrating that after a brief period of training, firemen, boy scouts, and almost anyone could establish a clear airway and provide effective ventilation (Fig. 56.3) [11]. Another anaesthesiologist, Archer Gordon of the University of Illinois, who had conducted many studies on techniques of artificial ventilation and who had been a strong advocate of manual methods, also became convinced that expired air resuscitation was the technique of choice, and produced incontrovertible evidence that the method worked in both children and adults [12]. Two years later, Kouvenhoven, Jude and Knickerbocker dramatically demonstrated that compressing the chest could produce effective artificial circulation after a cardiac arrest—completing the triad of Airway, Breathing and Cardiac compression (A, B, C) that was the basis for the emergency treatment of cardiac arrest for the next half-century [13, 14]. Although cardiac

Tidal volume was derived from the change in pressure within the two corrugated tubes surrounding the chest. (Photo donated to the author by Safar in 1976)

compression produces some ventilation, the American Heart Association still recommends that there should be 2 breaths to 30 heart compressions. However, it is now recognised that the reluctance of bystanders to perform EAR reduces survival, and that survival rates with some types of cardiac arrest are probably increased if cardiac compression is used as the primary treatment [15].

Intermittent Negative Pressure Ventilation

In the nineteenth century several attempts were made to inflate the lungs by reducing the pressure surrounding the chest. A Woillez in France was among the first to describe an effective negative pressure ventilator in 1876 [16, 17]. His “spirophore”, consisted of a metal chamber surrounding the patient’s body, the head protruding through a rubber collar that provided an airtight seal at the neck (Fig. 56.4).

Moving a lever connected to a flexible diaphragm that sealed the foot end of the box expanded the patient’s lungs. Opposite movement of the lever allowed deflation. His device had problems: an ineffective neck seal; inadequate decreases in chamber pressure; and reliance on manual power. Drinker and McKhann in Boston Massachusetts, solved these problems in 1929, with a machine powered by vacuum pumps (Fig. 65.9) [18]. However, Drinker’s machines cost about \$3,000, a lot of money in those days. In 1931, John (“Jack”) Emerson, an engineer working in Boston, manufactured a similar, but more efficient, machine from standard plumbing, electrical and automotive parts; that cost about \$1,000 [19]. Drinker sued Emerson, charging patent infringement, but Emerson fought back, showing that the principle had been described previously. After Harvard University intervened, Emerson was allowed to continue production. He made incremental improvements for the next 25 years and travelled country-wide for months at a time, with demonstration models in a motor home trailer.

Over the next thirty years these “iron lung” ventilators saved many lives during the poliomyelitis epidemics that repeatedly scourged the world (Fig. 56.5). Some patients (like Emerson himself) had only a transient paralysis, but in others a permanent paralysis meant a lifetime in the iron lung [20]. Cost limited availability of these machines. Only the huge popular support for the “March of Dimes Fund” enabled purchase of enough machines to cope with the epidemics of polio that recurred in the US until the Salk and Sabine vaccines were introduced in the late 1950s.

The Iron Lung in England: Morris and Macintosh

In 1930, a Drinker iron lung was imported into England. Similar machines were constructed under license. Attempts were also made to support breathing with a cuirass respirator. This generated intermittent negative pressures beneath a shell applied over the chest and upper abdomen, but achievement of an airtight seal was difficult and it was less effective than the tank ventilator.

In 1938 there was another severe epidemic of poliomyelitis in England. William Morris (later Lord Nuffield), a bicycle maker who developed the Morris Motor Company and who had made many philanthropic gifts to medicine, was concerned about the shortage of equipment and turned to his friend Robert Macintosh for advice. Macintosh, a New Zealander who had served in the British air force in World War I, been shot down and taken prisoner, and made remarkable escapes from various prisoner-of-war camps in Germany [21]. After training in medicine at Guy’s Hospital, London, Macintosh began training in surgery. To pay for his studies, he gave nitrous oxide (“laughing gas”) anaesthetics for teeth extractions in dental surgeries. His skill resulted

Fig. 56.4 The Woillez spirophore (1876). This drawing was made by one of Emerson's assistants in the 1930s to illustrate that the principle of the iron lung had been described long before Drinker had patented his device. in a lucrative Harley Street private practice. Shortly after the new intravenous agent Evipan (hexobarbital) had been introduced, Macintosh administered it to Nuffield. The experience was markedly different to the dreaming and struggling that characterised the “laughing gas” anaesthetics that Nuffield had suffered for removal of teeth in his youth. Thus began a friendship that influenced the course of anaesthesia in England and the world.

Macintosh and other doctors from Guy's Hospital played golf at Nuffield's club near Oxford. Nuffield sought their advice when considering his many medical benefactions. In 1936, he said he would finance the creation of a Postgraduate Medical School at Oxford, and that he had earmarked funds to provide chairs in Medicine, Surgery and Obstetrics and Gynaecology. Macintosh jested: “I see that anaesthetics has been left out again”. Saying nothing, Nuffield then added a

Fig. 56.6 Professor Robert Macintosh (left) and Lord Nuffield putting a “patient” (Richard Salt, Chief technician) into a Both ventilator made in the Morris works at Cowley, Oxford in 1938. Salt was Macintosh’s assistant in London and later became a Chief Technician in the Nuffield Department of Anaesthetics, Oxford. He made many of the prototypes of apparatus developed in the department from 1937 to the 1970s. (Courtesy of Nuffield Department of Anaesthetics, Oxford, UK)

Chair in Anaesthetics to his benefaction. The University resisted this addition because anaesthetics was not considered to be an academic subject. Nuffield responded: no anaesthetics, no benefaction. In 1937, Macintosh was appointed to the Nuffield Chair of Anaesthetics at Oxford, the first such Chair in the Commonwealth, and the second in the World.¹

There were only 6 iron lungs in the country when the 1938 polio epidemic started. Seeing a need for machines to support breathing, Nuffield turned to Macintosh for advice. C Pratt, a physiologist in the Nuffield department, produced a film to show Nuffield the available devices, and Nuffield responded by offering to provide a tank ventilator for every British Commonwealth hospital requesting one. Fortuitously, an ingenious Australian engineer, Ted Both, was in England to try and interest the Ministry of Health in his new direct-writing ECG. He had recently designed and built a simple wooden version of the Drinker “iron lung” in Australia, and agreed to allow Nuffield to use his design (Fig. 56.6). By 1947 the Morris car factory had built 1,750 Both ventilators (450 for British hospitals). This was a remarkable achievement, considering the wartime limitation on the supply of materials and labour, and the fact that the factory was concurrently producing Oxford vaporizers for anaesthesia, and mine-sinkers and other armaments for war purposes.

The Nuffield Department of Anaesthetics assumed responsibility for training medical and nursing staff in the use of the Both ventilator, and within five years of its introduction, the ventilator had supported respiration in patients with snakebite poisoning, diphtheritic diaphragmatic pa-

ralysis, and barbiturate poisoning, as well as poliomyelitis. In 1940, Macintosh attempted to tackle postoperative pain with large doses of morphine, treating the resultant respiratory depression with a Both ventilator. As he later wryly commented, “The idea did not catch on, since neither the patient nor the surgeon liked the idea of a patient waking up in a coffin.”

Disadvantages of Intermittent Negative Pressure Ventilation

The iron lung had major disadvantages: patients had to synchronise swallowing and phonation with the machine’s rhythm; the machine was bulky and expensive; the rigid walls of the device limited access to the patient and thereby hindered nursing care; and achievement of a satisfactory neck seal could cause discomfort and ulceration of the skin. Furthermore, paralysis of laryngeal or pharyngeal muscles often resulted in the aspiration of mouth secretions, lung collapse, pneumonia, and death. Inserting a tracheostomy tube could prevent aspiration, but the rubber neck seal on the iron lung impeded care of the tracheostomy. These disadvantages ultimately resulted in the demise of INPV.

Intermittent Positive Pressure Ventilators

Toward the end of the nineteenth century, surgeons started to operate within the chest but opening the chest caused the lungs to collapse. In 1887, George Fell of Buffalo advocated the use a bellows and tracheostomy to inflate the lungs. Later

¹ The first Chair was created for Ralph Waters, in Madison, Wisconsin in 1933.

he substituted a face mask for the tracheostomy. The next year Joseph O'Dwyer of New York (who had developed laryngeal tubes to maintain the airway in diphtheria) modified the technique by using a foot bellows that was connected to a laryngeal tube, and in 1899, Rudolph Matas, the innovative New Orleans vascular surgeon, reported that he had successfully used an anaesthetic modification of this apparatus to provide anaesthesia and ventilation during an operation to remove a chest wall tumour. He remarked at that time, that it was curious that surgeons had failed to use a technique that had been in use in the physiology laboratory since the time of Magendie [22].

News of these advances had probably not reached Germany, for in 1903, the great German surgeon Ferdinand Sauerbruch (1875–1951) adopted a grotesque, inadequate solution. To maintain lung inflation he enclosed the patient's body and the operating team within a giant chamber having a negative pressure of about 5 cm of water, the patient's head protruding from the chamber. This technique maintained lung inflation but since there was no mechanical link between the lungs and chest wall, ventilation was grossly inadequate. With the stubbornness characterising European professors of the time, Sauerbruch continued to use this method to support the performance of intrathoracic operations for many years.

In 1907, the innovative German engineer Bernard Dräger, produced the Pulmotor, a compressed gas powered intermittent positive pressure ventilator designed to breathe for subjects rescued in mines. Although several thousand Pulmotors were produced, and although fire and rescue squads were trained in its use, most of the medical establishment ignored it. In 1910, Lāwen and Sievers, assistants to the surgeon Friedrich Trendelenburg (1844–1924) in Leipzig, Germany, developed an electrically driven piston type ventilator to provide intermittent positive pressure during pulmonary embolectomy [23]. World War I however, precluded further progress in Germany.

Between 1906 and 1910 in New York, Nathan Green and Henry Janeway built machines to deliver intermittent positive pressure to the lungs through a box enclosing the head, or through a tracheal tube. This technique provided satisfactory operating conditions for oesophageal surgery in animals, and Green and Janeway made the important observation that apnoea resulted if they increased the rate or depth of breathing. Their technique, which they named *controlled ventilation*, greatly facilitated surgery because they could control the rate and volume of each breath, and because they could also control lung distension with positive airway pressures imposed during expiration [24]. Unfortunately, Green and Janeway did not continue their groundbreaking work, and for the next twenty years surgeons utilised the technique of insufflation introduced by Meltzer and Auer in 1909 [25]. The high flow of anaesthetic gas mixture blown down a narrow tube in the trachea, washed CO₂ out of the trachea,

reduced tidal volumes and produced a positive pressure in the airways. Although lung expansion was maintained, CO₂ removal became inadequate when the chest was opened, even if the lungs were intermittently deflated.

In 1927, the pharmacologist, Dennis Jackson of Cincinnati, Ohio (who had described CO₂ absorption during anaesthesia in 1915), reported on the combined use of an anaesthetic machine and mechanical ventilator [26]. Jackson repeatedly demonstrated the technique in animals, but no one was interested in using it in humans. The normally patient Jackson wrote:

“378 years ago Vesalius had demonstrated what artificial respiration may often accomplish...It would appear, however, that the interval of time required for artificial respiration in the dog to evolve into artificial respiration in man may be almost as great as that required for an animal comparable to a dog to evolve into man” [27].

Anaesthesiologists Arthur Guedel and David Treweek in Madison, Wisconsin rediscovered controlled ventilation in 1934 [28]. The technique quickly achieved acceptance for lung ventilation during thoracic surgery. Parallel progress had been made in Sweden. In 1916, the surgeon K Giertz described the advantages of IPPV over the Sauerbruch method, but his publication was in Swedish [29]. Not until 1934, when the engineer S Anderson, and the surgeons Paul Frenckner and Clarence Crafoord described the Spiropulsator ventilator [30], did Giertz' work become known outside Sweden. The ventilator initially utilised the flasher mechanisms from nautical buoys to provide rhythmical inflation of the lungs. For many years it was used successfully for thoracic surgery by Crafoord in Stockholm [31]. Although Crafoord demonstrated his methods in Los Angeles in 1940, and F Mautz developed a ventilator and anaesthetic machine in the US [32], most thoracic anaesthetists continued to ventilate the lungs by squeezing the reservoir bag.

The innovative Copenhagen anaesthetist, Trier Mørch (Fig. 56.7), knew of Crafoord's work, and during the World War II German occupation, built a piston ventilator out of an iron water pipe. Emigrating to the US after the war, he built a new piston ventilator and became one of the first anaesthetists to promulgate the use of IPPV for anaesthesia and prolonged mechanical ventilation [33, 34].

Lung secretions provided a major problem for pioneer thoracic anaesthetists and in 1944, a Manchester anaesthetist, K Pinson, (inventor of the “ether bomb” vaporizer) described a combined anaesthetic machine, suction apparatus and mechanical ventilator for use during thoracic surgery (Fig. 56.8). Mørch spent some time in England shortly after the war, and went to see it demonstrated. The machine was too large to pass through the door of the operating room and had to be taken apart and re-assembled before the demonstration could proceed. In nearby Liverpool, a city also being

Fig. 56.7 Ernst Trier Mørch 1908–1996. He was one of the first anaesthesiologists to build a ventilator in Denmark during the German occupation in World War 2 and subsequently emigrated to the USA where he pioneered the use of intermittent positive pressure ventilation. His remarkable life is described elsewhere. (From [34], with permission)

pounded by German bombs, a motor engineer, JH Blease (Fig. 56.9), who had manufactured apparatus for an anaesthetist friend, helped the hard-pressed medical staff by giving anaesthetics! Bored with bag-squeezing, he built a mechanical ventilator to do the job. He demonstrated the prototype at Wallasey Cottage Hospital in 1947, and produced a commercial model in 1950 (Fig. 56.10). This became the first successful anaesthetic ventilator in the UK. Blease continued to produce new ventilators for the next 30 years [35].

When thoracic surgeons began to operate routinely on the lungs and heart in the 1930s, anaesthetists assisted spontaneous breathing by gently squeezing the reservoir bag in time with the patient's inspiration (*assisted ventilation*). However, they soon learnt, as had Green and Janeway, that *controlled ventilation* provided better operating conditions, and by the 1940s, most UK and Scandinavian thoracic anaesthetists used manually controlled ventilation. Because no real-time methods allowed measurement of oxygen and carbon dioxide levels in blood or expired air, anaesthetists

Fig. 56.8 The Pinson anaesthesia machine and ventilator designed for thoracic anaesthesia. Since excessive secretions were a major problem in patients in the industrial north of England, the machine incorporated a suction apparatus for tracheal aspiration. (From [36] with permission)

used patient responses to gauge the adequacy of ventilation, increasing ventilation until spontaneous respiration ceased. When the surgeon had closed the chest, the anaesthetist reduced ventilation until spontaneous breathing returned. They then turned off the anaesthetic, and removed the tracheal tube as the patient recovered consciousness.

In the 1950s, in the US, manually assisted ventilation was still the norm in thoracic anaesthesia, but cardiac surgeons Gibbon, Dennis and Allbritten realised the need for mechanical ventilation during surgery with the open chest. They remembered Crafoord's demonstration of the Spiropulsator in Los Angeles in 1940, tried the latest version of this machine and that of Mautz, and then developed their own ventilator [38]. The original device (Fig. 56.11) was driven by a windscreen wiper motor, but the ventilator developed from this prototype, the well-known Jefferson ventilator produced in 1955, used a mechanism powered by compressed gas.

One other factor stimulated the development of mechanical ventilation. In the mid-19th century, physiologists administered the muscle relaxant curare to immobilize animals during experiments. This barbarous practice led to the 1876 Cruelty to Animals Act in the UK, limiting the use of muscle relaxants and ensuring the effective provision of anaesthesia for experimental procedures. Since curare impaired respiration, various devices were developed to maintain adequate gas exchange. In 1926, the physiologist EH Starling

Fig. 56.10 The prototype Blease ventilator. The 1950 model became the first commercially available ventilator in the UK. JH Blease continued to develop new ventilators and respiratory equipment for the next 30 years. (From [37], p. 204, with permission)

Fig. 56.11 Prototype of Jefferson ventilator. This was powered by a car windscreen motor. (From [37], p. 208, with permission)

described a simple, reliable piston ventilator, one used by many researchers for experiments in animals. In the absence of other suitable ventilators, this was used on 50 infants and children in 1960–1 [39].

The introduction of curare into anaesthesia in 1942 (see Chapter 50) increased the incentive to control ventilation. Initially, curare was given in small doses, to enhance the relaxation produced by ether or cyclopropane, while the anaesthetist augmented each spontaneous inspiration by squeezing the reservoir bag. In 1946, Cecil Gray and John Halton in Liverpool successfully applied this technique in 1000 cases [40]. However, increasing familiarity with curare prompted the use of larger, paralyzing doses mandating controlled ventilation. Anaesthesia with thiopental, nitrous oxide, oxygen, curare and hyperventilation, reduced arterial PCO_2 and respiratory drive, and it was claimed that this produced superior operating conditions, reducing the quantity of anaesthetic drug required to maintain unconsciousness [41]. Within a few years, controlled ventilation became an integral component of the thiopental-nitrous oxide-oxygen-intravenous analgesic-muscle relaxant sequence, still used today. Although the use of such light levels of anaesthesia increases the risk of awareness, a problem that is still engaging the profession, the use of controlled ventilation is a key component of modern anaesthesia. It was this technique that Bjørn Ibsen introduced into Blegdams infectious diseases hospital during the Copenhagen poliomyelitis epidemic of 1952. It was an event that completely changed the treatment of respiratory failure.

Summary

In 1952, a poliomyelitis epidemic struck Copenhagen, causing 2,722 hospital admissions. In those with spinal and bulbar paralysis, anaesthetist Bjørn Aage Ibsen implemented tracheostomy and manual intermittent positive pressure ventilation (IPPV) to manage respiratory failure, thereby markedly decreasing mortality. His experience led him to develop the world's first intensive care unit (ICU) in 1953. Further, it led to the creation of intensive care medicine. Intensive respiratory support was soon applied to patients with diverse diseases. In 1954, Lassen et al and Honey et al reported survival of patients with severe tetanus treated with curare and mechanical ventilation. In 1955, Björk and Engström used IPPV to provide adequate ventilation after thoracic surgery. In 1956, Mørch applied IPPV to manage a crush injury of the chest.

Following the Copenhagen epidemic, several physicians helped design their own ventilators. Many were primitive yet enjoyed widespread and long use (e.g., the Radcliffe ventilator introduced in 1953). Engström invented one of the world's most successful mechanical ventilators, tested in the 1952 Copenhagen and 1953 Swedish polio epidemics. The British parallel to the Engström was the Smith-Clarke, the 1962 Cape-Waine version of which was used in anaesthesia. Diverse and often less expensive ventilators followed (e.g., the Howells, Manley, and Barnet.) In the 1950s, US engineers Bird and Bennett developed ventilators powered by compressed gas where the patient could trigger inspiration. In 1965, Emerson, with anaesthesiologists Benson and Pontoppidan, produced the first dedicated postoperative/ICU ventilator in the US.

In 1967, Nash *et al.* described lung damage with prolonged ventilation at high airway pressures and high concentrations of oxygen. In the 1970s, techniques were designed to minimise the harmful pulmonary and circulatory effects of PEEP, including continuous positive airway pressure (CPAP) during spontaneous ventilation and the addition of "mandatory breaths". In the 1970s and 1980s, microprocessors allowed synchronized ventilation. Swedish physicians introduced high frequency positive pressure ventilation in 1971. Repeated opening and closing of small air sacs could damage lungs, leading to Hickling's 1984 use of end-expiratory pressure sufficient to prevent alveolar collapse with a decrease in peak inspiratory pressures. Although this caused hypercapnia (*permissive hypercapnia*), it shortened the duration of mechanical ventilation and decreased mortality.

For the past 70 years, US anaesthesiologists used rebreathing CO₂ absorption systems, whereas many European anaesthesiologists used non-rebreathing systems. Rebreathing systems provided mechanical ventilation by replacing the reservoir bag with a bag- or bellows-in-bottle system, the bag being compressed by the ventilator. Some manufacturers now make piston type ventilators that deliver precise tidal volumes despite changes in airway resistance or compliance.

Ventilators became increasingly complex. Physicians, particularly in the US, increasingly delegated ventilator settings to specialist technicians who developed new techniques and significantly contributed to the literature.

It Started with Polio

Egyptian images suggest that poliomyelitis is an ancient disease. The twentieth century saw many epidemics throughout the world, but in 1952, there was an epidemic in Copenhagen, Denmark, exceeding all others in severity. The scale is

difficult to imagine. Of the 1.2 million citizens of Copenhagen, 2,899 developed polio, an attack rate far exceeding that in previous severe epidemics in New York in 1916, 1931 and 1944. Of the 2,722 patients admitted to Blegdam Infectious Diseases Hospital, an unusually high percentage had paralyzed pharyngeal and laryngeal muscles (bulbar paralysis) combined with paralysis of respiratory and limb muscles (spinal paralysis). Oral secretions entered the tracheobronchial tree, causing collapse of areas of lung and pneumonia.

Fig. 57.1 Patient with respiratory paralysis in the 1952 polio epidemic being manually ventilated with a Waters CO₂ absorption system

Mortality exceeded 80% in patients with spinal and bulbar paralysis. Death, it was thought, was due to an overwhelming viral infection of the base of the brain [1, 2].

Six cuirass ventilators and one (Emerson) iron lung were available; woefully inadequate resources. By the end of the third week of the epidemic, Henry Cai Alexander Lassen, the Chief Physician at the Blegdam Hospital, realised that this epidemic differed from previous ones and that desperate measures were needed. Although it was not usual for Chief physicians to ask others for advice, his assistant, Mogens Bjørneboe, eventually persuaded him to call in the anaesthetist, Bjørn Ibsen, who had recently returned from a year in the anaesthesia department at the Massachusetts General Hospital, Boston (see Fig. 55.4). After examining some patients and the records and autopsy reports of those who had died, Ibsen concluded that the polio patients were dying from respiratory failure and not from an overwhelming viral infection. He suggested that IPPV would provide an effective treatment. Ibsen proposed to insert a cuffed tracheostomy tube in all patients with respiratory failure, thus providing an airway and preventing secretions entering the trachea. He also proposed that the lungs should be ventilated manually using the standard Waters breathing system and carbon dioxide absorber (Fig. 57.1). Two days after the

initial consultation, Ibsen demonstrated the technique on a 12 year-old girl and used a Brinkman carbovisor and a Millikan ear oximeter to show that the patient had severe CO₂ retention and that blood gas values could be returned to normal when adequate ventilation was provided. Lassen realised that Ibsen's plan might just work, and together they implemented it.

Logistics now became the problem. First, supplies of cuffed tracheostomy tubes, suction apparatus, anaesthetic breathing systems, and gas cylinders had to be obtained. Second, patients whose lungs required ventilating had to be concentrated in the hospital area containing the requisite resources. Third, trained teams of internists, surgeons, and anaesthetists had to provide skilled care continuously. Fortunately, the World Health Organisation had started an anaesthesia training centre in Copenhagen in 1950, and a number of these trainee anaesthetists were drafted to help supervise patient care. More help was needed: people to aspirate tracheal secretions, and manually compress the anaesthetic reservoir bags 24 hours a day for two to three months. Copenhagen medical students volunteered and soon organized their 6-hour shifts. Such care was a heavy responsibility for such untrained personnel: they not only had to maintain artificial ventilation, but also had to monitor the patient's condition and alert doctors to problems.

At the peak of the epidemic, the lungs of 70 patients were simultaneously receiving manual ventilation. From 28 August to 3 September, 335 patients were admitted to Blegdam with polio—48 per day. By November, the number of medical students became insufficient, so Lassen drafted dental students too. In total, 1,500 students put in 165,000 hours ventilating patients' lungs. Mortality in the severely affected patients decreased from about 80% to approximately 25%, a remarkable achievement.

A Defining Moment

The Copenhagen epidemic was a defining moment in the history of controlled ventilation. First, it demonstrated that airway control, secretion removal, and intermittent positive pressure ventilation could save the lives of patients in respiratory failure. Second, it stimulated development of mechanical ventilators. Third, it demonstrated the value of concentrating trained staff and essential facilities in one area, leading Ibsen to set up the world's first ICU in his hospital in 1953 [3]. Fourth, it convinced Poul Astrup, who had performed blood tests during the epidemic, that new techniques of determining acid-base balance were needed [4]. Fifth, it demonstrated a need for new methods of safely transporting seriously ill patients. And sixth, it led to the creation of the speciality of intensive care medicine.

The Immediate Aftermath of the Epidemic

European doctors responsible for the care of polio patients visited Copenhagen to learn and apply the new techniques. On returning home, many of these physicians enrolled engineers to build mechanical ventilators. They began to treat patients with other causes of respiratory failure, including a 16 year-old girl admitted to the Radcliffe Infirmary in Oxford in August 1953. Initially diagnosed as having polio, she was treated in a tank ventilator but developed swallowing difficulties and chest complications. W Ritchie Russell and John Spalding, two Oxford neurologists who had visited Copenhagen, ordered a tracheostomy and mechanical ventilation using the prototype Radcliffe ventilator. Within a few days she was only able to communicate by small movements of her eyes. Several physicians questioned the ethics of keeping her alive. Not Russell and Spalding.

Fortunately, the paralysis was due to acute toxic polyneuritis (Guillain-Barré syndrome) and not to poliomyelitis. The patient recovered and was discharged from hospital 6 weeks later. She became a nurse, worked in the respiration unit, married a farmer and had four children. Kudos came to the doctors looking after her, and society benefited because her story advanced the adoption of this form of treatment [5].

Another disease in which IPPV proved to be life-saving was tetanus (lockjaw). Tetanus may cause severe, sometimes fatal, muscle spasms. In 1952, Woolmer and Cates in the UK, abolished the spasms in an afflicted patient, using succinylcholine to relax the muscles and manually ventilating the patient's lungs for five days until the spasms wore off [6]. In 1954, Lassen *et al* in Copenhagen and Honey *et al* in Oxford, reported survival of patients with severe tetanus who received curare and whose lungs were ventilated mechanically [7, 8]. This technique also saved newborn babies with severe tetanus in Capetown, South Africa [9] and a randomized controlled trial in Durban showed that neonatal mortality could be reduced from more than 80%, to 40% [10, 11].

In 1955, Viking Björk and Carl-Gunnar Engström reported the use of the Engström ventilator to support patients breathing inadequately after thoracic surgery [12]. Three years later one of the pioneers of Swedish anaesthesia, Olof Norlander, and colleagues working in other hospitals, described the use of ventilator support to treat patients with other causes of respiratory failure [13].

In 1956, a 51-year-old Chicago railway worker was crushed and rolled in an 8 inch (20 cm) space: "Like pie-dough under a rolling pin his body diameter was reduced to the size of this space". The patient was in shock with multiple rib and other fractures, air in both pleural cavities, crush injuries to the liver and genitourinary tract, and gastrointestinal paralysis. Attempts were made to stabilise the chest by applying traction to the ribs, but only when Trier Mørch (recently

Fig. 57.2 Metal tracheostomy tube with detachable rubber cuff around outer tube and inner tube with extension to connect to ventilation system. Trier Mørch later used a similar tube but without a cuff. This enabled the patient to speak during inflation of the lungs

emigrated to Chicago from Copenhagen) connected his piston ventilator to the cuffed tracheostomy tube, did the patient's condition improve. Intermittent positive pressure kept the lungs inflated, providing an internal splint while the rib fractures healed. IPPV was continued for 30 days. The patient left hospital 51 days later, without apparent respiratory impairment. This incredible story revolutionised the treatment of crushed chest injuries [14]. The successful outcomes described above encouraged the development of ICUs with dedicated facilities and specially trained staff [15–17]. These early studies demonstrated successful treatments in patients with diverse types of respiratory failure, and resulted in the creation of numerous general and specialised ICUs over the next two decades.

Technical Developments After Copenhagen

The Airway

The standard metal tracheostomy tube used in Copenhagen was modified with an extension allowing connection to the breathing system, and an inflatable rubber cuff was applied over the lower end of the tube to provide an airtight seal with the trachea (Fig. 57.2). However, the tracheostomy tube and its modifications brought new problems. Bypass of the warming and moistening normally supplied by the nose, caused drying of secretions that became difficult to aspirate. The cuff tended to slip off the tube and traction from the breathing system pulled the tube from the trachea. These problems led to development of right-angled rubber, and later plastic, tubes with integral cuffs.

Humidification

Blockage of the tracheostomy tube from the drying of secretions prompted development of systems to warm and humidify the inspired gas. Marshall and Spalding in Oxford [18] examined possible methods and developed a simple hot water humidifier based on a biscuit tin with a thermostat and electric kettle element: this proved to be extremely effective but, since the inspired gas temperature varied with flow rate, it was necessary to monitor the inspired temperature close to the patient Y-piece. In 1971, a washing machine manufacturer in Auckland, New Zealand, produced the sophisticated Fisher and Paykel hot water humidifier that solved the problem [19]. Subsequently, heat and moisture exchangers were developed that could be connected to the tracheostomy tube and so function as an artificial nose.

Sterilization

In the 1960s, bacteria were found in the ventilator, humidifier and breathing systems. To overcome this problem, formaldehyde or ethylene oxide gas was recirculated around the ventilator circuit for 12 to 24 hours before use in a patient. The ventilator then had to be left running for another 24 hours to eliminate residual sterilizing agent. These problems initially forced manufacturers to design ventilators with autoclavable patient circuits (e.g. the Engström 300, and the Penlon Oxford ventilator). However, in the mid-1970s, improved low-volume bacterial filters that could be placed at the patient Y-piece became available, reducing the need for sterilization.

The AMBU Bag

In the hospital setting, manual ventilation with oxygen can normally be provided by a Waters circuit and expiratory valve with or without a CO₂ absorber, but in 1956 there was a strike of gasoline truck drivers in Denmark that threatened hospital oxygen supplies. What was needed was a means of providing artificial ventilation with air. The anaesthetist, Henning Ruben, took up the challenge. Ruben had qualified as a dentist before the war, and utilised his talents as a ball-room dancer, champion fencer, magician and thought-reader to pay his way through college. In 1943, he had to escape from Copenhagen in a fishing boat, when the Nazi occupiers started to round up the Jews. The escapees lay under a false bottom in the fish hold and children were sedated with barbiturate suppositories to keep them quiet during the voyage to Sweden. It is said that Trier Mørch and a pharmacist friend developed a mixture of rabbit blood and cocaine that was sprinkled on the deck to abolish the sense of smell in the

Fig. 57.3 The AMBU bag developed by Henning Ruben in 1956–1957. 1 Foam lining. 2 Ruben non-rebreathing valve. 3 Inlet valve. Oxygen could be added to a reservoir attached to 3. (Reproduced from Mushin WW et al. *Automatic ventilation of the lungs*, 3rd edition, 1980, p. 762, with permission from Wiley-Blackwell)

tracker dogs that searched the boats before departure to the fishing grounds. After the war, Ruben returned to Copenhagen, qualified in medicine and trained as an anaesthetist. He spent 6 months with Lucien Morris at the University of Iowa, and met James Elam. The two developed a lasting friendship and Ruben went on to demonstrate that neck extension, as practised in anaesthesia, provided a simple way of maintaining an airway in the unconscious patient.

Ruben developed numerous medical devices among which were a non-rebreathing valve and a portable suction apparatus. The latter was manufactured by the Danish company AMBU-TESTA, and it was this company that produced his next invention—a self-inflating bag. His first prototype consisted of a double-ended bag that was kept open by three bent bicycle wheel spokes, and was fitted with his non-rebreathing valve at one end and an air inlet valve at the other. Later, he filled the bag with lumps of foam rubber, the final version having a foam rubber lining to the bag (Fig. 57.3). Oxygen could be added to a reservoir attached to the air inlet. Many variants of this design have since been produced, and it has proved invaluable, not only in emergencies, but as a routine method of transporting patients with respiratory insufficiency [20].

The Development of Mechanical Ventilators After the Epidemic

Space limitations preclude a comprehensive description of ventilator development after the Copenhagen epidemic. This section is restricted to significant developments in Scandinavia, the UK and the US, although similar developments took place in many European countries, and the British Commonwealth. Readers desiring more information should refer to standard works [21–24]. Here I summarize the evolution of ventilators from the simple mechanical

pumps of the 1950s, to the sophisticated computer-controlled machines of today, and I describe how increasing knowledge of the physiology of mechanical ventilation and the pathophysiology of respiratory failure, influenced design considerations.

Many early ventilators were used in both the operating room and ICU. Those that utilised a non-rebreathing circuit, required a fresh gas flow equal to the patient's minute volume [25]. Others were connected to a CO₂ absorber circuit and so required a smaller flow of fresh gases. From the 1970s onwards, the introduction of microprocessor-controlled ventilators facilitated the development of new techniques of respiratory support in the ICU, but since these techniques were not needed in the operating room, anaesthesia ventilators remained relatively simple. Most anaesthesia ventilators now compress a bag or bellows in a rigid chamber connected to a standard CO₂ absorption circuit, so that low fresh gas flows can be used. This minimises environmental pollution with anaesthetic vapours and gases, and cuts the cost of expensive agents. There has however, been a recent trend to use sophisticated piston type ventilators to cope with the ventilatory problems introduced by the insufflation of CO₂ into the abdominal cavity and the extreme changes of body position required for laparoscopic surgery.

Ventilator Specifications

By 1950, it was known that that inflation of the lungs, whether by application of positive pressure to the airway or subatmospheric pressure to the chest wall, impeded venous return and so could impair cardiac output. It was also known that high inflation pressures could damage the lung. These findings suggested that: peak airway pressures should not exceed 25–30 cm H₂O; the duration of inspiration should be less than the duration of expiration; and airway pressure should be zero during expiration. Machines were designed to produce a normal range of tidal volumes and breathing frequencies with an inspiratory:expiratory time ratio of 1:2, and most ventilators incorporated a pressure relief valve set to 30 cm H₂O. These early machines ventilated normal lungs satisfactorily, but could fail to produce adequate ventilation when lung compliance decreased or airway resistance increased.

Because of the concern that the application of IPPV might decrease cardiac output, many early ventilators could also generate a subatmospheric pressure during expiration. However, it was soon found that a negative phase had little effect on the circulation and often impaired gas exchange, so cardiac output was optimized by infusing vasoconstrictor drugs or by increasing blood volume. Heart filling pressures were initially monitored by a central venous catheter

but from the 1970s onwards, the Swan-Ganz (pulmonary artery) catheter was increasingly used in critically ill patients. Although this catheter enabled left heart filling pressures to be monitored, its use was associated with a number of complications and there is no firm evidence to indicate that it reduces mortality in severely ill patients [26]. Indeed, some authors suggest that the use of the catheter increases morbidity and mortality [27].

Until the late 1950s, PCO₂ could only be measured by the tedious Van Slyke analysis and the use of rather crude pH electrodes. Thus, ventilators were usually set to provide a minute volume that was 20–30% more than the norms calculated from the Radford or Herzog ventilation nomograms [28, 29]. These nomograms were designed for patients with normal lungs and it would be expected that patients with diseased lungs would require more ventilation. But how much more? Because of this uncertainty, patients with respiratory failure were hyperventilated until apnea occurred, apnea being the sign that ventilation was sufficient. Apnea also ensured that the patient did not fight the ventilator. If ventilatory drive still prevented synchronisation with the ventilator, apnea was produced by the administration of opioids or muscle relaxants. The introduction of the rebreathing technique for measurement of PCO₂, the Astrup interpolation technique, and the development of O₂ and CO₂ electrodes in the late 1950s, revolutionised treatment and encouraged the attempt to produce normal blood gas values. In patients with severe lung disease, this often resulted in the use of high inflation pressures. Peak airway pressures increased further in the early 1970s, when it became known that the application of a positive end-expiratory pressure could improve gas exchange in the lung by preventing alveolar collapse during expiration. It soon became apparent however, that these high pressures (up to 70 cm H₂O) produced lung damage, leading to the development of techniques designed to minimise such harmful effects. These will be discussed later.

Post-1952 European Ventilators

Several of the physicians visiting Copenhagen during and after the 1952 epidemic, recruited local engineers to build their own mechanical ventilators, to provide long term respiratory support. Many were primitive. For example, the Radcliffe ventilator, introduced in 1953, was based on the Oxford Inflating bellows developed in the Nuffield Department of Anaesthetics. Oxygen was added to air in a T-piece reservoir and the mixture sucked into a weighted bellows by a mechanism driven by an electric motor. The weights then forced the gas into the lungs through a pressure-operated non-rebreathing valve. The motors were powered by mains

Fig. 57.4 Engström 150 ventilator in a Swedish Hospital. The warmed water humidifier is on the left and the gas meter recorded expired volume breath-by-breath. (From Safar P, *Respiratory Therapy*, by kind permission of the Publishers, F A Davis Company)

electricity or a 12-volt car battery, and 8 ventilation rates could be selected with a bicycle gear change and a hand-operated clutch. The latter allowed the ventilator to be powered by turning a gramophone handle in case of power failure. The non-rebreathing valve situated close to the patient sometimes failed when wet, and was later replaced by cam-operated valves in the machine. Since the Radcliffe ventilator was cheap, simple, robust and could be maintained by any bicycle mechanic, it was widely used in the UK and developing countries for over 30 years [30]. In 1962, the ventilator was modified so that it could be used both in the operating room and ICU. This flexibility resulted in its widespread use throughout the UK and Commonwealth [31]. The Radcliffe was classified as a *pressure generator* since the weights on the bellows produced a constant pressure during inspiration; the tidal volume depended on the compliance (stiffness of the lungs), the airway resistance and the duration of inspiration. Since the lung characteristics could change rapidly it was essential to monitor the expired volume at regular intervals.

Other ventilators, often powered by compressed gases or an electrically driven piston or bellows, produced a fixed pattern of flow (*flow generators*). In these machines (*e.g.* Engström, Blease, Smith-Clarke), changes in lung compliance or airway resistance resulted in changes in airway pressure, though tidal volume was maintained. Since a knowledge of ventilator characteristics is essential for effective therapy, the Cardiff anaesthesia department physicist, WW Mapleson, utilised these and other major differences in functional

characteristics (such as methods of initiating or controlling the duration of inspiration and expiration) to produce a classification of ventilator mechanisms that remains valid to this day [32]. In the course of his investigations, Mapleson found that many ventilators did not perform as predicted and over the next 20 years British and International Standards Organisations developed test lungs and procedures that revealed deficiencies in design and improved safety standards [33].

One man who did understand ventilator mechanics was Carl-Gunnar Engström, a doctor working in a Swedish infectious diseases hospital during the 1949 and 1950 polio epidemics [34]. He invented one of the world's most successful mechanical ventilators (Fig. 57.4). With remarkable percipience, he recognised that patients died because of inadequate ventilation and designed an intermittent positive pressure ventilator that delivered breaths of controllable volume and frequency. This ventilator was used successfully in Copenhagen towards the end of the 1952 epidemic, and the Swedish government then ordered several machines, no doubt anticipating the Swedish polio epidemic in 1953, where they demonstrated their effectiveness. The machine proved lifesaving in other conditions including respiratory insufficiency due to skull trauma, brain tumour, and barbiturate intoxication. It was also adapted to provide controlled ventilation during anaesthesia with either a non-rebreathing or partially closed circuit. Though the precision Swedish engineering made this machine and its successors expensive, they were and are widely used throughout Europe and other parts of the world.

Fig. 57.5 The Manley ventilator that normally sat on the bottom shelf of the Boyle's anaesthetic machine. (Courtesy of the author.)

The British answer to this machine was the Smith-Clarke, designed by the ex-chief engineer of the Alvis motor company. Like the Rolls Royce car, the ventilator came with a mahogany box containing an oilcan, but the operator had to supply his own engine driver's cap to fully enjoy oiling the cams. The Cape ventilator was the popular successor to this machine and incorporated an efficient, low-volume, hot-water humidifier. The Cape-Waine version of this ventilator was designed for use in anaesthesia with CO₂ absorption [35].

In the UK, two other ventilator systems were commonly used during anaesthesia. In one, the ventilator was part of a non-rebreathing system, the fresh gas being led into a weight- or spring-loaded bellows and intermittently discharged into the patient. In the Howells and Manley ventilators the inspiratory and expiratory valves were pneumatically controlled whereas in the Barnet they were controlled by solenoids. These ventilators sat comfortably on the lower shelf of the ubiquitous Boyle's anaesthetic machine, were relatively cheap, safe and simple to operate (Fig. 57.5). Some models could also be used in intensive care [36, 37].

The second type of ventilator system used during anaesthesia in the UK was based on the Bain (Mapleson D) breathing system. The anaesthetic gas mixture was delivered to the patient via a narrow bore tube situated concentrically within a light-weight 22 mm corrugated tube and the ventilator was attached to a fitting that replaced the Bain expira-

tory valve by means of a 1.5 m length of corrugated tube. This prevented dilution with the gases delivered by the ventilator. Interestingly, when tidal volume was set to 10 ml/kg body weight, CO₂ levels could be controlled by adjusting the fresh gas flow, an inflow of 70 ml/kg body weight providing normocapnia [38, 39]. An advantage of this system was that the delivery tubes could be lengthened so that the ventilator could be situated some distance from the patient (for example during magnetic resonance imaging), and it could be used with almost any ventilator. It was commonly used with the Pneupac, a simple, compact, fluid logic ventilator that was originally designed for resuscitation. There were four models, the one designed for anaesthesia having controls for flow rate and inspiratory and expiratory times [40]. This compact system was eventually displaced by the new generation of anaesthetic machines, fitted with integral ventilators and rapid response gas monitors that enabled low gas flows to be used safely, thus conserving expensive volatile agents and reducing pollution of the environment with anaesthetic gases and vapours.

Early US Intensive Care Ventilators

Two engineers (Bird and Bennett) devoted to the problems of flying at high altitude during World War II, developed popular ventilators in the US. Compressed oxygen drove the ventilators and the patient triggered inspiration. Although neither machine was developed for use in the ICU, both were widely used in ICUs when these opened in the US in the late 1950s [16].

Forrest Bird, an American aviator and inventor, was awarded the Presidential Citizens Medal by President George W Bush in 2008 and, the National Medal of Technology and Innovation by President Barack Obama in 2009. He developed his ventilator in Palm Springs, California for patients undergoing bronchodilator therapy for chronic respiratory diseases, the prototype being built from three tin cans and a doorknob (Fig. 57.6). Although Bird and Bennett ventilators dominated the US market until the late 1960s, the early versions of the Bird were not very suitable for long-term use. The control of oxygen concentration was poor, the nebulizer provided inadequate humidification, and mechanical delay and relative insensitivity of the triggering mechanism sometimes caused distress to patients. Bird discovered that he could administer drugs other than bronchodilators via the nebulizer, and once told the author that with a demanding patient he was sometimes tempted to replace the bronchodilator with cascara sagrada—but he never did.

The Bennett PR2 ventilator was developed from one of some forty devices that Ray Bennett and his colleagues produced to help treat polio patients (Fig. 57.7). These significantly decreased mortality [41]. The unique feature of

Fig. 57.6 Dr Forrest M. Bird with the prototype (in his left hand) and Mk 7 versions of his ventilator. (Courtesy of Dr Bird.)

Bennett's ventilator was a flow-sensitive valve that initiated inspiratory flow from the ventilator when the patient inhaled, and terminated flow when it had decreased to a predetermined level. The device was originally intended to augment ventilation of patients in tank ventilators when the patient developed lung complications and the tank could not provide sufficient ventilation, but it was subsequently used to provide IPPV to patients in the ICU independent of the tank. Although the Bird and Bennett machines could nebulize a bronchodilator drug, they could not supply adequate humidification. Bennett subsequently designed many other respiratory assist devices including the Puritan-Bennett MA-1 ventilator, one of the first electronically controlled devices, that was widely used in the 1970–80s.

Credit for the first dedicated ICU ventilator in the US goes to Jack Emerson of Boston, who cooperated with anaesthesiologists Donald Benson in Baltimore, and Henning Pontoppidan in Boston, to produce the Emerson post-operative ventilator in 1965. An electrically driven piston with a variable stroke drove gas into the lungs. Varying the motor speed throughout the cycle controlled the inspiratory

and expiratory times. Later, Emerson designed a ventilator allowing the patient to trigger each breath. Emerson's ventilator included a hot water humidification system that ensured that lung secretions could be aspirated easily. Another of Emerson's machines featured a sigh mechanism that intermittently increased tidal volume for a few breaths. This feature was introduced because the group at the Massachusetts General Hospital believed that such a sigh could re-expand collapsed alveoli in patients requiring long-term ventilation.

US Anaesthesia Ventilators

American anaesthesiologists have used anaesthesia machines with circle CO₂ absorption systems and relatively low fresh gas flows (thought of as 2 to 4 l/min in Europe and 2 l/min or less in the US), whereas in many European countries the non-rebreathing system has been more popular. The use of low fresh gas flows conserves anaesthetic agents, but the composition of gases entering the lung may differ from that in the fresh gas delivered from the machine. With a CO₂ absorption system, the obvious way to provide mechanical ventilation was to replace the reservoir bag with a bag-in-bottle system, the bag being compressed by the ventilator mechanism. The Jefferson ventilator was an early example of this system. The Bennett B₂A assistor introduced in 1957 utilised a hanging bellows instead of a bag and, despite its name, was one of the first US ventilators that could be adjusted to provide controlled ventilation with a predetermined tidal volume (Fig. 57.8).

The hanging bellows had the advantage that there was no impedance to expiration but, in the 1970s, it was realised that a leak in the circuit could dilute the anaesthetic mixture. As a result, manufacturers introduced bellows that expanded upwards in expiration. Failure to expand demonstrated the presence of a leak, but the bellows had to be made of light material to minimise the resistance to expiration. With the increasing sophistication of measurement techniques and the use of very low fresh gas flows to conserve expensive volatile agents and reduce pollution, manufacturers began to realise that bag- or bellows- in-bottle systems contained a large volume of gas that was compressed during each inflation. This not only reduced the tidal volume delivered to the patient, but also distorted the inspiratory flow pattern.

To counter these criticisms, manufacturers such as the Draeger company now use directly driven piston type ventilators that have minimal internal compliance and can be accurately calibrated to deliver precise tidal volumes, despite changes in airway resistance or compliance. With such devices and the sophisticated monitoring incorporated in modern machines, low fresh gas flows can now be used safely.

Fig. 57.8 Bennett assister. This was one of the first effective US anaesthesia ventilators and could provide controlled as well as assisted ventilation. (From Mushin WW et al. Automatic ventilation of the lungs, 2nd edition, 1969, p. 328, with permission from Wiley-Blackwell)

Neonatal Ventilators

In 1953, Ian Donald, a Scottish obstetrician at the Hammer-smith Hospital and Postgraduate Medical School in West London, recognised that many infants died of respiratory inadequacy at birth and that a mechanical device was needed to replace the midwives' use of mouth-to-mouth ventilation. There were many problems in developing apparatus for such a difficult clinical situation and the electronically controlled pneumotron ventilator that he designed met with only limited success [42]. The British Oxygen Company subsequently manufactured a patient-cycled intermittent positive pressure machine (the Pneumotron) that never achieved popularity. In the US, Goddard *et al.* also attempted to ventilate neonates, but again results were poor [43]. In 1958, Swedish workers used adult machines adapted to produce small tidal volumes, and reported the survival of three babies treated with IPPV [44]. In 1959, when the author attempted to treat neonatal tetanus using curare-induced paralysis and IPPV with the Smith-Clarke ventilator (minimum tidal volume 250 ml), he had to decrease the volume delivered to approximately 16 ml by adding a parallel compliance—a 500 ml reservoir bag sandwiched between two pieces of hardboard held together by elastic bands [45]. With the gradual development of appropriate apparatus and new techniques, neonatal resuscitation became a successful enterprise and the author recently had the great pleasure of seeing his 32 weeks-gestation grandson, who was ventilated for 8 days, depart for university. A Wellcome Trust Witness Seminar has nicely chronicled the development of neonatal intensive care in the UK [46].

Ventilator, Airway, and Vascular Pressures

During the 1960s, new ventilators were introduced, and research demonstrated how IPPV affected circulation and gas exchange. In 1967, Ashbaugh and colleagues [47]. described the adult respiratory distress syndrome (later called the acute respiratory distress syndrome or ARDS) in patients who had multiple injuries, shock or severe sepsis. ARDS reflected widespread damage to the lung, and severe impairment of oxygen transfer. It was often fatal. Increasing lung volume by applying positive pressure to the airway during expiration (positive end-expiratory pressure or PEEP) improved oxygenation by preventing collapse of the damaged air sacs. This was soon applied to improve oxygenation in ARDS, but it increased end-inspiratory and mean pressures throughout the respiratory cycle. The increased pressures in the airways and thus the inside of the chest, decreased the return of blood to the heart, decreased the output of the heart, and decreased blood pressure. Using monitoring of arterial and venous pressures, physicians learnt to restore heart output by increasing venous pressure, by transfusing fluid or using drugs to constrict the veins. The introduction of the Swan-Ganz catheter in 1970 enabled pulmonary artery and left atrial pressures to be measured at the bedside, but a 2006 Cochrane review concluded that the knowledge gained therefrom did not appear to improve patient outcome [48].

New Techniques of Respiratory Support

High airway pressures imposed other serious effects. In 1967, Nash *et al.* [49] described lung damage in adults whose lungs were ventilated for long periods with high airway pressures and high concentrations of oxygen. Northway *et al.* [50] also described lung damage in neonates mechanically ventilated to treat respiratory problems at birth. So, the 1970s saw the development of techniques of ventilation designed to minimise the harmful pulmonary and circulatory effects of high airway pressures, and minimize lung damage [51].

Since many patients with acute lung disease have alveolar collapse, reduced functional residual capacity and increased shunt, the first move was to increase lung volume by applying continuous positive airway pressure (CPAP) during spontaneous ventilation. This often increased oxygenation but in many patients the PaCO₂ increased, necessitating additional respiratory support [52]. The next development added “mandatory breaths” of predetermined volume delivered by the ventilator without any attempt to synchronise them with the patient’s spontaneous ventilation (intermittent mandatory ventilation or IMV). The BabyBird ventilator described in 1971 was first to use this technique [53, 54]. When patient-triggering technology improved in the 1970s, it became possible to synchronise these breaths with one of the spontane-

ous breaths (synchronized intermittent mandatory ventilation or SIMV). The volume of the mandatory breath was initially preset, but with the later introduction of *pressure support* the patient’s spontaneous breath could be augmented by a predetermined level of pressure developed by the ventilator. This technique is frequently used in current practice. Two other techniques that have been widely used in some centres are: airway pressure release ventilation (APRV), where the patient respire spontaneously at a high level of CPAP and elimination of carbon dioxide is assisted by allowing the lung to deflate to a lower CPAP level at regular intervals; and biphasic positive pressure ventilation (BIPAP) where the patient breaths spontaneously at two different levels of CPAP, the lower CPAP levels helping carbon dioxide elimination and the higher levels preventing lung collapse.

Microprocessor Controlled Ventilators

The introduction of the microprocessor-controlled ventilator made these techniques possible. The first such ventilator in Europe was the Siemens Servo 900 series, introduced in 1971. In the US, the earliest machines were the Puritan Bennett 7220 (1984), the Bear 5 (1985) and the Hamilton Veolar (1986). Unique to these new ventilators were their high sensitivity and the rapid response of the sensors and valve mechanisms. These eliminated the mechanical delay that vitiated patient-triggering in earlier ventilators.

Respiratory Therapists

Alas, these new machines were complex, offering many controls, and adjustment of one control often affected the impact of another. Those unfamiliar with the intricacies of a machine could worsen the patient’s condition by wrong adjustment of the settings. In Europe, doctors working in ICUs usually retained control of ventilator settings, but in the US, respiratory therapists assumed this aspect of treatment.

The development of respiratory therapy as a sub-specialty has two origins. First, in the pre-ICU era many American hospitals employed oxygen therapy technicians to set up oxygen tents and maintain supplies of oxygen. This service provided income for departments accepting responsibility for its organisation. The increasing tendency to concentrate seriously ill patients in a special unit, created a parallel need for technicians to service and sterilize mechanical ventilators and other respiratory equipment. The increased responsibilities of these tasks attracted more sophisticated technicians, and as ventilators became more complex, doctors increasingly left their settings to the technician. In the 1970s, the speciality of critical care developed, embracing emergency care, resuscitation and intensive care. This attracted physicians from

other disciplines and anaesthetists gradually returned from intensive care to the more lucrative practice of anaesthesia. Since intensive care physicians had less interest in technical devices than anaesthesiologists, respiratory therapists gained more control over ventilator therapy. These increasingly sophisticated workers have helped with the development of new techniques and the design of new ventilators, and indeed have made significant contributions to the literature.

High Frequency Ventilation

Another way to decrease airway pressures was to use high frequency ventilation, providing the same ventilation with smaller tidal volumes. Since the dead space didn't change significantly with frequencies of up to 100 breaths per minute, large minute volumes were required to maintain the same alveolar ventilation and CO₂ removal. Swedish doctors introduced the first technique (high frequency positive pressure ventilation or HFPPV) in 1971 to decrease the cyclical effects of IPPV during experiments on the brain circulation. A second technique, high frequency jet ventilation (HFJV) used a high gas pressure and a solenoid-controlled valve to produce jet pulses of 60 to 300 breaths per minute. Directed into a tube inserted into the trachea, the jet created the positive pressure that inflated the lungs. The resulting uncertain tidal volume depended on the design of the jet, the driving pressure, the entrainment of surrounding gas, and pulmonary compliance and airway resistance. Minute volumes were large and humidification difficult. The technique has proven useful in selected applications such as surgery on the larynx or in the trachea, where the absence of a tracheal tube facilitated surgery. Lunkenheimer, a Berlin physiologist, introduced a third technique, high frequency sinusoidal oscillations at 300–1800 (!) breaths per minute [55]. How the resulting small tidal volumes achieved gas exchange is unclear, but the technique has proven useful to sustain ventilation in infants who have suffered severe lung damage at birth [56]. Once again, Emerson had beaten the field, since he had noted the panting of a dog and applied for a patent of a device to emulate this pattern of breathing in 1954–5 [57].

Extracorporeal Membrane Oxygenator (ECMO) Support

Not surprisingly, some centres used a heart lung machine to maintain patients with extremely severe acute lung disease, hoping to buy the time needed to allow a natural recovery. Even ignoring the immense technical difficulties, trials have not shown a significant advantage over conventional treatments [58]. The technique may be of value in babies with neonatal respiratory distress, but treatment with nitric oxide

inhalation, surfactant replacement therapy and high frequency oscillation has decreased the use of ECMO in such patients.

In 1978, Kolobow and colleagues suggested separating oxygenation and carbon dioxide removal by passing only 20% of the cardiac output through a membrane artificial lung optimized for carbon dioxide removal. Oxygenation was accomplished by the patient's lungs plus the membrane lung [59]. Although Gattinoni and colleagues in Italy, and several other European centres achieved some success with the method, complexity and cost prevented its widespread application [60].

Permissive Hypercapnia and Low Volume Ventilation

Many patients with respiratory failure tolerate moderately increased levels of carbon dioxide without undue distress, but treatment with mechanical ventilation usually aims to accomplish normal levels. During the 1980s and 1990s, several studies confirmed that high inspiratory pressures could further damage lungs of patients with lung disease. It also appeared that repeated opening and closing of small air sacs at each breath could damage lungs, leading to the suggestion that end-expiratory pressure should be sufficient to prevent alveolar collapse, and that peak inspiratory pressure should be decreased by reducing tidal volume. In 1984, Hickling *et al* applied this pattern of ventilation, perforce moderately increasing carbon dioxide levels. They called this technique *permissive hypercapnia*, and showed that it shortened the duration of ventilator use and decreased mortality. Positive end expiratory pressure plus limited tidal volume producing permissive hypercapnia is now standard treatment for severe lung disease [61].

Non-Invasive Ventilation

Effective IPPV in severe lung disease requires tracheal intubation or tracheostomy. But intubation and tracheostomy may produce complications, thereby increasing interest in non-invasive methods of respiratory support using nasal or full-face masks. There are two main applications: IPPV to augment spontaneous breathing during acute attacks of respiratory infection in patients with chronic obstructive lung disease; and nasal CPAP to treat snoring and obstructive sleep apnoea. The problem with these approaches is air-leak at the mask-patient interface. A large capacity pressure-generating ventilator can increase flow to maintain the pressure profile despite a large leak. Modern lightweight plastic masks have decreased leakage, but success still depends on good nursing care and encouragement. The use of nasal

CPAP for treatment of obstructive sleep apnoea is usually successful, and greatly reduces daytime somnolence because of improved sleep.

Afterthoughts

The development of Intensive Care was recently reviewed by doctors and nurses who pioneered the speciality in the UK [62]. Doctors increasingly adopted mechanical IPPV after the Copenhagen polio epidemic. Over the next two decades much was learnt about the physiological effects of IPPV. It was shown to decrease mortality in many types of respiratory failure. Studies in the late 1960s demonstrated that high airway pressures could impair circulatory stability and damage the lungs. Techniques of respiratory support that limited mean and peak pressures reduced these complications. The advent of microprocessor-controlled ventilators facilitated the increased use of a spontaneous breathing component, further decreasing the circulatory effects of IPPV and possibly improving the distribution of ventilation. The use of CAT scans by Luciano Gattinoni and his colleagues in Milan from the 1980s, revolutionised our understanding of the pathophysiological changes accompanying the acute respiratory distress syndrome and other lung diseases [63, 64]. Other studies identified the mechanism of lung damage with IPPV and suggested methods by which such damage could be minimised. Although there is still much to be learnt about mechanisms of lung damage and the effectiveness of the various therapeutic options, there is no doubt that the use of mechanical ventilation can greatly decrease mortality in the seriously ill patient.

Jukka Takala

Summary

Most historians believe that Bjørn Ibsen's response to the 1952 polio epidemic in Copenhagen led to intensive care medicine (ICM) and intensive care units (ICUs). The epidemic involved thousands of patients, many dying from respiratory failure. Ibsen convinced his skeptical colleagues to concentrate all patients with respiratory failure in one area and institute tracheostomy and manual positive pressure ventilation in these patients. Attempts to understand the pathophysiology of respiratory failure and monitor its treatment accelerated the development of blood gas analysis by Poul Astrup.

Modern ICUs arose from the application of the concepts of managing respiratory failure from polio; intermittent positive pressure ventilation with mechanical ventilators; and locating all human resources and patients requiring high level care into a single location. Mechanical ventilation was an important theme, but the French, particularly Rabin in the 1960s, also focused on infections, with the world following suit decades later.

Many advances accompanied the development of ICUs. Cournand's work in the late 1940s suggested that positive end-expiratory pressure (PEEP) decreased cardiac output. However, in 1967, Ashbaugh and Petty reported that PEEP corrected severe hypoxemia during mechanical ventilation in patients with hypoxemia refractory to mechanical ventilation without PEEP, probably by expanding otherwise collapsed bronchi or alveoli.

The evolution of ICM in the 1970s and 1980s led to recognition of multiple organ failure. Patients now survived the acute phase of single organ failure but subsequently died from a poorly defined but clinically recognizable syndrome of failure of several organs, with sepsis as a postulated underlying cause. Knaus suggested that chronic diseases, combined with the severity of physiologic abnormalities during the first 24 hrs of intensive care, could predict outcome. Thus was born the APACHE scoring system in 1981, and then APACHE II, in 1984. Other scoring systems followed.

Until the early 1980s, research in intensive care medicine developed slowly. Large randomized controlled trials towards the end of the 1980s presaged the 1990s application of evidence-based medicine. Notwithstanding the high hopes placed on large randomized controlled trials, their results in intensive care medicine have largely been disappointing; new therapeutic interventions have not improved outcome. Some have even been harmful, and some positive results have not been reproducible. Perhaps these difficulties should have been expected, considering the complexity of underlying clinical problems in ICU patients. Several factors complicated ICM: poorly definable syndromes rather than clear-cut diseases, the heterogeneity of disease severity and treatment, and poorly understood but highly relevant interactions between treatments and underlying pathophysiology. There is still much work to do.

In the Beginnings

As a medical specialty or special area of competence, Intensive Care Medicine (ICM) is young—even compared with anesthesiology, one of its essential parents and partner specialties. Surgery, internal medicine, and pulmonology have also volunteered for parenthood. The present place of ICM in the spectrum of medical specialties varies in different countries. In some, it is an independent specialty. In others, it is a superspecialty open to multiple base specialties, a

subspecialty anchored to a specific basic specialty, or integrated within a specialty (e.g., anesthesiology). Some presently regard it as a special competence, based on a common skill-mix acquired by a competence-based training program open to physicians from multiple specialties. How did we get there?

It is tempting to outline the history of ICM based on “firsts”. However, in trying to do this, I found myself confronted by difficulties with definitions, conflicting dates, controversial and perhaps competing claims, and geographical and cultural bias. In contrast to the “firsts” of say, ether anesthesia, open heart surgery, or the discovery of penicillin, intensive care is defined by care processes and organization—issues of continuing importance to ICM. ICM can be defined as prevention, reduction, and

removal of the temporary risk of death. A concentrated investment of human, material, and technological resources for monitoring and treatment are employed to defeat death and morbidity. This view of ICM facilitates tracing its evolution.

Although the evolution of ICM took place just recently—the last half century, selecting the individuals associated with major contributions is difficult, partly because of the problem of fairly ranking of colleagues still actively contributing and practicing, and partly because of the evolutionary rather than revolutionary development of ICM. I have therefore approached the evolution in terms of ideas, themes and concepts, naming only some of the individuals involved. Due to this essayist's admitted bias, some of those who undoubtedly should have been included (either based on their own view or that of others) have been omitted, whereas other less famous individuals have been included to illustrate specific aspects of the story.

Cohorting and the Basic Concepts of High-Dependency Care

The need to treat war casualties or victims of major deadly epidemics, probably prompted the idea of concentrating cohorts of sick patients to enhance their monitoring and care. Many regard Florence Nightingale, the famous British nurse, as the first to establish an ICU (Fig. 58.1) [1]. During the Crimean war in the 1850s, she collected the most severely injured casualties in one area to observe them more effectively, and intervene when needed.

Some authors refer to an earlier postoperative ward in the Newcastle Infirmary, England, around 1801, with “two

five-bed rooms adjacent to the operating theatre”, reserved for the sickest patients and those recovering from surgery [2]. If the latter is correct, then the first efforts in high-dependency care preceded both Nightingale's efforts and the introduction of general anesthesia by several decades. Recovery rooms for patients undergoing ether anesthesia were introduced in the 1870s, in the Massachusetts General Hospital in the US. These facilities probably provided immediate care after anesthesia, and thus cannot be regarded as predecessors of ICUs. Postoperative high-dependency care units appeared on both sides of the Atlantic in the 1920s in parallel with the development of more complex surgical procedures.

Early Steps in Technological (R)evolution

In addition to the concentration of human resources, the application of technology and use of invasive therapeutic interventions have been associated with ICM. General anesthesia, airway management, mechanical ventilation and vascular access in the nineteenth and early twentieth centuries developed in parallel, and independently rather than evolving in association with high-dependency care concepts. Nevertheless, these parallel developments laid the foundation for ICM as we know it today. Ake Grenvik, one of the pioneers of critical care medicine in the US, and Michael Pinsky recently reviewed the evolution of the ICU as a clinical center, and ICM as a discipline, using the development of technology as the main reference [3]. According to Grenvik, “intensive care medicine owes its roots to the support of failing ventilation.”

If so, perhaps it began with Vesalius, who described the use of positive pressure ventilation in the sixteenth century

(a partial translation of the original reference “*De Humani Corporis Fabrica*” by Vesalius is available on the Internet at <http://www.ncbi.nlm.nih.gov/pmc/articles/PMC1965933/pdf/bullnyacadmed00859-0008.pdf>):

“That life may in a manner of speaking be restored to the animal, an opening must be attempted in the trunk of the trachea, into which a tube of reed or cane should be put; you will then blow into this, so that the lung may rise again and the animal take in air. Indeed with a slight breath in the case of the living animal, the lung will swell to the full extent of the thoracic cavity, and the heart will become strong and exhibit a wondrous variety of motions.”

It was then forgotten for centuries.

New trends and techniques in thoracic surgery in the early twentieth century triggered the next major steps in technology related to sustained artificial ventilation. Ferdinand Sauerbruch (1875–1951)—probably as notorious as he was famous for his surgical skills—influenced the evolution of future intensive care technologies [4] (Fig. 58.2). In 1904 he used a subatmospheric surgical chamber to inflate the lungs of patients undergoing thoracic surgery, but he forbade the addition of positive pressure ventilation. The patient’s head was outside the chamber, with the neck tightly sealed, and the patient’s body and the surgical team were inside the chamber. This created conditions equivalent to continuous positive airway pressure (CPAP), maintaining lung volume and supporting oxygenation by preventing atelectasis and thereby shunting, while the chest was open. Although the lungs might be inflated, diaphragmatic movement produced minimal ventilation when the chest was opened, and supplementary oxygen was necessary to prevent cyanosis—indicating progressive hypoventilation and increased alveolar pCO_2 . Sauerbruch thus advanced the development of future intensive care technology by demonstrating some of the beneficial effects of CPAP. At the same time, he may also have delayed other developments, most notably the use of tracheal intubation, positive pressure ventilation, and, as we will see later, vascular access. The sub-atmospheric surgical chamber shows Sauerbruch as the brilliant surgeon and innovator; the hindering of tracheal intubation and vascular access exemplify Sauerbruch’s negative influence.

Franz Kuhn (1866–1929), a German surgeon, described orotracheal intubation in 1902–1911 [5]. Others proposing tracheal intubation at the end of the nineteenth century included Karl Maydl (1853–1903), a Prague surgeon, and the Viennese physician Viktor Eisenmenger (1864–1932), but their ideas did not receive the attention that they deserved. Sauerbruch vigorously opposed the use of orotracheal intubation, and effectively delayed its introduction to clinical practice. Orotacheal intubation came into wide-spread use in the 1940s after the introduction of curare into anesthesia.

In the late 1920s, the first device suitable for prolonged artificial ventilation, the iron lung, was invented. Unlike

Fig. 58.2 In the early 1900s, German surgeon Ferdinand Sauerbruch invented a subatmospheric surgical chamber to prevent lung collapse in patients undergoing thoracic surgery, thereby demonstrating the benefits of continuous positive airway pressure. [Photo originally published as Plate 5 in *The Dismissal: the Last Days of Ferdinand Sauerbruch, Surgeon*, by Jurgen Thorwald. Thames & Hudson: London, 1961. Original copy owned by the National Library of Australia. Instructions also say to include persistent identifier or call number, possibly 610.92 SAU (2555658)]

the inventors of the surgical negative pressure chamber, the inventors of the iron lung—Philip Drinker and Louis Shaw—were interested in more than a short-term solution: their 1929 paper was appropriately titled “An apparatus for the prolonged administration of artificial respiration” [6]. John Emerson, the founder of the JH Emerson Co further developed their invention for larger-scale commercial production [7]. The iron lung (or tank respirator) enclosed the patient within a metal cylinder up to the head and neck, with an airtight collar surrounding the neck. Cyclic intermittent negative pressure around the body within the cylinder effected ventilation. Major problems in long-term use related to reliability, respiratory tract care, accessing the abdomen and thorax and comfort. Cuirass negative pressure ventilators were a modification of the iron lung, restricted to enclosing only the thorax. Although the cuirass allowed better access and was far less expensive, it was less effective as a ventilator, and nursing care and comfort remained problematic.

Neither device solved the crucial problem of the patient who could not maintain their own airway.

Major developments in vascular access paralleled the early steps of ventilatory support. The young German surgeon-in-training Werner Forssmann (1904–1979) summarized the problems related to the lack of central vascular access in the introduction of his 1929 paper “*Die Sondierung des rechten Herzens*” [8] (*Right heart catheterization*; freely translated from German by me): “In acute dangerous situations, where the patient is at risk of cardiac arrest, i.e. by acute collapse, in cardiac failure, or through complications of anesthesia or poisoning, rapid treatment with drugs locally is necessary. In such cases, attempting an intracardiac injection is often the only possibility to save the patient.” Forssmann then described the complications of cardiac puncture and proposed right heart catheterization as the solution [9]. He tested the feasibility of such a procedure during autopsies. Then, with the help of a “friendly colleague”, Forssmann advanced a well-lubricated ureteral catheter via his right brachial vein to a depth of 35 cm and verified the intrathoracic position of the catheter using X-ray. At this stage he broke off the experiment at the urging of the colleague, who considered the procedure too risky. One week later, Forssmann advanced a 65-cm-long ureteric catheter through his own left brachial vein to its full length, verifying the catheter tip in the right atrium by chest X-ray—he was disappointed that he did not choose a longer catheter. He then described the first clinical use in a patient in severe septic shock who initially responded favorably to fluids and drugs but died after a few hours. Sauerbruch rewarded Forssmann by firing him. Undeterred, Forssmann continued to develop right heart catheterization and pulmonary angiography as a diagnostic tool.

According to Forssmann [9], O Klein made the first measurements of cardiac output using a right heart catheter and the Fick principle in 1930 [10]. Next, Andre Cournand advanced his special catheters into the pulmonary circulation in the late 1930s and early 1940s, and shared the Nobel Prize in physiology/medicine with Forssmann in 1956 [11]. It took more than 40 years after Forssmann’s initial experiments to convert these tools to practical monitoring devices.

Polio Epidemics Jump Start Modern ICM

An outbreak of polio in California in the late 1940s resulted in many patients needing tank and cuirass ventilators and intermittent positive pressure ventilation. There is inconsistency in the reported numbers of patients that were treated with the different methods. Albert Bower and Ray Bennett reported their experiences with ventilator support in nearly 300 cases in 1948 [12].

The Californian epidemic was vastly overshadowed by the catastrophic polio epidemics in the early 1950s prompting

the next important technological and clinical developments in prolonged mechanical ventilation. The response to the epidemics, particularly the 1952 epidemic in Copenhagen, led to the development of ICM.

Numerous authors have debated details surrounding the Copenhagen polio epidemics and the roles of the various players [13–15]. The doctors, nurses, and other personnel confronted with the initial high mortality, and the large number of new patients arriving daily, had priorities that precluded precise record keeping. It is also meaningless to debate the “firsts”. The heroic efforts of individuals worldwide, especially Bjørn Ibsen, the pioneering intensivist [13–16], have been described in detail, and are also surrounded by folklore. I will summarize the framework, give an approximate temporal sequence of events, and then try to explain why the Copenhagen polio epidemic was so special and why it had such a large impact on the evolution of ICM.

As detailed elsewhere in this book, the late 1940s was an era of rapid development in anesthesiology. Departments of Anesthesia had been established in major hospitals, and the first positive pressure ventilators had been introduced for perioperative use during thoracic surgery. The role of anesthesiologists in Europe was undergoing a major change. European anesthesiologists visited the US, going especially to the Massachusetts General Hospital for training. Concurrently, various anesthesia-related activities commenced in Europe—particularly in Sweden. A commission for future organization of anesthetic services in Copenhagen recommended the establishment of independent departments of anesthesia for each hospital. The World Health Organization founded the Anaesthesiology Centre Copenhagen, in May 1950, drawing leading anesthesiologists from the UK, Sweden and the USA to teach in a one-year anesthesia training course. The “*primus motor*” (“prime mover”) of this course was Erik Husfeld, a thoracic surgeon, who served as the course director from the first course until 1973. Thus, perhaps fortuitously, there was already a considerable focus in Copenhagen, on this “specialty in the making [14].”

The scale of the epidemic, and the ultimate success in saving lives in Copenhagen, received much publicity. The struggle with polio elsewhere is less well known. During the polio epidemic in many other countries, medical communities endured frustrating experiences treating the severely paralyzed patients. In postwar Europe, resources were scarce, and innovative solutions were badly needed. In Germany, Alfred Dönhart, a pulmonologist from Hamburg, together with the Dräger company, converted old submarine torpedo-tubes into iron lungs (Fig. 58.3). Dräger became a major producer of ventilators, anesthesia machines, and other medical equipment.

In California, clinician Bower and engineer Ray Bennett described a comprehensive approach to the patient with respiratory failure, in their 1950 [9] paper reporting the results of their treatment of more than 70 polio patients with

Fig. 58.3 A prototype of an “iron lung”, developed by the German firm Dräger in 1947. (Courtesy of Drägerwerk AG & Co. KgaA.)

their combined approach, reporting improved outcomes with positive pressure ventilation in comparison with the use of the tank ventilator alone. They developed different types of positive pressure devices, primarily for use in combination with the tank ventilator, but also capable of supporting ventilation via mask during nursing care. Why they insisted on the combined use of the tank ventilator and the positive pressure device is unclear. They also developed tracheostomy tubes specifically for prolonged assisted ventilation. Blood gas analyses were used to assess the adequacy of ventilation. Humidifiers, monitoring devices and alarm systems were added. Special mechanical mattresses were developed to prevent pressure sores.

Until recently, these accomplishments received surprisingly little attention, although Ibsen, the pioneer in the subsequent Copenhagen epidemics, gave Bower and Bennett the credit they deserved. Bennett established a company manufacturing positive pressure ventilators, and the successor of his original company (Puritan-Bennett), became a market leader in intensive care ventilators worldwide.

The Danish polio epidemic began in August 1952, and by the end in April 1953, almost 5700 polio cases had been registered throughout the country. In Copenhagen, Blegdam Hospital received many of the more seriously ill victims, including 345 patients with either breathing or swallowing difficulties or both. During the second half of August 1952, the number of cases, especially those with paralysis, increased at an alarming rate. Eighty-seven percent of patients with bulbar polio (27 of 31) died. Most physicians incorrectly thought that these patients died from irreversible cerebral lesions of polio. Tank or cuirass negative pressure ventilators were used to support ventilation in patients with respiratory paralysis, but only one tank and 6 cuirass respirators were available.

The high mortality rate and rapid increase in new cases persuaded the chief of the hospital and professor of epidemiology, HC Lassen, to consult with Bjørn Ibsen—an anesthetist. Aware of the reports of Brower and Bennett from the California polio outbreak, Ibsen became convinced that the patients suffered from progressive severe hypercapnia, not irreversible brain injury. He believed that the high blood CO_2 content resulted from hypoventilation and not metabolic alkalosis, as was thought at the time. Ibsen convinced his skeptical colleagues to undertake a trial in a test patient, with tracheostomy and manual positive pressure ventilation. After initial difficulties (it was initially impossible to inflate the patient’s lungs due to secretions and bronchospasm, followed by hypovolemic shock), the patient’s condition was stabilized. Temporarily transferring the patient back to the cuirass resulted in cyanosis, which disappeared on returning to positive pressure ventilation. This convinced Lassen and his colleagues that Ibsen was correct. The new strategy was then applied to all polio patients with respiratory failure. This was no simple task, since at the peak of the epidemic, 30 to 50 new patients per day were admitted to Blegdams, 6 to 12 with breathing or swallowing problems or both. 1500 students were enlisted over the course of the epidemic to manually ventilate the patient’s lungs around the clock. [17] The new strategy decreased mortality from 90 to 25% in those severe cases. The personal memoir of one of the student “ventilators” gives special insight into the circumstances in Copenhagen [17].

I believe that the success of Ibsen, Lassen, and co-workers illustrates the approaches needed to solve problems in critically ill patients. First, Ibsen used clinical observations based on sound physiologic concepts. Second, he introduced a novel application of existing methodology. Third, he developed a treatment strategy. Fourth, he convinced the decision makers to supply substantial resources. Fifth, a multidisciplinary team was used. Sixth, the logistics necessary for the prolonged treatment of large numbers of patients were established. Seventh, the outcomes of the new strategy were carefully assessed.

The use of positive pressure ventilator support for polio patients with respiratory failure spread rapidly in Scandinavia, continental Europe, and the United Kingdom. It stimulated the development of positive pressure ventilators. The prototype of the Engström ventilator had already been tested in Copenhagen, and was further developed by Carl-Gunnar Engström before the 1953 Swedish polio epidemic. [15] Engström’s company became a major ventilator manufacturer, and was subsequently acquired by Datex—the Finnish manufacturer of anesthesia and intensive care technology and later by General Electric.

The need to understand the pathophysiology of respiratory failure, and monitor its treatment, accelerated the development of blood gas analysis technology. Analysis of blood

gases in the early 1950s was applied during the Copenhagen polio epidemic, but required a glass electrode to measure blood pH, a Van Slyke apparatus to measure CO₂ content, and application of the Henderson-Hasselbalch equation to calculate pCO₂. To circumvent this cumbersome and labor-intensive analysis, Poul Astrup introduced a new approach based on the linear relationship between blood pH and the logarithm of the pCO₂ [18]. This was subsequently used by the Radiometer company—a leading producer of blood gas analyzers today. A more detailed description of this development appears in Chapter 41.

ICUs Arise in the Post-polio Era

Modern ICUs arose in the wake of the polio epidemic. It was not a “big bang” but rather an evolution in which the concepts of managing respiratory failure from polio were applied to a wider patient population: providing intermittent positive pressure ventilation with mechanical ventilators, concentrating human resources, and congregating patients requiring intensive care, thus enabling continuous treatment and monitoring. Among many “firsts”, it appears that the first ICU started at Kommunehospital, the Municipal Hospital of Copenhagen, in December 1953, under Ibsen’s leadership.

In the next decade, ICUs developed in Europe, the US, and Australasia. The new possibilities for prolonged mechanical support of breathing made mechanical ventilation and management of respiratory problems a hallmark of ICUs. In parallel, it became apparent that concentrating human and technological resources covering a range of special skills enhanced care for severely ill patients.

This evolution is evident in the National Academy of Sciences—National Research Council Committee on Anesthesia’s “Workshop on Intensive Care Units”, held 14 October 1963 [19]. The pioneers attending the meeting pointed out problems related to intensive care that remain challenging today: the role of different specialties in the treatment of patients with multidisciplinary problems; the need for special training of nurses and doctors; and the need for attending specialists to be directly responsible for patient care.

John Kinney, a future pioneer in metabolic research in the critically ill [20] at Columbia Presbyterian Medical Center, New York, pointed out that no single physician can attend to a critically ill patient 24 hours a day for 5–6 days. Yet, this was an average length of stay in many units then, and now, necessitating shared responsibility—a fact still denied in many hospitals today. Henning Pontoppidan from the Massachusetts General Hospital, also best known for his contributions to management of acute respiratory failure [21], presented one of the first patient classification systems relevant for ICM. He defined “critical care” as care of patients actually or potentially needing life-saving devices or activities,

and needing highly skilled nursing care and close and frequent, if not constant, nursing observation. Peter Safar, who developed ICM in Baltimore and Pittsburgh, summarized the prerequisites for smooth functioning of intensive care: inter-departmental cooperation, well-defined responsibilities and authority, efficient design of ICU facilities, and standardization of certain procedures—principles that are all applicable today.

The topics discussed at the 1963 “Workshop on Intensive Care Units” reflected important international developments in intensive care. An influx of European anesthesiologists facilitated the adoption of the innovations of Ibsen and his colleagues in the US, after an initial delay, European anesthesiologists had already established connections in the US in the late 1940s, through training in anesthesiology, particularly at the Massachusetts General Hospital (MGH). Henrik Bendixen came to Boston to start his anesthesia residency in 1954, having graduated in Copenhagen in 1951. Henning Pontoppidan graduated one year later and also came to the MGH. Myron Laver and John Hedley-White shared Bendixen’s and Pontoppidan’s interests in respiratory and cardiovascular pathophysiology. This group of innovators produced physiologic and clinical research that established the basic tenets underlying mechanical ventilation in the operating room and in ICM [22–23]. They helped found the first respiratory ICU at the MGH in 1966.

Until the mid-1960s, mechanical ventilation with continuous positive pressure was avoided, largely because Cournaud’s early work in the late 1940s indicated that continuous positive pressure decreased cardiac output. But then David Ashbaugh and Thomas Petty published “*Acute Respiratory Distress in Adults*” (ARDS) in the *Lancet* in 1967 [24], reportedly after rejection by three major American journals. They described the use of positive end-expiratory pressure (PEEP) to correct severe hypoxemia during mechanical ventilation, in 12 patients with hypoxemia refractory to mechanical ventilation without PEEP. This led several groups of researchers, including the Boston group, to study the underlying mechanisms. By the early 1970s Pontoppidan, Laver, and co-workers established that the functional residual capacity of the lungs in ARDS was dramatically reduced, and that it could, at least in part, be restored by applying continuous positive pressure [25]. More Europeans came to Boston, among them Konrad Falke from Germany, who after participating in some of the important studies on PEEP [26], became a leader in using extracorporeal lung support in Europe, and a long-term Editor-in-Chief of *Intensive Care Medicine*.

ICM Evolution in Europe

Europeans who went to the US defined much of the evolution of ICM in North America, and ICM in Europe profited from

knowledge contributed by intensivists returning from the US. Still, the 1950s to the 1970s produced less interaction between English-speaking and non-English-speaking medical communities than today—partly due to language and cultural barriers.

In Germany, the first ICUs appeared in the late 1950s [27], well after 1953 reports of a large case series of patients requiring prolonged ventilation using the iron lung. Mechanical ventilation was an important theme in France as well—however, the French focused early on infections, with the rest of the world following suit decades later. Creative individuals in France had a decisive impact. One such person was Maurice Rapin in Paris who along with his colleagues applied mechanical ventilation to a broad spectrum of patients. His first publications on the use of prolonged mechanical ventilation stem from 1955, in patients with tetanus [28]. They were followed by applications in post-pneumonectomy respiratory failure [29], various paralytic conditions including polio, and postoperative respiratory failure of various etiologies. In 1958, he published two papers outlining the problems of respiratory failure in patients with chronic obstructive pulmonary disease (COPD) [30, 31]. Published in French, neither paper received the attention it deserved. Rapin then published several papers on barbiturate intoxication, and in 1960, his first paper on septic shock. In 1963, he described the risks of nosocomial infections (“Infectious complications in respiratory resuscitation. Etiological, symptomatic and therapeutic data”) [32].

Rapin placed an increasing emphasis on infections, with intoxications and tetanus as his “hobbies”. In 1967, he played a central role in organizing and publishing a Round Table report on “Indications and limits in medical resuscitation”—a first step in the continuing strong French tradition in ethics issues—published in French. At the time he had authored and co-authored nearly 200 papers on various aspects of ICM—all in French—a loss for the non-French-speaking medical community! Rapin and the institution he developed, subsequently produced several internationally prominent French intensivist-scientists, who made major contributions to the scientific basis of modern ICM: Francois Lemaire (respiratory failure, ethics), Christian Brun-Buisson (infectious diseases issues in intensive care), and Laurent Brochard (artificial ventilation). Both Lemaire and Brochard held the Editor-in-Chief position for *Intensive Care Medicine*.

Shifting from Lungs Alone to the Circulation: The 1970s

A conceptual turning point in the approach to caring for patients with acute respiratory failure and ARDS was the concept of “best” PEEP, published in 1975 by Peter Suter, H.

Barrie Fairley and Michael Isenberg [33]. Fairley pioneered respiratory intensive care at the Toronto General Hospital Respiratory Unit, a multidisciplinary respiratory ICU established in 1958 [34]. In the mid 1960s, Fairley moved to San Francisco, and in the early 1970s, Suter, a Swiss combat pilot and physician, joined Fairley’s group as a research fellow. According to Fairley, and described in his “how it really happened” report in 2001, [35] they showed that “the level of PEEP applied during mechanical ventilation could be adjusted in each patient to optimize the balance between recruitment of atelectatic lung and overdistension, and that this...coincided with optimal pulmonary gas exchange”. Their study should be seen as a fundamental change in thinking in intensive care, shifting from a focus on single organ failure (lung), to an emphasis on the body as a whole: for the first time, pulmonary gas exchange was considered relative to whole body oxygen delivery.

Cournand used right heart catheterization to study the physiology and pathophysiology of the circulation. Catheterization of the right and left heart was used routinely in the 1950s and 1960s. In 1967, Jeremy Swan, a California cardiologist, conceived of a catheter that would “sail through the heart”, while standing on a beach in Santa Monica watching sailboats. He and his cardiology colleague, William Ganz, described their eponymous catheter (Swan-Ganz pulmonary artery catheter) in 1970 [36]. Edwards Laboratories introduced the catheter commercially, and it was rapidly adopted for clinical monitoring in intensive care, and later during surgery. This invention facilitated bedside assessment and monitoring of cardiovascular and respiratory function, and oxygen transport.

The paper of Suter et al. [33], one of the first studies in intensive care using the Swan-Ganz catheter to measure oxygen transport, produced a new concept—that lung mechanics, gas exchange, and cardiovascular function interacted. Their finding that individuals differed in their responses to specific PEEP levels, indicated the need for individual titration based on physiologic response instead of a “one-size-fits-all” approach.

If studies in the 1950s and 1960s focused on mechanical ventilation, those in the 1970s and 1980s focused on circulation and cardiovascular function. Guyton, Cournand, Starling, and other twentieth Century physiologists established the central physiologic concepts of cardiovascular function and pathophysiology in the preceding decades. Subsequent pioneers in ICM began clinical research in cardiovascular pathophysiology in the 1950s and 1960s. Max Weil, a Californian cardiologist-internist (Fig. 58.4), and William Shoemaker, a Chicago surgeon (Fig. 58.5), investigated various types of shock in the mid 1950s. They recognized the importance of continuous monitoring to understand the pathophysiology of cardiovascular problems in unstable, critically ill patients. Both applied methods normally

available in the physiology laboratory, such as cardiac output measurement using dye dilution at the bedside—even before the new Swan-Ganz pulmonary artery catheter was available [37, 38]. Once the Swan-Ganz catheter was marketed, both applied it enthusiastically in patient care.

Weil's contribution to the evolution of ICM extended beyond shock [39], cardiovascular management, and cardiopulmonary resuscitation. In 1970, he and 28 other like-minded physicians founded the Society of Critical Care Medicine (SCCM), becoming the first President. Many of his trainees became leaders in ICM. Shoemaker was also an SCCM founder and President, and the Editor-in-Chief of SCCM's journal, *Critical Care Medicine*—a post he held for 18 years, from the first issue in 1973. Shoemaker left Chicago and moved via New York to California, where he studied oxygen transport variables as therapeutic targets for high-risk surgical patients [40–43]. In large-scale observational studies [40–42], he found that survivors had greater oxygen delivery and oxygen consumption values than non-survivors. He assumed that the lower values in non-survivors caused an oxygen debt. Using survivors' oxygen delivery

values as targets led to improved outcomes in high-risk surgical patients [43]. Although his studies may lack the methodological rigor expected today, he established the concept that avoiding tissue hypoperfusion improved outcome in at-risk patients. This concept led to several studies using “the Shoemaker goals”, with controversial results. Studies using a pre-emptive approach in high-risk patients mostly supported the original concept. But studies using “supranormal” oxygen transport targets in patients with cardiovascular or other organ function instability usually failed to improve, or even worsened outcome. Shoemaker left us the notion that it is best to prevent clinical instability, rather than intervene after instability has ensued.

The enthusiasm for invasively assessing the circulation had its down-side. Invasive hemodynamic monitoring was used to excess—partly from revenue-driven motivation. The pendulum swung to the other extreme: after the enthusiasm of the 1970s and 1980s, intensivists in the 1990s called for a moratorium on invasive hemodynamic monitoring. Since then, a new balance has started to develop, and despite new, less invasive monitoring technologies,

Fig. 58.6 Max Harry Weil (center, with stethoscope in pocket) and his many protégés, including Jean-Louis Vincent (second from the left in the second row). (Courtesy of Jean-Louis Vincent.)

invasive hemodynamic monitoring will return to the armamentarium of the intensivist. Ironically, Weil and Shoemaker actively advocated less invasive monitoring technologies in the 1980s—not to replace, but to complement invasive methods.

A New Generation in the 1980s

The concepts of organization of intensive care advocated by the pioneers became established in many institutions in the 1970s and 1980s. Safar moved to Pittsburgh to become the founding chairman of the department of anesthesiology and first director of the ICU at the Presbyterian University Hospital. Grenvik joined Safar in Pittsburgh in 1968—one more European to become a leader in ICM in the US and internationally [44]. Grenvik became Safar's successor in the ICU, and established a major academic interdisciplinary training program in ICM in Pittsburgh. This led to the formation of the first independent academic Department of Critical Care Medicine in the US. When he retired after 40 years of service, Grenvik had educated more than 400 trainees, many of whom became major figures in ICM.

Meanwhile, in Europe, a new generation of intensivists evolved—some with clinical and research training in the US, others home grown. In 1982, a group of enthusiastic young intensivists founded the European Society of Intensive Care Medicine (ESICM), among them Peter Suter, who became the first President. In a long career in clinical and academic

ICM, he held several leadership positions, including the Presidency of the Swiss Academy of Medical Sciences. He has helped shape ICM in Europe and currently contributes to health care reform in Switzerland. Another founding member was Jean-Louis Vincent, who trained with Max Weil (Fig. 58.6). An entrepreneur with endless energy and wit, he founded numerous journals and imported Weil's successful model of an annual scientific meeting to Brussels. With 30 years of continuing success, his meeting has become an institution and is one of the largest intensive care meetings in the world [45].

Luciano Gattinoni was also a founder of ESICM. Gattinoni applied extracorporeal lung support in the late 1970s; pioneered the use of computed tomography for studies of lung pathophysiology in ARDS [46]; and established a large network for multicenter trials in Italy. If he ever tired of ICM, he could switch at any time to professional piano playing!

Scoring Systems to Assess Prognosis

The 1980s and 1990s saw fundamental changes in ICM, particularly the development of severity of illness scoring systems, the concept of multiorgan failure or dysfunction as a syndrome with high mortality, and the concept of sepsis as an entity with high mortality, including a new approach to grading sepsis. Towards the end of the 1980s, large randomized controlled trials arrived, followed by the appearance of evidence-based medicine in the 1990s.

ICM is one of the pioneer specialties in medicine in assessing prognosis, outcome, and resource utilization—probably due to the cost of resources and survival from immediately life-threatening conditions as its most important outcome. William Knaus from Washington, DC, is the undisputed pioneer in severity-of-illness assessment and outcome prediction. In 1974, anesthesiologist David Cullen at the MGH, and surgeon Joseph Civetta at the University of Miami, introduced their Therapeutic Intervention Scoring System (TISS) for assessment of resource utilization, with the idea that the TISS could also reflect the severity of illness [47]. Knaus went further, suggesting that the underlying chronic diseases plus the severity of physiologic abnormalities during the first 24 hrs of intensive care could be used to predict outcome. Thus was born the first APACHE scoring system, introduced in 1981 [48] and its revision, APACHE II, in 1984. Others followed: the European SAPS system, developed by Jean-Roger LeGall from France, and the MPM system of Stanley Lemeshow from Boston. The various systems now extend to third to fourth generations. All use the same principle: assess severity of illness based on statistical models created and validated in large patient populations. These systems have helped us understand the case mix of ICU patients, facilitated comparisons of performance between ICUs, and provided a basis for classification of patients for clinical trials.

The evolution of ICM led to a new problem: multiple organ failure (MOF), multiple systems organ failure (MSOF), multiorgan dysfunction syndrome (MODS) ... various names (and acronyms!) for the same problem. Patients who previously died from single organ failure survived the acute phase and progressed to a poorly defined but clinically recognizable syndrome of simultaneous or sequential failure of several organs—a syndrome with high mortality. Shoemaker noted this in a 1973 editorial [49]. By the 1980s, the syndrome was well recognized, thanks to the work of surgeon-intensivists like Arthur Baue and Donald Fry. MOF was described as “a syndrome of the 1980s”.

Surgeon-intensivists observed MOF in surgical patients concurrently displaying infectious complications, and suspected that MOF reflected uncontrolled infection—although a causal relationship could not be proven. In parallel, intensivists with non-surgical specialty backgrounds had also connected severe infections to the pathogenesis of organ failures and mortality. In the 1980s, the first large sepsis trials, using new agents such as endotoxin- and other antibodies were completed. Definitions of sepsis were perceived as being too vague and too variable between trials. Roger Bone, a Chicago-based medical intensivist and researcher, with a special interest in ARDS and sepsis, proposed new definitions for sepsis in a series of opinion papers [50, 51]. Additional motivation to search for better definitions was

the increasing number of new drugs needing assessment in clinical trials. The American College of Chest Physicians and the Society of Critical Care Medicine held a consensus conference, launching new definitions of sepsis, severe sepsis, septic shock, multiple organ dysfunction syndrome, and systemic inflammatory response syndrome (SIRS) [52]. Although these new definitions helped to better conceptualize sepsis, they were not universally accepted, and consensus conferences often featured disagreements as much as consensus. As Bone et al. pointed out in an accompanying editorial, one of the items on the agenda was “to provide maximum flexibility in classifying patients for identification and treatment in both the clinical and research settings [53].”

Confrontation with Evidence-based Medicine

Until the early 1980s, research in ICM focused largely on evaluation of physiologic and pathophysiologic responses in small patient series, or on reporting selected case series on specific clinical conditions. Using the search terms “intensive care OR critical care” and the limits “clinical trial” and “randomized controlled trial” (RCT) in PubMed yields 84 papers between 1970 and 1980 increasing to 10,493 for 2000 to 2010 (Fig. 58.7). This rough quantification shows the enormous increase in intensive care research during the past decades.

Several reasons underlie the rapid proliferation of large-scale clinical RCTs in ICM. RCTs have been widely accepted as the “ultimate proof” in most fields of medicine, and ICM has accepted this trend. The new pharmacologic agents developed by industry and introduced for the treatment of sepsis, required support by larger RCTs often undertaken by investigator-initiated clinical trial networks. The most successful in performing and publishing larger RCTs in intensive care patients include the Australian and New Zealand Intensive Care Society Clinical Trials Group, the Canadian Critical Care Trial Group, and the National Heart, Lung and Blood Institute’s ARDS Clinical Network in the US. Notwithstanding the high hopes placed on these large RCTs, the results from most have been disappointing: new therapeutic interventions have not improved outcome, or have even been harmful, or the results have not been reproducible [54]. Controversies have developed over the validity and safety of study designs, and interpretations of some benchmark studies have been questioned [55]. Perhaps these difficulties should have been expected considering the complexity of the underlying clinical problems, the presence of poorly definable syndromes rather than clear-cut diseases, the heterogeneity of disease severity and treatment, and the poorly understood but highly relevant interactions between treatments and underlying pathophysiology.

Fig. 58.7 The number of ICU or critical care trials has grown exponentially over the past 4 decades, only recently showing a flattening of this trend

Evidence-based medicine was enthusiastically introduced to ICM in the mid-1990s [56]. However, the argument for evidence-based medicine did not convince everybody. The characterization of evidence-based medicine by its founders, as “de-emphasizing reasoning based on pathophysiologic rationale [57]” sounded odd. Martin Tobin, the former Editor-in-Chief of the *American Journal of Respiratory and Critical Care Medicine*, summarized these doubts: “...we are talking about a practice of medicine divorced from the scientific principles that are its foundation [58].” If the pendulum swung to one extreme in the early days of evidence-based medicine, it seems to have reached a more neutral position in the first decade of this century.

Focus on Organization and Care Processes

The introduction of scoring systems for the severity of injury in the 1980s and their subsequent large-scale use in quality and benchmarking initiatives in the next decades, revealed diverse results of severity-adjusted outcomes, (standardized mortality rates) and severity-adjusted resource utilization (standardized resource utilization) [59]. Hospital survival rates between individual ICUs for patients with similar severity of illness varied 2–3 fold. The resources needed for producing similar survival rates for patients with a specific severity of illness varied up to 6-fold. Variations in case mix, available resources, and structural factors could not explain such differences, suggesting that other factors, perhaps related to organization and care processes, may have a large impact. The differences in performance exceeded what might realistically be expected from any single therapeutic intervention.

Some clinicians applied treatment protocols based on individual components of patient care, such as sedation [60] or weaning from mechanical ventilation [61]. Others evaluated the impact of organizational issues, such as staffing patterns, on outcomes [62]. All these efforts blurred the distinction between classical hypothesis-driven research, and quality improvement and process control. Nevertheless, the use of these approaches has improved patient care. A prime example is the dramatic reduction in catheter-related infections when simple measures of cleanliness and check-lists are applied, as demonstrated by Peter Pronovost [63]. Concerns over both safety and efficiency have been major drivers behind the various efforts of quality and process improvement. Treatment guidelines based on consensus opinions of experts is a present trend [64]. But consensus opinions often lack the backing of solid evidence. Clearly, this trend has not yet reached its peak. Conclusions based on expert opinions ignore the probability that experts tend to share opinions and that experts as a group can be dead wrong. They ignore the basic rule taught in Logic 101: never appeal to authority to support/prove an argument.

The Forgotten Brain

The lungs, the cardiovascular system, and the immune system (in the context of sepsis) had received the lion’s share of attention in the decades preceding the new millennium. New imaging technologies facilitated monitoring and diagnosis of brain dysfunction, thereby adding a new group of patients to ICUs. They have helped us understand the pathophysiology of traumatic brain injury, and guide its treatment. Finally, the work of Peter Safar in the 1960s led to a breakthrough 40 years later—namely, cerebral protection after cardiopulmonary resuscitation that hypothermia offers. In 2002, mild therapeutic hypothermia after cardiac arrest was shown to improve outcome in a multicenter randomized controlled trial [65]. Despite this long delay from bench to bedside, Peter Safar could comment on this development in an accompanying editorial before he died in 2003 [66]. Subsequently, therapeutic hypothermia became an integral part of current treatment guidelines for cardiac arrest [67].

Training in ICM

Despite the early recognition of the need for a multidisciplinary approach to ICM, and the necessary broad skill-mix, training programs in ICM have remained highly variable, often fragmented, and unable to provide a uniform skill-mix and competencies. Australia was a pioneer in establishing formal qualifications for intensivists, and the Australian

Faculty of Anaesthetists organized the first examination for intensivists in 1979. In many European countries and in the US, several surgical and medical specialties as well as anesthesiology developed their own training programs, resulting in subspecialties of intensive care within a main specialty. In the Nordic countries and Italy, ICM developed as a natural extension of anesthesiology, although formal training programs in ICM were established relatively late, for example, in the late 1990s in Scandinavia. ICM has been established as a primary specialty in Spain and Switzerland, in the latter with multidisciplinary access, and the United Kingdom has been a leader in Europe in developing competence-based training in ICM, with access from multiple basic specialties. This approach emphasizes skills and competencies rather than knowledge alone. Competence-based training has been supported by the European Union, and the European Society of Intensive Care Medicine has played a leading role in its further development (<http://www.cobatrice.org/en/index.asp>). Consequently, the European Diploma of Intensive Care has been accepted by several countries as the official examination for intensive care.

Epilogue

Has ICM reached maturity? Ideas and principles presented by the pioneers in the 1950s and 1960s concerning organization, structure, responsibility, and training have been institutionalized. ICM has achieved recognition as an independent specialty. Competence-based training programs are growing, and open access to training in ICM. Ownership debates may have been relegated to the past.

In looking back, the description of intensive care, in Shoemaker's editorial for the third issue of the journal *Critical Care Medicine* in 1973, still seems apt today [49]:

“Traditionally, complicated cases are handled by calling for consultations. When the complications are few and they appear in staggered fashion, this approach may function reasonably well. But management of the critically ill patient with multiple vital organ failures often requires maximum coordination of a wide range of professional activities and close monitoring of the patient's course. This can best be attained in a multidisciplinary ICU where the maximum input of specialties may be coordinated with continuous surveillance and laboratory support. The patient with multiple injuries and the acutely ill patient with multiple vital organ failure have many common physiologic problems. As the same therapeutic modalities are used, the multidisciplinary team approach is optimally suited to coordinate therapy for multiple organ failure.”

Acknowledgments Thanks to Jeannie Wurz, Medical Writer/Editor, Dept. of Intensive Care Medicine, for research support and careful editing of the manuscript.

Kathryn E. McGoldrick

Summary

Long, Wells, and Morton provided outpatient anesthesia in the 1840s. Nicoll in Scotland and Waters in the US gave outpatient anesthesia in the early twentieth century. Modern outpatient anesthesia began in 1959, with Canadian anesthesiologists Webb and Graves' report of their 6-month experience with 494 surgical patients, cared for as outpatients. In 1962 at UCLA, Cohen and Dillon opened the first ambulatory surgery program, in 1966 describing the safety and economic advantage of their approach. Free-standing outpatient surgical facilities followed in 1968 in Rhode Island, and in 1969 in Arizona.

Ambulatory surgery grew rapidly, by the 1990s overshadowing in-hospital surgery. Important advances included new drugs providing rapid onset and offset of effect, management of postoperative pain without the nausea associated with opioids, antiemetics developed in the 1980s, the 1987 release of the laryngeal mask airway, and increasing use of regional anesthesia.

Studies during the 1980s estimated that ambulatory surgery centers (ASCs) decreased the cost per case by 25–75% relative to comparable inpatient care. In 2004, Ansell and Montgomery reported that ASA III patients had no obvious increase in morbidity or mortality relative to ASA I or II patients. Today, approximately 80% of elective surgical and diagnostic procedures in the US are performed on an outpatient basis.

Established in the US in 1984, the Society for Ambulatory Anesthesia (SAMBA) furthered the development of ambulatory anesthesiology as a subspecialty. Wetchler's *Anesthesia for Ambulatory Surgery* was published in 1985. The journal *Ambulatory Surgery* was introduced in 1993.

Until the late 1980s, local laws and third-party payers limited reimbursement for office-based procedures. Once that obstacle was removed, office-based surgery in the US grew rapidly, increasing from less than 2% in 1984 to an estimated 25% of all outpatient procedures in 2010. Financial, regulatory and safety factors limited acceptance of office-based anesthesia outside the US. In Australia and the UK comprehensive standards on facility, equipment, and practice requirements apply wherever anesthesia is conducted. In 2003, Vila and colleagues reported a 10-fold greater incidence of morbidity and death in patients anesthetized in offices versus ASCs in the US. An anesthesiologist was present in only 15% of cases resulting in death. The burgeoning growth of office-based surgery in the face of demonstrated risks may reflect the motivational strength of cost containment.

Historical Influences

The history of ambulatory anesthesia is as old as the history of anesthesia. Crawford Long, Horace Wells, and William Morton all administered anesthesia in office settings in the 1840s. Outpatient surgery and attempts at anesthesia go back to mankind's ancient attempts to treat illness invasively [1]. Drawings from 3500 BCE depict amputations and skull trephination performed in primitive surroundings long before hospitals existed.

Centuries before the discovery of anesthesia, hospitals were established to care for the sick, particularly to treat military conscripts and the indigent. Anesthesia enabled a gradual increase in the numbers of operations performed but, as before the discovery of anesthesia, surgery predominantly corrected problems on body surfaces and extremities—cataract removal, manipulations of fractures and dislocations, and lightning-fast amputations. A byproduct of the slow advances in surgery was a dependence upon hospitals to provide care.

Hospitals were a mixed blessing. A major deterrent to hospital-based care was infection, or “hospitalism” as it was termed in the pre-antibiotic era. (In recent years, however, the term “hospitalism” has expanded to include iatrogenic maladies acquired by hospitalized patients, maladies that are often more threatening than the primary condition) [2].

Consequently, the affluent arranged treatment, if possible, in their homes. Koller's 1884 introduction of cocaine, and subsequent local anesthetics facilitated use of the physician's office for minor surgery. With the application of Lister's 1867 demonstration of antisepsis and then Bergmann's 1886 application of asepsis, objections to hospitalization receded [1], and the hospital became the dominant site for advanced medical and surgical care

'Modern' ambulatory surgical and anesthetic practices largely evolved from the early work of itinerant dental surgeons, traveling their circuits by horseback and later on trains. They frequently operated from hotel rooms and then moved on. Only the fortunate (usually urban-located) dentist worked from an office, which was typically in the dentist's home. Those using anesthesia from 1846 to 1862, gave ether or chloroform via the drop-bottle method. In 1862, Gardner Colton resurrected the use of dentist-generated (baking of ammonium nitrate) nitrous oxide for near-asphyxial 100% nitrous oxide anesthetics (personal communication, George Bause). The cumulative effect of catastrophes from ether fires and chloroform-related mortalities increased interest in using local anesthesia with cocaine in dental offices after 1884. Gradually, local anesthetics other than cocaine became available, but it was not until 1904 that the first genuine alternative, stovaine, appeared.

Ambulatory Surgery Truly Began in 1899

In 1909, James Nicoll (Fig. 59.1), a pediatric surgeon in Scotland, wrote of his experiences with ambulatory anesthesia and surgery on nearly 9,000 children as outpatients, during a 10-year interval at Glasgow Royal Hospital for Sick Children [3]. Operations included cleft lip and palate repair, correction of pyloric stenosis, mastoidectomy, repair of inguinal and umbilical hernias, and even management of spina bifida and depressed skull fractures. Nicoll offered no details concerning surgical morbidity or mortality, or the results of the operations *per se*. Nearly one-half of the children were less than three years of age, and many were less than one year of age. Nicoll emphasized the disadvantages of hospitalization and the benefits of home care for convalescence, especially for frail children and nursing mothers.

Nicoll pleaded with his fellow surgeons to perform more pediatric operations on an outpatient basis. He thought that "... a large number of the cases at present treated in-door constitutes a waste of the resources of a children's hospital.... The results obtained in the out-patient department at a tithe (small part) of the cost are equally good [3]." He also stated that certain cases were unsuitable as outpatients. He believed that "as a rule" unsuitable cases tended to involve children as opposed to infants. "Cleft palate operations in suckling infants do well as out-patients, but the child of 3 or 4 must go into the wards, where care can be taken to prevent his putting

Fig. 59.1 A picture of James H. Nicoll. Nicoll was arguably the father of modern ambulatory anesthesia. (From Young DG, Carachi R. James H. Nicoll, MB, CM Glasg, FRFPS Glasg. Legion of Honour France. Father of Day Surgery. *SMJ [Scottish Medical Journal]* 2006;51; 48–50, with permission.)

hard edibles into his mouth." He commented that "Infants and young children in a ward are noisy, and not infrequently malodorous." Nicoll doubted that these babies benefited from "trained" nursing, arguing that they rested more quietly and comfortably at home, nursing in the arms of their mothers. The prescient Nicoll further commented that his experience with pediatric ambulatory herniotomy and other operations, suggested that similar cases in adults are kept too long in bed and that the average recumbent period should be "something under a week." In light of the scope of the operations performed and the primitive state of anesthesia, Nicoll's report is impressive.

Waters Came Second

The next pioneering communication came from Ralph Waters (Fig. 59.2), who in 1919, described the care of patients for ambulatory surgery, commenting that patient evaluation

Fig. 59.2 Ralph Waters, an icon of American anesthesiology, was a pioneer in the field of ambulatory anesthesia. Among his many accomplishments was his establishment at the University of Wisconsin of the first academic program for training anesthesiologists, but before that he developed an office-based practice of anesthesia. (Courtesy of the Wood Library-Museum of Anesthesiology, Park Ridge, IL.)

required "...careful physical examination on all suspicious risks [4]." Medical conditions had to be well controlled before surgery, and certain unspecified medical conditions precluded outpatient care. "Initially a modest office was equipped with a waiting room and a small operating room with an adjoining room containing a cot on which a patient could lie down after his anesthetic....In due time the place became popular and we moved....." [4] Waters used nitrous oxide liberally, and occasionally administered morphine and scopolamine sublingually. He allowed consumption of clear liquids until immediately before surgery and permitted patients having late morning or early afternoon surgery to ingest a light breakfast. With regard to his rather liberal fasting guidelines, Waters bluntly stated, "As to the preoperative preparation of the patient we worry little about it." Waters meticulously documented perioperative variables, including patient satisfaction. He did not use regional anesthesia in his Downtown Anesthesia Clinic in

Sioux City, Iowa, and apparently did not insist that patients be accompanied by a responsible adult when discharged. He advertised the economic benefits of his approach for all concerned parties.

Waters had an astute business sense, and he offered no apologies for his focus on the bottom line. He sought "to give satisfaction to operator and patient and charge a fee that will pay expenses and a good profit." He had no fixed fee schedule and charged according to the cost of materials and the time involved with the procedure. He appeared proud of the fact that "Many patients and some doctors object to the fees but they come back and their friends come back. Satisfactory anesthesia and too large fees work better than bargain sale fees and unsatisfactory anesthesia." Waters was keenly aware of the importance of pleasing his referral base, claiming "As for *business getting* activity, it is all with the dentists and physicians. The place is for their use and their convenience, and consideration for them comes first." Waters' Clinic, which offered anesthesia care for dental and minor surgical procedures, is the prototype for the modern free-standing ambulatory surgery facility.

Dentists and surgeons contributed substantially to the early progress in ambulatory anesthesia. Most important *clinical* advances in anesthesia emanated from surgeons (e.g., August Bier and William Halsted) and dentists (think of Wells and Morton) or obstetricians (e.g., John Cleland and James Simpson). A meager few of those practicing anesthesia made technical improvements involving innovations in technique or equipment. Most functioned largely as technicians making minimal contributions to advancing our understanding of the principles of physiology, pharmacology, physics, and chemistry that are the foundation of anesthesia practice.

Hospital-Based Outpatient Surgery

In 1959, two Canadian anesthetists, Eric Webb and Horace Graves, were concerned about a shortage of hospital beds in Vancouver, British Columbia, and proposed outpatient surgery as an alternative to inpatient care. They reported their experience with 494 patients cared for successfully during a 6-month period [5]. In fact, their experience with outpatient surgery began in 1949, but the expansion initially proceeded slowly. An estimated 12,000 patients, or 5% of all surgical patients, underwent outpatient procedures from 1949 to 1959.

Building on the experience of Webb and Graves, ambulatory surgical care developed momentum in the 1960s. In 1962, the first so-described ambulatory surgery program, under the direction of David Cohen and John Dillon, opened at the University of California Los Angeles [6]. In 1967, Mary Louise Levy and Charles Coakley [7], at George Washington University, reported a similar experience, again in a

hospital-based ambulatory surgery program that had opened in 1966. Cohen and Dillon [6] perceived a shortage of hospital beds and a rapidly growing population in the Los Angeles area, and postulated that outpatient surgery would redress this imbalance. They noted, moreover, that regulatory obstacles impeded efficient use of hospital beds and hindered creation of a favorable (more pleasant) environment for ambulatory surgery. For example, patients were admitted to the hospital for minor surgery because insurance only covered inpatients, or because they needed “major” anesthesia and the hospital’s rules mandated postoperative admission (insurance companies were not the only entities swayed by the profit motive). Further, insurance carriers required admission to the hospital for at least 18 hours, paradoxically increasing cost.

In 1966, Cohen and Dillon described the first two years of their experience [6]. The surgeon selected outpatients, based on the prediction that the patient should require only brief postoperative observation, owing to minimal likelihood of postoperative bleeding. Neither general nor regional anesthesia excluded prospective candidates. Only complications necessitated hospitalization. Types of surgical procedures were limited and most patients were healthy. However, some patients who were not in good health were accepted, if they were stable and “under good control [6].” Their personal physician completed a history and physical examination one week before surgery, and the anesthesiologist undertook a preoperative evaluation on the morning of surgery. In contrast to the criteria Waters described 40 years earlier, patients were enjoined to fast preoperatively, recruit a responsible accompanying adult, and not drive in the immediate postoperative period. Of their 804 patients, 31 (3.9%) were admitted overnight for administrative or surgical issues. There were no serious anesthetic complications, and only two patients (0.25%) were admitted for anesthetic reasons (prolonged emergence from general anesthesia). The use of ambulatory surgery produced savings that varied from case to case, but typically ranged from 30 to 46% [6].

The editorial board of the *Journal of the American Medical Association (JAMA)* initially rejected the Cohen-Dillon manuscript that described their experiences, because they considered that outpatient surgery was not “good practice of medicine.” Dillon responded that it was permissible to criticize his grammar or spelling, but that it was not acceptable to criticize something that was the future of medicine. He insisted that outpatient surgery was too important to ignore and *JAMA* finally acceded [8].

North America was not the only venue where freestanding units within hospitals were established. An existing hut at Hammersmith Hospital in London was converted in 1969 to a small outpatient surgery facility that provided care to about 750 patients annually. Despite the restricted space, this renovation enabled the waiting list for plastic surgery to be reduced by 1970 to nearly half of the 1968

Fig. 59.3 Growth of ambulatory surgery as a percent of elective surgery in the US grew linearly from 1970 to 2000, driven by economic forces and abetted by the development of drugs and devices that facilitated and made safe such practice

figure [9]. In March 1970, a former maternity ward at Gulson Hospital in Coventry opened as a surgical day unit [10]. The unit managed cases involving general, otorhinolaryngologic, orthopedic, dental, and plastic surgery. Virtually immediately, this facility greatly decompressed the long waiting lists for most minor and “intermediate” operations. Specifically, the waiting list for varicose vein operations, which was nearly 600 in 1970, was under 50 patients by 1972. Economic benefits were considerable, with initial annual savings of £40,000, and considerable sparing of nursing staff.

Starting in the 1980s, the number of patients undergoing ambulatory anesthesia and surgery in the US grew rapidly, and by the 1990s overshadowed in-hospital anesthesia and surgery (Fig. 59.3). A confluence of economic, technologic and pharmacologic factors contributed to this rapid growth. Pharmacologic advances included development of drugs facilitating rapid onset and offset, with fewer unpleasant side effects (Table 59.1). Improved analgesic agents enhanced the management of postoperative pain. Concern about escalating health care costs prompted the Medicare program to pay for care in freestanding ambulatory surgery centers. The development of a prospective payment system, based on diagnostic-related groups, created financial incentives for hospitals to shift less complicated surgery to outpatient facilities. Other insurers followed Medicare’s lead. Studies during the 1980s estimated that ambulatory surgery decreased the cost per case by 25 to 75%, relative to comparable inpatient care [11, 12]. And in a government-based health care system, ambulatory surgery decreased the waiting time for elective operations [13].

Such changes and motivations were not limited to the US. For example, in Australia, the motivation to expand outpatient surgery was primarily economic, and financial realities were a powerful impetus to the development of ambulatory surgery in other countries as well.

Table 59.1 Examples of pharmacologic advances enhancing the growth and safety of ambulatory anesthesia and surgery

Traditional agent (s)	Improved profile agent (s)
Diazepam	Midazolam
Thiopental	Propofol
Curare, pancuronium	Atracurium, cisatracurium, rocuronium
Halothane, Isoflurane	Desflurane, Sevoflurane
Morphine, meperidine	Fentanyl, sufentanil, remifentanyl
Labetalol	Esmolol
Droperidol	Ondansetron, aprepitant
Acetaminophen	Ketorolac, celecoxib
Bupivacaine	Ropivacaine, levobupivacaine

However, some economists worried that the ability to treat more patients in a given interval might increase total expenditures, the so-called “efficiency trap [14].” Analyzing direct and indirect costs of substituting ambulatory for inpatient care, Aviva Berk and Thomas Chalmers [15] concluded that putative savings largely depended on the closure of hospital wings or entire hospitals. If vacated beds were used to meet previously unmet demand for more hospitalization, then more care would be provided at a higher total cost [15]. In 1981, Detmer [16] observed that “Whether money is ultimately saved at the level of the health care system is difficult to determine.... Since we do not know what will happen to system-wide costs, a national policy with incentives favoring free-standing units over hospital-based units seems inappropriate.” Detmer further cautioned that the unlimited growth of independent free-standing surgical units might undermine the economic viability of traditional community and teaching hospitals. Even today, hospital administrators resent “cherry picking” by ambulatory surgery facilities, facilities not required to provide complex services 24/7, nor care for critically ill or indigent patients.

But by the mid-1980s, it seemed clear that ambulatory surgery offered relief from skyrocketing health care expenditures, and a 1985 survey of Fortune 500 companies ranked outpatient surgery as the most critical of 15 possible options for health care expenditure containment [17]. Insurance carriers and the federal government recognized the economic advantages of outpatient surgical care as reflected by their denial of reimbursement for some procedures, such as cataract surgery or inguinal herniorrhaphy, when performed on an inpatient basis.

Free-Standing Outpatient Surgical Facilities

Charles Hill, familiar with the efforts of Ralph Waters, re-introduced the concept of a free-standing ambulatory facility in 1968 [18]. In a medical office suite in Providence, Rhode Island, he opened a fully-equipped operating suite

Fig. 59.4 Wallace Reed (pictured) and John Ford, co-founded the first modern free-standing outpatient surgery clinic, the Surgicenter,[®] which opened in Phoenix in 1970. (Courtesy of the Wood Library-Museum of Anesthesiology, Park Ridge, IL.)

with a recovery room. However, the facility failed financially owing to lack of support from the State of Rhode Island Health Department, which maintained that the suite was a physician’s office. Blue Cross and other third party insurance carriers also denied support.

In 1969, in Phoenix, Arizona, John Ford and Wallace Reed [19] (Fig. 59.4) established the first modern, free-standing outpatient surgical clinic, (Surgicenter[®]), in the mode of Ralph Waters’ “Downtown Anesthesia Clinic.” They argued that almost any patient whose operation does not involve major trespass into the cranial vault, thorax, or abdomen is a candidate for outpatient surgery. They appeared to place more emphasis on the type of surgical procedure, than on the patient’s physical status, when determining suitability for care at Surgicenter.[®] However, in a 1976 publication, they wrote that their “...patients are good risk [20].”

Ford and Reed successfully anticipated obstacles before, and after, their Surgicenter[®] opened in 1970. These visionaries obtained clearance from the local health planning council, the Maricopa County Medical Society, and state planning

authorities, complied with local building requirements and zoning codes, and obtained approval from third-party insurers, including Medicare and Medicaid. By mandating that their surgeons were credentialed to perform a given surgical procedure at an inpatient institution, and by implementing procedures for quality assurance, the facility demonstrated that it functioned like a hospital, enabling payers to fund the surgical care rendered.

They created economies that seem obvious. They did not require a preoperative visit to Surgicenter.[®] Having been carefully screened by their surgeons as appropriate candidates for outpatient surgery, patients were instructed to arrive no more than one hour before surgery to undergo preoperative evaluation by the anesthesiologist. Ford and Reed did not require that ingrown toenails or infant foreskins be sent to a pathologist. They created staggered shifts for personnel to enable an employee/patient ratio of 1:1, as opposed to the 2.5 to 3:1 ratio associated with hospitals. They eliminated unnecessary preoperative laboratory testing and counterproductive premedication with long-lasting drugs. Safety was comparable to that in hospitals, but costs were considerably less. In their 1976 publication, Ford and Reed pointed out that they had cared for more than 33,000 patients since the opening of their facility, without a single death or malpractice suit [20]. Reed wisely arranged with a nearby hospital to admit patients who developed complications. He also relied on an increasingly sophisticated public to assume a greater share of its own care at home. This successful Surgicenter[®] became the model for similar facilities, both in the US and internationally.

In 1972, Reed and Ford received the Gerard B. Lambert Award from the Lambert Foundation for their contribution to medical care in the US. Gerard Lambert, whose father discovered Listerine and founded Lambert Pharmacal Company of St. Louis, was interested in honoring innovative ideas in health care delivery, especially if they originated from or pertained to hospitals. After he devised the compound that would eventually be known as Listerine, the senior Lambert, a chemist by training, scraped together sufficient funds to travel to London and there invested his last dollar in a beautiful carriage with a liveried coachman. Fortified by this elegant equipage, he coaxed from Lord Lister, the developer of antiseptic surgery, the right to christen the new formula with the great man's name.

Competition in the health care arena came to be viewed favorably, the *Federal Register* in 1982 stating:

"These proposed regulations would permit a new class of facilities, ambulatory surgical centers to compete with hospitals in providing ambulatory surgical services to Medicare beneficiaries.... We believe.... that the extension of coverage of reimbursement to ambulatory surgical centers will give beneficiaries and their physicians important additional options in their selection of sites for surgery. These options in turn will enhance the competition between ambulatory surgical centers and hospitals [21]."

The increase in outpatient surgery was not without opposition. The Wood Library-Museum of Anesthesiology offers a historical DVD wherein Reed and Ford chronicle some of the unsavory conflicts developing between them and local hospital administrators [22]. Once the negative financial impact of a free-standing competitor was appreciated, hospital administrators in the Phoenix area complained that Surgicenter[®] would be "skimming the cream," leaving their institutions with all the "...high overhead items of cost and poor reimbursement." (Steve Morris, former Administrator of Good Samaritan Hospital). A rate battle ensued, even before the first case was performed at Surgicenter.[®] Reed commented, "...in applying for similar approval to do outpatients in hospital-affiliated units, the hospitals somehow acquired copies of our schedules, used the same schedules with the same spelling errors, and reduced the price by five or ten dollars just to show that they were going to be less expensive than the outpatient facility." The hospital administrators also resorted to negative reinforcement, suggesting to surgeons that if they transferred their loyalty to Surgicenter,[®] they would no longer receive preferential treatment at this or that hospital (Daniel Cloud, Pediatric Surgeon and former President of the AMA) [22]. The situation became tense, despite Reed's assertion that he did not wish to endanger the hospitals' financial viability, because it was in the best interest of the entire community that a tertiary care facility be maintained. A few years after Surgicenter[®] opened, Reed wrote to Ralph Waters (then 90 years old), proudly informing him of its success. Waters responded in a handwritten note. "Just why the idea of 'outpatient service' did not progress I can't say. I always thought the idea was sound."

The invention of the laryngeal mask airway (LMA) and the cuffed oropharyngeal airway (COPA) enlarged the options for airway management, decreasing the need to administer muscle relaxants and their attendant reversal agents solely to secure the patient's airway. Also, surgeons increasingly embraced minimally invasive surgery. In 1988, the first meeting of the Society for Minimally Invasive Therapy, a multidisciplinary international group composed of surgeons, anesthesiologists, and radiologists, convened in London. The impressive development of endoscopic surgical techniques and the growth of this organization were inextricably linked, and added to the explosive growth of outpatient surgery.

Free-standing ambulatory surgery centers (ASCs) continue to proliferate to this day, when currently approximately 80% of all elective surgical and diagnostic procedures in the US are performed on an outpatient basis. Notably, the rate of visits to freestanding ASCs tripled from 1996 to 2006, while the number of visits to hospital-based ambulatory surgery centers remained unchanged. In the US in 2006, an estimated 19.9 million (57.2%) of the ambulatory surgery visits occurred in hospitals and 14.9 million (42.8%) occurred in freestanding ASCs [23].

Influence of Professional Organizations

The prescient Waters knew the importance of formal organizations defining and overseeing standards of education and practice. Establishment of the Society for Ambulatory Anesthesia (SAMBA) in the US in 1984, led to the development of ambulatory anesthesiology as a subspecialty. Early leaders of SAMBA included Bernard Wetchler (Fig. 59.5), Burton Epstein, Paul White, and Wallace Reed. Wetchler became President of the American Society of Anesthesiologists (ASA) from 1994 to 1995 and received the ASA's 2002 Distinguished Service Award. Epstein was the recipient of the ASA's 1999 Distinguished Service Award.

Textbooks on ambulatory anesthesia followed its recognition as a distinct subspecialty. Wetchler led the way in 1985 with *Anesthesia for Ambulatory Surgery* [24] and White's *Outpatient Anesthesia* [25] appeared in 1990. In 1995, Kathryn McGoldrick produced *Ambulatory Anesthesiology: A Problem-Oriented Approach* [26]. A handbook by Rebecca Twersky titled *The Ambulatory Anesthesia Handbook* [27] appeared in 1995. The journal *Ambulatory Surgery* was introduced in 1993, with Paul White and British surgeon Paul Jarrett as coeditors.

SAMBA first met in 1985 and now draws approximately 500 registrants to its Annual Meeting. SAMBA gained recognition as a leader in ambulatory anesthesia education. In addition to its annual spring meeting, SAMBA holds a one-day session before the ASA Annual Meeting, and a one and a half day meeting at the same venue as the World Congress of Anaesthesiologists. Shortly after 2000, the ASA Annual Meeting introduced an "ambulatory track." SAMBA also holds a seat on the Council of the International Association for Ambulatory Surgery.

An industry sprouted to address perceived needs associated with outpatient perioperative care [28]. Vendors, accrediting organizations, publishers, for-profit companies, consultants, and professional societies for physicians (SAMBA), nurses, and administrators all claimed a share of the action. In 1994, for example, certification for nurses caring for ambulatory surgical patients was created (Certified Ambulatory Perianesthesia Nurses [CAPAs]).

Clinical research in the subspecialty began to flourish. A multimodal preemptive approach to postoperative complications such as nausea and vomiting, and pain management, evolved [29–32]. Patients considered at high risk for postoperative nausea and vomiting now routinely receive prophylactic therapy with three antiemetics that have different mechanisms of action, such as low-dose droperidol, ondansetron, and dexamethasone. This approach has resulted in postoperative emesis rates of less than 10% [29]. Similarly, anesthesiologists and surgeons increasingly use multimodal analgesic regimens that incorporate non-opioid analgesics (e.g., local anesthetics, nonsteroidal anti-inflammatory

Fig. 59.5 Bernard Wetchler was one of the early founders of the Society for Ambulatory Anesthesia. He also served as President of the American Society of Anesthesiologists from 1994 to 1995. (Courtesy of the Wood Library-Museum of Anesthesiology, Park Ridge, IL.)

drugs, acetaminophen, ketamine, and α_2 agonists) to supplement or replace opioid analgesics [30].

Criteria for acceptance of patients for ambulatory surgery expanded from the initial restriction to ASA physical status I and II patients. A review of ASA PS III patients compared with ASA PS I or II patients having outpatient surgery identified no subsequent increase in unplanned admissions and postoperative complications [33]. Increasingly invasive and lengthy procedures were performed successfully in the outpatient milieu, and creative arrangements for 23-hour postoperative stays developed. Other innovations enabling further expansion of outpatient surgery included freestanding recovery care units and hospital hotels. Home health care nurses assisted families postoperatively, administering intravenous antibiotics and analgesics. A 1993 study of more than 38,000 consecutive patients undergoing ambulatory anesthesia provided one-month followup data [34]. Four patients died (1:11,273), two in automobile accidents, and two of myocardial infarction.

Ambulatory surgery also grew in most economically developed countries. Credit much of this development to outreach efforts of the International Association for Ambulatory Surgery (IAAS), an “organization of organizations” that held its first meeting in Brussels, Belgium in 1995. The IAAS exists to provide international practitioners with state-of-the-art information about types of patients and procedures that are appropriate for outpatient surgery, recognizing that socio-political and economic factors guide local decisions. For example, although Germany is a highly developed country, ambulatory surgery has not advanced as rapidly as one might expect, owing to financial and organizational issues. The German health care system favors inpatient treatment, which provides remuneration 3–10 times greater than that for ambulatory treatment [35]. Thus, only 3% of all the ambulatory surgery in Germany is performed in hospitals because hospitals would rather focus on more lucrative inpatient care, and 97% is conducted in freestanding ASCs. Since 1 January 2004, however, a new law opened part of the social health insurance (SHI) to the free market, partially limiting the “wall” between hospitals and day clinics by allowing contracts that individual sickness funds can sign with panel doctors for single or multiple procedures. These contracts are based predominantly upon the diagnostic related group (DRG) system, and the ambulatory payments typically amount to 50–90% of the DRGs for inpatient treatment [35].

In Australia, as of 2006, approximately 50% of all procedures were conducted as day surgery, either in hospitals or in freestanding ASCs. There were 248 freestanding ASCs. Nonetheless, ambulatory surgery has not reached its full potential, in part perhaps owing to the absence of extended (overnight) recovery in day surgery centers/units, and the absence of post-discharge convalescent limited-care accommodation facilities (medimotels) [36].

Evolution of Processes

Patient selection criteria, preoperative evaluation and preparation, intraoperative anesthetic techniques, and postoperative care have evolved. Dillon [37] stated in 1967 that diabetes, vascular insufficiency, or anemia precluded outpatient surgery. Not today. It is now common to care for optimally stabilized ASA physical status III and IV patients on an outpatient basis. Patient selection tends to be location-specific based on the facility’s resources and capability. As the complexity of patients’ medical conditions and surgical procedures have increased, so too has the importance of a thoughtful preoperative evaluation geared toward realistic risk stratification and minimization.

Until recently, most outpatients received a general anesthetic. Increasingly however, regional anesthesia and monitored anesthesia care are used, partially an outgrowth

of the increasing availability of minimally invasive surgery and advancement of endoscopic diagnostic/therapeutic procedures. The history of regional anesthesia has moved from the placement of local anesthetic based on anatomical landmarks to placement guided by paresthesia, to placement by nerve stimulation and, most recently, to placement by ultrasound guidance. Outpatient anesthesia has evolved with these changes and with the realization that regional anesthesia offers particular advantages to the patient having outpatient surgery. For example, effective analgesia lasting several days postoperatively is now provided in the home using mechanical or programmable pumps delivering local anesthetics through peripheral catheters [38]. Research on encapsulated formulations of local anesthetics that provide long-lasting postoperative analgesia may allow elimination of the pumps [39, 40]. These developments may further expand the types of procedures that can be successfully performed in the outpatient venue.

Office-Based Anesthesia

Interest in office-based surgery represents a return to the origins of ambulatory surgery, following in the footsteps of Long, Wells, Morton, and Waters. *Plus ça change, plus c’est la même chose*. Lewis Ferguson’s 1947 text, directed to surgeons and internists caring for minor surgical conditions in the office [41], discussed anesthetic techniques and agents, and issues germane to patient selection and recovery. Thio-pental, he said, was unsuitable for ambulatory surgery owing to slow emergence, and he advocated using divinyl ether, as opposed to diethyl ether, because the former afforded a more rapid induction and emergence. He cautioned against administration of cyclopropane by anyone other than an experienced anesthesiologist. He also presented techniques and agents for local and regional anesthesia. Ferguson no doubt hoped that his observations and recommendations would be useful to surgeons and internists because there was not a great deal of interest on the part of anesthesiologists to participate in office anesthesia during the 1940s and 1950s. Despite sporadic publications in the surgical literature, anesthesiologists made minimal efforts to pursue office-based opportunities until the 1980s when financial concerns prompted a re-evaluation.

Dillon stated in 1967, that outpatient surgery could be conducted in any facility that carefully selected appropriate patients [37]. The same forces propelling the expansion of outpatient surgery have driven the growth of office-based anesthesia [42]. Costs are less than in a free-standing surgery center, being the lowest overhead costs of all types of surgical locations. Nonetheless, until the late 1980s and early 1990s, local laws and third-party payers limited reimbursement for office-based procedures. Once that obstacle was removed,

office-based surgery grew and is currently the most rapidly expanding subset of anesthesia practice. In the US between 1984 and 1990, the number of office-based procedures increased from less than 2% to almost 5%, and by 1994, 8.5% of all procedures were performed in offices [43]. By the year 2000, approximately 15–20% of all outpatient procedures were performed in offices [44], and the 2010 estimate is that approximately 25% of all ambulatory procedures (which account for approximately 80% of all surgical procedures) are conducted in offices [45].

And in Australia, New Zealand and Other Parts of the World?

The current situation in Australia underscores the importance of financial considerations. Office-based surgery is not yet fully established, largely owing to the failure of health insurers to provide a facility rebate. Australian surgeon Lindsay Roberts states, “A large number of more minor operations/procedures, possibly 20–25%, could be carried out in such units and the Australian Day Surgery Council (ADSC) has published comprehensive *Guidelines for the Accreditation of Office-Based Surgical Facilities* to ensure that standards of quality and safety are not compromised [36].” Although the absence of this rebate is an important disincentive causing many healthy patients having relatively simple procedures to be cared for currently in day surgery centers at much greater expense, the situation is more complex.

It is not quite as simple as Roberts says. The Australian and New Zealand College of Anaesthetists (ANZCA) publishes comprehensive standards on facility, equipment, and practice requirements that apply no matter where anesthesia is carried out. (The standards are obtainable on the ANZCA website).

The most recent guidelines issued by the ADSC describe office surgery as surgery performed under local anesthesia, with or without sedation. The guidelines also state that if general anesthesia is to be provided, then the standards issued by ANZCA should be adhered to. In addition, it should be noted that the ANZCA standards are recognized by the Australian Council on Health Care Standards, the national accrediting body for health facilities. The ADSC guidelines are not seen in the same light. Hence, it is not surprising that insurers have not embraced “office” surgery, since few offices meet the required standards. Compounding this is a continuing trickle of disasters typically involving “cosmetic surgeons” operating in unaccredited facilities, usually without an anesthetist present.

Australia and New Zealand are not the only countries where more stringent guidelines apply to facilities and staffing for outpatient anesthesia. A similar situation applies in the UK, where regulations and published standards also exist.

Is Office-Based Anesthesia Safe?

Both patients and surgeons value the convenience of surgery performed in the office. Nonetheless, this can be a “double-edged sword”. Because most offices function without regulatory oversight, physicians have extraordinary autonomy, performing any surgical procedure without a need for credentialing. This freedom can, and has, resulted in tragedies [46, 47]. Three decades ago, anesthesia-related mortality was generally cited as approximately 1 per 10,000 healthy anesthetized patients. Now the commonly quoted figure is approximately 1 per 200,000–400,000, although these estimates may be optimistic [48]. However, the death rate for office-based surgery in Florida a decade ago was estimated at 1 in 8,500, and a 1999 report found that the mortality rate for patients undergoing liposuction may be as great as 1 in 5,000 [46]. Despite subsequent implementation by the Florida Board of Medicine of corrective actions, Vila and colleagues [49] recently reported a 10-fold greater rate of adverse incidents (66 in 100,000 versus 5.3 in 100,000) and deaths (9.2 in 100,000 versus 0.78 in 100,000) when comparing offices and ASCs, respectively, during the period from 1 April 2000 to 1 April 2002. An anesthesiologist was present in only 15% of cases that resulted in death. Unfortunately, we have no data indicating the percent of cases not resulting in death where an anesthesiologist was present. These lacunae underscore the need to create a mandatory national computerized database assembling this vital information.

However, Hoefflin et al [50] reported no office deaths in more than 23,000 cases in their accredited office staffed with board-certified anesthesiologists and surgeons, a level of care superior to most of the other comparison reports. The fact that anesthesiologists are present in nearly all ASCs and were present in the favorable 2003 report by Hoefflin et al. [50] emphasizes the importance of their presence for patient safety. In April 2002, the Florida Board of Medicine mandated the presence of an anesthesiologist for all office cases involving general anesthesia, regional anesthesia, and deep sedation. After implementation of this directive, injuries declined by 65% and deaths by 58% during the period from April 2002 through March 2003 [51].

Data from the ASA Closed Claims Project database are similarly instructive. Although most ambulatory malpractice claims involve relatively minor injuries, 60% of office-based anesthesia claims are for death. Moreover, more than 90% of office-based claims resulted in payment and ASA Closed Claims experts deemed most injuries preventable [52]. Despite formidable risks, about two-thirds of anesthesia practices provide some variety of office services [53]. Medicare has approved more than 2,500 procedures for the office setting. Most of the 9 million cosmetic surgical procedures performed annually in the US are done in physician’s offices. Approximately 25% of all elective outpatient procedures in

the US may be conducted in offices [45]. The burgeoning growth of office-based surgery in the face of demonstrated risks reflects the motivational strength of cost containment and convenience in contemporary society.

As office-based anesthesia gained acceptance during the last two decades, ASA and SAMBA jointly advocated for patient safety, and in 1999 developed the ASA Guidelines for Office-Based Anesthesia. Additionally, many states (with dates of enactment) including New Jersey (1998), Pennsylvania (1999), Texas (2000), California (2001), Florida (2002), Alabama, Connecticut and Virginia (2003), Ohio (2004), Tennessee (2005), and New York (2007) enacted legislation regulating office surgical practice. Many other states have safety guidelines that are not, however, legally binding. Accrediting bodies now include the Joint Commission, the Accreditation Association for Ambulatory Health Care (AAAHC), and the American Association for Accreditation of Ambulatory Surgical Facilities (AAAASF).

Accredited offices must maintain safety standards similar to those in a hospital or free-standing surgicenter [54, 55]. Office-based surgery is safe in carefully selected patients having appropriate procedures performed by highly qualified practitioners [54, 55]. More than 1.1 million operative procedures in AAAASF-accredited office-based facilities were studied from 2001 to 2006. Deaths were infrequent, occurring in 2.02 of 100,000 procedures or 0.002%, which is comparable to the overall risks of such procedures performed in hospital surgery facilities [56, 57]. Most deaths were due to pulmonary embolism rather than anesthesia-related complications. Only one death was attributable to an anesthetic event, an event which occurred in the absence of an anesthesiologist.

Conclusions

Although the history of ambulatory anesthesia is as old as the history of anesthesia, ambulatory anesthesia in the US grew little until the 1960s, increasing thereafter to the point where it represented 34% of all surgical cases in the mid-1980s, and 75–80% of all procedures today. Medical and economic forces combined to translocate patients from hospitals to freestanding ambulatory centers and offices. The medical advances enabling this translocation included improvements in anesthesia allowing patients to regain consciousness more quickly, with fewer complications, and the development of better analgesics and techniques for relief of postoperative pain. In addition, minimally invasive and noninvasive procedures, such as laparoscopy, laser surgery, and endoscopy, were developed and are being used with increasing regularity, thereby facilitating the movement from inpatient to ambulatory venues.

Contemporaneously, concern regarding increased health care expenditures led to changes in the Medicare program that encouraged the expansion of ambulatory surgery. In the early 1980s, Medicare began to reimburse for care in ambulatory surgery centers, and adopted a prospective payment system based on diagnostic-related groups for hospital inpatient care. These changes generated financial incentives for hospitals to shift less complex surgery to outpatient settings. This trend will probably continue until hospitals care for only the most complex patients having highly invasive, complicated surgery. As the US enters an era of health care reform, more comprehensive epidemiologic data on the utilization of medical resources and the outcomes of medical interventions will be carefully analyzed to make health care policy decisions. The effect of this analysis on the future growth of ambulatory surgery remains to be seen.

Acknowledgments The author thanks the late Patrick Sim, the Paul M. Wood Distinguished Librarian of the Wood Library-Museum of Anesthesiology (WLM), Karen Bieterman, Managing Librarian at the WLM, and Shawn Manning, Librarian at New York Medical College for their invaluable assistance in obtaining historical literature relevant to ambulatory and office-based anesthesia. She also thanks Felicia Reilly, Archivist of the WLM, and Margie Jenkins of the WLM for their gracious help in providing photographs of some of the pioneers in the field.

The Anesthesiologist and Pain: A Historical Memoir

60

Daniel B. Carr and Michael J Cousins

Summary

Pain has forever troubled humankind. Elucidation of nociceptive mechanisms and pathways, and appreciation of their diversity and adaptability, have been essential to understanding pain. Anesthesiologists have furthered such understanding and treatment, and advanced the appreciation of pain as a public health issue.

During the twentieth century, the concepts of post-injury sensitization and hyperalgesia were developed, and the role of humoral mediators recognized. The 1950s saw the emergence of anesthesia departments, facilitating research into acute and chronic pain by specialists whose daily task originated with the elimination of pain during operations.

Henry Beecher observed injured soldiers during World War II, noting that post-injury pain intensity and the dose of opioids needed to control their pain were both less than with comparable civilian injuries. He argued that the meaning of the injury, not the injury *per se*, dictates the intensity of pain. In the 1960s, Melzack and Wall described the gate control theory, providing a neurological basis to Beecher's concept. They proposed that rostral descending pathways modulate nociceptive afferent traffic at the spinal segmental level.

John Bonica pioneered pain advocacy, research and practice. His comprehensive 1953 monograph summarized available knowledge on pain. In 1973, he convened an international meeting that led to the formation of the International Association for the Study of Pain (IASP) and founding of the journal *Pain*. Anesthesiologists were influential in widening the focus of IASP from chronic pain to acute and cancer pain. Recognition that physical, psychological and environmental factors play a key role in all pain and its treatment remains Bonica's lasting legacy.

From 1950 to 1990, control of acute and postoperative pain received inadequate attention despite knowledge of effective treatments. Ready's watershed description of an organized acute pain service in 1988 accelerated the initiation of multidisciplinary pain teams in developed countries. Increasing understanding of the pharmacokinetic and pharmacodynamic properties of opioids and other analgesic drugs, together with an appreciation of the neural mechanisms governing pain perception, led to the use of multiple classes of analgesic and adjuvant drugs. This "multimodal approach" aims to optimize acute pain management and prevent the transition from acute to chronic pain. The IASP published *Management of Acute Pain: a Practical Guide* in 1992.

Anesthesiologists have advanced new concepts in pain management during the past 40 years, reported their findings in thousands of studies, and applied them to improve outcomes. In 2010, the IASP, through the Declaration of Montreal, affirmed that access to pain management is a fundamental human right.

Introduction

Since prehistory, pain has driven sufferers to pursue relief by any available means. Anesthesiologists have played a central role in advancing the understanding and treatment of pain, a primal experience shaped by meaning, and social and religious contexts [1–10]. This chapter describes pioneers in anesthesiology who extended pain management outside the operating room, to improve pain sufferers' quality of life by applying lessons learned from anatomy, physiology, pharmacology, neuroscience, and the study of human behavior [11]. We also describe how anesthesiologists recently framed pain as a public health problem and played an advocacy role in achieving access to pain management as a fundamental

human right [12]. Anesthesiologists have led governmental and nongovernmental initiatives, championed pain education for health professionals and the public, [13, 14] and elevated the standard of pain research and its subsequent translation into clinical practice [15].

In 1954, John Bonica described two roles for the anesthesiologist managing pain: first, as a technician skilled in performing specific diagnostic or therapeutic procedures “whose contribution will, of necessity, be an exercise rather than a discipline”; second, “as the individual who is responsible for the over-all management of the patient” [16]. The development of methods and techniques for regional anesthesia and neural blockade *per se* are described elsewhere in this volume. In the spirit of Bonica’s distinction, the present chapter focuses on the anesthesiologist’s roles in advancing the science of pain and translating new knowledge to benefit patients.

Numerous publications describe the history of pain from scientific, philosophical and literary perspectives. Bibliometric analyses provide objective measures of the number of published articles on pain, the evolution of popular topics, and the impact of these publications (defined as the number of citations according to article, subject or author) [17–21]. We intend to present a personal perspective, emphasizing people, places and events that we have known first-hand. In defense of this approach, we note that Thucydides himself conceded possible bias in writing at greater length about military campaigns in which he had fought, or political debates in which he had participated, but he claimed that the benefit of an eyewitness narrative outweighed the risk of myopic emphasis.

Antecedents

Anesthesiologists and anesthesia have woven much of the fabric of modern pain management. Long before the specialty was recognized as such, inhalational and local anesthetics transformed medical practice. In his graduate thesis in English and Comparative Literature, written in retirement after a distinguished academic career in anesthesiology, Emanuel Papper recounted Davy’s and others’ observations of the analgesic effects of nitrous oxide, a half-century before its clinical application [22]. Papper argued that attitudes of the emerging Romantic era, particularly its focus on the happiness of the individual independent of the group, prompted Western society to overcome prior disinterest in relieving individual suffering. By 1884, when Koller first described local anesthesia, the desirability of relieving intraoperative pain was no longer questioned. Early techniques for neural blockade applied cocaine to surgically exposed peripheral nerves or plexuses [23, 24]. The advent of percutaneous approaches to peripheral and neuraxial blockade expanded surgeons’ interest in and techniques of blockade during the late 19th century and early 20th century.

By the outbreak of World War II, differentiated anesthesia units had formed in some academic centers [23–26]. A few of these focused upon neural blockade (e.g., Mayo Clinic [27] or Bellevue Hospital [23–24]). In Europe, Leriche linked division of sympathetic ganglia and plexuses with improved blood flow to ischemic limbs and reduction of some forms of chronic pain. These included causalgias or phantom limb pain that had been observed for millennia, but were first described systematically during the US Civil War. By the mid-20th century, the anatomy of nociception was understood well enough to provide a rationale for neurosurgical division of spinal (cordotomy) or central (cingulotomy) pathways, among other neurosurgical techniques for pain relief [28, 29].

The German pain researcher Goldscheider questioned Von Frey’s and Muller’s 19th century hypothesis of specific receptors for pain. Goldscheider proposed that a single set of nerve receptors mediated both the sensation of non-painful touch and its central summation to become pain [30]. In the early 20th century, Henry Head, a British neurologist, distinguished between rapid, well-localized touch sensations (“epicritic”), and the slower onset of dull, poorly localized, highly aversive sensations (“protopathic”), characteristic of regenerating injured nerves. Sherrington, a contemporary of Head, introduced the term “nociceptor” and the concept of descending inhibition. Working in St Louis, Missouri in the 1930s, Erlanger and Gasser identified distinct neuronal populations with differing conduction velocities, within peripheral nerves. Their classification of neurons, using Roman letters A to D to describe groups according to axonal conduction velocity, and Greek letters alpha to gamma to delineate subgroups, remains in use today. During these studies, Zotterman and Adrian employed the oscilloscope to record an action potential from a single nociceptive neuron.

In the first half of the 20th century, researchers investigated phenomena we now term post-injury sensitization and hyperalgesia [30–31]. Anticipating the current practice of multimodal analgesia, the UK internist, Lewis, postulated in the 1930s and 1940s that humoral mediators (including histamine, bradykinin and substance P) of injury, in the vicinity of a primary lesion, enhanced sensitivity to stimuli. Others during these pre-war decades, including Livingstone in Oregon, and Hardy and Wolff at Yale University, focused upon activation of a neuronal pool of variable excitability within the spinal cord, as the basis for post-injury hyperalgesia (excessive sensitivity to pain). Research on hyperalgesia and sensitization echoed prescient clinical observations at the beginning of the 20th century by George Crile, surgeon and founder of the Cleveland Clinic [32]. Crile proposed that using local anesthesia to block transmission of nociceptive impulses from the periphery to the central nervous system, could avert the debilitating effects of surgery or trauma. Crile’s hypothesis (“anoci-association”) anticipated not only the concept of central sensitization, but also the benefit of

regional anesthesia in inhibiting what were later identified as catabolic and immunosuppressive postoperative stress responses. He argued that untreated pain facilitated the development of central sensitization and the stress responses (see below). Not surprisingly, recognition of the importance of regional anesthesia and pain control by its leadership, led the Cleveland Clinic to continuing prominence in these fields.

Thus, by World War II, a substantial foundation supported the growth of pain research and treatment. Observations of combatants and veterans during World War II were pivotal to the careers of pioneers such as Henry Beecher and John Bonica. Progress in this field accelerated in postwar developed nations witnessing the return of veterans (many of them with chronic pain from wounds), and a baby boom demanding better obstetric pain relief. By the 1950s, many departments of anesthesiology had differentiated from their surgical antecedents. Circumstances were ripe for clinicians, clinical researchers, and research scientists in or affiliated with these departments to address major gaps in scientific knowledge and clinical practice. Bacon documented the relatively low, constant number of citations to both pain and conduction anesthesia from the early part of the 20th century until about 1950, [23] when a steady upsurge of citations began, roughly doubling in each subsequent decade [11]. We describe how this progress unfolded in the past 60 years using selected highlights of pain research and practice in which anesthesiologists and their basic science collaborators have changed medical practice.

Boston: Beecher, Analgesic Trials, and the Placebo Effect

Beecher was a Midwesterner born with the improbable surname of Unangst [33]. A month before entering Harvard Medical School, he legally changed his surname to Beecher (the maiden name of his maternal great-grandmother) perhaps to be more acceptable to Boston's Brahmin society, and possibly to distance himself from his irresponsible father with whom he had a strained relationship. Beecher was a high-energy iconoclast. His research was influenced by early positions teaching chemistry and physiology, award-winning laboratory studies in respiratory physiology as a medical student, and a year (1935) studying in Copenhagen with the 1920 Nobel laureate in medicine August Krogh. In 1936, and without training in clinical anesthesia, Beecher became the first Anesthetist-in-Chief at the Massachusetts General Hospital (MGH), and chairman of this new department within the Department of Surgery. In 1938, he published a 388-page monograph on the physiology of anesthesia.

During World War II, Beecher was mobilized to Europe where he made an insightful observation concerning pain at the 1944 Anzio beachhead. Beecher noticed that battlefield

casualties had less intense pain and required less morphine than civilian counterparts suffering equally severe injuries. He surmised that the soldiers thought, "I have survived and will go home and not return to the front line!" Despite major nociception, the soldiers' pain was minimal—implying that the meaning of the injury and not the injury *per se* dictates the intensity of pain. Two decades later, when working at MIT, on the other side of the Charles River from Boston, Melzack and Wall supplied a neurological basis for Beecher's insight in their now classic 1965 paper describing the gate-control theory [34]. They proposed that rostral descending pathways modulate nociceptive afferent traffic at the spinal segmental level.

Pain research fascinated Melzack, and he generously encouraged others involved in such research. He became President of the International Association for the Study of Pain (IASP). Wall could be intimidating on first meeting, and in his role as the first Editor-in-Chief of the journal *Pain*. He could be devastatingly critical of sloppy work or adherence to outdated concepts. Both he and Melzack became warm friends of the current authors (MJC & DBC), and inspired many pain researchers who remain active to this day.

Beecher's personal library was placed "up for grabs" before it was to be discarded by his successor Richard Kitz, on Kitz's retirement [25]. A young staff anesthesiologist, DBC, grabbed as many books as he could. These volumes covered neurochemistry, central nervous system metabolism, regional blood flow, oxygen consumption, pharmacology and physiology, mental health issues including opioid addiction, mathematical biophysics modeling synaptic conduction, and the biological basis of fatigue and stress. Just as Beecher's group found that a single pencil stroke made by a patient on a visual analog pain scale could offer insight into that person's perceptions, Beecher's underlining and marginal scrawls in these rescued volumes document a deep, career-long interest in neuroscience. One of the earliest of the volumes is a 1929 printing of Haldane's and Huxley's *Animal Biology* [35]. Unlike later volumes that all bear the stamp "Property of the Department of Anesthesia of the Massachusetts General Hospital" along with the purchase date and Beecher's signature, this has none, suggesting that it was acquired before the department was organized. The handwritten notes are identical in appearance (including sole use of pencil, never pen) to those in later volumes bearing the MGH stamp. The notes are concentrated in sections on neuronal physiology. A copy of Page's 1937 monograph *The Chemistry of the Brain*, purchased in 1940, shows Beecher's questions about the validity of the methods then used to assess cerebral metabolism, particularly their inability to observe regional vasoconstriction [36]. Bartley's and Chute's 1947 monograph on *Fatigue and Impairment in Man* [37] is heavily underlined in sections on sleep deprivation as a means to induce psychosis. A 1953 research monograph on metabolic and toxic diseases

of the nervous system, [38] is densely highlighted—but only in the chapter on psychoses produced by administration of drugs, with stars drawn alongside specific descriptions of the effects of LSD and mescaline. “Get” is scrawled next to several chapter references on delirium and clinical studies of hallucinogens. Of the latter, one of these has “8/17/57” written alongside—just four days after the volume’s receipt date. The near-immediate attention Beecher gave to this chapter coincides with his active, secret research funded by the Central Intelligence Agency (see below).

Beecher assembled a remarkable team to initiate modern analgesic trials. Many methods they introduced or refined remain in use today. Louis Lasagna, the first author of this group’s influential 1954 study quantifying the magnitude of the placebo response in postoperative analgesic trials, [39] became “the father of modern clinical pharmacology”, an FDA advisor (one of three consultants who developed the current regulatory framework of phase 1–3 trials to demonstrate safety and efficacy of medications prior to FDA approval), and a pain researcher in his own right (e.g., inventor of the vertical “pain thermometer” scale) [40]. Lasagna advocated rigorously controlled clinical trials, yet privately described such trials as “hothouse medicine” whose results were often over generalized to real-world patients. In print, he pleaded for “the naturalistic study of medicines”, anticipating the current emphasis on comparative effectiveness research. Lasagna later became a graduate dean at Tufts, where he founded its Center for the Study of Drug Development, and was instrumental in inaugurating its Master of Science program in pain research, education and policy. In the mid 1990s DBC heard a lecture by Lasagna, during which he uncomfortably revealed that in the Cold War era of the 1950s, Beecher and his group conducted secret studies of the effects of LSD in healthy subjects, research supported by the Central Intelligence Agency. Each week’s results would be placed in a sealed envelope and handed to a government courier in civilian garb who had traveled from Washington to Boston solely to receive them. Perhaps it was a sense of guilt at participation in this classified program—identified 50 years later in newly declassified documents as the CIA’s notorious MKULTRA project, exploring drugs for mind control—that led Beecher in the 1960s to advocate for the ethical conduct of clinical trials [41]. Beecher not only underlined those sections in his books focusing on hallucinogens, sleep deprivation and other means to induce psychosis, but devoted a lengthy chapter to psychotomimetic drugs in his classic 1959 text *The Measurement of Subjective Responses in Man* [42]. In retrospect, the almost disproportionate comprehensiveness of that chapter is another clue to his intense yet clandestine Cold War research.

Statistical Studies and the Emergence of International Collaboration

Donald Todd, a Beecher protégé and co-author of the 1954 study of deaths associated with nearly 600,000 anesthetics in 10 institutions, [43] devoted his later career to clinical care of patients with pain. DBC once asked Todd why death was selected as the sole outcome analyzed in the 1954 study. He chuckled and replied “because it was the only outcome whose definition everyone could agree upon”. His use of regional anesthesia to diagnose and treat painful conditions dated from a 1940s collaboration with William Sweet, a neurosurgeon and pioneer in pain studies. This collaboration led him to provide anesthesia care for trigeminal thermal or glycerol ablations, cingulotomies, and to test the effect of local anesthetic sympathetic blocks prior to planned surgical sympathectomy. Todd formed a “diagnostic and therapeutic nerve block unit” that DBC joined in 1986, at Kitz’s suggestion. The suggestion acknowledged DBC’s prior research fellowship in endocrinology and peptide chemistry, measuring β -endorphin. That work resulted in reports on neuro-immune interactions and the effects of physical exercise upon β -endorphin secretion (the 1981 “runner’s endorphin” publication) [44]. The nerve block unit expanded to a multidisciplinary pain clinic following the Seattle model (see below), to which a clinical fellowship was subsequently added. The blueprint for the evolution of this nerve block unit into a multidisciplinary center was provided in the mid-1980s, through a comprehensive consultation arranged by Kitz with his friend MJC. At that time, in his capacity as President of the IASP, Cousins was codifying desirable features for various types of pain treatment facilities worldwide. The authors’ personal interactions and multiple collaborations date from this time.

Frederick Mosteller developed the statistical methods for Beecher’s (and hence the field’s) early analgesic trials. Later, with his colleague Tom Chalmers, Mosteller originated the technique of meta-analysis. In 1990, DBC co-chaired the first US federal clinical practice guideline panel; its topic was acute pain [45]. Mosteller and Chalmers provided support with systematic reviews and meta-analyses, for example, of patient-controlled analgesia [46] and the respiratory benefits of postoperative epidural analgesia [47]. Bucknam McPeck, another Beecher protégé, personal medical advisor to Mosteller, and senior member of the MGH acute pain team, facilitated an expanded international co-operation. McPeck’s European connections included Edmond Neugebauer and Stefan Schug from Germany, whose productivity in translational pain research, particularly in relation to acute pain and often based upon international collaborations, led them to organize IASP’s Acute Pain Special Interest Group (APSIG) in the months leading up to its 2005 World Con-

gress in Sydney. The APSIG's inaugural meeting took place at that World Congress. DBC, currently Chair of the APSIG, enjoyed additional collaborations with French and Greek clinical scientists. Chalmers and Mosteller continued to support evidence-based analyses for a subsequent guideline on cancer pain, after which their protégé Joseph Lau at Tufts picked up the task, becoming Director of Tufts' Evidence-based Practice Center, funded by the Agency for Healthcare Research and Quality [48]. Anesthesiologists were not only involved in the first evidence-based US federal guidelines, but to this day have participated in numerous international evidence syntheses [15] and related policy efforts such as providing expert guidance and testimony to the US FDA.

The pioneering advances of Beecher and his collaborators continue to guide how medical science worldwide quantifies subjective responses, conducts regulatory affairs such as drug approval, and monitors pain in everyday practice [49]. Today's routine uses of placebo or sham comparators in analgesic trials, and current neuroscience research on placebo, also reflect Beecher's influence. One indication of this impact is the selection of publications from Beecher, Laskagna and Mosteller (on placebo) and Lau (on cumulative meta-analysis) by the Editor of *The Lancet* for his personal 27-item "core canon of medical literature" [50]. Others so selected included Hippocrates, Galen and Koch.

In the 1960s, Todd's colleagues cautiously began using small doses of morphine as an antitussive for patients requiring prolonged controlled ventilation following cardiac surgery [51]. The patients did so well that larger and larger doses of morphine (and later, fentanyl) were given earlier in their course, culminating in what for the time were unprecedented large doses of opioids being given routinely during cardiac anesthesia, as reported by Edward Lowenstein in 1969 [52]. That practice was adopted worldwide.

Boston is replete with academic medical activity, facilitating cross-fertilization. Benjamin Covino—in the 1970s a senior executive at Astra, a global pharmaceutical firm self-termed "the house of regional anesthesia"—decided to pursue clinical training in anesthesiology after years as a clinical researcher and pharmaceutical executive. He completed his anesthesiology residency at the MGH, occasionally swapping on-call dates to catch a flight overseas to a corporate board meeting. Upon completing his residency in 1977, he became the first and still only MGH anesthesia trainee whose initial post-residency position was as an academic chairman (at the University of Massachusetts). In 1979, he succeeded Leroy Vandam as Chairman of Anesthesiology at the Brigham and Women's Hospital. That hospital's patients included many with arthritis undergoing joint replacements under regional anesthesia, and many parturients whose labor pain was managed with epidurals. Covino's department included stellar clinicians along with clinical and

preclinical scientists, including Gary Strichartz, the 1987 ASA Excellence in Research Awardee, honored for his work on mechanisms of action of local anesthetics [53] and other pain-related topics. Many Brigham graduates advanced pain research and practice, including two Past Presidents of AS-RA-PM, Michael Ferrante and Mark Lema. Lema, an MD with a PhD in pharmacology, is also a Past President of the ASA. As the long-term Chair of Roswell Park Cancer Institute's Department of Anesthesiology, Critical Care & Pain Medicine, he has focused upon cancer pain control. He has mentored prominent clinician-researchers including Oscar de Leon-Casasola. Carol Warfield, the Edward Lowenstein Professor (see above) of Anesthesiology at the Beth Israel Deaconess Medical Center, is another Boston-based leader in pain medicine known for numerous educational and organizational activities and a multi-edition textbook on pain.

Other major metropolitan centers had their own pioneers in pain treatment and research. In New York's Bellevue Hospital, Emery Rovenstine established one of the nation's first outpatient pain clinics in 1936, focusing on nerve blockade. About a mile away, Raymond Houde's group at Cornell and Memorial Sloan Kettering Cancer Center advanced analgesic trial design and produced leaders in opioid research. The growth of pain research and care in recent generations led many centers to assemble critical masses of pain clinicians and researchers not only in the Americas but also in the United Kingdom, the European continent, and Asia including Australia (in Adelaide, Brisbane and Sydney).

Bonica, Chronic Pain as Disease, Multidisciplinary Pain Clinics, and IASP

John Bonica, working in Tacoma and Seattle, was the second pioneer of the current worldwide era of clinical pain research and treatment. Like Beecher, he rose from humble beginnings to join the first generation of academic anesthesiologists. Although Giovanni Giuseppe Bonica's parents Americanized their 12-year-old's name to John Joseph Bonica when they fled Mussolini's Italy and emigrated to the US, unlike Beecher, Bonica never discarded his ethnicity [54]. MJC recalls that Bonica's forceful personality sometimes evoked suspicions of a subterranean connection with a powerful Italian organization, a link for which no justification existed, but that Bonica chose not to refute.

Remarkable physical strength and endurance complemented Bonica's dominating personality. Apart from Resh Lakish in imperial Rome, and Bonica in democratic America, history offers few examples of professional wrestlers who went on to careers as distinguished scholars [55]. Bonica began wrestling in secondary school, became New York City's high school middleweight champion, and two years

later the regional intercollegiate champion. His biography in the Professional Wrestling Hall of Fame describes his competing as Johnny “Bull” Walker, and once defeating all 36 members of a college wrestling team in a single day. He wrestled professionally for 14 years (1936–1950), including as “The Masked Marvel” during military service. In 1939, he won the light heavyweight championship of Canada and in 1941 was world champion at that weight. He fought in 1485 professional bouts, and 2000 additional matches in carnivals and circuses where he earned money for medical school tuition by taking on all comers. Chaperoned by her mother Angela, his wife Emma often sold tickets at these carnivals. His wrestling career and numerous consequent operations, including hip replacements, left him with lifelong pain that underlay his interest in pain management.

As with Beecher, clinical observations in World War II proved fundamental to Bonica’s career. In 1944, Bonica entered the Army directly from residency, and was assigned to the then largest military hospital in the world, the 7700-bed Madigan Army Medical Center in Fort Lewis, Washington. His orders stated “You will be in charge of pain control”. He read classic works, corresponded extensively, yet was baffled by the many pain problems in wounded soldiers under his care [56]. He began a regular lunch meeting to which he invited an orthopedist, a neurosurgeon and a psychiatrist to discuss such cases. Years later, he stated “These early experiences convinced me that complex pain problems could be more effectively treated by a multidisciplinary/ interdisciplinary team, each member of which would contribute his/her specialized knowledge and skills to the common goal of making a correct diagnosis in developing the most effective therapeutic strategy” [56]. From this came the multidisciplinary pain clinic. He continued such a clinic as Chairman of Anesthesiology at Tacoma General Hospital after Army service, and later in 1960, as founding Chairman of the Department of Anesthesiology at the University of Washington in Seattle. Influenced in part by early visionaries such as Leriche, Bonica considered chronic pain to be a disease entity *per se* (see below) in which psychosocial features were substantial. The “father” of operant conditioning, the psychologist William Fordyce, oversaw Bonica’s pain rehabilitation program [57].

The concept that chronic pain has important psychological and systemic comorbidities is an ancient one. The Roman general and emperor Marcus Aurelius wrote in his *Meditations* that “many other things which we find uncomfortable are of the same nature as pain: feelings of lethargy, or a feverish temperature, or loss of appetite” [58]. Robert Burton, in his voluminous 17th-century *Anatomy of Melancholy* voiced similar observations, [59] as did the US Civil War physician Weir Mitchell. These insights appear to have been nearly forgotten by early 20th century medical research. The slender 1948 monograph on pain by Wolff and Wolf, for ex-

ample, describes pain solely in nociceptive terms without mention of psychological factors [60]. Its single index entries for both “brain” and “cortex” refer simply to the insensibility of each to direct stimulation. It was the “charismatic entrepreneur” [2] Bonica who laid the foundation for today’s view of chronic pain as a disease entity best treated in a multidisciplinary fashion.

Building upon Bonica’s early work, MJC and Philip Siddall were the first to assemble and integrate a wide range of basic and clinical (including psychological) evidence that chronic pain is a disease entity *per se* [61]. They observed that “continuing nociceptive inputs result in a multitude of consequences that impact on the individual, ranging from changes in receptor function to mood dysfunction, inappropriate cognitions, and social disruption” [61]. They maintained that the changes brought about in multiple bodily systems “as a consequence of continuing nociceptive inputs argue for the consideration of persistent pain as a disease entity in its own right.” Anticipating the current interest in pain and its control from the perspective of public health (see below), Siddall and Cousins pointed out that “the best outcomes will be obtained when those involved in the treatment of persistent pain recognize and also tackle the variety of environmental factors that may be contributing to the presence of persistent pain.”

Bonica’s desire to optimize acute postoperative pain control (see below) led to the formation of one of the earliest organized acute pain services based in anesthesiology, described in 1988 by Brian Ready and colleagues [62]. His work on chronic pain led to the founding and expansion of the IASP (see below), now the single largest global interdisciplinary organization focused upon pain. In 1953, Bonica authored a 1500-page monograph summarizing the world’s preclinical and clinical knowledge of pain and emphasizing the distinctive nature of chronic pain [63]. He accomplished this while working full-time in Tacoma! A major theme of this watershed text was that “whereas in acute pain, the pain is a symptom of the disease or injury, in chronic pain the pain itself is the disease” [64]. He lectured extensively about his ideas and served as President of the ASA and the World Federation of Societies of Anaesthesiologists (WFSA). As Baszanger [2] and others [65] pointed out, a less obvious but ongoing powerful factor was the worldwide assignment of increasing importance to the wishes of patients and their families for enhanced quality of life and hence improved pain control.

In 1972, Bonica invited an international group of researchers to a meeting, with the goal of founding a global organization to establish pain as a differentiated field of study. To organize the meeting, he recruited his department’s editor, Louisa Jones. The May 1973 meeting attracted 102 international speakers and 237 other delegates to Issaquah, Washington, where the IASP charter (modeled after the char-

ter of WFSA) was promulgated [66]. A Council was established, and planning began for a new journal, *Pain*. Jones asked Bonica what to do next. His simple response was “You handle it” [66]. Although Jones said Bonica had a reputation as a difficult supervisor, the two worked well together. Jones attributed their collegiality to a similar outlook, resulting from having grown up within a half mile of each other in Brooklyn, New York. DBC and MJC interacted with Jones for decades, in awe of her administrative and editorial capacities and her work ethic, noting her unofficial maternal counseling of members of IASP including its officers.

MJC’s close relationship with Bonica extended from the 1970s into the 1990s. He recalls that:

“I first met Bonica in 1970 when I visited Seattle to discuss my acute pain research carried out under the supervision of Bromage in Montreal. I knew that Bonica had a reputation for being ‘imposing’ and engendered a feeling that one did not want to be ‘on the wrong side of him’. He had a handshake like a steel clamp and had shoulders almost equal in breadth to his height. He listened with some apparent irritation to my research findings and then fired off a series of staccato questions which dashed my hopes of his approval (even though the editors of *Surgery, Gynecology and Obstetrics* had already agreed to publish my manuscript). In the end he said ‘Not bad. Keep up the good work. Follow me and I will show you what we do here’. Before I left he gave me some advice for the future ‘Remember always to get your facts straight...and never, never give up’. Subsequently Bonica appointed me as a Regional Vice President and then IASP Councilor. I learned as a junior Councilor ‘Never say no to Bonica’. He involved people from diverse specialties and balanced basic with clinical input. His tireless work in fostering the development of the careers of many IASP members besides myself spanned many others too numerous to name.

“Some interpreted Bonica’s apparent ‘grumpiness’ as being ‘difficult’. More likely the underlying cause was injuries from his wrestling career resulting in his having close to 50 operations and severe chronic pain. His ability to pursue ‘active approaches to pain control’ by keeping busy was an object lesson to any pain patient—he just kept going even after 70 years of age. However, when his beloved wife Emma died he did not persevere much longer. He took the unusual step of calling me, and his other close friends, to say goodbye about 24 hours prior to his death—as always he was in control of the situation.”

We can only speculate to what degree Bonica’s drive to establish the field of Pain Medicine resulted from his own chronic severe pain, poor postoperative pain control after his dozens of operations, or Emma’s near-fatal response to a general anesthetic, poorly administered during delivery [54]. Perhaps part was a reaction to his earning a livelihood for decades by defeating opponents in hand-to-hand combat.

He did not comment upon his personal motivations when he wrote “the anaesthetist in his daily practice sees and cares for patients who fear pain and consequently he naturally develops a sympathetic understanding, a considerate feeling for those who suffer. This is, without doubt, the most important and greatest single qualifying attribute” [67].

As more people entered the fields of pain research and treatment, they built on the contributions of individual post-war pioneers such as Beecher and Bonica, resulting in group efforts on a national or international scale. This pattern of pioneers succeeded by numerous followers is typical of the diffusion of all types of knowledge [17–21, 68].

Early Years of the IASP

Anesthesiologists played an integral role in IASP from its beginning. Bonica sought to link basic researchers to clinicians and thus asked Denise Albe-Fessard, PhD (head of a basic pain neurophysiology research group at INSERM, in Paris) to be the First President of IASP. Bonica became President-elect, ensuring long service in three consecutive presidential positions: President-elect, 2nd President and Past-President. He also would continue to serve on IASP’s Executive for that organization’s first nine formative years [69]. Another anesthesiologist from Bonica’s department in Seattle, B Raymond (“Ray”) Fink, served as the first IASP Secretary. Still other anesthesiologists on the first Council were Fausto Molina (Argentina), Joseph Sodipo (Nigeria), Jean Lassner (France) and Hideo Yamamura (Japan). Bonica achieved his vision of IASP fostering interaction among basic scientists and clinicians. IASP presently has more than 8000 members in 126 countries and chapters in 85 countries. Of 12 IASP Presidents to date, besides Bonica only two (MJC and Eija Kalso) were anesthesiologists. On the other hand, given IASP’s tradition of nominating pre-clinical scientists alternating with clinicians for President, that figure corresponds to half of the clinicians elected.

During Melzack’s and MJC’s Presidencies (1984–1990), IASP’s brief increased from a focus largely on chronic pain, to include acute pain and cancer pain. An official NGO relationship was developed with the World Health Organization, with the Norwegian anesthesiologist and researcher, Harald Breivik, in the long-term liaison role. Several task forces were formed by MJC including Acute Pain Management (1984); Pain in the Workforce (1987); Core Curriculum for Professional Education in Pain (1987); and Undergraduate Curriculum in Pain (1987). Membership in IASP was extended to those from developing countries and countries with currency difficulties—increasing international interactions. Anesthesiologists comprised the majority of the considerable increase in IASP membership during this time.

Acute Pain: Services, Multimodal Control, Pre-emption, and Prevention

Anesthesiologists drew attention to inadequacies of traditional acute pain management. Ferrante and Covino (see below) assembled a historical “core literature” of 18 reports, in 1990 documenting the inadequacy of conventional intramuscular injections of opioids for postoperative pain [70]. The earliest of these reports, published in 1952, was a collaboration between anesthesiologists Papper and Rovenstine and the clinical pharmacologist Brodie [71]. This paper reported that a third of conventionally managed patients experienced inadequate postoperative analgesia. Arthur Keats reported a similar incidence (range 26–53%) in 1956 [72]. In 1961, Roy Simpson’s group in London (University College) pioneered the use of postoperative thoracic epidural analgesia, [73] as did Bruce Scott’s group later in Edinburgh [74]. Two internists, Marks and Sachar, in 1973 found that fewer than half of adult medical inpatients with acute pain received adequate pain relief [75]. An Australian 1983 study by Mather and Mackie (the first in children) similarly reported that 50% of children did not receive adequate pain relief [76]—a disturbing statistic given the universal instinct to comfort the young. In 1986, MJC and Phillips reported on acute pain management in critical care patients, a neglected area with few research publications appearing subsequently [77]. The consistent theme from this literature, is the documentation of poorly controlled acute pain in numerous research studies and editorials, from the 1950s until the first report of a formal acute pain service by Ready in 1988 [62]. Knowledge, drugs and techniques existed to successfully treat 90% of postoperative and other acute pain, [77, 78] but only a third to a half of patients were adequately treated [70]. In developing countries, undertreatment of acute pain remains the rule [12].

Correlative opioid pharmacokinetic-pharmacodynamic (PK-PD) studies on patient-controlled opioid analgesia by Mather at Flinders Medical Centre in Adelaide [79, 80] (and see below), focused attention on management of postoperative and other forms of acute pain. Thus, an increasingly sophisticated “acute pain service” began to evolve in 1975. Relying entirely on clinician researchers and research staff of the Flinders Academic Department of Anaesthesia & Intensive Care, the improvement in acute pain management, and encouragement of the surgeons who witnessed the benefit, increasingly drew clinicians into involvement in the acute pain service. Some surgeons initially believed that their residents could handle opioid infusions, resulting in numerous cases of under-dosing and a few overdoses and acute admissions to the ICU.

On commencing his Presidency of IASP in 1987, MJC appointed a Task Force on Management of Acute Pain. Concurrently, the National Health & Medical Research Council (NHMRC) of Australia established a Working Party (includ-

ing MJC) on management of all forms of pain. The NHMRC recommended a team approach to acute pain management. MJC appointed anesthesiologist Brian Ready from Seattle to Chair the IASP Task Force, resulting in the IASP Document on Acute Pain. Ready’s team, including a nurse, anesthesiologist, and anesthesiology fellow, had published their experience in postoperative pain in 1988 [62] followed by Macintyre’s 1990 publication from Australia, [81] Sinatra’s from New Haven (US) in 1998, [82] Schug’s from New Zealand in 1995, [83] and Rawal’s from Sweden in 2005 [78]. In retrospect, the delay in establishing such anesthesiology-based services is surprising, since the scientific basis of acute pain management had long been known. Patient-controlled analgesia devices, for example, were first described in the late 1960s and early 1970s [84–86]. Publication of correlative PK-PD studies occurred with nearly a 10-year time lag until their application. One might speculate that routine use of PCA devices was awaiting development of clinically useful pulse oximetry, permitting continuous monitoring of the patient’s ventilatory status. The issue of postoperative monitoring to detect opioid-induced hypoventilation remains an ongoing one.

The IASP document “Management of Acute Pain: a Practical Guide” was published in 1992. The Royal College of Surgeons of England and the College of Anaesthetists concurrently published a collaborative “white paper” on pain control after surgery [87]. Also in 1992, a US Government effort to link evidence to recommendations resulted in the first federal clinical practice guideline on any topic. Its focus was acute pain management after operative or medical procedures and trauma. DBC co-chaired the panel preparing this report, with contributions from many anesthesiologists [45]. In 1995, Australia’s NHMRC appointed a Working Party (chaired by MJC) which reported in 1998 on the current management, scientific evidence and recommendations for improved treatment of all forms of acute pain. The Australian & New Zealand College of Anaesthetists published a second edition in 2005, with a third edition in 2010 [88]. No other English language evidence-based exhaustive document on all types of acute pain currently exists—resulting in multidisciplinary and multinational endorsement of the document. Similarly comprehensive documents have been prepared following parallel French and German efforts. The ASA prepared an evidence-based clinical practice guideline on acute postoperative pain in 1995, updated in 2004 and 2012 [89]. The ASA produced and updated companion guidelines for cancer pain and chronic non-cancer pain, with an authorship consistent with the many contributions that anesthesiologists have made to these latter two classes of pain.

Acute Pain Services became common during the late 1980s, facilitated by the then-new, patient-controlled analgesia that with specialized supervision could, for the most part, be safely used in general wards. Patient-controlled epidural

analgesia could be implemented on general surgical wards using low dose local anesthetic and opioid combinations. However, safe deployment of such neuraxial modalities required development of clinical protocols, education of staff, and appropriate monitoring. The trend towards multimodal perioperative therapy required knowledge of the properties of opioids, NSAIDs, COX-2 inhibitors, anticonvulsants, antidepressants and more. Thus the anesthesiologist on the Acute Pain Service became the clinical pharmacologist, and the acute care internist who managed concurrent acute medical problems in surgical patients. Increasing numbers of anesthesiology departments renamed themselves to include “Anesthesiology, Pain Medicine, and Perioperative Care”. To the detriment of Acute Pain Services, recent fiscal pressures have obliged some anesthesiologists to minimize time spent outside of the Operating Room.

Multiple factors determine the risk that acute pain from surgery might evolve to chronic pain. Hence, “multimodal analgesia”—the use of multiple (including non-drug) strategies acting concurrently through multiple pathways and mechanisms—is logical. As Egbert, Battit and colleagues described in 1964, [90] a multimodal strategy may include allaying pre-operative anxiety by a clear explanation of the operation, expected adverse effects, and plans for pain relief. A pharmacological multimodal approach uses different drug classes aimed at different analgesic targets. Appreciation of the different neural mechanisms involved in pain perception, has led to the use of two or more classes of analgesic and “adjuvant” drugs, drugs with different mechanisms and/or sites of action. This approach aims to maximize pain relief, particularly for pain associated with movement, while minimizing side effects. Acute pain management occurs in the context of factors such as wound care, drain placement, temperature maintenance, hydration, provision of nutrition (particularly protein), glycemic control, and early mobilization—which together with pain management embodies a multidisciplinary strategy of “acute rehabilitation”. Anesthesiologists have developed and applied these concepts over the past 30 years to improve outcomes, [91] including the quality of recovery [92]. The results have shortened postoperative stays sufficiently to perform many previously inpatient operations on an outpatient basis [93].

Studies of the benefit of multimodal systemic analgesia were shown in 1960, for the addition of an NSAID to an opioid [94]. The 1992 review of evidence by DBC and colleagues confirmed the safety and efficacy of the combined use of opioids and NSAIDs in postoperative pain [45]. The then-recent availability of an injectable NSAID (ketorolac) further encouraged the use of this combination. In 2005, a meta-analysis by Marret, Bonnet, and other French colleagues added support for perioperative opioid-sparing, and the decrease of some opioid side effects by use of diverse injectable NSAIDs, including acetaminophen (paracetamol) [95].

By the late 1980s, the WHO had developed a simplified, step-wise “Analgesic Ladder” for the management of cancer pain: acetaminophen +/- NSAIDs +/- opioids, supplemented with adjuvant drugs at any step of the ladder. Space limitations do not permit discussion of the important ways in which anesthesiologists brought specialized skills to bear on the relief of cancer pain, e.g., through neurolytic blockade or intrathecal drug delivery. Most anesthesiologists dealt with acute pain differently from cancer pain, and thus the WHO publication on cancer pain relief had limited impact on the management of acute pain. Since the release of the AHCPR and NHMRC documents, there have been numerous studies of multimodal treatment. In addition to NSAIDs, evidence supports the use of intravenous lidocaine, low-dose ketamine, and anticonvulsants such as gabapentin and pregabalin to provide postoperative opioid sparing, and thereby a reduction in opioid side effects. The 1996 development by Brennan of an animal model that replicated essential features of postoperative incisional pain, has furthered progress in understanding the preclinical pathophysiology of acute postoperative pain [96]. This model imposes a plantar incision into a rat hind paw followed by closure of the incision with sutures [96]. It is now employed worldwide to elucidate the cascade of cellular responses evoked by incisional pain [97].

The increasing use of patient-controlled and epidural opioids to provide postoperative pain relief (see below) saw a parallel increase in the incidence of catastrophic respiratory depression [98]. This led to recent initiatives spearheaded by the Anesthesia Patient Safety Foundation (APSF) in the US [100] and elsewhere (e.g., by Pamela Macintyre and David Scott of the Australian and New Zealand College of Anaesthetists). These initiatives call for close monitoring of patients receiving postoperative opioids, including frequent checking of their level of sedation, or the use of oximetry and capnography to trigger alarms when blood oxygen and carbon dioxide levels move outside safe ranges [99].

Pediatric Pain Control

The Boston Children’s Hospital established the position of Chief of Anesthesia immediately after World War II, a role filled by Robert Smith from 1946 until his retirement in 1980. Smith was a founding father of pediatric anesthesiology in the US, training more than 800 residents and fellows, many remaining in the Boston area to advance pediatric anesthesiology and develop early pain treatment services. The second generation of such clinicians involved in pediatric pain included Charles Cote and John Ryan. Well into the 1980s, it was commonly taught worldwide that newborn infants had immature nervous systems and required muscle relaxation but not analgesia to undergo surgery. Attracted by the opportunity to extend his earlier studies on pediatric pain

at Oxford in the 1980s, Kanwal (“Sunny”) Anand accepted a research fellowship at Boston Children’s Hospital. During that fellowship his studies of pediatric stress responses to surgery and their inhibition by analgesia, demonstrated infants’ sensitivity to noxious stimuli and the benefit of analgesics to blunt their catabolic perioperative stress responses. Charles Berde, a contemporary of Anand, developed Boston Children’s multidisciplinary program to treat chronic pain in children, and conducted laboratory studies leading to novel extended-release delivery systems for injected local anesthetics.

Clifford Woolf, a student of Patrick Wall in London, immigrated to Boston in 1997 as the first Richard Kitz Professor of Pain Research at the MGH, moving in 2010 to work at Children’s Hospital with Berde. His initial research established the importance of central (e.g., spinal) sensitization in the amplification and persistence of pain resulting from noxious stimuli in the periphery (see below). More recently his laboratory has identified specific genes and gene products, such as intracellular enzymes whose presence and/or activation make their bearers more likely to experience a transition from acute to chronic pain. His distinguished research career was honored by the ASA’s 2004 Excellence in Research Award.

Concern regarding pain in burned children led to the establishment of “Project Pain” in 1980, at the MGH and the adjoining Shriners Burns Institute, directed by Stan Szyfelbein. Clinical studies involving a pharmacologist, Patricia Osgood, and a pain nurse, Nancy Atchison, commenced along with a laboratory research program [100–101]. Resulting innovations included the use of low concentrations of epinephrine and lidocaine injected under skin graft donor sites to reduce pain and blood loss, daily multidisciplinary pain rounds by a physician, nurse and pharmacologist to assess pain using a large “thermometer” scale easily read by children within bacterial isolation units, and formulation of the concept of burn pain as a neuropathic entity arising from the newly coined term “phantom skin”. Most importantly, through careful correlations of burn depth and extent with pain intensity, they overthrew the prevailing view that third degree burns don’t hurt—they do! In retrospect it is hard to believe that conventional wisdom could have been blind to the obvious agony of severely burned children.

Sensitization and Pre-emptive Pain Management

It is a small step to extend the concept of treating pain as soon as possible after it occurs, to applying preoperative interventions such as neural blockade to avert surgical pain. As noted above, in the 1900s, the surgeon George Crile introduced a concept he termed “anoci-association” [32, 102]. He

used peripheral neural blockade to prevent afferent noxious signals from reaching the spinal cord and brain lest they trigger harmful neurohumoral responses and compromise recovery from injury or surgery. Crile, and later, O’Shaughnessy and Slome, [103] produced evidence supporting this concept, including experiments with spinal anesthesia in traumatized patients. The Montreal anesthesiologist Philip Bromage picked up this concept, reporting in 1971 that epidural blockade blunted neurohumoral responses to surgery [104].

In 1976, Danish gastrointestinal surgeon Henrik Kehlet began to explore stress responses to surgery [105]. His studies of hormonal changes associated with surgery and postoperative pain, found that epidural local anesthesia begun before surgery and continued postoperatively, could attenuate the catabolic (i.e., protein-wasting) effects of surgery. At issue was whether trauma or surgery would trigger “central sensitization” unless afferent nociceptive traffic were blocked completely. In general, the response was “yes”; avoiding central sensitization requires a sufficiently dense neural afferent blockade for a sufficient time, over a sufficient spatial extent. Clifford Woolf, a clinician-turned-researcher, like his mentor Patrick Wall, reported in 1983 that post-injury sensitization could be averted if spinal analgesia was in place pre-injury [106]. Wall supported these concepts in multiple editorials and lectures. Subsequent clinical studies designed to compare analgesia given before or immediately after surgery (often continued only briefly after surgery) frequently failed to show a favorable effect because they did not provide a sufficiently dense neural blockade, extended over a duration outlasting the tissue injury response. Thus, Moiniche’s 2002 evaluation of published studies purporting to test the efficacy of pre-emptive analgesia was negative [107]. Later studies with a more effective pre-emptive intervention, using a more powerful analgesic regimen (e.g., epidural neural blockade, systemic ketamine) over a longer time course, did report reduction of pain and decreased use of supplemental analgesia. For example, Lavan d’homme reported that perioperative epidural analgesia combined with intravenous ketamine decreased hyperalgesia and long term pain for up to one year after colon surgery, compared with intravenous analgesia alone [108]. The importance and frequency of chronic post-surgical pain had not previously been appreciated, nor had the consequent significant disability.

“Protective analgesia” applies techniques that reduce sequelae of central sensitization, such as secondary hyperalgesia. “Preventive analgesia” is the modern terminology for what Crile and Wall espoused, namely, applying measures sufficient to avoid central sensitization in the first place. To be effective, preventive treatment must be continued for as long as the injury response is active. This appears to be for at least 3 days following major surgery. Such an approach holds the best hope for reducing the development of persistent post-surgical pain. As James Eisenach noted in 2010,

anesthesiologists and other pain researchers have joined with the US NIH, and pharmaceutical companies to answer the question “can effective acute pain management prevent transition to chronic pain?” [109].

Contrary to prior views that acute pain is separate from chronic pain, it now appears that acute pain triggers cascades of neuronal processes initiating the transition to chronic pain. Some of these processes occur in nearly all people while others are specific to an individual’s genes. Physical, psychological and environmental factors also influence the transition from acute to chronic postoperative pain. Indeed, in the 1990s, Kehlet and Rathmell [110] and anesthesiologist William Macrae [111] identified risk factors for this transition, including severity of pain, repeat surgery, preoperative anxiety, female gender, genetic predisposition, surgical technique, radiation therapy to the surgical area, neurotoxic chemotherapy, depression, psychological vulnerability (e.g., a tendency to perceive even minor setbacks as heralding catastrophe), and postoperative anxiety. Coordinated management by a team consisting of surgeons, anesthesiologists, nurses, clinical psychologists and other healthcare professionals can minimize the impact of these risk factors on the transition from acute to chronic pain.

Intriguingly, as suggested in another chapter, preclinical studies and retrospective surveys suggest the possibility of another major long-term benefit of optimal perioperative analgesia, achieved using regional anesthesia to decrease stress responses and lower morphine requirements during cancer resection. Not yet confirmed clinically, the possible benefit is a lower likelihood of cancer recurrence, attributed to better immune function in patients whose pain and stress responses are minimized, and opioid requirement decreased, by regional anesthesia [112].

Spinal Analgesia and the Gate Control Theory

The development of caudal and lumbar epidural as well as spinal subarachnoid blocks intertwines with the history of obstetric analgesia and conduction anesthesia [23, 24, 113]—topics that are dealt with in other chapters of this volume, and that will not be duplicated here. For the sake of the present narrative focusing upon pain, we note that texts by Bromage [114] and Nicholas Greene [115] in the 1950s, presented the scientific and practical bases of central neuraxial analgesia. In 1967, Bromage described the use of a thoracic extradural catheter for analgesia following chest trauma, thereby implying that extradural analgesia at an appropriate spinal level could successfully treat acute pain. In 1969, working with surgeon Wright and Bromage at McGill, MJC found that perioperative epidural analgesia improved graft blood flow in patients undergoing lower limb vascular surgery [116].

Increasing attention to spinal and other central modulation of afferent nociceptive stimuli during the late 1960s, culminated in the most influential pain research paper ever published: Melzack’s and Wall’s 1965 description of the Gate Control Theory of Pain [34]. Initially this new theory drew little attention. However, a 1967 report by Wall and MGH neurosurgeon William Sweet, described abolition of pain by vibration devices in human volunteers, aimed at activating A β fibers that in turn would “close the gate” [117]. This demonstration of the applicability of the Gate Control Theory prompted a resurgence of interest in transcutaneous electrical nerve stimulation (TENS), and led to the development of spinal cord stimulation (SCS) for pain control. In the present era of close attention to early patenting and commercial development of scientific advances by academic investigators, it is noteworthy that Melzack revealed to MJC that neither he nor Wall sought or received any royalties for the development of TENS, SCS or other applications of the “Gate Theory”.

In 1974, Brazilian Octavio Calvillo (also a prior “Fellow” at McGill) studied cats, finding arguably the first evidence of a spinal action of morphine [118]. Also in 1974, anesthesiologist Luke Kitahata described a spinal action of morphine but inferred that the specific site of action was lamina V rather than the substantia gelatinosa [119]. In 1976, neuroscientists Arthur Duggan and Tony Yaksh provided unequivocal evidence of the spinal site of action of morphine. Duggan described morphine/enkephalin effects on the substantia gelatinosa [120] and Yaksh reported the “direct spinal action of narcotics” [121].

By the late 1970s, informed by advances in applying patient-controlled analgesia and spinal opioid analgesia, Mather and colleagues observed that “the plethora of new parenteral agents which the pharmaceutical companies have introduced over the past 25 years is *not* a reminder that we have not found the right drug but a reminder that we have not found the optimal mode of administration of perfectly adequate analgesic drugs” [122]. With this perspective in mind, when MJC moved to Adelaide in 1975, he recruited basic scientist/pharmacokineticist Mather, who in 1976–79 studied the PK/ PD of oral, intramuscular and intravenous administration, including PCA. Wang and colleagues [123] conducted a small case series of intrathecal morphine in 1979, prompting MJC et al. to begin concurrent PK-PD studies of intrathecal and epidural opioids—research that has continued to the present and has included “combination” intrathecal analgesia using concurrently administered opioid and non-opioid drugs [124].

In the meantime, Wall, while visiting Israel, stimulated Florella Magora and her colleagues to administer morphine epidurally to decrease various types of pain. Their results were published in a letter to *The Lancet* on 10 March 1979 [125]. Seeing that publication prompted MJC’s group to issue

a preliminary report of the PK-PD study of intrathecal morphine and pethidine (meperidine in the US), and epidural pethidine. Since the blood and CSF PK-PD data, and neurological assessment strongly suggested a spinal site, with sparing of normal non-noxious sensation, motor power and sympathetic function, MJC titled the Letter “Selective Spinal Analgesia” [126]. The letter was accepted 24 hours after receipt and published on 26 May 1979. In the same volume, a letter [127] from Samii and colleagues in Paris reported hyperbaric intrathecal injections of 20 mg morphine (6–20 times the doses in MJC’s study). All patients had complete pain relief. Others soon began to report delayed respiratory depression after intrathecal morphine, and lower intrathecal doses of 0.25–0.5 mg morphine subsequently emerged as a safer standard for opioid naïve patients [128]. MJC’s group published the full data from the 1979 Lancet letter, in 1981 [129].

Anesthesiologists undertook most of the research on efficacy and side effects of spinal opioids from the 1980s onward. Continuing to extend the scientific foundation to guide clinical dosing of increasing numbers of opioids administered by various routes, Torda *et al* from Sydney demonstrated in 1980 that epidural administration of opioids provided longer-lasting and more efficacious analgesia than intramuscular administration [130]. In 1983, Swedes Nordberg *et al*, described cerebrospinal fluid (CSF) concentrations of morphine after spinal injection, [131] confirming the results of the Adelaide group that analgesia correlated with CSF concentrations of opioid, not blood concentrations. In 1984, Rawal and colleagues [132] observed patients undergoing gastropasty for obesity. They found that, compared to those receiving intramuscular morphine, those given epidural morphine postoperatively were better able to sit, stand, or walk unassisted within 6, 12, and 24 hr, respectively, and that they better tolerated vigorous physiotherapy, resulting in fewer pulmonary complications. Earlier postoperative recovery of peak expiratory flow and bowel function in the epidural group contributed to a shorter hospital stay. This second major contribution from Sweden did much to support the ongoing clinical use of spinal opioids. The status of spinal opioids as a clinical entity can be gauged by the numerous citations of articles on this topic in citation analyses of the literature on anesthesiology and pain [17]. The 1984 review [133] of intrathecal and epidural administration of opioids, by Cousins & Mather, was by far the most frequently cited paper.

Pain as a Public Health Issue: Education, Evidence, Global Health Policy and Human Rights

Although Bonica’s statement of future needs and goals in his monograph did not employ the phrase “public health”, the points he made concerning the prevalence and societal

burden of pain do so *de facto*. In particular, he wrote that “the challenge to the biomedical scientific community, health professionals and society as a whole is to organize, mount and support a multipronged program” [65]. Included in this program, was the need “to markedly increase our efforts in the education and training of students, house officers, and physicians and other health professionals in order to improve the care of patients suffering from pain.” Responding to Bonica’s call, in the 1990s both DBC and MJC established inter-professional educational programs at their institutions to supplement anesthesiology-based physician fellowships [13, 14].

Prophetically, in 1999, pain physician Rollin Gallagher wrote “Chronic pain is a public health problem crying out for a reorganization of the manner in which the health care system manages pain” [134]. Pain is a public health problem because it affects many people. In addition, pain is linked with other aspects of health through complex networks. Pain is amenable to preventive efforts such as education, exacts a higher burden on the lower socioeconomic population, and access to pain relief has a social justice dimension. Pain is now on the agenda of mainstream healthcare, governmental and nongovernmental organizations. In the US, the Joint Commission has advocated for pain management as a standard of care, and provides resources for health care systems to support this standard [135]. Both the World Health Organization (WHO) and the US Institute of Medicine (IOM), describe pain as a public health problem [136]. Anesthesiologists have actively participated in high-profile initiatives (including development of educational materials) by all of these organizations. Through the efforts of the anesthesiologist Michael Ashburn (then a health policy fellow in the office of a senior US senator) in late 2000, Congress declared the ten-year period that began 1 January 2001 to be the Decade of Pain Control and Research. This successful legislation continues to influence governmental activities such as funding for pain research and the recent establishment of an NIH pain consortium.

Repositories of clinical trial data and their analysis in systematic reviews provide a basis for evidence-guided care [137]. The Oxford group at Churchill Hospital, led by anesthesiologists Henry McQuay and Andrew Moore, [15] and their former research fellows including anesthesiologists Eija Kalso and Martin Tramer, have made major contributions to aggregating relevant clinical evidence through the Cochrane Collaboration. Registration of a specific new Cochrane review group on pain, palliative and supportive care, followed a 1997 visit by the Oxford pharmacist Phil Wiffen with DBC in which the two began drafting their application. Registration was approved the following year. Ewan McNicol, a pharmacist in Tufts’ Department of Anesthesiology and 2001 graduate of Tufts’ pain education program, succeeded DBC as an editor for this group, whose reviews include many prepared by anesthesiologists.

A pivotal chapter in the relationship between IASP and WHO occurred when DBC heard a lecture by Christopher Murray of Harvard Medical School, describing a long-term WHO project to assess the worldwide disease burden of major conditions. WHO had previously been unresponsive to IASP's request for collaboration, arguing that it had no resources to devote to pain while it confronted a world full of killer diseases. Hearing Murray's lecture, DBC realized that the WHO's own data would, if analyzed in greater detail, establish pain as integral to the worldwide disease burdens of conditions such as cancer, diabetes, war trauma, and HIV. DBC contacted the IASP's liaison to WHO, the anesthesiologist Harald Breivik of Oslo, who then visited DBC in Boston. Together they outlined a strategy to present to the WHO, based upon WHO's own data [138]. As a result, the WHO supported IASP's inaugural Global Day Against Pain, held in Geneva in 2004.

In 2010, at the urging of MJC, and chaired by him, the IASP convened the first International Pain Summit during its World Congress on Pain in Montreal. This summit resulted in the Declaration of Montreal, affirming that access to pain management is a fundamental human right [139]. Further initiatives including those seeking to improve pain control internationally on the basis of a quality improvement strategy, [140] and to reduce disparities in access to pain assessment and treatment, [141] are now occurring. MJC's efforts to enlist the Australian public as an ally to improve pain control led him to prepare the first national-level detailed pain strategy and to establish PainAustralia, a nonprofit organization, in 2011 to implement it [142]. One early success of PainAustralia was the commitment of 26 million Australian dollars by the New South Wales Ministry of Health and Medical Research to advance pain care services, research and education. In the US, California and Massachusetts now mandate several hours of continuing professional education in pain and related topics, such as opioid prescribing, for every physician (and many non-physicians) to maintain an active license. These examples from the authors' personal experience illustrate the many national and international initiatives to advance pain-related research, education and policy now taking place worldwide.

In 2011, in its report *Relieving Pain in America*, the IOM summarized findings of a multidisciplinary blue ribbon panel that included anesthesiologists such as Stanford's Sean Mackey and other professionals with primary appointments in departments of anesthesiology nationwide [136]. Describing pain as "a public health challenge" the IOM called for a "population-level prevention and management strategy". This strategy aims to

"heighten awareness about pain and its health consequences; emphasize the prevention of pain; improve pain assessment and management in the delivery of health care and financing programs of the federal government; use public health communication strategies to inform patients on how

to manage their own pain; and address disparities in the experience of pain among subgroups of Americans."

Back to the Future?

In 1956, Eckenhoff published a prophetic essay on the anesthesiologist and the management of pain, in the *Journal of Chronic Diseases* (even the choice of journal was far-sighted) [143]. In words current today, he pointed out that

"anesthesiologists have made highly significant advances to our understanding of pain and its treatment. This has been particularly true within the last decade. New local anesthetics have been introduced and tested; simplification and popularization of regional nerve blocks has been widespread among the specialty; inquiries into the action, effectiveness, and limitations of analgesics and sedatives have been made; investigations concerning the effect of drugs upon the intangibles of mood and mind have been published; diagnostic tests employing spinal anesthesia have been reported; researches into the sites of action of intravenously injected local anesthetics have been made; and a major reference work on pain has been published. As a comparatively new specialty, anesthesiology can be proud of its already significant contributions to our knowledge and treatment of pain."

Eckenhoff's essay suggested how far we had come by mid-century, but the 1950s marked just the beginning of the modern era of pain research and management. With World War II succeeded by the less destructive Cold War, the world entered an era of relative peace and progress. Watson and Crick published their model of DNA. The first computers were marketed, the integrated circuit was invented, and the first widely adopted high-level programming language (FORTRAN) enabled persons with limited training to harness computers for personal purposes. The Beat Generation energized music and literature. Capturing the spirit of the times, Kerouac wrote, "We had finally found the magic land at the end of the road and we never dreamed the extent of the magic" [146].

Eckenhoff clearly felt in the 1950s that anesthesiology had traveled far towards understanding and treating pain. Yet we doubt that he, Beecher or Bonica dreamed the extent of what anesthesiologists and basic scientists working in collaboration would achieve. These pioneers might well have viewed as magical the precision with which molecular pain research has elucidated mechanisms of normal and disordered nociception, e.g., genotyping to identify patients at risk for persistent pain after operations or lumbar disc herniation, or those likely to need sub- or supranormal doses of opioid analgesics. The design and interpretation of analgesic trials have advanced to a high degree of sophistication. Modern computers that allow clinicians, scientists and patients to explore massive databases have transformed every corner of science. Biomedical informatics allows discernment of

relationships from the level of DNA through large clinical populations, and consolidation of results from worldwide clinical experience to guide bedside clinical decisions. Real-time computational power supports functional MRI studies of awake and conversant human subjects. Mobile phones' data capture and transfer capacities now surpass those of mainframe computers 20 years ago, and allow real-time monitoring of individual patient outcomes including physical activity.

Key advances since the 1950s include the current trend towards shared decision-making between clinicians and patients. Patients increasingly have access to knowledge and guidance (albeit not all equally credible, and some frankly erroneous) over the Internet, and participate in online chat rooms and blogs to reduce social isolation. Patient-centered outcomes including satisfaction with care are now an integral part of clinical analgesic trials and routine hospital-based quality assurance — the latter influencing quality-based payment. Patients' personal illness narratives are now being elicited, heard and read.

Anesthesiologists and their preclinical collaborators have led and will lead in the ongoing advances described in this chapter. A recent glimpse into the future of medicine by senior editors of the *New England Journal of Medicine* merits reading by all who practice pain medicine. Echoing Bonica's insight that "a considerate feeling for those who suffer...is, without doubt, the most important...attribute" of the pain physician, [67] their comments also bring to mind new challenges such as the need to balance freer prescribing of opioids for pain, versus undesired consequences such as rising drug diversion and abuse. "The high-technology, information-rich medicine of the future will provide powerful and useful tools... (but) will not, of course, solve all problems, and it cannot prevent violent or self-destructive human behaviors. Patients will continue to rely on physicians and the medical community for the guidance, support, and help that only a skilled and caring health professional can offer" [147].

Edward Lowenstein and J. G. Reves

Summary

In 1953, Gibbon used a heart-lung machine to allow closure of an atrial septal defect under direct vision. In 1967, Barnard performed the first heart transplant. In 1973, surgeons stopped the heart beating (cardioplegia), thereby protecting it, by infusing cold hyperkalemic solutions into the coronary arteries.

Advances in cardiac surgery spurred the development of cardiac anesthesiology. We changed from open drop ether to modern anesthetics and ventilation via tracheal tubes. In 1951, Keown described anesthetic management with hypothermia for the conduct of mitral commissurotomy. In 1964, Wynands used postoperative tracheal intubation and mechanical ventilation to increase survival.

In 1972, Civetta and Gabel described the use of the pulmonary artery (Swan-Ganz) catheter intra and postoperatively. The results were inconsistent, sometimes suggesting increased risk. Matsumoto introduced M-mode (one dimensional) transesophageal echocardiography (TEE) in 1980, followed in 1982 by Cahalan's description of 2-dimensional TEE, and deBruijn and colleagues' report of color-flow Doppler TEE in 1987. TEE made cardiac anesthesiologists into intraoperative cardiac diagnosticians who guided the surgeon.

Before 1969, cyclopropane, ether, or halothane dominated cardiac anesthesia. Lowenstein reported the use of high dose morphine for cardiac anesthesia in 1969, and Stanley reported use of high dose fentanyl in 1973, suggesting benefit in patients with valvular and congenital disease. Two randomized trials in 1973 found no advantage with morphine compared with halothane or ketamine. Studies in the 1970s and 1980s did not reveal an ideal "cardiac anesthetic". While anesthetic choice might matter little, in 1989 Slogoff and Keats reported that the choice of anesthesiologist did matter. Finally, research at Duke in the 1980s suggested that protecting central nervous system function from the deleterious effect of cardiac surgery required multiple strategies.

In the 1980s, Slogoff and Keats showed that increased heart rate endangered the myocardium of patients with coronary artery disease (CAD). Cardiac anesthesiologists then showed that beta blockers decreased long term mortality after non-cardiac surgery. In 2006, Mangano's group demonstrated that although aprotinin decreased transfusion requirements in patients undergoing open heart surgery, it increased the incidence of kidney failure and death. Anesthesiologists and surgeons added and removed "fads" such as early extubation (in the 1970s) and "off-pump" coronary artery bypass (in the 1990s).

Maturity of cardiac anesthesia required new technologies and knowledge promulgated in books and journals (e.g., *The Journal of Cardiothoracic Anesthesia*, first published in 1987). It required the development of leaders, training programs, and a sufficient cohort of practitioners. The Society of Cardiovascular Anesthesia, founded in 1978, now has 7,000 members.

Introduction

"A surgeon who would attempt such an operation [cardiac suture] should lose the respect of his colleagues." Billroth [1]

"No discovery can overcome the natural difficulties that attend to a wound of the heart." Padget [2]

"In the late fifties, the cardiologist...surrendered the patient to the surgeon after administration of the last rites." Teasdale-Scott [3]

"The production of relief of pain for the patient and provision of good operating conditions for the surgeon are relatively minor problems for the anesthesiologist compared with his problem of keeping the patient alive and safe." Pender [4]

"Since before recorded history, people died from narrowing (stenosis) of the heart valves, obstructing blood flow. Stenosis of the mitral valve predisposes to flooding of the lungs and people with stenosis might struggle for each breath. In 1956, an apparently healthy young woman with mitral stenosis suddenly had difficulty breathing while climbing the Pyramid of the Sun God in Mexico. She was flown to Boston for an emergency operation on her heart."

“Such patients often died during induction of anesthesia because their apprehension of surgery caused their heart to beat faster and flood the lungs. Mindful of this danger, the anesthesiologist Burton Briggs went to their hospital rooms to deliver small increments of intravenous thiopental; small enough to avoid cardiovascular collapse but large enough to sedate the patient and prevent the increased heart rate. There followed a race to the operating room, where the actual anesthetic was meticulously delivered so the surgeon could split the fused, narrowed valve, enabling natural blood flow through the valve. The patient lived a subsequently normal life.” (Personal Communication EL)

This anecdote from the early years of heart surgery indicates the challenges faced by anesthesiologists—the need to preserve life while enabling an operation on the heart. The first operations were not performed on adults, but on infants and children with congenital malformations of the heart and great vessels, malformations that if uncorrected, caused early death. Surgeons and their anesthesiology peers next addressed the correction/replacement of damaged heart valves, and then the treatment of coronary artery disease. We then accomplished heart transplantation and used artificial pump devices to sustain life. The measures that preserved life in these patients were next applied to patients with similar heart diseases but undergoing non-cardiac surgical operations previously considered too dangerous to apply.

Hessel’s review [5] supplies an authoritative rendering of the history of cardiac anesthesiology, and Mushin [6] and Benunof [7] similarly describe the related field of thoracic anesthesiology. A portion of our essay derives from such sources. We shall convey aspects of this history from a participatory perspective, spanning nearly half a century, the life of contemporary cardiac anesthesiology. The story includes anecdotes not easily found elsewhere.

Maintaining Life in the Presence of an Open Chest

Wounds allowing air into the chest—the “pneumothorax problem”—can fatally compromise breathing [6, 7]. Before we learned to breathe for such patients, surgeons only operated on the chest wall. Nineteenth century physiologists performed intrathoracic surgery in animals by inserting a tube into the trachea and rhythmically inflating the lungs through the tube with a bellows. Tuffier and Hallion reported to the Société de Biologie in 1896 on “Intrathoracic operations with artificial respiration by insufflation,” using a rhythmic inflation method. Surgeons applied these principles to humans many decades later [6].

The “pneumothorax problem” compromises oxygen delivery to the lungs, a delivery needed for survival. Surgeons initially expanded the lungs by a negative pressure chamber around the body (leaving the head exposed) or applied positive pressure around the head. These cumbersome techniques might expand but did not ventilate (intermittently

bring oxygen into and remove carbon dioxide from) the lungs. Chest surgery was thus rare and hazardous in the last decade of the nineteenth century.

We learned to insufflate, blow gas—including oxygen—continuously into the trachea, and this led naturally to tubes into the trachea and then to effective ventilation. William Macewen in Scotland described tracheal intubation in 1878; and in 1899, American physician scientist, Rudolph Matas pioneered intermittent positive pressure ventilation (the rhythmic application of pressure to the gases delivered to the lungs).

In 1906, Franz Kuhn (1866–1929) developed an intermittent positive pressure apparatus which he used with tracheal intubation. Tiegel, in 1908, used a face-mask, with an ingenious system to collect vomit (overcoming one of the major problems with early positive pressure ventilation). His system used a rebreathing bag allowing the addition of ether or chloroform. However it took Guedel and Waters in the United States and Nosworthy in Great Britain, in the 1930s, to allow successful surgery inside the chest by applying Macewen and Matas’ principles, using tracheal tubes and rebreathing bags [6].

The safe use of the respiratory depressant anesthetic gas, cyclopropane, in the 1930s, and the introduction of pharmacologically induced paralysis in the 1940s, necessitated the increasing application of positive pressure ventilation. It demanded control of ventilation—and facilitated the subsequent development of surgery on intrathoracic great vessels that began modern cardiac surgery and anesthesiology (*vide infra*).

Major Historical Events in Cardiac Surgery

In 1896, the year that Padget predicted the impossibility of cardiac surgery [2], Rehn in Frankfurt sutured a wound to the heart [6]. Luther Hill repeated the feat in Montgomery, Alabama in 1902 [5]. Fig. 61.1 demonstrates the symbiotic relationship of cardiac surgery and anesthesia, showing the parallel landmark advances in each specialty.

Modern cardiac surgery began with operations on intrathoracic blood vessels—rather than on the heart itself. In 1938, at the Children’s Hospital of Boston, surgical resident Robert Gross (1905–1988) successfully ligated a patent ductus arteriosus, a daring unsupervised feat. William Ladd, “the surgeon,” was away on holiday! In 1944, Clarence Crafoord (1899–1983) repaired a coarctation (narrowing) of the aorta in Stockholm [5].

In Baltimore, in 1944 Alfred Blalock (1899–1964) performed the first palliative surgical procedure for cyanotic congenital heart disease (blue baby). The Blalock-Taussig operation involved creating an artificial connection (shunt) between one of the major systemic arteries and the

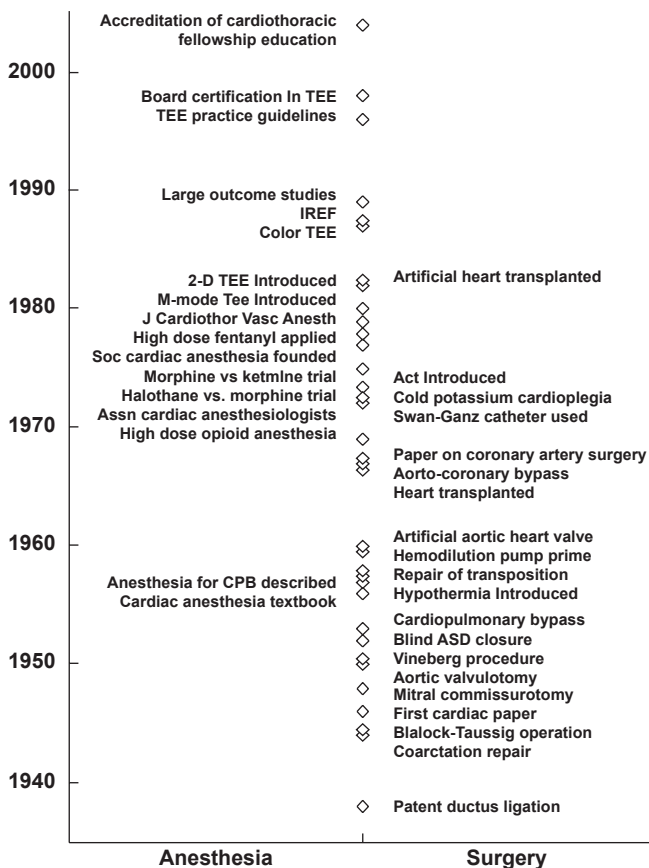

Fig. 61.1 A timeline of advances in cardiac anesthesia and surgery. Anesthesia by Morton enabled modern surgery, allowed the development of myriad new surgical procedures. Conversely, as Fig. 61.1 shows, the development of new surgical procedures, in this case those on the heart, came before and animated the development of people, techniques, and pharmacological approaches to support the work of the surgeon, developments led especially by anesthesiologists. Note that the figure does not include three events of import in the nineteenth century: tracheal intubation, first heart surgery, and positive pressure ventilation, all accomplished by surgeons

pulmonary artery, enabling greater mixing of the oxygenated and deoxygenated blood in the circulation. In 1946, Merel Harmel (1917-; Fig. 61.2) and Austin Lamont (1905–1969) described the anesthesia for the first 100 Blalock-Taussig Operations, the first cardiac anesthesiology paper [8]. Here follows an abridged contemporary memoir from Harmel (personal communication):

“About two weeks before the operation, Lamont mentioned that we might be faced with operations upon the heart and/or great vessels. Imagine my surprise, apprehension and excitement, when shortly before the operation was scheduled, he informed me that Dr. Blalock proposed to operate upon a 15 month old cyanotic infant with a tetralogy of Fallot, weighing 4 Kg. Earlier, Lamont had refused to anesthetize the infant for some minor operation because he felt she would not survive. So the prospect of a major experimental procedure involving a thoracotomy would surely hasten the baby’s death. Blalock however was determined to operate. He had discussed the seriousness of the operation with the family, telling them the operation had never

Fig. 61.2 Merel Harmel was the first to administer anesthesia for the successful palliation of Tetralogy of Fallot. (Photograph from the private collection of J. Reves)

been attempted before and the chances were good that the child might die on the operating table. (This is a sterling example of providing informed consent years before the requirement was widely recognized! EL and JGR)

“The day the operation was posted, Lamont offered me the ‘opportunity’ to anesthetize the baby! He would of course be with me in the operating room. He thought that the experience of anesthetizing this infant would be educational (I was just completing my 11th month of training). In 1944, at Hopkins there was no appropriate equipment for conducting endotracheal anesthesia in 4 Kg. infants. We thought to fashion an endotracheal tube from a large bore urethral catheter should intubation be necessary.

“On the 29th of November, Eileen Saxon was brought to the operating room. She was anesthetized with open drop ether, and oxygen was delivered by catheter under the mask. The only monitor was a finger on the carotid pulse. Blalock had Vivian Thomas (an African American laboratory assistant who had devised the procedure in Blalock’s dog lab and who is credited with much of the success of the operation) at his side during the procedure. William Longmire (later the Chairman of Surgery at UCLA) and Denton Cooley (subsequently a pioneering cardiac surgeon in Houston) assisted Blalock, performing a subclavian to pulmonary artery anastomosis in 1 hour and 45 minutes. Helen Taussig who had proposed the concept of the operation to Blalock was also in the room. When the subclavian and pulmonary arteries were clamped, the pulse became slow and almost imperceptible. Breathing became shallower and cyanosis

deepened. The outlook appeared dismal, but she rallied and the operation continued. Toward the end of the operation we thought she might be obstructed and attempted unsuccessfully to intubate her trachea with our makeshift catheter. Positive pressure was applied with our smallest mask in an effort to re-expand her lung. At the end of the procedure her color dramatically improved. The atmosphere was jubilant. Against seemingly insuperable odds, she had miraculously survived and dramatically improved. Eileen recovered and was discharged almost two months later.

“A palpable excitement accompanied the operation, a feeling that something historic was happening. The initial presentation by Blalock and Taussig to the Hopkins Medical and Surgical Association meeting was accompanied by a standing ovation. The “blue baby” turning pink caught the hearts and imagination of parents, surgeons and the general populace. Surgeons from around the world came to see Blalock operate, and patients were referred from home and abroad. By 1946, when our article was published, we had completed over 200 operations, most with an anesthetic technique suggested by Elisabeth Lank (Fig. 61.3), the nurse anesthetist at the Boston Children’s Hospital who had demonstrated the advantages of managing infants with intubation and anesthesia with cyclopropane.”

Before 1948, except for repairs of wounds to the heart during World War II, cardiovascular surgeons did not invade the heart or touch its valves. The temptation however, to relieve mitral stenosis (a narrowing of the valve joining the two chambers of the left side of the heart) by dilating the narrowed valve, was great. On January 29, 1948, Horace Smithy of Charleston (Medical University of South Carolina) successfully performed the first mitral commissurotomy using a device he designed [9]. The commissurotomy was performed “closed,” blindly reaching the deformed valve through a small hole made in the heart’s left atrium. Smithy’s affliction with mitral stenosis, from which he died at age 34, surely animated this heroic effort. Smithy had tried to convince Blalock to perform the operation on him, but Blalock refused.

In 1950, Charles Bailey (1910–1993) attacked aortic valve stenosis, performing a closed aortic valvotomy in Philadelphia [10]. With both major left sided heart valves surgically accessible, cardiac surgery had reached major milestones of palliating and/or correcting congenital and valvular heart disease.

Two fears daunted these early cardiac surgeons. One was fear of damage to the heart, either physical damage or damage consequent to impaired blood flow to the heart, injuring the heart muscle so it could not pump effectively. A second parallel fear was concern that they might impair blood flow to the brain and injure that vital organ.

The cardiac surgeon and anesthesiologist extended the time to safely abolish blood flow to the heart and brain by cooling the patient. Cold protects the bloodless brain or heart by decreasing tissue metabolism and oxygen consumption. In the “early days”, i.e., the 1950s,—the anesthetized patient was lowered into a tub of ice water with ice cubes floating in the tub—a tricky business because if the patient became too cold, the heart might stop and not start again. This limited

Fig. 61.3 Elizabeth (Bessie) Lank was a nurse anesthetist of enormous clinical skill. She taught many anesthesiologists who later became leaders in cardiac and pediatric anesthesia. As indicated in the text, she gave the anesthesia for many “firsts” in cardiac surgery. (Courtesy of Mark Rockoff and the archives of Boston Children’s Hospital)

the lowest temperature to about 28 °C. Furthermore, with insufficient anesthesia, the patient shivered, opposing cooling. Cooling for cardiac surgery was debated and even transiently abandoned over the past 50 years. Conventional practice now uses moderate cooling (to 32–34 °C).

A few procedures required cessation of blood flow to heart and/or brain, and for these a much lower temperature was achieved, sometimes in just the heart by application of cardioplegia (see below) [11]. Sometimes so called deep hypothermic cardiac arrest (DHCA) was required for brain protection [12]. In DHCA the entire body was cooled to <20 °C and the circulation halted, while complex congenital anomalies in infants, and (rarely) the aorta in adults, were repaired.

Coronary artery disease, the limitation of arterial blood flow to the heart causing oxygen deprivation, and inadequate function or death of the heart muscle, became recognized as the greatest killer in industrialized countries. It was a topic of surgical attention as early as the 1930s [13]. How could the cardiac surgeon fix this problem?

Two early operations were developed by Vineberg. The first interrupted the two internal mammary arteries, coursing down the back of the sternum or breast bone, on the premise that bilateral ligation (BIMAL) of these vessels “downstream” of the heart would increase “upstream” flow to the coronary arteries. This operation achieved increasing popularity in the mid to late 1950s because it was simple, safe and *some* patients experienced decreased severity and/or frequency of angina pectoris. However, animal studies failed to confirm the premise, and many doubted the improvement. Two groups then performed randomized, “double blind” placebo controlled studies in a total of 35 patients [14, 15]. The control patients had a

sham operation consisting of only a skin incision. These studies each revealed random and equivalent improvements of angina among patients who had undergone the placebo operation and internal mammary ligation, proving the ineffectiveness of the operation and putting an end to its performance. These results prompted anesthesiologist Henry Beecher's landmark article, arguing that it was unethical to perform new surgical operations *without* first establishing effectiveness [16]. Unfortunately, this call has been largely unheeded.

Contemporary cardiac surgery lacks placebo-controlled, sham operated studies of effectiveness, a reluctance based largely on claims that performing hazardous sham operations is unethical. Whether this is a wise decision, or whether more lives would be preserved and fewer people subjected to hazardous and ineffective operations by conducting sham studies in fully informed cardiac surgical candidates, remains an ethical conundrum that probably will not be confronted.

The second Vineberg operation for relief of angina pectoris actually improved (albeit not immediately) blood flow to the heart in both experimental animals and patients. Devised in the 1940s, and performed in patients in the 1950s and 1960s, the Vineberg operation implanted an internal mammary into the heart muscle [17], and over a period of weeks thereby brought new collateral vessels to the heart. These patients posed a challenge to the anesthetist because the heart lacked adequate blood flow, the muscle was injured by the operation itself and no immediate improvement in flow accompanied the additional stress of surgical trauma. Managing these patients inspired Earl Wynands (Fig. 61.4) to develop principles for anesthetic management of patients with severe coronary artery disease that are valid to this day [18]. Most importantly, Wynands sought to maintain coronary artery perfusion pressure by infusing phenylephrine as needed. He was the first to recognize that patients with unstable angina sustained a higher mortality rate than those with stable angina. Another major contribution was his observation that a resting electrocardiogram was of no use in predicting which patients would experience perioperative problems. Finally, he promoted the life-saving notion of maintaining tracheal intubation and ventilatory support postoperatively.

The inability of the Vineberg procedure to immediately improve coronary blood flow led, in 1967, to a third operation, one constructing a vascular (initially a vein but later a segment of artery) conduit between the ascending aorta and the diseased coronary artery segment, the coronary artery bypass graft operation or CABG [19]. It achieved almost immediate acceptance, and has been performed (without placebo controlled proof of effectiveness) upon millions of people worldwide.

Now we retreat to the 1950s to describe developments enabling modern cardiac surgery on the valves and vessels of the heart. In 1952, Gross (now having graduated from residency) performed the first true "open heart surgery",

Fig. 61.4 Earl Wynands who advanced cardiac anesthesiology despite being more or less blind from macular degeneration

repairing an atrial septal defect (a hole between the right and left sides of the heart). Widely opening the right atrium and attaching a "well" to avoid the lethal entrainment of air into the circulation, he closed the hole in the septum, blindly suturing below the air-blood interface in the well [5].

However, applying the axiom that "necessity demands invention", widespread conduct of open heart surgery required invention of the heart-lung machine (cardiopulmonary bypass). This device collected venous blood, oxygenated it, removed carbon dioxide, and pumped the nourishing arterialized blood back into the aorta (i.e., back to the body). Thus, while the heart was not pumping and the lungs were not functioning circulation of oxygenated blood to the body was continued. Such a device permitted operations on the heart using direct vision. While a premedical student in 1952, one of the authors, EL, heard with great excitement that this seemingly impossible feat of stopping the heart and repairing it without killing the patient would soon become feasible. Indeed, it became a reality within the year.

On May 6, 1953, John Gibbon Jr (1903–1973) at Jefferson Medical College in Philadelphia, first successfully used a heart-lung machine in a patient in whom he closed an atrial

septal defect in an empty heart under direct vision [20]. He and his wife Mary had taken two decades to develop the machine beginning the age of true invasive open heart surgery. He found minimal support for his initial work in the Department of Surgery at the Massachusetts General Hospital (MGH)—his chief, Edward Churchill, suggested that it had little promise. This prompted Gibbon to relocate to Jefferson Medical College in Philadelphia. During the ensuing 20 years, he addressed problems concerning filtration and coagulation of blood, and reestablishing normal coagulation after completion of the surgery. He had to enable oxygen and carbon dioxide gas exchange (as in the alveoli), and devise a pump that could reliably and controllably perfuse the systemic circulation.

Gibbon's invention, refined and adopted by many, revolutionized cardiac surgery by giving the surgeon a bloodless field and a time limited by how long a hypothermic heart could tolerate no coronary blood flow (about 30 minutes). The reintroduction in 1973, of myocardial protection techniques with a cold hyperkalemic (high potassium concentration) solution (cardioplegia) facilitated the expansion of cardiac surgery [11], giving surgeons well over an hour to perform their work. Because the heart resists longer periods of ischemia than does the brain, Arthur Keats (1923–2007) commented: “The heart is a very tough organ, and when it malfunctions, we simply cannot look to a brief period of ischemia for its failure” [21]. However, the heart is not invincible, and prolonged ischemia during intra-cardiac surgery required a protective strategy. Cardioplegia during intentional interruption of coronary blood flow to the heart was second only to the invention of the heart-lung machine as a factor in the development of cardiac surgery.

Perhaps the last major surgical accomplishment was heart transplantation. Christian Barnard (1922–2001) performed the first cardiac transplant in Capetown, SA in 1967 [5]. The anesthesiologist, J Ozinsky reported: “From the anesthetist's point of view, it was not anticipated that we would be faced with anything we had not been faced with before, and the anesthesia was conducted with optimism” [22]. Ozinsky and Barnard did not fear their daring venture into the unknown. Perhaps, however, they ventured too soon. Barnard's patient lived but a short time. Norman Shumway (1923–2006) of Stanford University thought the effort was premature. He believed that success required the development of a multidisciplinary team, one particularly focused on issues of tissue rejection. Indeed, the discovery of the immunosuppressive drug cyclosporine, provided the key to success [21].

Cardiac Anesthesiology

“Anesthesia for patients undergoing cardiac surgery” differs, in our minds, from “cardiac anesthesiology.” Skillful physicians and nurses provide the former; individuals developing

the science and art so that others may practice it more safely comprise the latter. Using this definition, we can point to a number of cardiac anesthesiologists. Kenneth Keown's 1951 description of the anesthetic management and hypothermia for patients undergoing mitral commissurotomy [23] recognized the importance of light anesthesia with minimal cardiac depression, and the benefit of letting the temperature drift down, i.e. of producing mild hypothermia. Artusio's use in the early 1950s of “ether analgesia” during mitral commissurotomy may be the ultimate in light anesthesia. Patients managed in this fashion responded appropriately to questions and commands during the procedure but experienced no pain or recall [24]. Patrick et al.'s 1957 [25] description of anesthesia for patients undergoing cardiopulmonary bypass, merits special attention, because they used animal experimentation to test hypotheses regarding control of physiologic variables such as pump flow, temperature, and blood gas management during cardiopulmonary bypass. They surmised that these factors were of greater interest than the anesthetic management *per se*: “The management of anesthesia for patients undergoing intracardiac surgery by means of a Gibbon type pump-oxygenator differs in no important respect from the anesthesia management of patients for ordinary intrathoracic procedures.” Their work established the principle, that attaining physiologic ends was paramount rather than the means to achieve them.

Monitoring

The first patients undergoing cardiac surgery were anesthetized with minimal monitoring, such as a finger on a temporal or carotid artery! However, as the surgery became more complex, and particularly after cardiopulmonary bypass was employed, monitoring of hemodynamic variables became an important component of cardiac anesthesiology. In 1972, Civetta and Gabel described the use of the pulmonary artery (Swan-Ganz) catheter intra and postoperatively [26], and in 1973 Lappas et al. demonstrated that pulmonary capillary wedge pressure accurately reflected left atrial pressure intraoperatively, which in turn reflected left heart filling and function [27]. Indeed, invasive monitoring and expertise sometimes seemed to define cardiac anesthesiologists, who demonstrated their expertise by their ability to “slip in” invasive lines quickly and deftly, equating this skill, perhaps erroneously, with superior knowledge. The need for arterial pressure measurement and access to arterial blood samples provided sufficient reason for inserting an indwelling arterial catheter. Measurement of central venous pressure seemed similarly beneficial in helping estimate adequacy of blood volume and heart function, although echocardiography is now considered a better reflection. At the MGH, Laver (personal communication) explained the philosophy of

hemodynamic measurement versus the clinician's intuition: "If the measurements contradict your clinical impression, change your clinical impression!"

The introduction of the pulmonary artery catheter in the early 1970s provoked vigorous controversy. Some outstanding cardiac anesthesiologists considered this technology essential for optimal intra- and postoperative management. Others eschewed the routine use of such costly catheters, fearing the complications they could bring (e.g., death), or unconvinced that the additional data facilitated a positive outcome. Reports in 1987 indicated that information supplied from a pulmonary artery catheter added little to the successful management of many cardiac surgical patients [28, 29]. Like all tools and drugs, the risks and benefits needed to be balanced. In selected patients, particularly those with impaired pumping function of the heart at any perioperative stage, the use of a pulmonary artery catheter facilitated successful management, but in many others it imposed unnecessary risks and expense [28, 29].

Until recently, monitoring in cardiac anesthesia practice lacked visualization of the anatomy of the heart. Anatomy is crucially important because many operations propose to repair or palliate anatomic defects such as incompetent mitral valves or ventricular septal defects, and because visualization of malfunctioning areas of the heart can provide clues to explain impaired circulation. Cardiac anesthesiologists and surgeons had no view of the internal anatomy of the heart as complexity of surgery progressed. Transesophageal echocardiography (TEE) changed that.

The 1980 introduction of M-mode (one dimensional) TEE by Matsumoto [30] was followed in 1982 by Cahalan's description of 2-dimensional TEE [31], and deBruijn and colleagues' report of color-flow Doppler TEE in 1987 [32]. Each of these gave different information. M-mode alone was least useful, almost uninterpretable in real time. Two dimensional TEE allowed a rapid meaningful interpretation of structure. Color Doppler TEE enabled visualization of flow allowing anatomic and physiologic interpretations (e.g. seeing turbulent backward flow through an aortic valve means significant aortic valve regurgitation.) Most recently, TEE allows a 3-dimensional view of structures and even better visualization [33]. TEE has permitted cardiac anesthesiologists to literally look into the heart and become intraoperative cardiac diagnosticians, the intraoperative counterpart of the cardiologists providing the preoperative diagnosis guiding the surgeon to the appropriate procedure. Cardiac anesthesiologists can now inform surgeons in real time, of new intraoperative findings, make new diagnoses, confirm proper repair of the cardiac lesion, and specify needs for further immediate surgical management [21].

TEE has transformed the intraoperative experience for patients, anesthesiologists and surgeons alike, particularly in congenital [22] and valvular surgery. Clinical anecdotes

demonstrate its value: A surgeon believes a ventricular septal defect in a 6-year-old child has been successfully closed. However, when preparing to terminate cardiopulmonary bypass, high pulmonary artery pressures and blood gas analysis indicate a continuing left to right shunt, and examination by TEE reveals the precise location of a second major but previously unappreciated hole in the ventricular septum. Before the advent of TEE, the second hole would have awaited an emergency postoperative cardiac catheterization, and would have required a second operation to obtain a satisfactory result. Likewise in adults with mitral valve rupture, the anesthesiologist determines which valve leaflet is flailing and whether it is repairable or requires a prosthesis. Once the repair is done, the anesthesiologist assesses valvular integrity. This diagnostic information has reduced re-operations and prevented further heart damage. No other monitoring technology has provided comparable benefit to intra-operative decision making.

Anesthetic Drug Regimen (or Anesthetic Pharmacology)

Before 1969, cyclopropane, ether or halothane dominated anesthesia for cardiac surgical patients. The flammability of the first two led to dominance of the non-explosive halothane. Death during induction of anesthesia, and inability to differentiate cardiac from pulmonary failure after cardiopulmonary bypass and postoperatively, were common. A search for better approaches to anesthesia led to the introduction, at MGH, of high dose morphine. This was the era before coronary revascularization; cardiac surgical patients had primarily valvular or congenital disease. Reminiscing about this introduction, Lowenstein (Fig. 61.5) wrote: "At least three things were necessary to set the stage for a new concept of anesthesia for our most ill patients: an environment that tolerated and even encouraged radically creative solutions; a clinical problem that caused an unacceptably high death rate; and a cast of characters with imagination, vision, courage, and clinical credibility" [34]. It was noted that large doses of intravenous (IV) morphine given postoperatively could relieve pain and, by depressing ventilation, could enable patients to tolerate tracheal intubation and mechanical ventilation. Morphine had recently been demonstrated to not depress heart contraction [35]. Why not deliver large doses of morphine *preoperatively* to produce insensibility yet not impose cardiovascular collapse during induction? Continuing this regimen postoperatively would produce the already appreciated salutary benefits.

The paper, published in 1969 in the *New England Journal of Medicine*, documented the hemodynamic effects of enormous doses of morphine in patients with valvular heart disease and patients without heart disease, and changed the

Fig. 61.5 A photograph of Edward Lowenstein (*left*) and Jerry Reves, happily at the water's edge

conduct of cardiac anesthesia [36]. It increased interest in the physiological consequences of drugs used to conduct cardiac anesthesia, for example, documenting a different hemodynamic response to the same drug in patients with and without valvular heart disease. Valvular heart disease leads to heart failure and large blood volumes that predispose to pulmonary edema. Morphine improved the circulation of these patients by causing vasodilation, decreasing systemic vascular resistance and reducing the work required of the heart. On the other hand, patients with uncomplicated coronary artery disease had neither increased blood volume nor cardiac failure, nor had they adapted to the continual release of endogenous catecholamines as had patients with valvular heart disease. Thus, in patients with uncomplicated ischemic heart disease, surgical stimulation during morphine anesthesia was accompanied by increased blood pressures and heart rates, dangerous changes that increased myocardial oxygen demand and consumption.

The increasing number of patients with coronary artery disease prompted a search for better cardiac anesthesia techniques. In retrospect, this was ironic since Wynands' 1967 article had defined many of the optimal principles, if not specific drugs, for managing such patients [18]. "Recipes" followed, each describing different "ideal" anesthetic regimens. However, two randomized trials in the early 1970s failed to demonstrate an outcome difference with different anesthetic drug regimens [37, 38]. A 1978 trial advocated "industrial-sized" doses of fentanyl, a synthetic opioid devoid of the histamine liberating effect of morphine, to provide "stress-free" anesthesia [39].

The originators of high-dose "opioid anesthesia" documented limitations of the technique including patient awareness [40, 41]. Patient awareness may occur more commonly in cardiac surgery than in other settings, because less anesthetic may be given to avoid cardiac depression, and because high

opioid doses provide unreliable amnesia. As early as 1951—before opioid use as anesthetics—awareness was recognized as a possible outcome: "At the time of the pre-anesthetic examination, and again before anesthesia is induced, an attempt is made to explain the stages of the procedure of which the patient may be aware during operation" [23]. It continues to be a problem. In 2007, Pollard described the incidence of awareness in 87,361 surgical patients [42]. Of the six who remembered events, 4 had undergone cardiac surgery.

The obligatory period of postoperative ventilation was an initial stimulus for using high-dose opioids. While advantageous in many patients, it proved to be unnecessary in others, and may be accompanied by awareness. Subsequent small and then large studies revealed, not surprisingly, that there is no single ideal "cardiac anesthetic" [37, 38, 43, 44]. Harmel and Lamont recognized this in 1946: "...one cannot be dogmatic in regard to choice of anesthetic agent and technique" [4]. Optimal care for any given patient requires matching patient pathophysiology with the pharmacology of anesthetic and other drugs by knowledgeable and skilled clinicians [45].

The Cardiac Anesthesiologist

While choice of anesthetic regimen may matter little, Slogoff and Keats at the Texas Heart Institute found that the choice of anesthesiologist did [46]. In their study of postoperative myocardial infarction as a function of anesthetic choice, in patients operated upon for coronary artery disease, they incidentally found that outcomes of patients anesthetized by one of the nine attending anesthesiologist's stood out. The frequency of myocardial infarction associated with "Anesthesiologist Number Seven," significantly exceeded that for the other eight [34]. Patients anesthetized by number seven had more variability of blood pressure and heart rate, the two factors most affecting myocardial supply and demand. Whether this was due to inattention, pharmacologic ignorance, poor choice of drugs or drug doses, or chance, is not known.

Present day cardiac anesthesiologists deliver a mixture of drugs. Moderate doses of an opioid (usually fentanyl or sufentanil) are used to minimize adrenergic responses to noxious stimulation. Muscle relaxants keep patients from moving. Potent inhaled anesthetics augment relaxant effect, protect the heart [47], modify hemodynamic perturbations, and together with benzodiazepines, curtail memory of intraoperative events.

Vexations in the Present Care of the Cardiac Surgical Patient

The level of blood pressure during cardiopulmonary bypass has periodically been a matter of much controversy—the primary concern being whether inadequate brain perfusion

during non-pulsatile CPB produced postoperative brain damage. After several decades addressing this issue, Newman et al demonstrated in 1994, that cerebral blood flow is well preserved during cardiopulmonary bypass as long as CO₂ levels are normal and perfusion pressure is maintained within the autoregulatory range of 50 to 90 mmHg [48]. The controversy disappeared.

How long should postoperative tracheal intubation continue? In his 1967 study of anesthesia for patients undergoing Vineberg operations, Wynands discovered that postoperative tracheal intubation and elective mechanical ventilation increased survival [18]. In 1968, John Viljoen at the Cleveland Clinic confirmed this result in a larger surgical population, decreasing mortality from 10 to 2% [49]. Such findings strengthened the case for high-dose opioid anesthesia. Immediate removal of tracheal tubes and resumption of spontaneous breathing after cardiac surgery became rare.

But nothing comes for free. Prolonged controlled ventilation through a tracheal tube also carried risks of injury to the trachea, trauma to the lung, and pulmonary infection. Newer shorter-acting opioids and anesthetics decreased the need for prolonged ventilation that the large doses of morphine had imposed. In the 1970s, when aortocoronary bypass graft operations in patients with normal heart function became common, earlier tracheal extubation was advocated to minimize complications. This also decreased intensive care unit (ICU) and hospital stay and costs. But policy then went too far. Many “fit” patients having coronary artery grafts had tracheal extubation in the operating room, as though they had just undergone a simple herniorrhaphy. If it was possible, it was done...and frequently...for a while. However, urgent postoperative reintubation sometimes followed tracheal extubation in the operating room. Reintubation was required because of respiratory insufficiency, cardiac arrhythmias or dysfunction, or bleeding. Rather than waiting a few hours after establishing satisfactory postoperative conditions, tracheal extubation in the operating room did not improve patient outcomes, nor did it reduce ICU or hospital stay, or cost. The fad passed.

“Off-pump” coronary artery bypass to treat coronary artery disease became a popular deviation from optimum care in the late 1990s. As cardiologists expanded catheter-based methods to treat coronary artery disease, surgeons responded with their own approaches. Coronary artery bypass graft (CABG) surgery was performed without cardiopulmonary bypass (“off-pump CABG”), prompted by the notion that avoiding cardiopulmonary bypass (CPB) would prevent the adverse consequences of CPB on the brain. The lack of CPB required that the heart continue pumping while in unnatural positions and while grafts were placed in difficult-to-reach locations. These positions often compromised venous return and cardiac output, requiring vasopressors to maintain blood pressure and avoid myocardial ischemia. Surgeon Denton Cooley quipped: “We have successfully made cardiac surgery more painful for the surgeon (and anesthesiologist) than

the patient.” Studies subsequently established that the revascularization achieved was less effective, and that the brain did not benefit [50]. This fad has also faded.

Influential Individuals and Groups

The authors of this chapter are not professional historians, and have wrestled with the problem of how to recognize contributions made by individuals, versus those made by groups united by their motivation to improve the care and outcome of patients. By its very nature, cardiac anesthesiology must be practiced collaboratively, if only because surgeons, nurses, perfusionists, cardiologists and laboratories are requisites. Nevertheless, we have done our best to differentiate individuals versus groups making particularly important contributions. The historian also tends to provide a chronologic tale. We found this challenging due to the brief period we describe, the fact that many individuals and groups emphasized different activities during this period, and affiliations changed as people worked in different institutions and with different people.

Thus, arbitrarily, we have divided this section into Individuals and Groups who, in our opinion, most altered the development of cardiac anesthesiology (Table 61.1 and Fig. 61.6). The former tend to be those either working alone or with a small group, or who made contributions despite moving to different environments, whereas the latter tended to be gatherings of investigators whose collaborations appeared to synergize each other to make the effort stronger.

Individuals

As documented above, Harmel together with Austin Lamont successfully managed blue babies with cyclopropane, tracheal intubation, and intermittent positive pressure ventilation. They used IV morphine to suppress spontaneous gasping respiration that they attributed to cerebral hypoxia, secondary to hypotension during the repair [8]. They achieved a mortality rate of 23%, considered astoundingly low since no previous treatment had been available for these afflicted babies. They attributed this to the “immediate benefit” of the operation.

In 1951, and two years out of residency, Kenneth Keown et al. published a report describing anesthesia for patients undergoing mitral commissurotomy. Anesthesia began with atropine premedication, followed by establishing IV access by surgical cutdown of the anterior tibial vein. They used a continuous procaine infusion for both sedation and arrhythmia suppression, thiopental, decamethonium for neuromuscular blockade, tracheal intubation, and a nitrous oxide oxygen mixture with “augmented respiratory function whenever indicated” [23]. This anesthetic regimen used non-explosive

Table 61.1 Groups and Individuals Influencing the Development of Cardiac Anesthesiology

Initial year & duration of activity	Faculty ^a	School, city
1938–1959	Lank, Smith	Boston Children's Hosp, Boston
1951–1967	Keown	Hahnemann, Philadelphia
1952–1977	Buckley, VanBergen	University of Minnesota, Minneapolis
1957–1978	Theye, Patrick, Tarhan, Tinker, Moffitt	Mayo Clinic, Rochester
1958–1980	Sykes ^b	Hammersmith
1960–1967	Wynands	McGill University, Montreal
1966–1998	Viljoen, Estafanous	Cleveland Clinic, Cleveland
1966–2000	Laver, Lowenstein, Bland, Hallowell, Dalton	MGH, Boston
1966–2004	Prys-Roberts, Foëx, Sykes	Oxford University
1968–1988	Ream, Garman	Stanford University, Stanford
1968–1993	Branthwaite	University College, London
1972–2002	Lell, Reves, Samuelson, Allarde, Oget	University of Alabama, Birmingham
1976–present	Barash, Hines	Yale University, New Haven

^b Hammersmith to 1980; Oxford thereafter

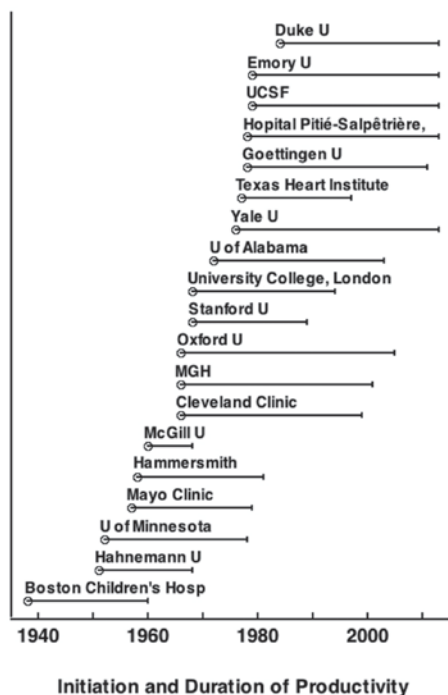

Fig. 61.6 Dozens of institutions and greater numbers of individuals contributed to the advancement of cardiovascular anesthesia and the management of patients with cardiovascular disease. This figure indicates many of those institutions and *roughly* illustrates when the individuals in those institutions began their contributions, and the period over which they had their greatest impact

agents, years before halothane was available. The trachea was extubated at the end of the surgical procedure, and the IV catheter was removed to avoid the “temptation to administer excessive IV fluids.” Keown published the first cardiac anesthesia textbook in 1956 [51]. Keown, first in Philadelphia and after 1957 at the University of Missouri, may be considered the father of *academic* cardiac anesthesia.

In contrast to the Keown regimen, Pender, reporting on the Mayo Clinic experience in patients undergoing mitral commissurotomy, avoided atropine for fear of tachycardia and avoided procaine because of its capacity to cause myocardial depression [4]. He noted, “our past opinion about what constitutes a safe minimal blood pressure during anesthesia has been too high,” “the depth of anesthesia seems much more important than the agent employed” and “little anesthetic agent is necessary.” These two contrasting descriptions make the point that empiricism, and trial and error, enabled markedly different but equally successful regimens. Keats praised these pioneers: “These (early cardiac anesthetists) were heroes, because of their courage to face new challenges without guidance or precedence, without sophisticated monitors or equipment, and with only their intelligence and clinical acumen to contribute to the surgical outcome” [21].

At the Mayo Clinic in the 1950s, Richard Theye profoundly influenced the advancement of cardiac surgery with cardiopulmonary bypass [52, 53]. Anesthesiologist Emerson Moffitt supported cardiologist HJC Swan and physiologist Earl Wood in studying 45 patients undergoing open heart

surgery with cardiopulmonary bypass [53, 54]. This interdisciplinary team worked in a collegial environment that surgeon John Kirklin created at Mayo, and later reproduced at the University of Alabama in Birmingham.

Robert Smith, a pioneering pediatric anesthesiologist, worked at Boston Children's Hospital after World War II with Robert Gross. In 1951, he published an exhaustive article on the circulatory factors affecting anesthesia in congenital heart disease. His 1959 textbook on pediatric anesthesia included further experience with anesthetic techniques for palliative and corrective repairs of congenital defects in infants and children [55]. Smith followed a remarkable nurse anesthetist. Elizabeth (Bessie) Lank came to Boston Children's Hospital in 1935, after 3 months of training in anesthesia. For decades, she anesthetized most of Gross' cardiac surgical patients, including the first child for ligation of a patent ductus arteriosus in 1938, when Gross was a resident acting without supervision [56]. She also taught Harmel and Lamont to use cyclopropane and perform tracheal intubation. (For more on the extraordinary Ms. Lank, see Harmel's memoir above, and George Gregory's Chapter 51 in this book). Smith's and Keown's books, were the standard reference texts for—and thus profoundly influenced the development of—the fledgling field.

As noted above, Earl Wynands in Montreal published his notable 1967 paper describing the anesthetic care of patients undergoing Vineberg's novel operation for myocardial revascularization [18]. These patients presented extraordinary challenges: they had severe ischemic heart disease, marginal cardiac reserve, and postoperative heart function worsened by the surgery.

Wynands' accomplishments are remarkable given his development of bilateral macular degeneration (Doynes' maculopathy) during medical school. He had only peripheral vision! The following reflections speak to his pioneering spirit and courage (Personal communication from Wynands):

"I wasn't sure how long my career would last but decided to give it a shot. At this point I could barely read with a magnifying glass and did not know how much further my vision would deteriorate.

"Mr. Pierre Morin challenged me to do a blind cannulation of the artery. In spite of my efforts to hide my visual problems he was obviously aware that I inserted needles and plastic cannulas into veins by feel. He told me outright that I should be able to insert one into an artery by feeling the pulse and I took up his challenge. I was successful on the first attempt and that put an end to the surgeons doing a cut down on the radial artery and limiting blood flow to the hand."

Wynands was awarded the Order of Canada and remains vibrant and active to this day.

Arthur Keats, who trained at the MGH and started his career with a primary academic interest in pain and narcotics. He arrived at Baylor University in Houston as Professor

and Chief of Anesthesia in the early 1950s. There were two competing surgeons (DeBakey and Cooley) and surgical programs (Methodist and St Lukes Hospitals) within that system that he bridged for twenty-five years before continuing with just one (Cooley). He became an integral and crucial member of the success of that program, pioneering advances in vascular surgery and adult and pediatric cardiac surgery. Keats possessed a towering intellect and was a protean contributor. He mentored several junior associates who went on to productive careers, but achieved his most striking scholarly advances together with his trainee, Steven Slogoff. Between 1977 and 1991, they reported on randomized, controlled trials defining the effect of different anesthetics and beta blocker management, steal prone anatomy, prebypass ischemia, cardiopulmonary bypass flow and pressure, and prebypass hemodynamic variables, postoperative myocardial infarction, and renal and cerebral outcomes [46]. These series of reports included as many as 1000 patients, extremely large for that time.

Slogoff and Keats observed that tachycardia was the most deleterious, and in their hands, the *only* hemodynamic parameter associated with adverse outcomes [46]. They debunked several ill-founded but widely believed clinical dogmas, such as the hazard of continuing beta adrenergic blockers until the time of surgery [57], and the hazard of isoflurane in patients with coronary-steal prone anatomy [58, 59]. Their work can be considered as an important positive incremental step between studies using surrogate markers rather than true outcomes, and between small series that lacked power to draw conclusions and larger series from which generalizations could be made. They presaged the large series (though primarily observational) of Mangano, and the even larger but randomized, controlled studies of Devereaux (see below).

Keats questioned conventional wisdom. In his 1983 Rovenstine Lecture, he examined the collaboration of surgeon and anesthesiologist in the development of the field, noting that surgeons led the way. He advocated that only important questions be addressed, and identified and discussed unimportant ones on which much time and effort had been wasted. He challenged our emerging field to stop talking to itself in its publications, and to populate non-anesthesiology journals with the new knowledge that we had generated [21]. He served as Editor-in-Chief of *Anesthesiology* and President of the American Board of Anesthesiology. His achievements and his firm leadership make him, in our opinion, the single-most important figure in the history of cardiac anesthesiology.

Dennis Mangano, a native of New York, earned a BS in electrical engineering and PhD in physics from New York Polytechnic Institute. After working at Bell Laboratories, where he developed a mathematical theory of physical acoustic phenomena using a multivariate statistical model, he earned an MD in 1974 from the University of Miami in

their innovative program for PhDs, and joined the faculty at UCSF after completing the anesthesiology residency.

Starting with basic cardiac physiologic research in cardiac surgical patients, Mangano soon recognized the importance of myocardial ischemia as a determinant of survival and well being, and began studies in both non-cardiac and cardiac surgical patients. He has determined predictors of myocardial infarction in non-cardiac surgical patients, revealing in 1990, that postoperative ECG changes are the best predictor of adverse cardiac outcomes in high risk patients undergoing non-cardiac surgery [60]. This led him to search for methods of preventing postoperative ischemia. His two hundred patient, randomized, double-blind study of perioperative beta adrenergic blockade claimed a two year survival advantage for blockade. For many years, it was a major impetus for widespread acceptance of this class of drugs as a standard treatment despite criticism due to exclusion from the analysis of in-hospital deaths [61]. It fundamentally changed management of patients at risk of developing perioperative myocardial ischemia, and formed the basis for the American College of Cardiology-American Heart Association Guidelines for Perioperative Cardiovascular Evaluation and Care for Noncardiac Surgery [62].

In the late 1980s, Mangano organized two non-profit independent, international research organizations, Ischemia Research and Education Foundation (IREF) and Multicenter Study of Perioperative Ischemia (McSPI). Over two decades, they performed observational studies of more than 7,000 patients, producing two comprehensive data bases, developing the careers of many investigators, and affecting the conduct of anesthesia and of cardiology and cardiac surgery.

The resulting publications changed our understanding and management of patients with myocardial ischemia and decreased morbidity and mortality. Important examples include the demonstration that aspirin after CABG surgery decreased mortality, heart attack, stroke, and gastrointestinal bleeding without increasing hemorrhage, gastritis or delaying wound healing [63]. This elicited an editorial in the *NEJM* entitled “Aspirin with Bypass Surgery-From Taboo to New Standard of Care” [64]. Another study demonstrated a reduced mortality after CABG in patients receiving preoperative statin therapy. Remarkably, Mangano demonstrated that impeccably conducted observational studies can be used in place of randomized Phase IV studies—studies often mandated by the FDA but almost never conducted. An editorial in the *New England Journal of Medicine* commenting on the aprotinin study described below stated “Mangano and colleagues provide an example of the type of study that may be a model for the future” [65]. The paper to which the editorial referred had found that aprotinin, a controversial substance intended to decrease bleeding and transfusion, was associated with an increased incidence of kidney failure and death [66]. Aprotinin had been vigorously marketed and had gained widespread acceptance. Shortly

following an FDA meeting at which the manufacturer contested the findings, the manufacturer admitted withholding data supporting these complications. Aprotinin was withdrawn worldwide about two years later. Mangano commented that

“Good medicine demands you protect the patient. That’s the issue, not the drug and not the profit margin...Approximately 22,000 lives could have been saved if the drug had been withdrawn in 2006 (when the data were published)...”¹

Even larger randomized, placebo controlled trials have been conducted after the turn of the twentieth Century, by cardiologist-epidemiologists PJ Devereaux, Salim Yusuf, and colleagues at MacMaster University. Yusuf was one of three Oxford University investigators revolutionizing cardiology research in the 1980s with ISIS-1, the International Study of Infarct Salvage [67]. Stimulated by cancer epidemiologist Richard Peto (of Doll and Peto/lung cancer fame) they conducted a 16,000 patient randomized, placebo controlled study of beta adrenergic blockade, in patients with acute myocardial infarction. This demonstrated a remarkable 20% decrease in mortality. In addition, it led to the practice of using acronyms to name studies!

Yusuf and his student Devereaux turned their attention to perioperative administration of beta blockers, after performing a meta-analysis establishing equipoise, despite the widespread perioperative acceptance of beta blockers. The 8,000 patient Perioperative Ischemia Evaluation Study (POISE) documented a decreased incidence of myocardial infarction, but higher stroke and death rates in patients receiving metoprolol [68]. Thus, beta blockade was effective in decreasing the primary outcome of the study but had unanticipated safety issues. Controversy exists regarding whether this is an intrinsic issue with beta blockade, or is a result of using uniform and possibly excessive metoprolol dosage rather than titration to effect. The adverse effects appeared to be related to prolonged postoperative hypotension. This led the authors to search for a method of controlling postoperative heart rate to prevent heart attacks, not associated with hypotension in the ongoing POISE 2 trial. Thus, Keats’ call for large studies using true outcomes, rather than surrogate markers, has come progressively closer to fruition, and yielded enhanced insights and patient safety.

Cardiac Anesthesia Groups

The MGH Group

The seeds for the first and perhaps the most influential academic cardiac anesthesia program, were sown at the MGH in the 1950s and 1960s. Two groups of physician-scientists laid

¹ Interview 17 Feb 2008 on “60 Minutes”

the foundations. Keats later noted that “Most of the important conceptual advances in cardiovascular surgery occurred in (this golden era in) the 1950s” [21].

First, in 1951, three faculty members were charged with initiating a program to provide anesthesia for patients undergoing closed mitral valvulotomy. One of those, William Brewster, demonstrated that ether depressed the myocardium of dogs that had sympathetic blockade from total spinal anesthesia, but not that of dogs with intact sympathetic systems [69]. This revealed why patients with low cardiac reserve but intact adrenergic systems tolerated ether well. Initially, the equipment used for this research performed in dogs was wiped clean and taken to the operating room to monitor the patients’ cardiovascular responses to anesthesia and surgery! This established the practice of intra-operative research grade monitoring of cardiac surgical patients at MGH, and facilitated clinical research.

Second, four individuals at MGH established the RICU, or Respiratory Intensive Care Unit in 1961. Henrik Bendixen (later chair at UCSD and then Chair and Dean at Columbia) and Henning Pontoppidan (perennial Director of the RICU and later Jenney Professor at Harvard), had participated in the ventilation by hand (the anesthetist’s hand squeezing the reservoir bag) of polio patients in the 1952 Copenhagen polio epidemic (see also chapters 43 and 44). Added to this pair, were Myron Laver (later professor at Harvard and University of Basel) and John Hedley-Whyte (A British anaesthetist who had taken a second anesthesia residency at MGH and who was later Sheridan Professor and Chief at Beth Israel Hospital in Boston). These physicians focused primarily on the nascent field of intensive care, and saw cardiac surgery/anesthesia as one aspect of that area.

When Richard Kitz became MGH Anesthetist-in-Chief, in early 1969, he assured Ed Lowenstein, (who had replaced Hedley-Whyte when Hedley-Whyte left to found the department at Beth Israel Hospital), that he could continue to concentrate on cardiovascular anesthesia if he stayed at MGH, rather than accept a position he had been offered elsewhere. The first formal cardiac anesthesia group (CAG) meeting was held before Kitz arrived on 31 July 1969, almost two decades after the initial steps. Tasks were assumed, challenges of the field discussed, and plans developed to address the challenges. Lowenstein was elected to head the group. He wrote: “Without realizing the implications, we had formed the first (1969) academic organization devoted exclusively to the anesthetic management for patients undergoing cardiac surgery” [70]. The first articles from the Group were published in 1971 in *Anesthesiology* [40] and the *New England Journal of Medicine* [71].

Emblematic of the CAG was its sense of mission and control of its destiny. There was pleasure working in a multidisciplinary environment with colleagues from cardiology, cardiac surgery, radiology and pathology who valued each others’ opinions and contributions. This culture recurred in many CAGs formed subsequently at other institutions.

In these early days of cardiac anesthesia and surgery (truly frontiers at that time), the participants relished the excitement and challenge. Their common aspiration was to be “cardiac doctors” who understood the heart and circulatory system, and who collegially interacted within the entire spectrum constituting the cardiac surgical environment. Clinical and research excellence were equally respected. Laver, the intellectual leader at MGH, was a charismatic and fearless clinician who worked hardest and longest. He was recognized for his brilliance, but did not monopolize the glory. He jokingly said (personal communication), “I don’t care who does the work as long as I get the credit.” Indeed, each member believed that good work would be rewarded appropriately and resources seemed generous if not unlimited. There was a spirit of give and take among the surgeons and anesthesiologists, who often made observations about something in the other’s realm that improved care, observations that were accepted with gratitude. Lowenstein characterized education of cardiac anesthesia fellows as the greatest contribution of the MGH to cardiac anesthesiology [70]. Through these fellows, MGH influenced cardiac anesthesiology development worldwide. Between 1972 and 1983, 50 fellows completed the program: 15 became professors, 12 led cardiac anesthesia groups (which they usually started), 12 became department chairs, and 3 became vice chairs.

The Emory Group

A second leading Division of Cardiothoracic Anesthesia was started at Emory University and initially directed in 1974 by Joel Kaplan, who had served his residency at the University of Pennsylvania, and served in the armed forces at Wilford Hall Air Force Hospital. Kaplan was an energetic leader who with his colleagues Carl Hug, John Waller, Jim Zaidan and later Jerrold Levy (the latter three, MGH trainees) developed a fellowship rivaling and larger than that at MGH. Approximately half of their trainees stayed in academic practice.

Kaplan organized and edited the “standard” textbook of cardiac anesthesia (now in its sixth edition). The first, 1979 edition, was entirely written by the Emory faculty, while subsequent editions have included national and international authors [72]. Kaplan and his colleagues published and popularized clinical measurements and interventions such as the use of the modified V lead for ischemia monitoring [73], and described the use of IV nitroglycerine for moment to moment control of myocardial ischemia [74]. While nitroglycerine had previously been administered intramuscularly by Viljoen at Cleveland Clinic, and sublingually by Lappas at MGH, IV administration added a degree of controllability that made it far more effective. This experience facilitated approval by the FDA. Kaplan became an active leader in cardiac anesthesia organizations, and in 1987, he founded the first journal devoted to cardiac anesthesiology, *The Journal of Cardiothoracic Anesthesia*.

Following Kaplan’s move in 1984 to Mt. Sinai Hospital in New York, the Emory Division of Cardiothoracic anesthesia

remained active in education, clinical work and scholarship. It was subsequently directed by Carl Hug, a Michigan trained pharmacist, pharmacologist, and anesthesiologist with particular expertise in opioids, and who has spent his entire career at Emory. He used minimal doses of morphine, avoided neuromuscular blockers in cardiac surgical patients, and would elicit patient responses intraoperatively including during cardiopulmonary bypass, much as Artusio had done using ether analgesia in patients undergoing mitral commissurotomy. He did much to elucidate the “ceiling effect” of opioids; no matter how large a dose is administered, breakthrough responses to stimulation occur despite analgesia, differentiating it from true anesthesia [75]. Hug delighted in describing Boston (personal communication) as “the city where both ether and morphine were rediscovered,” referring to the fact that ether anesthesia had been used by Crawford Long in Georgia years before it was publicly demonstrated at MGH.

The Duke University Group

The third cardiac anesthesia group we cite is at Duke, a group initiated by Jerry Reves (Fig. 61.5) and succeeded by his former trainee, Mark Newman. Reves spent two years at the US Naval Hospital in Bethesda, MD, where he and Bill Lell, the first MGH clinical fellow in cardiac anesthesia worked together “doing hearts.” They performed but belatedly published an early randomized study comparing outcomes between two anesthetic regimens [38].

Pioneering cardiac surgeon, John Kirklin, had left Mayo Clinic and started an outstanding cardiac surgical program in the 1970s at the University of Alabama. After discharge from the Navy, Lell joined Kirklin as Chief of Cardiac Anesthesia. Reves followed, and in 1975 joined him and performed translational pharmacologic research, including introduction of the ultra short acting beta blocker esmolol, for control of heart rate during extreme surgical stimulation [76].

Most importantly however, Reves and the UAB group began investigations of the impact of cardiac surgery on cerebral blood flow and neurological function, with the object of making cardiopulmonary bypass and cardiac surgery safer for the brain [77]. Early cardiac surgeons and anesthesiologists had observed brain damage and attributed it to air emboli streaming to the brain because the inside of the heart had been exposed to the air. But with CABG, the inside of the heart was not exposed, and brain damage disappeared from the consciousness of cardiac surgeons and cardiac anesthesiologists (though not from the patients!). The UAB program resurrected this focus by beginning systematic examinations of the association between alterations in cerebral blood flow during surgery and changes in subsequent neurological function—work that Reves continued at Duke University, after moving there in 1984 to head cardiac anesthesia.

Research at Duke led by Reves and then by Mark Newman in the following decade, revealed several strategies that decreased the deleterious cerebral effects of cardiac surgery

[78]. These included maintaining cerebral perfusion, minimizing cerebral embolization, temperature management, acid-base management, metabolic control (e.g. tight control of glucose), and advanced neurologic monitoring (e.g. near infrared spectroscopy, EEG) [78].

However, despite these understandings, cognitive decline after CABG remains common as the age of surgical patients increases. Cognitive dysfunction is present in 40% of patients five years after surgery, according to careful prospective investigations by Newman and Reves [48]. Early postoperative neurocognitive decline is a strong predictor of late neurocognitive deterioration. This occurs at a greater rate than that following noncardiac surgery. Their work has been at the forefront of making the entire physician community aware of this devastating effect, and rekindling interest in avoiding it.

Subsequent investigations from the Duke group have continued to define hazards to cerebral function. A randomized study demonstrated that older patients were more susceptible to cognitive decline with profound hemodilution [79]. Current investigations are defining the role of genetic variants in post cardiac surgical cognitive decline. The tragedy of cognitive impairment in the face of improved heart function, gives particular importance to these investigations.

The Duke group adopted and investigated echocardiography in the early 1980s. Reves introduced a mandatory year of research in addition to a clinical year for all cardiac anesthesia fellows, a first in the US. This program produced a number of outstanding contributors, including Debbie Schwinn, now Dean at the University of Iowa School of Medicine. Mark Newman, who headed the cardiac anesthesia division after Reves, and succeeded him as Chairman of Anesthesiology, is an outstanding example of the success of this two year fellowship. The Cardiac Anesthesia Division at Duke appears to be the most productive in the US today, as defined by numbers of fellows educated each year, research publications, presentations at scientific meetings and external research funding.

Thus, in the 1970s and early 1980s, the field “took off” in America and around the world. Although many groups and individuals influenced the development of cardiac anesthesia during this period [5], we consider those in Table 61.1 most noteworthy.

Important Organizations and Institutional (Organizational) Developments

Validation of a specialty in medicine requires “academic homes” responsible for disseminating knowledge created by that specialty. Do scientific organizations, meetings, textbooks, journals, accredited educational programs, and certifications distinguish the specialty? For cardiac anesthesiology, the answer is indeed, yes.

The Association of Cardiac Anesthesiologists, the first professional organization of the subspecialty, formed in 1972 after a 1970 survey by Brian Dalton of the MGH, revealed that twelve centers in the United States performed more than 200 cardiac surgical cases per year and that a small number of anesthesiologists focused on that area [80]. First envisioned as a discussion group to promote interchanges and to encourage education and research, the membership was restricted to 50 members, with the intention of forming additional chapters when membership exceeded fifty. However, multiple chapters never developed, and the association continues as a small active group of self-selected authorities in cardiac anesthesia, with emeritus members such as your essayists.

The smallness of “the Association” indicated a need for a larger organization open to all who were interested in cardiac anesthesiology. In 1978, Robert Marino, George Burgess and Martin Peuler of the Oschner Clinic, founded the Society of Cardiovascular Anesthesia (SCA) in New Orleans. The organization grew rapidly, (Fig. 61.7) and membership now exceeds 7,000, reflecting national and international interest in the field [81]. The progressively richer annual scientific meetings and workshops have been fully subscribed from inception. They have covered cardiopulmonary bypass, coagulation issues, transesophageal echocardiography and more

The SCA initially sought joint publication with the *Journal of Thoracic and Cardiovascular Surgery* (JTCVS). However, after promising discussions, the editor in chief of JTCVS, John Kirklin, who had led the planning with the SCA, unexpectedly vetoed the plan. Determined not to create a new subspecialty journal, in 1994, the SCA agreed with the International Anesthesia Research Society to publish a cardiac anesthesiology “journal” within *Anesthesia and Analgesia*, one of the oldest English language anesthesia journals. In the inaugural issue of this joint publication, Editor-in-Chief, Ron Miller and Ed Lowenstein, Chair of the SCA Publications Committee wrote, “Principles elucidated by anesthesiologists concentrating their efforts in the care of patients with cardiovascular disease should be within the scientific province of all anesthesiologists” [82].

Prompted by SCA leaders, the National Board of Medical Examiners® approved Board certification in transesophageal echocardiography in 1998. An effort led by Alan Schwartz and Daniel Thys, to secure fellowship status for cardiothoracic anesthesia, saw success July 1, 2008, when the Accreditation Council for Graduate Medical Education approved accreditation. We hesitate to prophesize about accreditation of the subspecialty by the American Board of Anesthesiology, but others believe it should happen.

North American Emphasis of This Chapter

In this chapter, we have stressed the advancements originating in North America, almost to the exclusion of the rest of

Fig. 61.7 Membership in the Society of Cardiovascular Anesthesia grew rapidly from its inception in 1976, recently stabilizing at approximately 7,000. (Data obtained from the Society by JGR.)

the world. As opposed to earlier advances in thoracic surgery and anesthesia, both cardiac surgery and cardiac anesthesia largely started in North America before spreading to other countries as distinct entities. In this respect, they represent a microcosm of scientific medicine including cardiac surgery and anesthesiology after World War II. The US emerged from the war as a singularly wealthy, powerful and ambitious nation, with leaders determined to grow the medical-scientific enterprise required to develop cardiac surgery. As British cardiac surgeon W P Cleland wrote in 1983 [83], “There seems little doubt that in the realm of cardiac surgery the United Kingdom has been a follower rather than a leader and it has been the United States that that has made most of the running. Undoubtedly, this is largely due to the greater efforts and money into research and development.”

This is not to imply that there has been an absence of scientific effort regarding cardiovascular anesthesia in locations other than North America. For instance, Melrose in Great Britain had developed a pump oxygenator that was used in 1953 some months after Gibbon’s initial use [84]. He also used potassium citrate to provide cardioplegia in 1955 [85]. Hans Sonntag of the University of Göttingen, was documenting the coronary blood flow response to anesthetics in human beings with and without coronary artery disease in the late 1970s [86]. Margaret Branthwaite in London, was studying filling pressures and differential function of the two sides of the heart after open heart surgery, as well as cerebral blood flow during, and neurologic complications after, open heart surgery [87, 88]. Beta adrenergic blockers were developed by Imperial Chemical Co in the UK, where Cedric Prys-Roberts and Pierre Foëx performed in the 1970s, the first studies documenting their effects upon the heart and myocardial ischemia during anesthetic induction [89].

In the 1980s, the number of anesthesiology articles from continental Europe and Asia to American anesthesiology journals increased progressively. Since then, anesthesiology, including cardiac anesthesiology has become truly international. In particular, a myriad of investigators from every continent have been active and productive in the influential multicenter observational studies of cardiac anesthesia performed by McSPI.

Why Did Cardiac Anesthesia Develop?

Three factors explain the development of this subspecialty. First, severe heart disease imposes special, perhaps unique, demands on the anesthesiologist, dictating a need for greater in-depth knowledge of these conditions than most generalist anesthesiologists possess. Cardiac anesthesiologists are cardiac doctors who are also anesthesiologists and manage patients with heart disease throughout the perioperative period. Quoting Myron Laver, in 1984 Keats wrote: “Anesthesiology is at its best when the observations it makes on the sample of patients we care for apply equally to all patients and contribute benefits to medicine at large” [21].

Second, the cardiac surgical environment presents unusual technological demands, including management of anticoagulation, knowledge of cardiac assist devices and pacemakers, and interpretation of measurements obtained from pulmonary artery catheters and of echocardiography images. The expertise demanded of the cardiac anesthesiologist exceeds that possessed by the generalist, requiring the constant use, reinforcement, experience and education obtained in the cardiac surgical environment. Does the technology focus of cardiac anesthesiology cause scholarly research in the field to suffer? As JGR asked: “Do we run trade schools or professional ones where all are imbued with, or at least honor, the thirst for new knowledge through true scholarship?” [90].

Third, successful cardiac surgery demands a collegial relationship among surgeons, cardiologists, perfusionists, nurses, intensivists, and of course anesthesiologists. O’Donnell and McDermott commented on the need for this team approach in 1955: “These are cases in which the affected specialties working as a harmonious team can contribute a great deal to the patient’s welfare” [91], indeed to life or death. The cardiac anesthesiologist contributes crucially to this team, as noted in 1979 by Charles Hatcher, Jr., former chief of cardiac surgery at Emory: “A major factor, if not *the* major factor, in the current remarkably low operative mortality for open heart surgery has been the emergence of the cardiac anesthesiologist” [92]. Surgeon John Kirklin made a similar case nearly a decade later: “For the anesthesiologist to reach his or her potential and for the patient to receive the best care, the anesthesiologist should be a specialist in cardiovascular anesthesia and supportive treatment” [93].

Conclusion

This essay is primarily about the past. We recognize that “the future is important because we have to live and work in it, and it will be what we make of it” [94]. Nevertheless, there are individuals, who if not remembered now, will fade from memory even though their contributions have been responsible for the present and the future.

William Camann

Summary

Women's quest to relieve the pain of childbirth is timeless. A few religious leaders opposed the relief of childbirth pain, but most clergy did not, nor did lay people. In 1847, Fanny Longfellow, the poet's wife, received ether to aid in delivery. In 1853, Queen Victoria chose chloroform to relieve labor pain during the birth of Prince Leopold, ending any moral opposition to pain relief during childbirth. In 1956, Pope Pius XII approved pain relief during childbirth.

US and British movements advanced obstetric anesthesia from the early 1900s to the present. Women lobbied to assure pain relief during labor and sought greater control over delivery. The medical establishment haltingly increased anesthetic availability. In 1914, some US women organized the National Twilight Sleep Association, bringing this popular European technique to the US. But when one of its prominent advocates died during childbirth in 1915 while using twilight sleep, the Association came to an end. Some use of twilight sleep persisted in the US until the 1960s. In the 1920s, one in two hundred British women died during childbirth. In 1928, British women formed the National Birthday Trust Fund to decrease mortality, and make modern pain relief during childbirth available.

In the 1940s, Hershenson established the first "Division of Obstetric Anesthesia" in the US at the Boston Lying-In Hospital. In 1953, Apgar invented her simple "score", "the Apgar", which defines the condition of all of today's new babies, and correlates with their immediate outcome. In 1968, 6 physicians formed the Society for Obstetric Anesthesia and Perinatology (SOAP), the primary advocate for the world-wide interests of obstetric anesthesia. It now boasts more than 1000 members world-wide.

In the first half of the twentieth century, some mothers and physicians (e.g., Dick-Read, the father of the modern natural childbirth movement) sought a natural birth experience. In the late 1940s, Bradley included the husband as an active *participant* in the birth process. In the 1980s and 1990s, women increasingly demanded a pain-free childbirth, replacing the generation seeking natural childbirth. The percentage of mothers given spinal or epidural analgesia during childbirth tripled to 66% or greater. Infusions of low concentrations of local anesthetics, use of the local-anesthetic sparing properties of epidural opioids, and the advent of patient-controlled techniques, collectively increased safety and efficacy, and hence popularity, of epidural analgesia.

In the 2000s, approaches to obstetric anesthesia increasingly combined regional anesthesia with "alternative" medicine. Women requesting epidural analgesia tried hypnosis, water immersion, aromatherapy, birth balls (big plastic balls similar to those used in exercise training), upright posture during labor and birth, acupuncture, and doula (trained birthing coaches). The attitude that epidural analgesia is at least compatible with, perhaps synergistic with, various non-medical techniques contributed to the popularity of a blended approach.

Introduction

"Medical men may oppose for a time the use of anaesthesia during childbirth, but they will oppose it in vain; for certainly our patients themselves will force use of it upon the professions. The whole question is, even now, one merely of time."—James Young Simpson, who in 1847 became the first physician to use anesthesia during childbirth [1].

Childbirth literature sometimes suggests, incorrectly, that women's quest for labor pain relief is a modern phenomenon. "*Women have been giving birth for centuries without the benefit of modern pain relief*" has been argued. What isn't stated as often, is that women in almost every culture and at every time have sought effective *relief for* pain during childbirth.

But why should a natural event, childbirth, be painful? Does pain confer a survival benefit; is it protective—and therefore should it be welcomed? Have the anatomic characteristics of evolution conferred pain during labor upon humans (creatures with big heads) in ways not seen in other animals? Or is pain an unnatural development of the human

intellect, a fearful response to the birthing process? These issues remain unsettled. Regardless of the origin of pain during labor, regardless of any advantage it may confer, women's quest to relieve the pain of childbirth is timeless. Some methods used for centuries were innovative, some were quaint, some hazardous, and some were odd. This chapter will discuss the attitudes towards pain relief during childbirth at different points throughout history.

Pain Relief Before Anesthesia's Discovery: Including the Odd and Unusual

Anesthesia began 16 October 1846, with the public demonstration of ether given to a patient undergoing surgery, at Massachusetts General Hospital, in Boston. How did women lessen the pain of childbirth before this discovery? The ancient civilizations of Babylon, Egypt, China and Palestine tried to relieve labor pain [2]. They applied positive thinking, using magical rings, necklaces, and charms. These may have diminished the *anticipation* of pain, rather than help with the *actual* pain during delivery; and they may have supplied a placebo effect. In ancient cultures, laboring women inhaled concoctions made of poppy extract and hemp (perhaps not so unusual, as opioids remain the most commonly used labor analgesic medication), drank herbal tea mixtures or a beverage sprinkled with powdered sow's dung, sometimes mixed with honey wine [3]. Such primitive methods, methods that distracted women's attention from labor pain, paralleled some modern methods, such as hypnosis, warm compresses, massage and herbal teas.

Donald Caton (1937), an academic historian on obstetric anesthesiology, described an early version of the warm compress and massage during labor.

"One of the earliest references to the management of childbirth pain appeared in a gynecologic text written in the first century CE, by a Greek physician. He suggested that physicians should 'soothe the pains by touching with warm hands and afterwards drench pieces of cloth with warm, sweet olive oil and put them over the abdomen as well as the labia and keep them saturated with the warm oil for some time, and one must also place bladders (containers) filled with warm oil along side.'"

Caton described the pain relief potions recommended by a Puritan Minister well-versed in medicine, Cotton Mather (1663–1728), who advised women to use potions such as the 'livers and galls of eels, dried slowly in an oven,' or 'date, stone, amber and cumin seeds' [4].

Mesmeric Pain Relief (Hypnosis)

In 1836, a decade before the introduction of anesthesia, a French physician and hypnotist, Grubert, suggested

that "magnetic sleep" (a euphemism for hypnosis), might provide labor pain relief [5]. Hypnosis had been tried for surgery, with mixed results, and it did not gain immediate popularity for use during childbirth. A decade later, however, two successful cases of pain relief through the use of hypnosis were recorded. William Fahnestock (ca. 1880) of Lancaster, Pennsylvania, reported the American case, but his report did not stimulate widespread application, possibly because of the therapy's ineffectiveness. Today, such techniques have some popularity, and are often taught in modern childbirth classes, under monikers such as "hypnobabies" or "hypnobirthing".

Blood Letting (Leeches)

In the early nineteenth century, American physician Benjamin Rush (1745–1813), a statesman who signed the Declaration of Independence, recommended the use of leeches to remove three or more pints of blood a day to minimize labor pain. He reasoned that the pain of childbirth could stimulate the woman's central nervous system, and thereby cause harm. Bloodletting, he proposed, would depress the mother's nervous system and avoid the danger. Although absurd in light of today's knowledge, this technique followed the then popular use of bloodletting for treatment of a variety of medical conditions.

Attitudes Toward the Introduction of Pain Relief During Childbirth

Long before the introduction of anesthesia during labor, and for some time after, religion affected the experience of childbirth. A few religious leaders, men who strongly influenced society's laws and social mores, opposed the relief of childbirth pain. They argued that pain was God's punishment to Eve and her descendants (all women) for having disobeyed Him in the Garden of Eden; Genesis 3:16, "*I will greatly multiply thy sorrow and thy conception; in sorrow thou shalt bring forth children.*" To avoid the pain of childbirth was to disobey the will of God. In Germany, in 1521, a physician dressed in women's clothes (men were not allowed to participate in childbirth care at that time) entered the labor room of a woman to provide pain relief. He was discovered and burned at the stake for his offense [6]. It is oft-cited in medical historical literature that the religious objections to pain relief in labor were widely implicated. Simpson did indeed publish a pamphlet answering religious objections to the use of pain relief during childbirth, but there is little evidence that this was a serious concern among clergy or the populace at large [7, 8].

Physicians used opium for centuries for pain relief, and morphine was discovered in the early 1800s, but neither was given to women during childbirth, in part probably because physicians correctly surmised that such drugs might pose risks to both the mother and infant. In addition to questionable historical religious attitudes against the use of pain relief in childbirth, some physicians believed that the pain of childbirth was a natural phenomenon, not requiring intervention. The interpretation of labor pain as God's punishment has been challenged in modern times, and most modern religious leaders do not see pain relief during childbirth as contradicting God's will. In a major address in 1956, Pope Pius XII (1876–1958) gave approval for pain relief during childbirth. John Bonica (1917–1994), the father of modern pain management, assisted in the preparation of this address, (more to follow on Bonica). Modern interpretation by biblical scholars of the Genesis passage 3:16 translates the words concerning childbirth to mean women will bring forth children “in toil or labor,” signifying hard work, rather than pain [9].

Anesthesia, a Blessing for Humankind, Emerges: A Brief Timeline

The 1846 demonstration of anesthesia enabled the painless performance of surgical procedures. Today we take anesthesia for granted, but for thousands of years, surgery and other painful medical interventions caused agony in fully aware, conscious patients—although it is possible that many were less than conscious because they had been given alcohol or other mind-altering potions. The discovery of anesthesia profoundly benefited surgical patients and laboring women.

In 1847, four months after the first successful demonstration of anesthesia for surgery, James Simpson, (1811–1870; Fig. 62.1) a Scottish obstetrician, used ether to successfully relieve the pain of childbirth for a woman with a deformed pelvis. Subsequently, he devoted his career to the advancement of anesthesia used during childbirth, increasing the number of pain relief substances by his discovery of the anesthetic properties of chloroform, improving techniques of the day, and enhancing the birth experience of women throughout Europe and the US. Simpson was created a Baronet in 1866, by Queen Victoria [4].

The First Women to Benefit from Anesthesia: The Royal and the Wealthy

In 1853, Queen Victoria's use of chloroform to relieve her labor pain during the birth of her eighth child, Prince Leopold, ended any lingering moral opposition to the relief

of pain during childbirth. She also received chloroform in 1857 for the birth of her ninth child, Princess Beatrice. It is reported by the Queen's biographer, Elisabeth Longford, that she wrote in her diary after the delivery of Prince Leopold: “Dr. Snow gave the blessed chloroform and the effect was soothing, quieting and delightful beyond measure.”

Those fortunate enough to find a physician willing to provide chloroform or ether soon followed the Queen's example. Women with political and economic power began to challenge the medical establishment, demanding pain relief during childbirth in particular, and better maternal and infant care for all women.

In England there was a literary connection [10]:

“Mrs. Charles Dickens was expecting her eighth child in 1849. Her husband first ‘made himself thoroughly acquainted in Edinburgh with the facts of chloroform’, and then (as described in a letter to a friend) he insisted on the attendance of a gentleman from Bart's Hospital who administers it in the operations there and has given it four or five thousand times. It saved her all pain (she had no sensation, but of a great display of sky-rockets) and saved the child from all mutilation. It enabled the doctors to do in ten minutes what might otherwise have taken them one and a half hours; the shock to her nervous system was reduced to nothing, and she was to all intents and purposes well, next day. Administered by someone who has nothing else to do, who knows its symptoms thoroughly, who keeps his hand upon the pulse and his eyes upon the face, and uses nothing but a handkerchief, and that lightly, I am convinced that it is as safe in its administration as it is miraculous in its effects.”

Obviously, the anesthetist from Bart's (St. Bartholomew's) was John Snow.

“I feel proud to be the pioneer to less suffering. This is certainly the greatest blessing of this age and I am glad to have lived at the time of its coming...” Fanny Appleton Longfellow. 1847, Cambridge Massachusetts [11]

The first American woman to use analgesia during childbirth was Fanny Appleton Longfellow (1817–1861), wife of the famous poet and scholar, Henry Wadsworth Longfellow [12]. For aid in her third delivery, Fanny Longfellow sought out a prominent physician, Nathan Keep (1800–1875), who had experience in the use of ether, and became the Dean of Dentistry at Harvard [11]. In 1847, while under the influence of ether, Fanny Longfellow gave birth to a little girl (also named Fanny) in Cambridge, Massachusetts, and enthusiastically endorsed the use of this new pain relieving substance (see box). Boston, Massachusetts continued to pioneer American obstetric anesthesia; a colleague of Keep's, Walter Channing (1786–1876), gained great popularity with his use of ether to relieve childbirth pains (Fig. 62.2). Channing was from an aristocratic New England family [13]. His

Fig. 62.1 a Scottish obstetrician James Young Simpson was the first to use inhalation anesthesia (ether) for labor pain relief. Shortly thereafter he discovered the anesthetizing capacity of chloroform and applied it, too, for labor pain relief. (Courtesy of http://commons.wikimedia.org/wiki/File:Princes_St_Gardens_James_Young_Simpson.jpg)
b Dining room of the home of James Young Simpson, in Edinburgh, Scotland, where the initial experiments with anesthetic and euphoric properties of chloroform were noted by Simpson and his friends. (Courtesy of the author)

brother, William Ellery Channing (1780–1842), founded the Unitarian Church, and his grandfather, William Ellery (1727–1820), was a Supreme Court Judge of Rhode Island and a signatory of the Declaration of Independence. Not all these fellows were upright citizens. Harvard College expelled Walter for his participation in a notorious food fight, known as the “Rotten Cabbage Rebellion of 1807”, a student-led protest concerning the poor quality of the food served in the dormitories. Harvard College has a long tradition of student-led revolts, and a tree, planted in the late 1700s, at the East end of Hollis Hall, is known as the “Rebellion Elm” (protests often centered around this tree).

After finishing his medical education at the University of Pennsylvania in 1812, Walter Channing returned to Harvard Medical School to become Professor of Obstetrics and Medical Jurisprudence, and then the first Dean of the Medical School, (1816–1847). In 1832, he assisted with the founding of the Boston Lying-In Hospital, a forerunner of today’s Brigham & Women’s Hospital. Channing detailed his extensive experience with ether during childbirth, in his 1848 book entitled “*A Treatise on Etherization in Childbirth*” [11]. Note that Channing and Keep, the first Deans of both Harvard Medical School and Harvard Dental School respectively (although the term was not used until years later) were anesthesiologists, largely remembered for their

work in obstetric pain relief. They reflect the strong tradition of prominent physician practice of pharmacological means of pain relief.

Obstetric Anesthesia From the Start of the Twentieth Century to the Present

Two interconnected threads led to the advancement of obstetric anesthesia from the beginning of the twentieth century to the present. First was the movement to assure pain relief during labor, a movement that took several forms. Some approaches had pain prevention as the immediate goal; others acted as a distraction. Pain prevention included administration of opioids; administration of inhaled anesthetics, particularly ether, chloroform and nitrous oxide, but also ethylene, trichloroethylene, methoxyflurane, and cyclopropane; and finally (and dominant today), administration of epidural analgesia. The application of epidural analgesia required development of methods of anesthetic delivery that provided analgesia with minimal interference in the progress of birth. Second was the movement to give women greater control over their participation in the delivery experience. It increased participation of the father in the birth process.

Fig. 62.2 Walter Channing, American professor of midwifery and sometime Dean at Harvard was an early advocate of ether inhalation for labor pain relief. He assisted in the founding of the Boston Lying-In Hospital. (Courtesy of Brigham and Women's Hospital, Boston)

Women's Struggle for Pain Relief During Childbirth in the Early 1900s

In the US and Britain, shortly after the discovery of anesthesia, the quest for pain relief during childbirth became aligned with women's advocacy for the advancement of their own political and economic power. This included demands for better health care for themselves and their children, improved maternal and child health, and a less painful birth experience. Because of the absence of medical birth control, women had many children and spent much of their adulthood pregnant.

Well into the early 1900s, childbirth remained dangerous for women throughout the world, even in medically advanced countries. Physicians contributed to the high mortality rate of women and infants by not washing their hands after examining and treating patients, particularly after conducting autopsies on patients dying from infection. They thereby facilitated the spread of the infectious disease also known as “puerperal”, or “childbed” fever. Ignaz Semmelweis (1818–1865), a Hungarian physician, noted in 1847 that far fewer women died from puerperal fever in midwife-led

wards (where no autopsies were performed), than in physician-led wards. His observation preceded the germ theory of infectious disease, and was thus without explanation. Semmelweis' simple admonition to wash the hands offended contemporary physicians (doctors were considered clean, not “dirty”), who ridiculed him. However, even before the advancement of the germ theory, physicians eventually recognized that they might spread infections from one patient to another, and increasingly washed their hands. The number of women dying from infection markedly decreased. Years later, when Pasteur's and Lister's studies explained these results, Semmelweis was given full credit for his insightful observations. As an aside, the Semmelweis Reflex is a rejection of a new idea that confronts what may be thought of “conventional wisdom” in this case that doctors were considered clean and thus not possibly a source of disease.

Women's rights leaders in the US and Britain fought for a more humane birth experience for all women, not just the wealthy few. During the mid to late 1800s, and well into the early 1900s, only wealthy and well-connected women could benefit from the new “miracle” of a pain-free birth. Several organizations (see below) sought to remedy this social injustice.

“One of the most cruel class divisions yet remaining in this country is that rich mothers need not suffer in childbirth as though we were still in the Stone Age, while poorer ones far too often do.”
A letter from a British writer, which appeared in the publication, *“The Lady,”* in 1942 [14].

The slowness of the medical establishment to make anesthesia widely available during childbirth frustrated early feminists who championed improved healthcare for all women and children. Some physicians believed that the risks to the mother and infant outweighed the benefits of pain relief, fearing, with good cause, that anesthesia could produce unintended side effects on both mother and newborn. Moreover, some physicians believed that pain was a natural part of the birth process. For example, a noted Russian surgeon who performed the first thyroid surgery under ether anesthesia, Nicolai Pirigoff, (1810–1881) claimed: “Haven't midwives and parturients and indeed all others always viewed the agonies of delivery as an indicator of safety and a well-nigh holy accompaniment of childbirth?” [4] Charles Meigs (1792–1869), one of the most prominent American physicians of the nineteenth century, an outspoken opponent of pain relief in childbirth, and noted for making inflammatory social and cultural comments, pointed out that the “pain of labor had never been great enough to prevent women from having more children” [4]. Several political organizations

consequently arose to overcome physician resistance toward the use of anesthesia during childbirth.

In the early 1900s, American journalists, Marguerite Tracy and Constance Leupp, wrote that the success of the campaign undertaken by women urging physicians to rid women of labor pain would, “relieve one-half of humanity from its antique burden of suffering which the other half of humanity has never understood.”[4]

The National Twilight Sleep Association

In 1914, several wealthy and politically influential US women formed an organization that sought to bring to all women in the US, a new pain relief technique, reportedly used with success in Europe in the first decade of the twentieth century. The Twilight Sleep method of pain relief combined morphine and scopolamine. Morphine dulled the pain and scopolamine produced memory loss, but had the unintended side effect of lowering women’s inhibitions. Laboring women given “twilight sleep” might exhibit bizarre and uncontrolled behavior. The small amount of morphine used was often ineffective against the pain, and women might thrash and scream wildly. (“As an intern, I well recall ordering an intramuscular injection of 10 mg morphine and 0.6 mg scopolamine for a laboring woman who later bit me as I tried to restrain her from climbing over the side rails and who later described the entire experience as absolutely without any discomfort—for her but not me!” *Personal communication, Lawrence J. Saidman*). Unaware of the pain they endured due to the amnesia produced by scopolamine, women often reported a pain free birth experience.

The women who formed the National Twilight Sleep Association successfully campaigned for the use of this technique during childbirth [4]. They held rallies and inspired women to demand that the medical establishment provide twilight sleep—or some form of pain relief—for all laboring women. Their well-organized, well-funded efforts had one critical flaw: twilight sleep did *not consistently* provide adequate pain relief although the scopolamine usually (not always) erased the memory of labor pain. Physicians often put cotton and oil in patient’s ears, and blindfolded them to reduce perception of stimuli, but of course the bigger stimulus was that of labor. Often women were restrained to prevent harm to themselves or others. Of note, the husbands were sequestered in waiting rooms, unaware of all this activity. When one of its most prominent and outspoken advocates (Mrs. Francis X Carmody) died during childbirth in 1915, after receiving this method of pain relief, the National Twilight Sleep Association came to an end. Although

Fig. 62.3 The National Birthday Trust Fund in the UK used promotional materials such as those portrayed here. (Courtesy of the Wellcome Library, London)

twilight sleep probably did not contribute to her death, (which may have been caused by hemorrhage), this tragic event fueled a rising public concern about its safety. Nonetheless, some US hospitals continued to use twilight sleep until the 1960s.

Britain’s National Birthday Trust Fund

In 1928, slightly more than a decade after the demise of the Twilight Sleep Association in America, wealthy and politically influential British women formed an organization to improve all aspects of healthcare for women and children [15]. At that time in Britain, nearly one in two hundred women died during childbirth, largely from hemorrhage, sepsis and complications of poor nutrition. The organizers of the National Birthday Trust Fund aimed to reduce this death rate by improving maternity care through programs that would train professional midwives and maternity nurses. The fund also had the goal of making modern pain relief during childbirth available for all women, regardless of their social status or income (Fig. 62.3). The NBTF still exists and continues to support improvement in various women’s health issues.

The 1940s to the 1970s: Returning to the Past: from Anesthesia Back to Natural Childbirth

By the 1950s, birth was an institutionalized event for women in the US and parts of Europe. Women had minimal control over the birth process once the hospital and physician assumed responsibility for their care. A new generation of mothers and physicians opposed this institutionalized experience. They sought a more natural birth experience, one free from interventions such as the use of pain relief medications.

A British obstetrician, Grantly Dick-Read (1890–1959) profoundly influenced this shift from advocacy for medical pain relief, to advocacy for a natural birth [16]. He opposed the use of pain relief medications during childbirth, and inspired women to believe that “Healthy childbirth was never intended by the natural law to be painful” and that mothers should be fully conscious and aware, to enjoy childbirth. Fear, he argued, activates a flight-or-fight response, which releases body chemicals, preventing normal functioning of the uterine muscles, causing tension, and resulting in pain. He recognized the importance of keeping baby and mother together after birth and encouraged inclusion of fathers in the birth experience.

Then and today, some physicians challenged Dick-Read’s conclusion that only fear causes the pain of contractions, and some denied his claim that information and knowledge about childbirth can eliminate such pain. Nonetheless, he enjoyed popular support among women disheartened by the regimented and institutionalized birth experiences on maternity wards. His book *Childbirth Without Fear*, published in 1933, is still read today, and his theory on the fear-tension-pain syndrome during birth inspired the development of other natural childbirth techniques. Although the physiological explanations for his theories may be questioned, Dick-Read is widely acknowledged as the father of the modern natural childbirth movement.

The US obstetrician, Robert Bradley (1917–1998), developed a natural drug-free childbirth philosophy in the late 1940s. He advocated a birth approach called “Husband-Coached Childbirth.” Inclusion of the husband, not just as a witness to the act of birth, but also as an active *participant* in the birth process, was a radically new idea. He taught the use of a particular breathing technique to manage the pain of childbirth, believing that with proper education, preparation and the support of a coach, women could give birth naturally and with minimal pain. By the mid 1960s, the Bradley Method became a popular natural childbirth technique, a technique still used today by women wanting an entirely natural childbirth experience, in the US and around the world.

Parisian obstetrician, Fernand Lamaze (1891–1957), developed a parallel approach to that proposed by Bradley. In the 1940s, Lamaze traveled to Russia, where he observed women using a method called “psychoprophylaxis”, simple breathing and relaxation techniques for pain management during childbirth. Lamaze next advanced the idea that controlled rapid breathing during labor would divert attention from the painful contractions, and allow women to give birth without medication. The Lamaze Organization began in the US in the 1960s, and its breathing and relaxation techniques became the most popular approach to the control of pain during birth throughout the country. However, the rapid shallow, “dog-breathing” techniques originally advocated by Lamaze are now recognized as relatively ineffective, and may even

cause dangerous degrees of hyperventilation. Today’s Lamaze instructors emphasize additional techniques such as movement and position change during labor, labor support personnel such as doulas, massage, dance, water immersion, and other modalities to relieve or diminish pain during labor.

Notable and Quotable Obstetric Anesthetists

Some notable pioneers played crucial roles in the development of obstetric anesthesia as a specialty. In the 1940s, Bert Hershenson was one of a few, perhaps the only, physician to provide obstetric anesthesia full-time (Fig. 62.4). He practiced at the Boston Lying-In Hospital, (the forerunner of the now Brigham and Women’s Hospital) where he established the first “Division of Obstetric Anesthesia” in the nation, and served as its director from 1942 until his death in 1956. He wrote the first textbook devoted solely to obstetric anesthesia. Although the anatomical and mechanical tenets of epidural and caudal anesthesia had been developed in the early 1900s for surgical applications, it was not until the 1950s that interest developed in the use of this technique for childbirth pain relief. Jess Weiss, (for whom the “Weiss” epidural needle is named) a successor of Hershenson in Boston, and a future president of the American Society of Anesthesiologists, advocated the use of epidural analgesia, and further promoted obstetric anesthesia as a specialty.

Virginia Apgar’s (1909–1974) fame extends beyond anesthesiology, to all of medicine. Her “score”, “the Apgar”, is used to define the condition of essentially all babies born in the world today (Table 62.1) [17]. “Ginny”, began her career at Columbia University in 1938, became the first woman full professor at that institution and directed the division of obstetric anesthesia until 1959. She tirelessly advocated for safe delivery, and safe provision of pain relief in labor. In her later years, she also advocated for women’s rights in the medical field, an outcome of her own experiences as a female physician in a male-dominated field, and she worked to prevent crippling birth defects, taking a leadership role in the March of Dimes Foundation. The US Postal Service honored her achievements with a stamp providing her likeness, a rare recognition indeed for an anesthesiologist (Fig. 62.5). She was named the American Society of Anesthesiologists Distinguished Service Awardee in 1961.

The importance of the Apgar Score to the practice of obstetrics, anesthesiology, and pediatrics is enormous. Over the years, some questioned the value of this simple 10-point scale, but the score has stood the test of time, correlating with amazing reliability to the immediate outcome of the newborn. Apgar’s contribution, for the first time, allowed physicians and nurses to quickly quantify the condition of a newborn infant. While more probing and complex methods of infant evaluation were developed (e.g., the Brazelton

Fig. 62.4 Bert Hershenson wrote the first textbook of obstetrical anesthesia. (Title page given here)

Table 62.1 The Apgar Scoring for Newborns is typically given for each sign at one minute and five minutes after birth^a

	Sign	0 Points	1 Point	2 Points
A	Appearance (skin color)	Blue-gray, pale all over	Only extremities blue-gray	All body normal color
P	Pulse	Absent	Below 100 bpm	Above 100 bpm
G	Grimace (reflex irritability)	No response	Grimace	Sneezes, coughs, pulls away
A	Activity (muscle tone)	Absent	Arms and legs flexed	Active movement
R	Respiration	Absent	Slow, irregular	Regular breathing, crying

^aA score of 7–10 is considered normal, while 4–7 possibly indicates a need for some resuscitative measures, and a baby with a score of 3 and below requires immediate resuscitation

Fig. 62.5 Virginia Apgar’s image was honored on a US Postal Service stamp

neurobehavioral test), these required specialized training and were rarely applied outside research investigations. Although imperfect as a test for evaluating the effect of drugs or anesthetics on the neonate, or even for determining the extent of resuscitation needed by a neonate, the simplicity of the Apgar score and its excellent correlation with outcomes (in populations, although perhaps less so in individual cases) remain its great strengths. Use of the “Apgar” prompts those involved in childbirth to pay systematic attention to the baby. It is noteworthy that the first description was published (in 1953) in an anesthesia (rather than an obstetric or pediatric) journal *Current Researches in Anesthesia and Analgesia*, the forerunner of *Anesthesia & Analgesia* (Fig. 62.6) [18]. More details of her life, including pictures, can be found at a website maintained by her family: www.apgar.net

John Bonica (1917–1994) practiced in Seattle, first at Tacoma General Hospital and later at the University of Washington, in the 1940s–1970, where he pioneered regional anesthesia techniques, including epidural analgesia, for pain relief in labor. He authored arguably the most comprehensive textbook on regional anesthesia ever published. He devoted the later part of his career to the relief of chronic pain, a deeply personal endeavor. Bonica suffered

from injuries incurred as a young man using professional wrestling to supplement his income while also training to become a physician. He had several monikers, including “The Masked Marvel” and “Johnny The Bull Walker” (Fig. 62.7). He had badly injured hips, multiple rib fractures, and chronic back pain. His dear wife Emma nearly died in childbirth in 1943, further prompting his personal interest in obstetric anesthesia. (“I remember his heart-breaking ‘Ciao, Emma’, at her burial. He died shortly thereafter.” *Personal reflection, E. Eger*)

The quintessential development in the specialty of obstetric anesthesia occurred in 1968, with the formation of the Society for Obstetric Anesthesia and Perinatology (SOAP). Six physicians—James Elam, Robert Bauer, Brad Smith, Robert Hustead, Richard Clark, and James Evans met at the Chicago O’Hare airport, and officially held the first organizational meeting of SOAP, which is the primary advocate for the interests of obstetric anesthesia as a specialty in the world today. The Society first met in 1969, in Kansas City, and the first president was Robert Hustead. Today, SOAP boasts over 1000 members world-wide, and has an active annual meeting. More information about the society, including historical information about its founding fathers, can be found at www.soap.org.

One of the more colorful personalities in the specialty of obstetric anesthesia was Gertie Marx (1912–2004). Born and medically trained in Germany, she moved to the US in 1937, initially to the New York Beth Israel Hospital, and in 1955 to New York’s Albert Einstein Medical Center, where she remained for the next 40 years. I remember being a visiting professor at Einstein in the early 1990s. Her office was on the 11th floor of the building, and although she was well into her 80s, she made me WALK up the stairs to her office! Tough as nails, she was.

Gertie was a tireless researcher, publishing several hundred articles related to obstetric anesthesia. She was a constant and outspoken fixture at the annual SOAP meetings, and could almost always be counted upon to be at the microphone, her diminutive frame asking some pointed question to a (usually) petrified presenter. Gertie received many awards and accolades during her illustrious career, including the Distinguished Service Award in 1988 from the American Society of Anesthesiologists and the prestigious College Medal of the Royal College of Anaesthetists in London. According to Gerry Bassell, a good friend, (and a former SOAP president) the award reception was attended by Queen Elizabeth II, who asked Gertie what she did. Gertie replied, “*Your Majesty, I take care of mothers and babies*”.

Another colorful character was Sol Shnider (1929–1994). Sol, originally from Yorktown, Saskatchewan, Canada, trained in anesthesiology at Columbia University in New York City, where he worked with Virginia Apgar. In 1962, Sol moved to San Francisco, to establish the division of obstetric

Fig. 62.6 This illustration is from the title page of the original paper describing the Apgar Score, published in 1953 in *Current Researches in Anesthesia and Analgesia*

Fig. 62.7 John Bonica (here in his professional wrestling pose) wrote the classic textbook on pain management

anesthesia at the University of California, San Francisco. He was president of SOAP in 1973. He performed much of the early work on regulation of uterine blood flow and the effects of anesthetic drugs on the uterus and fetus. Shnider also was co-editor (with Gershon Levinson) of one of the major modern obstetric anesthesia textbooks; a work still widely

read. In his honor, a popular annual meeting is held in San Francisco, the “Sol Shnider Obstetric Anesthesia Review and Update course”. Sol was known for his flamboyant clothes, his love of music, wine, food, and especially opera, and for his mantra “the mother, the baby”. As with Gertie Marx, his boundless enthusiasm for obstetric anesthesia motivated

Fig. 62.8 Sol Shnider and Gertie Marx, in a typical scene at the microphone during a discussion session—or was it an entertainment?—at a SOAP meeting. (Author’s personal collection)

many fellows and junior faculty, A regular fixture at the microphone at SOAP meetings (usually just behind Gertie) Sol was always ready to ask a pointed question (Fig. 62.8).

The 1980s and 1990s: The Epidural Becomes Popular; Natural Childbirth Declines

In the 1980s and 1990s, the use of epidural analgesia (regional anesthesia) grew dramatically. The offspring of mothers who had given birth without medication, now chose to give birth using medical pain relief, particularly epidural analgesia. A generation of women demanding pain-free childbirth replaced the generation of women who fought for natural childbirth. The “medicalization” of in-hospital childbirth also prompted a rise in popularity of out-of-hospital births, such as at birthing centers and home births. The number of women receiving spinal or epidural analgesia during childbirth increased dramatically from 1981–1997 [19]. In large hospitals nationally, the use of epidurals tripled to 66%, and is higher today. Advances in epidural techniques probably explain the increase. Infusions of low concentrations of local anesthetics, local-anesthetic sparing application of epidural narcotics, and the advent of patient-controlled techniques, collectively increased safety and efficacy, and hence popularity, of epidural analgesia. The epidural allowed women to remain awake, alert, and actively participate in the birth process, without amnesia or drug-induced sedation. This represented a major advantage over previously used forms of labor pain relief, and undoubtedly contributed to the increasing popularity of regional anesthetic techniques for labor pain relief. Concerns that epidural analgesia might adversely affect the progress and outcome of labor have been largely disproven. Secular attitudes may have contributed to the increase in medical

labor pain relief; a more technologically sophisticated society easily accepted medical pain relief.

Pain Relief in the 2000s: Medical Pain Relief Advances and Natural Methods Return to Labor and Delivery Rooms

Traditional medical practice has increasingly embraced “alternative” medicine. Increasingly, patients and their physicians accept the idea that non-medical interventions and techniques may promote good health. This trend also affected the childbirth experience. More women, even those requesting epidural analgesia, willingly try techniques that even a few years ago were considered outside of the mainstream. Techniques and devices previously not found on labor and delivery units are now becoming more widely available [20]. These include hypnosis, water immersion, aromatherapy, birth balls (big plastic balls similar to those used in exercise training), advocacy for upright posture during labor and birth, acupuncture, and doulas (trained birthing coaches). The attitude that epidural analgesia is compatible and perhaps synergistic with various non-medical techniques contributes to the popularity of a blended approach. Many leaders in the natural childbirth community accept the role of epidural analgesia. Years ago, many doulas would consider their role finished (even failed) and leave a patient in labor if the patient requested and received epidural analgesia. Today, most doulas remain with their patients throughout labor, regardless of the methods of pain relief chosen, including epidurals; something I refer to as an “epi-doula”. Recognition and acceptance by both obstetric anesthesiologists and doulas of the complementary roles of trained labor support personnel and epidural analgesia surely benefits the experience of women in childbirth.

Attitudes toward the use of pain relief, and the actual application of pain relief during childbirth have changed. At present, over eighty percent of women in the US receive some form of medical pain relief during childbirth, but the form taken continues to be debated among caregivers and women themselves. It has been more than 160 years since anesthesia was discovered. What form will the debate over pain-free childbirth take in the next several decades?

Summary

South American Indians perhaps applied cocaine as a local anesthetic, long before its importation to Europe in the 1800s. Freud prompted Koller's discovery of topical anesthesia with cocaine, who reported eye surgery under topical anesthesia in 1884. Soon, surgeons applied cocaine anesthesia for eye surgery, local anesthesia, peripheral nerve blockade, and spinal anesthesia. In 1904, Einhorn synthesized procaine, but its effect was brief, and there were allergic responses to its metabolite, para-aminobenzoic acid. Dibucaine (1925) and tetracaine (1928) were useful, but had narrow therapeutic ratios.

In the late 1800s and early 1900s, surgeons popularized regional anesthesia, describing virtually all modern techniques. In 1901, Crile used regional anesthesia to block "surgical shock", presaging "pre-emptive analgesia". Spanish surgeon Pagés-Miravé described lumbar epidural injection in 1921. In 1920, Labat popularized regional anesthesia. His enthusiasm led to organization of the American Society of Regional Anesthesia in 1923. This original ASRA dissolved in 1939. In 1940, Lemmon's malleable needle facilitated development of continuous spinal anesthesia. Hingson and Edwards adapted this technology in 1942 for caudal anesthesia. In 1949, Curbelo placed a ureteral catheter in the epidural space to allow the production of continuous epidural anesthesia.

The use of regional technique reached a nadir in the mid-twentieth century, partly reflecting perceived limitations of regional (especially spinal) anesthesia. But in 1954, Dripps and Vandam found no severe neurologic problem in 10,098 patients given spinal anesthetics, thereby helping revive regional techniques. Moore and Bonica added to the resurrection. The introduction of aminoamide local anesthetics, first lidocaine (1947) and then mepivacaine (1957), prilocaine (1960), and bupivacaine (1963) further increased the use of regional techniques.

In the 1980s, peripheral nerve stimulators facilitated safer and simpler peripheral nerve blockade, and intrathecal and epidural opioids were shown to provide segmental analgesia without anesthetic or systemic effects, other than rare instances of respiratory depression. In the 1990s, University of Vienna investigators identified peripheral nerves using ultrasound, decreasing the volume of anesthetic required, and decreasing patient discomfort from paresthesia-seeking techniques or the motor responses caused by nerve stimulators. Finally, improved techniques (incremental injections), safer new anesthetics (ropivacaine), and "rescue" injection of lipid emulsions overcame concerns in the 1980s regarding the safety of local anesthetics injected intrathecally or intravenously.

In 1973, Winnie revived ASRA whose journal (*Regional Anesthesia*) first appeared in 1976. The European Society of Regional Anesthesia was founded in 1985. The Asian-Oceanic Society of Regional Anesthesia and Pain Medicine in 1991 and the Latin American Society of Regional Anesthesiology in 1995.

Introduction

Regional anesthesia evolved from the cross-currents of fascinating individuals, new drugs, and innovative technologies (Table 63.1). This evolution dictated an inherently overlapping and sometimes redundant narrative. The resulting pathways separated into three arbitrary (and non-distinct) phases—early developments, the "dark ages", and the modern era.

The Age of Experimentation

Before anesthesia developed, pressure or ice might be applied to skin overlying peripheral nerves to produce numbness in extremities. True "regional anesthesia" followed the introduction of the first local anesthetic, cocaine. South American Indians knew of the numbing properties of this plant alkaloid long before its importation to Europe in the 1800s. The German chemist Fredrick Gaedcke (1828–1890) isolated cocaine in 1855, and Albert Nieman (1834–1861) achieved further purification in 1860. However, its capacity to produce local numbness and systemic excitation were initially viewed as curiosities, delaying its clinical application.

Table 63.1 Timeline of Historical Developments in Regional Anesthesia

Date	Development
1840s	Importation of coca leaves
1855	Isolation of cocaine
1860	Purification of cocaine
1884	Koller describes the surgical use of cocaine
1884	Halsted, uses cocaine for peripheral nerve block
1885	Coming produces the first epidural anesthetic with cocaine
1889	Bier produces the first subarachnoid block, using cocaine
1901	Sicard treats pain with sacral injections of local anesthetic
1903	Amylocaine (stovaine) synthesized
1904	Procaine synthesized
1921	Pagés-Miravé uses epidural injection
1923	Organization of first American Society of Regional Anesthesia (ASRA)
1925	Dibucaine synthesized
1931	Dogliotti publishes on epidural injections
1932	Tetracaine used clinically
1940	Lemmon introduces the continuous (malleable) spinal needle
1942	Hingson describes continuous caudal anesthesia
1944	Touhy provides continuous spinal anesthesia through a catheter
1947	Curbelo describes continuous epidural anesthesia
1947	Gordh describes the clinical use of lidocaine
1952	2-chloroprocaine used clinically
1957	Mepivacaine used clinically
1960	Prilocaine used clinically
1963	Bupivacaine used clinically
1972	Chapman uses a nerve stimulator to guide local anesthetic injection
1972	Etidocaine used clinically
1975	Organization of second American Society of Regional Anesthesia (ASRA)
1976	Yaksh and Rady describe the use of spinal opioids for analgesia
1977	Selander provides continuous axillary nerve blockade
1979	Cousins et al popularize epidural analgesia
1979	Bupivacaine cardiotoxicity discovered
1980	2-chloroprocaine neurotoxicity described
1985	European Society of Regional Anesthesia founded
1994	Kapral introduces ultrasound detection of nerves
1994	The New York School of Regional Anesthesia website appears
1997	Ropivacaine used clinically
1998	Weinberg describes lipid rescue for local anesthetic cardiotoxicity

Early Pioneers

In 1880, Basil von Anrep reported that injecting cocaine into his arm produced numbing of his skin, but this did not lead to clinical application [1]. Sigmund Freud (1856–1939) prompted the first clinical research into the drug. He had heard of the stimulating effects of cocaine, and began to research those aspects, hoping to find a drug to help a friend overcome his morphine addiction. His initial investigations produced a treatise on cocaine [2]. He subsequently enlisted the help of Carl Koller (1857–1944), a Vienna hospital intern whom he had befriended, Freud gave an envelope containing the powder to Koller, who immediately noticed that his tongue became numb when he licked some spilled powder. Koller, a physician in the ophthalmology clinic in Vienna, recognized

the potential use of the numbing effect on the cornea, demonstrating this in animals. Then (true to his nineteenth century medicine tradition), he experimented on himself and a colleague, instilling cocaine into their eyes before touching each others' corneas with the head of a pin. This successful self-experimentation led to an operation under topical cocaine anesthesia, in September of 1884 [3]. Koller reported this triumph a few weeks later to the German Ophthalmological Society Congress in Heidelberg. The paper was read by a colleague because Koller could not afford to attend the Congress. The news spread rapidly, and in that year, ophthalmologists in New York employed cocaine anesthesia for eye surgery. Prominent American surgeons (William Halsted [1852–1922] and Richard Hall [1856–1897]) at the Roosevelt Hospital in New York infiltrated cocaine to numb surgical fields.

In the next year, 60 reports from individual surgeons described successful local anesthesia of the skin. Halsted and Hall were first to describe the use of cocaine to block peripheral nerves, including a report of brachial plexus anesthesia by injection under direct vision. Again, in the tradition of self-experimentation, some of the original investigators, including Freud and Halsted, became addicted to cocaine. Halsted used morphine to end his dependence on cocaine—trading one devil for another. Although he never overcame his addiction, he managed to continue functioning at a high level. He moved to the Johns Hopkins Medical Center in Baltimore, and had a distinguished career as the father of modern surgical training in the US. Halsted's early papers attest to his enthusiasm for the use of conduction anesthesia with the new local anesthetic [4]. After becoming addicted he ceased publishing work related to local anesthesia, and it is unclear whether he continued to use local or regional infiltration techniques in his practice.

Development of Spinal Anesthesia

The application of cocaine dramatically increased after the discovery of its beneficial properties as a spinal anesthetic. An initial report by James Corning (1855–1923) in 1885, of cocaine injected into the spinal column [5] appears, from his description, to have been the first epidural, rather than the first spinal, anesthetic. Corning's injection into a single human subject followed a successful animal injection. No widespread use followed his report.

"Spinal" anesthesia followed from the improved descriptions of spinal anatomy by the German surgeon Heinrich Quincke (1842–1922) who used the spinal canal as an avenue for the treatment of tuberculous meningitis. His descriptions of the anatomy of the dural sac and the spinal cord led to the relatively "safe" insertion of hypodermic needles in the lower lumbar area. His surgical colleague, August Bier (1861–1949), performed the first intentional subarachnoid block [6]. Bier and his assistant, August Hildebrandt, performed subarachnoid injections of 5mg cocaine on each other in 1899. Hildebrandt's initial attempt to inject the drug into Bier failed because the syringe outlet did not fit the hub of the needle. Bier suffered from a spinal headache for nine days. Injection into his assistant resulted in anesthesia of the lower extremities, as evidenced by lack of sensation in response to blows to the shin. Fortunately, the initial subarachnoid injection followed the introduction of aseptic technique, including the routine use of surgical gloves, and infection did not mar the early history of neuraxial block. In 1908, Bier described the first "intravenous regional anesthesia", a technique that did not achieve popularity until the 1960s. Perhaps it was the perceived necessity to expose the veins surgically, or the short duration of procaine that limited en-

thusiasm, but the report by CM Holmes in 1963 described the percutaneous approach, using the "new" lidocaine, that became an accepted technique.

Bier and Hildebrandt's success with subarachnoid injection addressed concerns regarding the toxicity and short duration of action of cocaine injections; a small dose of drug could profoundly block sensation to half the body. The news of their success spread rapidly to the US, and in 1899, Frederick Tate and Guido Cagliari in San Francisco, performed surgical procedures under spinal anesthesia [7]. Spinal anesthesia soon became the most popular form of regional anesthesia because of its simplicity and low toxicity. In many countries it was popular because the surgeon could act, sequentially, as anesthetist and surgeon. Surgeons dealt with concerns regarding hypotension by controlling the level of spinal blockade through the use of hyperbaric and hypobaric solutions, and adjustment of patient position.

Some colorful and cavalier European surgeons, such as Thomas Jonnesco (1860–1926) of Bucharest, combined thoracic or cervical level injections of hypobaric stovaine with strychnine, to produce anesthesia for thoracic and even head and neck surgery [8].

"NEW AID IN SURGERY...Special Cable to The New York Times. LONDON, Nov 20 (1909). The safe use of stovaine as an anaesthetic was proved to-day by a remarkable operation performed by Prof. Thomas Jonnesco, Dean of the University of Bucharest, at the Seamen's Hospital in Greenwich...To-day's operation was the removal of a mass of tubercular glands in the neck...Prof. Jonnesco inserted a small hypodermic needle into the spinal canal, passing it between two of the vertebrae at the base of the neck. Attaching a small syringe to the needle three centigrammes of stovaine and five centigrammes of sulphate of strychnine were injected into the spinal canal. The patient was told to lie down on the operating table. His head and shoulders were lowered, so that the action of gravity would cause the numbing fluid to spread upward. Two minutes later the operation was carried out in an ordinary manner, the patient being perfectly conscious and talking to the surgeon during the whole proceeding. 'Do you feel any pain?' asked one surgeon. 'No, Sir,' replied the patient. 'I am quite comfortable.'...Five minutes after the operation was finished the patient got off the operating table, walked into the next room, and was taken back to bed."

The reader may wonder, "Why strychnine?" The above article explained that "...by coupling with (stovaine) an exhilarating drug like strychnine the bad effect on the heart is neutralized without interfering with the desired numbing influence of the anaesthetic." Most surgeons were content with lumbar level injections, and the judicious use of the new vasoconstrictor, ephedrine, to manage hypotension.

Development of New Local Anesthetics

The inherent drawbacks of cocaine tempered enthusiasm for neural blockade. Cocaine's potential for addiction was well documented. More limiting was its short duration of action

(approximately 45 minutes) and relatively small margin of safety. Thus, investigators searched for local anesthetics with minimal issues of toxicity and addiction, and a longer duration.

Niemann's work with cocaine revealed its benzoic acid structural component. The first derivative of this moiety was amylocaine (stovaine), released in 1903. It was used for spinal anesthesia until identified as a nerve irritant. In Germany, Alfred Einhorn (1856–1917) synthesized the amino-ester, procaine, in 1904 [9]. Heinrich Braun (1862–1934) documented procaine's favorable properties compared to those of stovaine. It was not a nerve irritant, and did not have the excitatory and addictive properties of cocaine, and therefore replaced stovaine for clinical use [10]. However, procaine also had a short duration of action, and introduced a new problem, allergic reactions to its metabolite, para-aminobenzoic acid. Other amino esters were synthesized to overcome these issues. Dibucaine (1925) and tetracaine (1928) were clinically useful, but displayed a narrower therapeutic ratio (tetracaine, for example, is 8 times more potent than procaine, but 12 times more toxic, partially related to its slower hydrolysis by plasma esterases). Systemic toxic reactions were more common with tetracaine when used in higher doses for topical anesthesia (bronchoscopy) or peripheral blockade, and thus its use was often limited to spinal anesthesia, where smaller doses of drugs were effective. Further development of regional techniques awaited the synthesis of aminoamide compounds in the 1940s.

Early Leaders

Evangelical-like proponents (e.g., Jonnesco), virtually all surgeons, fathered the development of regional techniques. Braun in Germany published the first textbook describing these techniques in 1905 [11] along with enthusiastic reports of regional anesthesia. Another enthusiastic surgeon, Victor Pauchet (1869–1936) in France, likewise published a textbook of regional anesthesia based on the practice at his surgical theater in Paris. This period of energetic experimentation developed virtually all currently used regional anesthetic techniques, at least in a preliminary form. Subsequent expansion resulted from emergence of new local anesthetics, and new technical equipment for performance of blocks [12].

Gaston Labat (1876–1934) is credited with the wider introduction of regional anesthesia to the US. After graduating from medical school in 1916, he moved to Paris and practiced at the University of Paris under Pauchet. He was the third author of the third edition of Pauchet's textbook on regional anesthesia. Labat was administering anesthesia when Charles Mayo happened to visit Pauchet's surgical clinic, including Labat's operating room in 1920. Impressed with Labat and his regional anesthetic techniques, Mayo invited him to join the faculty at the Mayo Clinic—to teach regional anesthe-

sia and write a textbook in English. Labat moved to Rochester, Minnesota, in October 1920. He expanded interest in regional techniques, and, despite the brevity of his tenure at the Mayo clinic, wrote the textbook. Unfortunately, Labat and the Mayo administration appeared to have disagreed on the publication and royalties of his textbook (although Mayo wrote a positive introduction in the book). Perhaps because of this and perhaps because of marital discord, he left the Mayo Clinic before completing his one-year appointment, and moved to Bellevue Hospital in New York. Labat was a surgeon and there is no record of his assuming the title of “chief” of anesthesia at Bellevue. Emery Rovenstine (1895–1960), who succeeded Labat, established a residency and a department of anesthesia—which he headed. Published in 1922, [13] many of the illustrations and much of the text in Labat's book resembled those in Pauchet's French text. Labat's text was the first comprehensive practical manual of regional techniques in English, and sold 7000 copies in three printings. Labat acknowledged his debt to Pauchet in the preface to the second edition in 1928, which sold an additional 3500 copies [14].

Labat developed a following in New York, including colleagues who met regularly to foster their skills. His enthusiasm led to the establishment of the American Society of Regional Anesthesia (ASRA) in New York in 1923. The organization met quarterly to discuss research in regional anesthesia. Several research papers were subsequently published in the new journal, *Current Researches in Anesthesia and Analgesia*, edited by Francis McMechan. The Society remained small (58 active members in 1937), but changed from a group dominated by surgeons to one including many of the prominent figures in the developing specialty of anesthesiology. The original ASRA then dwindled, voting to dissolve in 1939. Several factors were responsible for the decline in interest, including the development of new general anesthetic drugs (cyclopropane in 1930, thiopental in 1934,) at a time when there was ongoing concern about hypotension with spinal anesthesia and toxicity of the local anesthetics. Another factor was political, involving the positioning of the various societies of anesthesiologists to become the national representative of the specialty [15]. Rovenstine, Labat's successor as president, chose to join the American Society of Anesthetists in endorsing the new American Board of Anesthesiology, and the prominent members of ASRA transferred their interest to those organizations.

Other American Pioneers

Rovenstine, a founder of the ASA, succeeded Labat as chief of anesthesia at Bellevue Hospital in 1935. With the help of a Labat disciple, surgeon Hippolyte Wertheim, Rovenstine continued an emphasis on regional anesthesia at Bellevue [16]. Rovenstine largely abandoned the operating room, to

apply regional techniques to patients having problems with pain, presaging a movement that gained momentum in the second half of the century.

George Crile (1864–1943), founder of the Cleveland Clinic and the American College of Surgeons, explored the effects of anesthesia on the phenomenon of “surgical shock” [17] in 1901. Using animals, he found that inhalational anesthetics did not block this physiologic response, while regional techniques prevented nociceptive impulses from reaching the brain, thereby abolishing the response. His concept of “anoci-association” foreshadowed concepts of “pre-emptive analgesia” presently described in conjunction with regional and multimodal analgesic techniques.

The surgeon, George Pitkin (1885–1943), an early American experimenter with spinal anesthetic techniques, shared Crile’s interest in reducing surgical stress. In 1927, he invented and popularized a mixture of procaine, strychnine (nominally to act as a vasoconstrictor), and alcohol (the formula was 0.195 gm procaine, 0.0022 gm strychnine, 0.324 gm alcohol, and normal saline to a volume of 2.2 ml) to produce a hypobaric solution which he named “Spinocain” [18, 19]. Spinocain appears to have been widely used, with no suggestion of toxicity. Pitkin described the effect of position and gravity on the spread of spinal anesthesia, and developed a tilt indicator to assist in positioning the patient. He also developed a hyperbaric solution for obstetrical anesthesia. His life-long dedication to regional techniques culminated in his massive tome on *Conduction Anesthesia*, [20] the second major American text on regional anesthesia.

Pitkin’s contemporary, William Babcock (1872–1963), of Temple University in Philadelphia, also advocated the use of hypobaric spinal anesthesia. He preferred amylocaine (stovaine) mixed with alcohol, strychnine, distilled water and lactic acid, a combination he developed in 1909. Like the Mayo brothers, a visit to France in 1904 had impressed him with the benefits of regional anesthesia. Concern about the hypotension associated with spinal block caused him to advocate measuring the blood pressure and treating hypotension with adrenalin. He preferred spinal anesthesia because of the perceived lower mortality when compared with that of general anesthesia at the time [21].

In 1923, Lincoln Sise (1874–1942), a soft-spoken anesthesiologist, joined the Lahey Clinic in Boston to partner with the renowned surgeon, Frank Lahey. Sise started in general practice but gave anesthesia to supplement his income. He rapidly became a master in anesthesia for patients undergoing abdominal procedures. At the time, regional anesthesia centered on spinal anesthesia because of its short duration and the systemic toxicity associated with peripheral blocks. The introduction of procaine decreased toxicity, but hypotension and post-spinal headaches remained as concerns. Although surgeons appreciated the muscle relaxation provided by “high spinals”, a sufficiently high block often precipi-

tated severe hemodynamic changes. Sise pioneered the use of hyperbaric solutions, administered to patients positioned laterally and in a slight Trendelenburg’s position, with the head and shoulders elevated. He tilted the table to adjust the block height to an optimum level. Sise deserves the credit for using fluid administration to minimize hypotension. He was also an early proponent of the use of ephedrine to combat hypotension.

Notable was his development of an introducer needle to penetrate the skin and interspinous ligaments, enabling use of a smaller gauge needle for the final dural puncture, thereby decreasing the frequency and severity of headaches. Allowing the spinal needle to bypass the skin may also have reduced the risk of infection, a key consideration in an age preceding antibiotics. And what was the right size needle? Fine gauge needles equaled fewer spinal headaches, but use of finer gauge or malleable needles could lead to broken needles, a phenomenon so common that Sise’s partner, Lahey, described how to extract broken needles in 1929 [22]. Other innovators designed new needles, including Green’s rounded bevel needle in 1923, subsequently shown to reduce the incidence of headaches. It was not commercially produced until almost sixty years later.

Labat had impressed the surgical staff at the Mayo Clinic. With his departure, they looked for a successor to establish a true department of anesthesia. William Mayo, Charles’ brother, accidentally met John Lundy (1874–1973) at a dinner meeting during a visit to Seattle in 1924. Lundy had not performed research or published since graduating from Rush Medical College in 1919, but the young man’s enthusiasm and curiosity about anesthetic topics impressed Mayo, and he recruited Lundy to assume the directorship of the anesthesia section at the Clinic. Mayo’s decision was based on little evidence, but in hindsight was justified. Lundy went on to introduce thiopental, establish a blood bank, and open the first recovery room. He also established an anatomy laboratory and a strong teaching program. Lundy had never performed a regional anesthetic before he assumed the role of Director of Regional Anesthesia. Nevertheless he joined ASRA, where he met Labat. Lundy continued the tradition of reliance on regional techniques at the Mayo Clinic, often combining regional with general anesthesia. He developed a concept of “balanced anesthesia” wherein a hypnotic agent produced anesthesia, neuromuscular blocking drugs facilitated relaxation, and a regional technique provided postoperative pain relief [23].

Technical Advances: Continuous Analgesia Techniques

The pioneers of spinal anesthesia sought to increase the duration of spinal anesthesia by inserting a needle that could remain in place, and through which repeated doses

of local anesthetic could be administered. In 1940, William Lemmon inserted the tip of a flexible (malleable) needle into the subarachnoid space, (SAS) and then had the patient lie on a mattress specially designed to accommodate the protruding needle. This allowed subsequent injections to be made through the needle into the SAS of the supine patient. Such intermittent injections presaged the development of “continuous” spinal anesthesia. Robert Hingson and Waldo Edwards adapted this technology in 1942 for injections into the caudal canal to produce prolonged lower extremity and pelvic analgesia, [24] and extended analgesia for labor and delivery. Hingson taught the technique to Gertie Marx in New York during her training. Edward Tuohy (1908–1959), of the Mayo Clinic, took the next step. Using the needle with a curved tip designed by Huber, Tuohy introduced a small-gauge ureteral catheter into the subarachnoid space to allow continuous spinal anesthesia [25].

Continuous Peridural Techniques

In 1901, Jean Sicard (1872–1929) injected cocaine into the caudal peridural space to treat sciatica, and Ferdinand Cathelin used the technique for surgical anesthesia. The Spanish surgeon, Fidel Pagés-Miravé (1886–1923), was the first to describe lumbar epidural injection, in 1921. The Italian, Achille Dogliotti, (1897–1966) popularized the technique 10 years later [26]. Finally, in 1949, Manuel Curbelo of Cuba used the Tuohy needle to introduce a ureteral catheter into the epidural space enabling the first continuous epidural anesthetic [27].

Beginnings of Obstetrical Anesthesia

John Snow popularized general anesthesia for childbirth, recognizing however, the potential for maternal aspiration of gastric contents. A regional anesthetic technique would minimize the occurrence of this complication. O Kreis in Switzerland and S Marx in the US applied single injection spinal anesthesia in 1900. The approach did not become popular, perhaps because of the short and unpredictable duration of cocaine anesthesia after a single injection. In 1909, the gynecologist, W Stoeckel, used procaine by Cathelin’s caudal peridural approach, to produce sacral analgesia for obstetrics, [28] but again the short duration of the single injection limited acceptance. Regional obstetrical analgesia became popular when the continuous techniques mentioned above came into vogue. Hingson’s group, and a publication by Manalan in the 1940s, [29] popularized continuous caudal techniques. Gertie Marx (1913–2004) [30] in New York, and John Bonica [31] in Seattle, both employed caudal techniques to provide obstetric analgesia in the 1940s

The Renaissance of Regional Anesthesia

The middle of the twentieth century marked a nadir of regional techniques. Partly this reflected the introduction of improved drugs and techniques for general anesthesia. Thio-pental and cyclopropane, agents allowing a more rapid onset and emergence than that associated with diethyl ether, became available by the 1940s. Curare became available in the 1940s to facilitate muscle relaxation. Tracheal tubes were used with increasing frequency. Nonflammable halogenated agents, particularly halothane, arrived in the 1950s, and displaced all previous flammable and more toxic agents.

Regional anesthesia seemed less safe. Peripheral nerve block was of limited duration unless tetracaine was used, and tetracaine could cause systemic toxic reactions because large doses were needed. Overall, anesthetic mortality associated with spinal anesthesia was no greater than with general anesthesia (10–12 deaths per 10,000 anesthetics), but reports of deaths elicited editorial concern, [32] prompting a rebuttal, [33] “A Defense of Spinal Anesthesia” published in 1952. Foster Kennedy, a British-trained American neurologist, published a paper describing what appeared to be another blow to acceptance of spinal anesthesia. In an editorial in the 1950 journal *Surgery, Gynecology and Obstetrics* entitled “The Grave Spinal Cord Paralysis Caused by Spinal Anesthesia,” he reported 12 cases of permanent paralysis caused by spinal anesthesia, observing that this “paralysis below the waist is too large a price for a patient to pay in order that the surgeon should have a fine relaxed field of operation.” [34] In 1947, the permanent paralysis produced in two British patients had already caused reservations about the use of this technique in Great Britain. Although the cause of their paralysis was never clearly determined, it appeared there may have been contamination of the local anesthetic or the injection equipment. Nevertheless, this internationally publicized disaster precipitated a rapid retreat from regional techniques [35].

Fortunately, some proponents of spinal analgesia scientifically examined these concerns. The Department of Anesthesia at the University of Pennsylvania, led by Robert Dripps and Leroy Vandam, prospectively studied 10,098 spinal anesthetics. No case revealed severe neurologic problems, [36] suggesting the safety of subarachnoid block when performed with tetracaine. Coupled with the introduction of the new aminoamide family of local anesthetics, the Dripps and Vandam findings supported a resurgence of interest in regional techniques in the US.

New Champions, New Drugs

The emergence of new “champions” of regional techniques in Seattle, Washington, Daniel Moore and John Bonica, aided in the resurrection of local anesthetic techniques. So did the development of new local anesthetics.

Daniel Moore (1918-present)

Moore obtained his medical training during World War II in Chicago, at Northwestern University, where he developed an interest in regional anesthetic techniques under the tutelage of anesthesiologist Mary Karp. Senior surgeons at the Virginia Mason Clinic in Seattle, seeking high quality anesthesia for increasingly complex surgical procedures, hired Moore. Moore established a Department of Anesthesia at the Clinic and obtained approval for a residency program in 1948. Within five years, 50% of patients undergoing surgery at the Clinic received a regional technique. His skill and enthusiasm made him a prominent local and national advocate. In a series of 2,500 patients, he demonstrated the safety of tetracaine for peripheral nerve blocks [37]. He followed this paper with more than 100 publications, primarily on the clinical use of regional techniques for obstetrics, pain management, and surgery. NIH funding supported his studies of local anesthetic blood levels and systemic toxicity. Local anesthetics developed in the 1960s were tested at the Clinic. Moore published his textbook on regional anesthesia in 1952, a richly illustrated practical guide [38]. His election as President of the American Society of Anesthesiologists in 1959, and his colorful presentations in word and in print gave further prominence to the usefulness of regional anesthesia.

John Bonica (1917–1994)

Simultaneous with Moore's arrival at Virginia Mason after World War II, Bonica established a private practice in Tacoma, Washington. Anesthetic complications during his wife's childbirth experience prompted a focus on regional anesthesia with a particular interest in obstetrics and the management of patients with chronic pain. He published the first major American textbooks on both subjects. In 1947, at Tacoma General Hospital, he established the first anesthesia residency in Washington, a residency emphasizing regional anesthesia. In 1960, he assumed the Chairmanship of the Department of Anesthesiology at the University of Washington in Seattle, where he fostered a multidisciplinary pain clinic and formalized the role of the anesthesiologist for the management of complex pain syndromes, including the use of diagnostic and neurolytic nerve blocks. Bonica became a founding member of the International Society of Pain and was a Director of the second American Society of Regional Anesthesia (see below). Though "competitors", Moore and Bonica were lifelong friends, and deserve much of the credit for advancing regional anesthesia immediately after World War II.

New Local Anesthetics

Key to increasing the use of regional techniques was the introduction of the aminoamide local anesthetics. Lidocaine was the first of these. Lofgren and Lundqvist synthesized lidocaine in 1943 and sold the patent to the Astra Pharmaceutical Company in Sweden. Torsten Gordh (1907–2010) at the Karolinska University in Sweden performed volunteer and patient studies leading to the clinical release of lidocaine in 1947. Gordh found that lidocaine acted more rapidly and its anesthetic effects lasted longer than with procaine. Absence of the benzoic moiety in the molecule eliminated the allergic reactions associated with procaine. Subsequent research resulted in the introduction of longer-acting aminoamides, including mepivacaine (1957), prilocaine (1960), and bupivacaine (1963). Bupivacaine offered a larger therapeutic ratio than tetracaine. It provided a longer duration of surgical anesthesia, even extending analgesia into the postoperative period. Extensive clinical studies suggested their safety and efficacy. The aminoamides, with their longer stability in solution than the esters, became the mainstays of regional anesthesia techniques.

The Renaissance—The Modern Age

The early champions of regional anesthesia, combined with new local anesthetics propelled regional anesthesia into new prominence. New champions and technological and organizational developments supported an increasing focus on regional anesthesia.

New Champions

Benjamin Covino (1931–1991) started his career as a physiologist-physician. After obtaining his medical degree in 1962, he joined the small Swedish company, Astra Pharmaceutical Products. As the medical director from 1962–1966, and then as vice-president for scientific affairs until 1974, he oversaw the basic science and clinical research on the new long-acting amino-amide local anesthetics. He completed an anesthesia residency at the Massachusetts General Hospital in 1977, and after a short term at the University of Massachusetts in Worcester (near his old Astra headquarters), he assumed Chairmanship of the Department of Anesthesiology at the Brigham and Womens' Hospital in the Harvard Medical School, from 1979 to his sudden untimely death in 1991. He brought an emphasis on scientific research to the clinical delivery of regional anesthesia, supporting the laboratory work of prominent local anesthetic researchers such as Gary Strichartz, Sanjay Datta and Aaron Gissen. He was a warm

and supportive clinical educator who knew all his residents by their first name, and his graduates included many prominent leaders in regional anesthesia such as J Anthony Wildsmith, Mark Lema, Michael Ferrante and William Urmev. As the second Editor-in-Chief of *Regional Anesthesia*, he increased the scientific standards of the published reports. He published 150 papers and five textbooks on regional anesthesia topics, and served as a leader for what he described as the “third phase” of the development of regional anesthesia, the “Scientific Era” [39].

Gerard Ostheimer (1940–1995) a Covino protégé, served as Covino’s Vice-Chairman. Ostheimer loved obstetrical anesthesia, which he directed at the Brigham and Women’s Hospital, and taught enthusiastically to several generations of residents. He led one of the first studies of the efficacy of epidural blood patches, [40] and was active in the cooperative movement in the 1970s between the ASA and the American Society of Obstetricians and Gynecologists (ACOG) to ensure that anesthesia services were considered as an essential and appropriate part of a delivery service [41]. He was a popular speaker and prolific author, and succeeded Covino as the Editor of *Regional Anesthesia*. He served as a president of the reestablished ASRA, and joined the newly formed (1969) Society for Obstetric Anesthesia and Perinatology (SOAP) (an outgrowth of the interactions between ASA and ACOG), editing their Newsletter. SOAP marked the culmination of efforts to provide a forum for obstetrical issues and recognition, and remains today as a thriving subspecialty organization.

Champions also emerged in Europe. Donald (Bruce) Scott (1925–1998) at the Royal Infirmary in Edinburgh “both practiced and promoted regional anesthesia in the UK at a time when it lay under the cloud of the notorious Woolley and Roe case.” [42] He was noted for his research on the management of hypotension in the supine parturient, for his collaboration with Astra Pharmaceuticals (and his friend Ben Covino) in the development of new local anesthetics, and as the founding president of the European Society of Regional Anesthesia (ESRA) in 1979. On the continent, Egor Lanz in Mainz, Germany, performed some of the early work on epidural morphine analgesia, and scientific documentation of the distribution of anesthesia with the various approaches to brachial plexus blockade. In Belgium, Albert van Steenberge (1925–2010) promoted techniques such as low-dose epidural analgesia for obstetrics, and the combined spinal-epidural technique, but his major contribution was as the founding force in ESRA.

Philip Bromage’s (1920-present) clinical and research activities straddled two continents. Born in London, he discovered the advantages of regional anesthesia as a wartime ship’s medical officer, and eventually trained under J Alfred Lee at Southend Hospital in England. He investigated epidural anesthesia in England, continuing such studies after his move to

Montreal, Canada, in 1956. He published over 80 articles on the anatomy and physiology of epidural blockade (including epidural opioid analgesia), [43] leading to his text on epidural analgesia after his move to Duke University in 1981.

Alon Winnie (1932- present) completed the restoration of regional anesthesia. He was the most productive champion of regional anesthesia in the 1970s. Although crippled by polio during his residency, and confined for life to a wheelchair, he became an articulate advocate and pioneer of regional techniques, notably simplified single-injection techniques for brachial plexus [44] and lumbar plexus anesthesia. Although others later challenged his concept that a “single sheath” enclosed each plexus, his straight-forward illustrations and enthusiastic descriptions led many to undertake regional blocks. His textbook of plexus anesthesia was a popular handbook, [45] and guided many to a first-time attempt of plexus blocks. He became a central figure in the new ASRA, which is perhaps his greatest legacy.

ASRA is Reborn

Renewed interest in regional anesthesia, and emergence of mid-century experts/champions, led to a rebirth of the American Society of Regional Anesthesia. Winnie was frustrated by the lack of an educational forum for regional techniques, feeling that neither the ASA nor the IARS offered sufficient teaching programs for regional blocks. In 1973, he initiated the idea of resurrecting the original ASRA with P Prithvi Raj, and co-opted L Donald Bridenbaugh, Harold Carron, and Jordan Katz, [46] to join together as “founding fathers.” The newly reconstituted society, a society dedicated to the promotion, investigation and teaching of regional anesthesia, had its first scientific meeting in March 1976. The society’s journal *Regional Anesthesia*, (*Pain Medicine* was added to the title in 1998) was first distributed in October 1976. Membership grew from 300 original members to 6,500 by 2005, an anesthesia membership second only to that in the ASA. Winnie served as the first president, from 1975–1980. The organization attracted extensive support and expansion of regional anesthesia, and created a Carl Koller Fellowship to encourage junior members to engage in research in regional anesthesia. With the continued expansion of interest in chronic pain management, the Society expanded its educational programs to 2 annual scientific meetings. It has survived twice as long as the original ASRA.

The new ASRA encouraged formation of societies for regional anesthesia in other areas of the world. The European Society of Regional Anesthesia (ESRA) was chartered in 1979, and had its first scientific congress in 1981. The Latin American Society of Regional Anesthesiology, founded in 1993, had its first scientific congress in 1994, and the Asian-Oceanic Society of Regional Anesthesia emerged in 1989,

hosting its 11th Congress in 2011. Starting in 1992, these societies have sponsored international symposia in conjunction with each subsequent World Congress of Anesthesiologists. Most recently, the African Society of Regional Anesthesia was established in 2010.

Bumps in the Road

In 1979 and 1980, two challenges described in case reports transiently damaged the standing of regional anesthesia, but eventually improved the drugs available and techniques used. In 1979, [47] cardiotoxicity followed unintentional intravascular injections of bupivacaine. In 1980, an unintended subarachnoid injection of a large dose of preservative-containing 2-chloroprocaine produced neurotoxicity [48]. Animal research demonstrated neurotoxicity from 2-chloroprocaine injected at an acid pH with sodium bisulphite as a preservative. This discovery led to reformulating chloroprocaine in a preservative-free preparation, a safer preparation for either epidural or peripheral nerve injection.

The bupivacaine story is more complex. Results from animal models suggested that the R-enantiomer could produce intractable cardiac arrest, by inducing a prolonged blockade of sodium channels in myocardial tissue, at blood levels slightly greater than those associated with seizures [49]. Three advances, each adding safety, followed identification of this phenomenon and its probable cause. First, safer injection techniques were developed, including careful aspiration, incremental injections, and the use of “test doses” to identify intravascular injection. These techniques alone appear to decrease the incidence of systemic toxic reactions to one percent of the previously reported frequencies [50]. Second, less toxic (than bupivacaine) long-acting aminoamide medications were developed, primarily the levo-enantiomers, ropivacaine and levobupivacaine. Third, was the finding that boluses or an infusion of a lipid emulsion could remove the highly lipid soluble long-acting aminoamides from their channel blocking sites [51]. Intralipid is now stored as a “lipid rescue” drug in locations where high doses of long-acting aminoamides are used.

What about the “safest” of the aminoamides, the original lidocaine, the ‘poster’ child for safety? Cases of nerve toxicity followed its use with newly developed microcatheters for subarachnoid injection, demonstrating the toxicity of concentrated solutions injected in a localized area. This resulted in removal of microcatheters from the market. These findings increased awareness of the potential toxicity of all local anesthetics in high concentrations. Other investigations revealed a syndrome of Transient Neurologic Symptoms (TNS), consisting of back pain radiating to the legs and persisting for 2–4 days after spinal anesthesia. This transient

pain was 4 times more likely when lidocaine was used, particularly for outpatient procedures [52].

Further Technical Developments

New technical developments in the last quarter of the twentieth Century increased the world-wide use of regional anesthesia. Peripheral nerve stimulators now aided nerve localization. A 2 Hz current of 2 mA or less could provoke a motor response in a mixed peripheral nerve without producing sensory stimulation or patient discomfort, a significant advance over the use of paresthesias to identify nerves. Nerve stimulators now allowed delivery of a variable current: a higher “seeking” current could be reduced as the needle approached the nerve. Movement in response to a current of less than 0.5 mA indicated proximity to the nerve sufficient to provide a good anesthetic block. The development of insulated needles, which concentrated the electrical current at the tip of the needle, further improved efficacy of nerve localization. In sum, these incremental advances in the 1980s–1990s, greatly enhanced the performance of peripheral nerve blockade and the anesthetist’s confidence.

Simultaneously, the technology of needle and catheter design improved. Better production techniques made disposable equipment a reality. New fine-gauge needles with rounded bevels produced a lower incidence of post-dural puncture headache, reviving this regional technique. Evidence in animals from a study reported in 1993 suggested that new peripheral nerve block needles with a blunter tip than the original Quincke point decreased the incidence of nerve injury [53]. The use of nerve stimulation and ultrasound (below) to localize needle placement further reduced the incidence of nerve injury.

Early catheters for epidural use were adapted from ureteral catheters. Development of smaller gauge Tuohy-type needles in the 1970s–1980s, demanded a parallel development of smaller epidural catheters that passed through an 18 or 19-gauge needle, and were flexible yet rigid enough to maintain patency indefinitely. First adopted for obstetrical anesthesia, these catheters became the mainstay for postoperative analgesia both for continuous peridural blockade, and in the 1990s, for continuous blockade of peripheral nerves for both inpatients and outpatients. They expanded the ability to provide prolonged analgesia.

Pumps

The small catheters prompted the development of portable mechanical and electrical pumps to deliver local anesthetic solutions for 2–3 days. These infusions improved analgesia

after major joint replacements and shoulder and knee procedures, expediting a return to movement. Several large series documented the safety and efficacy of these techniques, and by the 2000s they became popular for pain relief following peripheral orthopedic surgery [54].

Epidural Opioid Analgesia

In the 1980s, opioids placed in the spinal and epidural space were shown to provide segmental analgesia without anesthesia or systemic opioid effects. Tony Yaksh demonstrated the analgesic effects of epidural and subarachnoid morphine in rats [55]. Application of these results to humans showed that postoperative epidural opioid infusions provided efficacious pain relief after major abdominal and thoracic surgery [56, 57]. Subsequent clinical studies in the departments of Bonica and Moore demonstrated that these drugs could be given safely on hospital wards [58] with patient-controlled devices [59].

Addition of small concentrations of local anesthetic, such as 0.05–0.0625% bupivacaine, enhanced analgesia, and hastened the return of bowel function [60] and the ability to ambulate. By 2000, it was accepted that epidural opioid-local anesthetic solutions provided superior analgesia for upper abdominal and thoracic surgery [61]. There was improved patient outcome with reduced pulmonary [62] and cardiac [63] complications, and a reduction in the potential to develop chronic pain syndromes after surgery [64].

Nothing is perfect, however. This approach to pain management can produce rare instances of respiratory depression, with an incidence that may be no greater than following parenteral opioids. It is not yet clear whether lipid soluble opioids (e.g., fentanyl and sufentanil), injected intrathecally, act on spinal cord activity or are effective because of systemic absorption and a subsequent action on the brain—or both.

Ultrasound Nerve Localization

Investigators from the University of Vienna in the 1990s first described ultrasound technology for identification of peripheral nerves [65, 66]. Ultrasound guidance enhanced the ability to identify nerves, enabling reduced volumes of anesthetic to be used, with potentially fewer complications. It was soon widely applied, including for peripheral nerves previously avoided because of their deeper location, e.g., the mid-femoral sciatic nerve. The ultrasound approach decreased patient discomfort, compared with the paresthesia technique or with the muscle contractions associated with the nerve stimulator. More importantly, the approach allowed identification of normal variations in anatomy that had previously presented difficulties in locating nerves using standard surface land-

marks. Because this approach allowed observation of the tip of the needle during the entire performance of the block, ultrasound could also increase safety, by facilitating avoidance of intravascular and intraneural injections. Further research is needed to substantiate these advantages, but ultrasound localization is rapidly becoming the technique of choice for identification of peripheral nerves [67]. It is presently limited by the cost of equipment.

The Internet

Internet technology has expanded the teaching of regional techniques. Vincent Chan at the University of Toronto (usra.ca), and Brian Sites at Dartmouth College (dhmc.org) have contributed to this form of information about regional anesthesia. The “New York School of Regional Anesthesia” (NYSORA.com) established by Admir Hadzic in 1994 with Jerry Vloka has a detailed website. This group, based at St. Luke’s Roosevelt Hospital (the home of Halsted’s original experimentation with cocaine in the 1880s), has established an extensive educational support for regional anesthesia, including workshops, educational programs, and the most recent textbook on the subject.

Reflections

The history of regional anesthesia has been colorful and tumultuous, filled in its early days with self-experimentation, daring and charismatic personalities, and evangelical supporters. The initial enthusiasm retreated before the advance in new general anesthetic drugs and anesthetic adjuvants in the 1930s to 1950s. It took the introduction of long-acting local anesthetics and development of techniques for their safe use in the last quarter of the century that resurrected the fortunes of regional anesthesia. The development of new delivery techniques, particularly ultrasound guidance and continuous epidural and peripheral nerve catheters has supported the renaissance of regional blockade. The detailed and rigorous science of the last 30 years has confirmed a critical role for regional anesthesia and analgesia as a superior perioperative technique, one that the early pioneers may have only partially envisioned, but one they would certainly be pleased with.

Summary

Many countries practiced trephination from 10,000 BCE. Cocaine spat in the wound may have minimized pain in Peru. Alcohol, laudanum, henbane, opium or lettuces may have been used in other countries. The 1,700 BCE Edwin Smith Papyrus described the effects of central nervous system trauma.

Surgeons pioneered neurosurgical anesthesia. Horsley in the UK preferred chloroform, and with physical chemist Harcourt, he constructed a vaporizer for chloroform delivery. The Scot Macewen developed metal tubes for tracheal intubation in 1878, and he trained his residents in anesthesia. Cannon monitored intracranial pressure (ICP) in 1901. In the early 1900s, Krause fathered German neurosurgery and introduced operations to treat epilepsy. He used chloroform to produce hypotension and decrease bleeding. Butzengeiger and Eichholtz used tribromethanol in 1923 for neurosurgery as did Dandy in 1931 to decrease ICP. Anesthetists Magill and Rowbotham introduced tracheal intubation to manage neurosurgery in the early 1930s. By 1930, Cushing had decreased neurosurgical mortality from 50–60% to about 10%. With Codman, he developed the prototype of today's anesthetic record. White in Boston showed that anesthetics, increased carbon dioxide, and oxygen lack all increased ICP.

Research in neuroanesthesia accelerated in the late 1950s. In 1952, Faulconer developed electroencephalographic monitoring, and Stockard and Bickford's 1972 compressed spectral arrays made EEG patterns comprehensible to most anesthesiologists. In the 1960s, anesthesiologist Wollman and colleagues, defined the cerebrovascular effects of hypotension, hyperventilation and anesthetics. Physiologist Rehder with anesthesiologist Theye, and surgeons Kirklin and MacCarty, applied profound hypothermia during aneurysm clipping. Anesthesiologist Michenfelder fostered neuroanesthesia as a specialty in the US, particularly with his 1969 review. He studied cerebral protection from hypothermia and anesthetics, incidentally devising measures of cerebral blood flow and metabolism. In the 1970s, Shapiro studied ventilation-induced ICP changes, and began neuroanesthetic intensive care. In 1947, Dawson described evoked potential monitoring, and in 1982, Grundy made it popular.

In the UK, Hunter published the first modern book on neuroanesthesia in 1964, and Canadian Gilbert published the second in 1966. 36 anesthesiologists and 4 neurosurgeons formed the Neurosurgical Anesthesia Society in 1973. In 1976, the American Society of Anesthesiologists recognized neuroanesthesia as a subspecialty society. In 1989, the Journal of Neurosurgical Anesthesiology arose from the Newsletter of the Society of Neurosurgical Anesthesia and Critical Care.

Neuroanesthesia resulted from collaboration with other specialists and will be needed to answer questions regarding monitoring of intracranial dynamics, brain survival after head injury, spinal cord regeneration, and long-term cerebral effects of anesthetic agents.

Introduction

Neuroanesthesia would not exist without neurosurgery. Nor would neurosurgery have developed so successfully without advances in anesthesia and other areas. For example, the ubiquitous use of cautery required nonexplosive agents; intracranial maneuvering required meticulous respiratory and hemodynamic control; adaptations had to be made for

off site locations; and the patient had to remain immobile for hours but awaken promptly without systemic sequelae. What follows is a chronology of these stories. While surgery on the central nervous system has been practiced for many millennia, the advances made over the past 150 years, many due to developments made by pharmacologists, physiologists, and anesthesiologists, far outweigh any previous progress.

Ancient Times

The oldest known medical papyrus, the Edwin Smith Papyrus, was written in black and red hieratic, the Egyptian cursive form of hieroglyphs. It dates from the seventeenth century BCE and is named for American Egyptologist, Edwin Smith (1822–1906) who purchased the manuscript in two parts from Mustapha Agha in Luxor in 1862 [1]. Some attributed authorship of the manuscript to the writer of a much earlier treatise, the priest and physician of the Old Kingdom, Imhotep (3,000–2,500 BCE). Sixty-nine explanatory notes (glosses) appear to have been added several hundred years after 1,600 BCE [2, 3]. With the medical advice of Arno Luckhardt (of ethylene fame) in 1930, James Breasted provided the first translation of the papyrus [3]. Breasted's translation demonstrated that Egyptian medical care was not limited to the magical modes of healing postulated in other Egyptian medical sources, such as the Ebers Papyrus. Rational, scientific practices followed from observation and examination [4]. The rare book section of the New York Academy of Medicine houses the Smith papyrus (at present on long term loan to the Metropolitan Museum of Art in New York). Allen, the curator at the Metropolitan Museum, undertook subsequent interpretations of the text.

The discourse describes 48 typical (rather than individual) surgical cases, most involving trauma to the head, neck, face and spinal cord. Each case is divided into case or diagnosis, examination, and a treatment decision. Rational surgical treatments are differentiated from the much less employed medico-magical measures. Treatment options are classified as: “An ailment which I will treat”; “An ailment with which I will contend”; or “An ailment not to be treated”.

The papyrus also describes the cranial sutures and fontanelles, the meninges, the external surface of the brain, the cerebrospinal fluid, and intracranial pulsations [3, 5]. The symptoms and signs of brain injury are given. Feeble pulse and fever predict hopeless injuries. Deafness and aphasia follow fractures of the temporal region [6]. Immobilization is advised for head and spinal cord injuries, as well as lower body fractures. Surgical stitching of wounds of the lip, throat, and shoulder are described [6]. So are dressings, including the application of fresh meat (to stop bleeding) [6] and honey (honey is still used, especially in war zones, as a type of occlusive and antiseptic dressing). Case 8 describes hemiplegic contractures. Injuries of the cervical spine are noted to change body functions. In Case 31, for example, quadriplegia, urinary incontinence, priapism, and seminal emission followed cervical vertebral dislocation.

Although the patient in Case 4 obviously has pain, the author does not attempt to advise analgesia despite knowledge of drugs such as the poppy [4]. For example:

“If thou examinest a man having a wound in his temple, penetrating to the bone, (and) perforating his temporal bone, while his two eyes are blood shot, he discharges blood from both his

Fig. 64.1 A trephined skull from 3,500 BC demonstrates a rounded edge of the hole, indicating that healing had taken place and that the patient had survived the procedure. (From Wikipedia, accessed 3 June 12)

nostrils, and a little drops; if thou puttest thy fingers on the mouth of that wound (and) he shudder exceedingly; if thou ask of him concerning his malady and he speak not to thee; Thou shouldst say concerning him: ‘One having a wound in his temple, penetrating to the bone, (and) perforating his temporal bone; while he discharges blood from both his nostrils, he suffers with stiffness in his neck, (and) he is speechless. An ailment not to be treated.’”

Trephination: The Cure All

Nowhere does the Edwin Smith treatise mention trephination (trepanation), although it was probably performed in the Mesolithic period (10,000 BCE–5,000 BCE) and continued to modern times. Skulls excavated from graves in all countries of the world except China, Japan, the Malay Peninsula and Australia reveal rounded, often multiple defects, suggestive of trephination. Many show evidence of healing without infection (Fig. 64.1) [7]. A seizure state may have prompted trephination. So might have headache, a passage into manhood, or spiritual or religious reasons such as removal of amulets or postmortem embalming. It may have been used to clean wounds after trauma in battle [8]. Trephination was a form of primitive emergency surgery after head wounds [9] to remove shattered fragments of bone from a fractured skull, and clean out the blood that often pools under the skull after a blow to the head. Such injuries were typical for primitive weaponry such as slingshot projectiles and war clubs. Hippocrates, who also described the systemic effects of head injury, recommended trephination for simple skull fractures and for contusions of the brain without fractures, in this latter case to prevent bad consequences [9, 10].

Surgeons believed that boring a hole in a patient's head would increase the brain's metabolism (that is, replace depression with happiness), heighten cranial blood flow (release tension as caused by a hematoma within the cranium), or release evil spirits that resided within the skull. Many “patients” survived, as shown by signs of healing in their skulls [8]. (Fig. 64.1) Individuals undergoing trephination for spiritual reasons reported a new and glorious understanding of themselves and the world around them. In addition, this “third eye” was said to bestow psychic abilities and an understanding of mysticism upon the patient. Some reported that trephination heightened the body's senses.

During the Middle Ages, did the familiar haircut of monks and friars (a ring of hair around the circumference of the head) evolve from holy men who had tops of their heads shaved in preparation for trephination? The phrase, “I need that (some unwanted object) like I need a hole in the head,” may be a throwback to trephination.

Trephination, or trepanning as preferred by some authors and cultures, persisted in primitive civilizations until the early twentieth century [11]. Although widely considered to be pseudoscience, the practice of trephination continues in some societies. Proponents point to “recent research” on the increase in cranial compliance following trephination, with increase in blood flow, as justifying the practice. They believe that once the skull is opened, it introduces oxygen, which provides knowledge, significant of a divinity. Some individuals have practiced non-emergency trephination for psychic purposes [12]. A prominent proponent of this view is Peter Halvorson, who, in 1962 drilled a hole in the front of his own skull to increase “brain blood volume” [13]. In 1998, he established the International Trepanation Advocacy Group, which maintains a website and purports to support research into this practice. Theoretical support for the benefits of self-trephination, was offered by Bart Huges (or Hughes, 1934–2004) who claimed that trepanation increased “brain blood volume” and thereby enhanced cerebral metabolism in a manner similar to cerebral vasodilators such as ginko biloba. No published results support these claims. Huges, a Dutch librarian published “The Mechanism of Brainblood-volume (‘BBV’)” (also known as “Homo Sapiens Correctus”) in 1964. Based on an ancient belief, he proposed that when mankind began to walk upright, brains drained of blood while trephination allowed blood to flow in and out of the brain better, causing permanent euphoria.

How was pain minimized for trephination? Coca leaves were widely used in Peru. Perhaps an early anesthetist chewed the leaves and spat in the wound, a technique described for centuries in South America—but possibly ineffective because of the small amount of free cocaine in coca. Or perhaps as in the painting ascribed to Heironymus Bosch (1450–1516), “Extraction of the stone of madness”, the figure standing to the side held a jug of wine at the ready (Fig. 64.2). While Bosch was known for his fantastic imagery illustrating moral and religious concepts and narratives, in recent decades, scholars have also viewed his art as reflecting then orthodox religious beliefs.

Peter Treveris is credited with an engraving in the “Handywarke of Surgeri” by Heironymus von Braunschweig, showing the method of trephination in 1525. Treveris also published “The Grete Herball” in two editions in 1526 and 1529. This compendium of herbal and plant remedies was translated from the French “Le Grant Herbiere”. The author describes laudanum, henbane, opium and lettuces as narcotics for pain relief. These preparations and alcohol may have been used during these procedures.

Fig. 64.2 A surgeon makes a hole in the skull while an assistant stands by with a pitcher of wine. (Attributed to Heironymus Bosch, 1450–1516, from “The Extraction of the Stone”, 1490, oil painting, Museo del Prado. From Wikipedia, accessed 3 June 12.)

The use of trephination declined in the nineteenth century. In 1829, Astley Cooper, a consulting surgeon to Guy’s hospital in London wrote “Trephining in concussion is now so completely abandoned that in the last 4 years I do not know that I have performed it once, while 35 years ago I would have performed it 5 or 6 times a year”. More advanced medicine replaced the practice: bleeding, purges and application of leeches [14].

Nineteenth Century and the Discovery of Anesthesia

After the momentous demonstration by William Morton on 16 October 1846, knowledge and application of the benefits of ether, and then chloroform, (James Simpson, 4 November 1847) spread quickly around the world. However, anesthesia for neurosurgical procedures was slow to be accepted, perhaps because it was recognized that the brain does not possess pain endings, and thus unconsciousness might not be necessary. Also the dangers of working within the brain might mandate a responsive patient.

A notable case illustrating the dangers of anesthesia achieved local fame. In Lumberton, New Jersey, on 7 February 1887, Mary Anderson was shot in the head by her thwarted lover [15]. Two weeks later, 4 prominent physicians, Girdner, Spitzka, Pancoast, and Spiller assembled in a tiny cottage, and with a telephonic probe¹ tried to locate and remove the bullet. Under ether anesthesia and breathing spontaneously, her condition rapidly deteriorated as her brain swelled and the procedure was abandoned. She died without regaining consciousness a further 2 weeks later. Her assassin was accused, tried, convicted and executed.

During the nineteenth century, several prominent surgeons, especially neurosurgeons, made important advances in anesthetic techniques for neurosurgery.

Victor Horsley (1857–1916)

In the latter part of the nineteenth century, a few general surgeons performed neurosurgery. Chipault in France and von Bergman and Krause in Germany, Macewen in Scotland, and Keen in the US all performed cranial and spinal procedures as well as general surgery. Victor Horsley studied neurophysiology extensively in his early career. He was also a leader in the temperance movement in the UK, having observed many inebriated head injured patients admitted to hospital. Horsley was the first neurosurgeon appointed to the hospital in Queen Square, London, now called the National Hospital for Neurology and Neurosurgery—the Victor Horsley Department of Neurosurgery is named in his honor. The Walton Centre for Neurology & Neurosurgery NHS Trust in Liverpool, England, another leading Neurosurgical Hospital dedicated their Intensive Care Unit to Sir Victor Horsley and is called the Horsley ward [16].

Horsley investigated the intracranial effects of chloroform, ether and morphine after experimenting on himself (Fig. 64.3). He concluded that because ether caused hypertension, excessive bleeding, postoperative vomiting and general excitement, it was not to be used in neurosurgery [17]. He considered morphine valuable because of the apparent increase in cerebral blood flow and more readily controlled hemorrhage in the surgical field. The respiratory

¹ On 2 July 1881, President James Garfield was shot in the back while ambling through the Washington railway station. He was 49 years of age and in excellent health. Known for experiments he conducted with metal detectors in England, Alexander Graham Bell was called to the President's bedside. The metal probe which he and a team of assistants had worked to perfect, could not locate the bullet lodged in the President's back, and Garfield died from infection weeks later. Distraught over the President's untimely death, Bell worked tirelessly to create an efficient surgical probe, producing a successful model in October 1881. He named his invention the telephonic probe.

Fig. 64.3 Victor Horsely photograph accessed from Wikimedia Commons, 3 Aug 13.

depression caused by the opioid (an effect that he had noted from self experimentation) could also cause problems. He preferred chloroform, advising the “judicious use of chloroform to control hemorrhage [18]. However, death during chloroform anesthesia was all too common. In 1890, the Hyderabad Commission concluded that death was due to respiratory failure. The need for control of the dose remained unclear, although it was realized that slightly less than 2% chloroform induced anesthesia and much less allowed maintenance. It was argued that this amount might just as easily be achieved, by sprinkling the liquid onto a cloth. Horsley disagreed and together with a physical chemist, Vernon Harcourt, developed an inhaler that could control the percentage of chloroform administered.

In 1901, the British Medical Association appointed a “Special Chloroform Committee” including Waller, Sherrington, Harcourt, Buxton and Horsley to introduce science to the art of anesthetic administration. The committee concluded that a chloroform dose exceeding 2% was unsafe because the resulting inhibition of the vagus nerve could cause cardiac arrest. They determined that several inhalers were suitable for administering accurate measures of chloroform including those of Snow, Junker, Clover, Paul Bert, Harcourt, Roth-Drager, Waller and Collingwood [19].

Fig. 64.4 William Macewen. (From Wikimedia commons, accessed 3 June 12.)

Harcourt's inhaler delivered no more than 2% chloroform. Horsley believed that administration should be reduced to <math><0.5\%</math> after bone removal during craniotomy, because of potentially adverse effects on intracranial dynamics [18].

William Macewen (1848–1924)

Macewen, medical superintendent of the Glasgow Fever Hospital, dealt with many deaths from respiratory obstruction due to diphtheria. (Fig. 64.4) He developed metal tubes that he inserted into the tracheas of cadavers, and then patients, following the observations of Desault some 100 years previously. He reported the case of a Glaswegian who popped a hot potato into his mouth. A few hours later and after some libation, the man had difficulty breathing and went to the emergency room of the Royal Infirmary. Macewen passed a metal tube into the Glaswegian's trachea and relieved the obstruction. On 5 July 1878, he passed a tube into the larynx of a patient before inducing chloroform anesthesia for removal of an epithelioma from the base of the tongue [20]. He later developed red rubber tubes that were better tolerated by patients, especially those with diphtheria, when the intubation was maintained for 36 hours or longer [19].

After an anesthetic death and much national publicity, a resolution was adopted on 7 March 1883, in Glasgow, requiring training in anesthetics for all medical students and

Fig. 64.5 A photograph of Harvey Cushing taken around 1900. (From Wikimedia commons, accessed 3 June 12.)

clerks [21]. Formal anesthetic training was not adopted in the rest of Britain until 1911. In the US, although the American Board of Anesthesiology was established in 1938, formal training for all medical students has only slowly been accepted, and is still not universal, similar to that in many 3rd world countries.

Macewen became a leader in neurosurgery in the UK. He demanded that his patients be anesthetized only by residents that had been appropriately trained and certified under his supervision.

Harvey Cushing (1869–1939)

An American pioneer of neurosurgery and anesthesia, Cushing studied at Yale and Harvard Universities, and trained at Johns Hopkins Hospital with William Halsted (Fig. 64.5). During his residency with Halsted, he became interested in neurosurgery and determined to develop better diagnostic methods, becoming one of the first in American surgery to employ X-rays.

As a medical student he was asked to stand in for the anesthetist Frank Lyman. As recounted in other chapters in this book, Cushing's anesthetic ended in disaster. As the surgery began, the patient vomited, aspirated the vomit, and died.

“To my perfect amazement I was told it was nothing at all, that I had nothing to do with the man's death, that he had a strangulated hernia and had been vomiting all night anyway, and that sort of thing happened frequently and I had better forget about it and go on with the medical school. I went on with the medical school but I have never forgotten about it [22].”

True to his word, Cushing never forgot this terrible event, and to the benefit of anesthesia, he did something about it [23]. With Codman, Cushing developed the anesthetic record on which anesthetists noted the patient's heart rate and blood pressure (itself, a new measurement in medicine) at five minute intervals, an approach little different from that used in today's anesthetic record. His suggestions were not immediately accepted. In 1903, a Harvard Medical School committee considered “the importance of blood pressure observation in surgical diagnosis and treatment”. The committee concluded that the skilled finger was of much greater value clinically for determination of the state of circulation than any pneumatic instrument. They suggested that Cushing's work (and also George Crile's work in Cleveland) should be put aside. Cushing appeared to agree:

“I am not so sure that the general use of a blood pressure apparatus in clinical work has done more than harm. Just as Floyer's pulse watch led to two previously unknown diseases, tachycardia and bradycardia, so the sphygmomanometer has led to the uncovering of the diseases of hypertension and hypotension which have vastly added to the number of neuroasthenics in the world” [24].

Cushing became professor of surgery at Harvard Medical School (and chief of surgery at the Peter Bent Brigham Hospital in Boston) in 1912. A perfectionist, he brought to neurosurgery crucial refinements in pre-operative preparation and operative technique. His skill reduced the mortality rate of brain operations from 50–60%, to about 10% by 1930 [25].

In 1898, inspired by Halsted's work with local anesthesia and by observations of deaths under ether anesthesia, Cushing applied local infiltration of cocaine to his surgeries, especially brain cases, but also to hernia and thyroid operations [25]. He kept detailed records of his work, insisting that records similar to current anesthetic records (see above) be maintained on his patients.

Fedor Krause (1857–1937)

The father of German neurosurgery, Krause introduced operations to treat epilepsy into Germany, performing over 400 operations on epileptic patients during his career (Fig. 64.6). He is also remembered for his work in plastic surgery, and

Fig. 64.6 A photograph of Fedor Krause from around 1930. (From Medscape; Source Neurosurg Focus Copyright American Association of Neurological Surgeons.)

was an early practitioner of intraoperative electrostimulation of the cerebral cortex. He developed operative techniques for tumors of the brain and spinal cord.

Krause was also concerned about the neurosurgical implications of anesthetic actions. As an assistant to Richard Volkman, Krause noted the effects of morphine-chloroform anesthesia, and was unconvinced that it offered advantages for neurosurgical procedures. He preferred chloroform alone, [26] but recognized the usefulness of small doses of morphine for postoperative pain relief. He felt that increased venous bleeding offset the safety of ether, and reserved its use for patients with cardiac failure. He advocated increasing the concentration of chloroform to produce controlled hypotension and decrease bleeding during tumor extirpation. He also noted that sudden death might occur if respiration ceased during tumor surgery (respiration was mainly spontaneous or controlled by an assistant under the drapes holding a mask to the patient's face), and he preferred the Roth Dräger apparatus that allowed administration of 100% oxygen. Like others, he emphasized that the brain was insensitive to pain, indicating the need for only light planes of narcotization [26]. Nevertheless he did not advocate local anesthesia, believing that pain was not the only problem. Optimum patient preparation for surgery demanded a positive attitude and calmness. Severe anxiety could contribute to death. He concluded that a good outcome required a rapid, aseptic technique, minimal blood loss, normothermia and general

anesthesia, noting that spinal procedures were amenable to local infiltration [27].

Semmelweis and Clean Hands

The frequency of wound infection, which Horsley found to be as high as 40%, hindered the advancement of surgery and thus also of anesthesia. Ignaz Semmelweis (1818–1865) was a Hungarian physician and early pioneer in the use of antiseptic procedures (Fig. 64.7). Described as the “savior of mothers” [6] Semmelweis discovered that hand disinfection in post partum obstetric clinics drastically decreased the incidence of puerperal fever [28]. In mid-nineteenth-century hospitals, puerperal fever was common and often fatal, with mortality rates of 10%–35%. Semmelweis worked in Vienna General Hospital’s First Obstetric Clinic where patients on doctors’ wards had three times the mortality of those on the Second Obstetric Clinic, the midwives’ wards (Fig. 64.8). He noted that the doctors performed autopsies on patients dying of puerperal fever, but the midwives did not. Semmelweis postulated that washing of hands and arms with chlorinated lime solutions, especially after cadaveric dissection, would reduce infection rates.

Fig. 64.8 Puerperal fever mortality rates for the first and second clinic at the Vienna General Hospital 1841–6 differed. The first clinic, run by doctors, had a higher mortality rate than did the second, run by midwives. (From Wikimedia commons, accessed 3 June 12.)

Semmelweis’ astounding results showed that hand-washing reduced infection to less than 1%, but such data conflicted with contemporary scientific and medical opinions, and the medical community rejected his ideas. The suggestion that they should wash their hands offended doctors, and Semmelweis could not offer a scientific explanation for his findings. His ideas finally earned widespread acceptance years after his death, when Louis Pasteur (1822–1895) confirmed the germ theory by proving that microorganism (yeast) growth causes fermentation, and that bacteria emerge in nutrient broths from biogenesis and not from spontaneous generation [29]. In 1865, Semmelweis was committed to an asylum, where he died at age 47. It is not clear whether he died of a beating or, ironically, of septicemia.

Lister, von Bergman, Antisepsis and Asepsis

A stream of discoveries provided the knowledge and means to minimize, abolish, and treat infection. In 1867, Joseph Lister (1827–1912), Professor of Surgery at the Royal Infirmary in Glasgow, killed bacteria in the air and on the skin with a carbolic acid spray, thereby giving the world antisepsis. Other antiseptic rituals such as the use of masks, operating gowns, hats, and sterile gloves evolved thereafter. In 1886, Ernst von Bergmann (1836–1907) added asepsis, with his steam sterilization that ensured the sterility of instruments. Alexander Fleming grew penicillin from the mould *Penicillium notatum* in 1928, thereby beginning the antibiotic revolution. Together with Florey and Chain, who further refined penicillin, Fleming received the Nobel Prize in Medicine in 1945.

Anesthetic improvements had made neurosurgeons bolder, but infection had held them back. Now, advances could leap forward and with them, further anesthetic developments would appear.

Fig. 64.9 This photograph of Wilhelm Roentgen was taken around 1900, shortly after the discovery of X-rays. (From Wikimedia commons, accessed 3 June 12.)

X-rays

Yet another breakthrough played a major role in the expansion of neuroanesthesia. During 1895, William Röntgen (1845–1923), a German physicist, discovered a new form of electromagnetic radiation while investigating the effect of passing electrical discharges through various vacuum tubes [30]. (Fig. 64.9) He named the new rays, X-rays, a designation for something unknown. Nearly two weeks after his discovery, he took the first picture using x-rays, of the hand of his wife, Anna Bertha. He later reported that at this point he determined to continue his experiments in secrecy, because he feared for his professional reputation if his observations were incorrect. X-rays (Röntgen rays) earned him the first Nobel Prize in Physics in 1901. The resulting development of imaging underlies modern devices such as fluoroscopy, computerized tomography (CT) scans, and magnetic resonance imaging. Röntgen’s discovery profoundly altered surgery in more subtle ways than anesthesia and antisepsis. Before X-rays, doctors relied on their five senses. X-Rays provided a sixth sense that facilitated more precise diagnoses.

Few discoveries, apart from anesthesia, spread as fast as that of X-rays. Röntgen’s original paper, “*On A New Kind Of Rays*” (*Über eine neue Art von Strahlen*), appeared on 28 December 1895 [28]. X-rays had an enormous impact on surgery. Soft organs could be visualized by introducing a “contrast material”. For the brain, that included the use of air to allow pneumoencephalography, a technique introduced in 1919 by the US neurosurgeon Walter Dandy. Actions of anesthesiologists have enabled the increasing use of interventional neuroradiology in ever more disease states amenable to less invasive therapy. These include interventions such as aneurysm coiling, vertebroplasty, kyphoplasty and carotid stenting. Such offsite venues can be challenging because they may lack OR-oriented personnel or a PACU, and may be equipped with unfamiliar equipment.

Early Twentieth Century

Towards the end of the nineteenth century, many substances were touted as anesthetic agents. In his 1881 textbook, *Artificial Anaesthesia and Anaesthetics*, Henry Lyman listed 47, including benzene, acetone, and kerosene. He also included an intriguing drug, puff ball (also known as Indian bread and tuckahoe), described as a curious fungus found on the roots of fir trees in the southern US [31]. Other means of inducing insensibility included hyperventilation (instructing the patient to breathe 100 times/minute) and electricity. In this last method, an insulated forceps was applied to a tooth, forming the negative electrode, while a positive electrode was held by the patient. A current was applied and the patient became insensitive, and teeth could be extracted. The surgeon directed administration of the anesthetic. Regarding the responsibilities of the anesthetist, Lyman wrote:

“Death sometimes occurs during the use of an anaesthetic. If inhaled by the decedent in private and of his own motion, was it a case of suicide, or was it an accidental death? If administered by the hand of another...was it given by a person skilled in the theory and practice of etherization or by an individual destitute of these qualifications? [31]” This question remains for legal debate today.

Anesthetic management became an integral part of neurosurgery. In the early 1900s, open drop ether was still the technique of choice. A tourniquet was placed around the skull just above the eyes in an attempt to decrease cutaneous bleeding. Clearly there was no effect on intracranial bleeding. The development of electrocoagulation by William Bovie at Harvard made the use of open circuit explosive agents problematic [32]. Cushing introduced the use of the Bovie, a standard method of halting bleeding today, on 1 October 1926, at the Peter Bent Brigham Hospital, to facilitate removal of a vascular myeloma involving the scalp [33]. He also introduced silver clips to occlude cerebral blood vessels and staunch bleeding.

In 1919, Irish born Ivan Magill (1888–1986), accepted a post as anesthetist at the Queen's Hospital, Sidcup, a hospital established to treat facial injuries sustained by soldiers in World War I. Working with plastic surgeon Harold Gillies, and his colleague in anesthesia, Stanley Rowbotham (1890–1989), Magill developed numerous items of anesthetic equipment but most particularly the single-tube tracheal anesthesia technique, driven by the immense difficulties of using a mask to administer chloroform and ether to men with severe facial injuries. In 1920, Rowbotham described blind nasal intubation, particularly useful for surgery on the oral cavity. Magill and Rowbotham were instrumental in reintroducing tracheal intubation in 1921. Gradually adopted over the next 2 decades (it was in general use in neurosurgery by the early 1930s), it used rubber tubing rather than the flexible metal tube as developed by Macewen [34]. These developments were essential to the furtherance of neuroanesthesia.

Greater understanding of intracranial dynamics developed. The Monro-Kellie doctrine, a synthesis of the works of eighteenth century Scottish anatomist (Alexander Monro) and nineteenth century American physiologist (George Kellie), stated that the cranial cavity is a closed rigid box, and that the quantity of intracranial blood must change through the displacement or replacement of cerebrospinal fluid [35, 36].

Walter Cannon, an American physiologist (who coined the phrase “fight or flight”) described intracranial pressure (ICP) monitoring in 1901, as an expansion of the work of Claude Bernard on homeostasis [37]. White et al in Boston, showed in animals, that various anesthetics perturbed ICP and that carbon dioxide accumulation and oxygen lack produced dramatic increases [38]. To minimize these concerns, Andrew Hunter advocated the use of an 8 l/min inflow of 25% oxygen and nitrous oxide into a semi-closed anesthesia circuit [38]. His preferred opioid was heroin, in 1 mg increments for supretentorial procedures, when reduction in brain bulk was important [39]. Also, some years earlier, CB Courville published a book on adverse effects of nitrous oxide, suggesting that cortical and lenticular damage could be attributed to administration of the gas even if hypoxia had not occurred [40]. In the 1950s–1970s, the Swedish neurosurgeon, Nils Lundberg contributed to our understanding of ICP waves [41, 42]. Lundberg worked with Leksell who developed stereotactic equipment, another important advance that called for flexibility and adjustments by the neuroanesthesiologist.

Various anesthetic techniques were advocated for neurosurgery. Willstaetter and Duisburg synthesized the rectal anesthetic tribromethanol (Avertin) in 1923, and Butzengeiger and Eichholtz used it as the sole anesthetic agent for neurosurgical procedures in the same year. Dandy used it in 1931 to reduce intracranial pressure [43]. Leo Davidoff, professor of neurosurgery at the Albert Einstein College of Medicine in New York, and a former resident with Harvey Cushing, considered that the effects of tribromethanol wore off too

Fig. 64.10 The date of this photograph of Andrew Hunter is unknown. (Photograph courtesy of the Wood Library-Museum and the kind assistance of K. Bieterman)

quickly and advised additional infiltration with local anesthetic [44]. Trichlorethylene with nitrous oxide was popular in the British Commonwealth but not the US or other parts of the world. After DE Jackson described the anesthetic effects of cyclopropane in 1934, BB Hershenson used it for neurosurgery in low concentrations in a closed circuit, publishing his experiences in 1942 [45, 46]. The explosive potential of cyclopropane mandated draping the machine and the patient's head with wet towels. Thiopental, synthesized by Volwiler and Tabern in 1930, was introduced into clinical practice by Waters and Lundy in 1934, and advocated for neurosurgery by Shannon and Gardner in 1946 [47]. The popularity of thiopental as a *sole* agent disappeared with the discovery of fluorinated anesthetics.

Hunter (Fig. 64.10) defined anesthesia for neurosurgery in an address to the diploma candidates in anaesthesia (then a 3 year course) at McGill University in 1947 [38]:

“The anaesthetist whose duties bring him into contact with neurosurgery will find that in this specialty the problems which confront him differ markedly from those which he will meet in other fields of his work. No longer is it necessary to provide profound anaesthesia with extreme relaxation. The primary aim is to find some agent which can be given over periods up to 8 hours or longer with complete safety yet have no tendency to increase intracranial pressure. Further, this drug must be without adverse effects on exsanguinated patients and as electrocoagulation will normally be used to arrest haemorrhage, it should for preference be non-explosive.”

A few years later, Hunter, then a visiting anaesthetist at the neurosurgical unit, Royal Infirmary, Manchester, England, noted [48]:

“There is a belief in some quarters that anaesthesia for neurosurgical operations involves merely patience and the use of non-toxic agents.... (But) neurosurgical operations are begun which cannot be completed for reasons directly traceable to the activities of the anaesthetist and...the numbers of such cases varies inversely with his skill...(T)here appear warning signs which only the anaesthetist can detect. If he fails to make the necessary observations...it may well be that the operation which from the surgeon’s point of view was technically perfect, results in the death of the patient.”

Later Twentieth Century

A major advance for neurosurgery, and anesthesia in general, occurred at the start of the second half of the twentieth century. The main anesthetic gases used at the time were chloroform, cyclopropane and diethyl ether, all of which had drawbacks. When given in oxygen, cyclopropane and ether were explosive, an increasing danger as electrical equipment such as diathermy became more common. Chloroform was toxic to the liver. A British chemist, Charles Suckling, worked on fluorinated compounds during World War II, where they were used in the production of high-octane aviation fuel and the purification of uranium-235. In 1951, while working at Imperial Chemical Industries’ (ICI) Central Laboratory in England, Suckling synthesized 12 compounds in a search for a better volatile inhaled anesthetic. Number 9 was halothane [49]. Suckling investigated halothane’s anesthetic action in mealworms and houseflies, then sent it to Jaume Raventos, a Catalan pharmacologist, for evaluation in other animals [50, 51]. After Raventos established its pharmacological properties, Michael Johnstone, an anesthetist in Manchester, England, undertook the first clinical trial in 1956. This systematic study of chemical compounds evaluated with a set of pre-defined characteristics, provides one of the first examples of modern drug design. Halothane was quickly incorporated into neurosurgical procedures. However, a few years later, an anonymous report suggested that halothane caused unacceptable increases in ICP (see below).

Controlled ventilation was not used in neurosurgery until the 1960s. Although it was realized that spontaneous ventilation increased intracranial pressure, anesthetists usually tried to preclude adverse situations by maintaining a good airway and improving venous drainage. One benefit of ether was that carbon dioxide remained normal even at deeper levels of anesthesia [38]. However, the introduction of electrocautery required that the machine, breathing system, the patient’s face and even part of the anesthesiologist, be covered with wet towels. Halothane was nonflammable but caused respiratory depression. Ventilators gradually came into use for long neurosurgical cases. Hyperventilation was shown to cause cerebral vasoconstriction and was soon introduced in the treatment of head injured victims, as a means to quickly lower intracranial pressure [41]. It took more than 40 years to recognize that cerebral hypoxia accompanied the decrease in intracranial pressure and should not be routinely used for these patients [52].

Neuroanesthesia Emerges as a Specialty

Neuroanesthesia as a specialty emerged slowly, although it was becoming increasingly clear that neurosurgery had special requirements, not met by anesthesia as used in the general surgical arena. Until then, anesthesia had remained a field based largely on clinical skills. Now it was to gradually become founded on scientific enquiry. In the late 1950s, at the University of Pittsburgh, Peter Safar focused on cerebrocardiac resuscitation, and established national standards that are required knowledge for all health care workers today [53].

Just as in other fields such as obstetrical, pediatric, and cardiac anesthesia, the need for further study and specialization became desirable. AR Hunter published the first modern day textbook on the subject, in England in 1964, and RGB Gilbert in Montreal published the second in 1966 [39, 54]. In 1960, a Commission of Neuroanesthesia, with anesthetists from 9 countries, was formed in Belgium to further research into intracranial dynamics. In 1961, the World Federation of Neurology sponsored a North American working group on neuroanesthesia, composed of Howard Terry (Mayo Clinic), JD Michenfelder (Mayo Clinic), M Albin (Case-Western Reserve), and chaired by Gilbert (McGill). In 1965, Brown of Edinburgh and Hunter in Manchester established the Neuroanaesthetists’ Travelling Club of Great Britain. In the US, a review article by Michenfelder (Fig. 64.11) and others appeared in *Anesthesiology* in 1969. It established the specialty of neuroanesthesia in North America, coining the term “neuroanesthesiologist” (which of course, remained “neuroanaesthetist” in other countries) [55]. The first US text, now in its fifth edition, was written by Cottrell and Turndorf in 1980, to be followed by *Clinical Anesthesia in*

Fig. 64.11 John (Jack) Michenfelder was 58 when this photograph was taken in 1989. (Photograph courtesy of the Wood Library-Museum and the kind assistance of K. Bieterman)

Neurosurgery in 1984 by Frost, and *Clinical Neuroanesthesia* by Cucchiara and Michenfelder in 1990 [56–58].

In the 1960s and 1970s, centers of research arose on both sides of the Atlantic. In Scotland, neuroanaesthetist Gordon McDowell, collaborated with physiologist Murray Harper at the University of Glasgow to study the effects of anesthetics on intracranial dynamics. Two clinical neuroanesthetists, John Barker and William Fitch, took McDowell and Harper's findings into the operating room, showing that anesthetic agents increased cerebral blood flow and decreased metabolism, effects of particular concern in patients with intracranial mass lesions [59–63]. Bryan Jennett, a neurosurgeon famous for the description of the Glasgow Coma Scale, a prognostic indicator of outcome after head injury, joined the team later. He and Graham Teasdale, both professors of neurosurgery at the University of Glasgow's Institute of Neurological Sciences at the city's Southern General Hospital published the scale in 1974 [64].

An unfortunate outcome of this interdisciplinary collaboration may have been an editorial, published anonymously in the *British Journal of Anaesthesia*, that condemned the use of halothane in neurosurgery, claiming that it increased

intracranial pressure despite hyperventilation [65]. The “evidence” was probably obtained from pressures measured in non ventilated supine cats, but nevertheless the “report” inhibited the use of halogenated agents in neurosurgery for years. Intravenous drugs and nitrous oxide combined with muscle relaxants (and often hyperventilation) again became the agents of choice for neurosurgery.

In the US, two centers established neuroanesthesia as a specialty in the 1960s. At the University of Pennsylvania in Philadelphia, Wollman, Pierce, Alexander, Smith, Dripps, and Cohen, studied the cerebrovascular effects of thiopental, cyclopropane, nitrous oxide, neuroleptic agents, and later, halothane and enflurane [66–68]. They also investigated the effects of hypotension and hyperventilation. At the Mayo clinic, in Rochester, Minnesota, Kai Rehder, a research assistant in physiology collaborated with anesthesiologist Richard Theye and surgeons Kirklin and MacCarty, to study the effects of profound hypothermia during aneurysm clipping [69]. Perhaps more than anyone else, neuroanesthesiologist John Michenfelder fostered neuroanesthesia as a specialty in the US. Working clinically in collaboration with neurosurgeons such as Professor Sundt, and in the laboratory, he assessed cerebral protection produced by hypothermia, anesthetic agents, and other pharmacologic agents such as nimodipine. With other physicians (e.g., Lee Milde and William Lanier) from the Mayo Clinic, he investigated means to measure cerebral blood flow and metabolism [69–73].

Michenfelder believed that decreased metabolism, caused by either hypothermia or agents such as barbiturates, could protect the brain. He experimented extensively on several animal models of ischemia. Working with Steen, he showed in a pig model, that barbiturates did not provide protection in complete cerebral ischemia [74]. However, in animals with normoglycemic levels, outcome was improved. The importance of controlling blood glucose levels has recently been re-emphasized in neurosurgical patients [75]. His findings regarding hypothermia were inconclusive, but studies in this area continued. A recently concluded study, the Intraoperative Hypothermia Aneurysm Study Trial (IHAST) indicated that mild hypothermia did not improve outcome in patients [76]. But, given the fact that cerebral metabolism is reduced, and thus should result in a better outcome, studies with hypothermia to different degrees continue, as shown by the multiple on-going studies referenced in a recently published text on stroke research [77]. Michenfelder was later awarded the ASA Award for Excellence in Research.

In the 1970s, Harvey Shapiro in Philadelphia studied intracranial pressure manipulation associated with ventilatory changes. With Kenneth Shulman (a neurosurgeon), Anthony Marmarou (a physiologist), Kenneth Shapiro (another neurosurgeon) and Frost (an anesthesiologist), Shapiro emphasized the importance of respiratory control in brain injured patients,

specifically showing that hyperventilation per se, did not improve outcome and that improvement in oxygenation by application of positive end expiratory pressure would reduce raised intracranial pressure [78, 79]. Compartmental analysis of the intracranial space allowed conversion of the compliance curve to a more readily understood straight line [80, 81]. Pre and post pressure measurements after injection or subtraction of small amounts of fluid from the intracranial space could, depending on the amount of increase or decrease, determine if the patient was in a potentially dangerous part of the curve. Harvey Shapiro also expanded neuroanesthetic management to intensive care [82, 83]. An intracranial pressure society was established with neurosurgeons from the UK (Douglas Miller) and the US (Kenneth Shulman), but the untimely deaths of the two principle investigators led to the demise of this small organization.

By the 1960s, neuroanesthesiology had developed as a specialty in the US. Standard techniques for measurement of cerebral blood flow, cerebral metabolic rate, intracranial pressure and neurochemical moieties were introduced. The physiologic basis of cerebrovascular dynamics was established and instrumentation design leapt ahead. Multidisciplinary research groups in Europe and North America shared findings. In Japan, Takeshita studied the effects of anesthetics on cerebral blood flow and metabolism [84–86]. His life long interest in brain death and resuscitation aided organ transplantation by better defining donors.

While visiting Pittsburgh in 1972, Thomas Langfitt (Professor of Neurosurgery at the University of Pennsylvania) met with anesthesiologist Maurice Albin, to discuss the formation of an organization for neuroanesthesiologists and neurosurgeons. Working with James Harp (Chair of Anesthesia at the University of Pennsylvania), they compiled a list of possibly interested parties. An organizational assembly of 36 anesthesiologists and 4 neurosurgeons met in June 1973, in Philadelphia, to form the Neurosurgical Anesthesia Society (NAS) [87]. The Society officially met on 7 October 1973, during the annual meeting of the American Society of Anesthesiologists in San Francisco (annual dues were established at \$15.00). Michenfelder was elected first president of the fledgling Society of Neurosurgical Anesthesia and Neurological Supportive Care, an immediate name change to acknowledge incorporation of more diverse disciplines. Langfitt included the society in the programs of the Harvey Cushing Society (subsequently named the American Association of Neurologic Surgeons), cementing the collaborative spirit.

Central nervous system trauma was also soon seen as the bailiwick of the neurosurgical team. Head injury kills more young people than any other cause. During the 1970s and early 1980s the National Institute of Health funded four centers (in the Bronx, Houston, San Diego, and Minneapolis/St Paul) to study traumatic brain injury. This multi-institutional study supplied much information, and indeed several subsequent advances have been made. The conclusions included

the need to rapidly transfer the injured patient to a tertiary care center (the principle of swoop and scoop took precedence over stay and play), and to avoid hypoxia, hypotension and hyperventilation. Increasing age, male gender, cardiothoracic injury and drug abuse increased risk. The concept of the “Golden Hour” is credited to R Adams Crowley but may have been derived from French military data acquired in World War I. Crowley taught that “There is a golden hour between life and death. If you are critically injured you have less than 60 minutes to survive. You might not die right then; it may be three days or two weeks later—but something has happened in your body that is irreparable [88].” Philip Gildenberg expanded the concept to include brain injury. Gildenberg, a neurosurgeon with a special interest in anesthesia (perhaps because of his association with the anesthesiologist Burnell Brown in Tucson) showed that immediate tracheal intubation improved survival. Securing the airway within 1 hour of severe brain injury could reduce mortality from around 38 to 22%, a finding repeatedly confirmed [89, 90].

During the latter part of the twentieth century, technical advances furthered developments in instrumentation. Air embolism, which Gildenberg had earlier quantified, could be detected by a Doppler monitor, transesophageal echocardiography and end tidal CO₂ measurement [91]. In the late 1960s, a system to monitor spinal cord function was prompted by the risks of using Harrington rods during curvature correction for patients with scoliosis. A neurosurgeon, Brodkey, summed the cortical expression of distal peripheral nerve stimulation, a process reported by Dawson in 1947 [92–94]. Combining this knowledge with that of a biomedical engineer, RH Brown, working in the laboratories of Frankel and Burstein at Case Western Reserve, showed that pressure on the cord, time and blood pressure were all critical variables. A stand alone, portable spinal cord monitoring system was produced, at first a 4 channel system that soon expanded to 8 channels with all data stored on a tape for later analysis.

Electroencephalographic monitoring had been advocated as early as 1937, but it was not until Stockard and Bickford described compressed spectral array in 1972, that the patterns became comprehensible to most anesthesiologists [95]. Betty Grundy, an anesthesiologist who was one of the pioneers in spinal cord monitoring, popularized evoked potential monitoring as a standard for anesthesiologists, using the technique Dawson described in 1947 [96].

From the 1950s (and earlier) to the 1980s, posterior fossa procedures and decompressive craniotomies for trigeminal neuralgia (the Jannetta procedure) might be performed with the patient in the sitting position (Fig. 64.12) [97, 98]. It became clear that when veins were opened above the level of the heart, air could be entrained. Clinical and laboratory studies identified the pathophysiology, treatment and preventative measures [99, 100]. Because of the potentially catastrophic effects of entrained air,

Fig. 64.12 A semi-sitting position produced by adjustment of the operating table, the use of pillows and tape, and the pull of a wire connected to the Crutchfield caliper attached to the patient's head allows access to the posterior fossa [93]. It also facilitates the potentially lethal intrusion of air into veins opened by the act of surgery. (Photograph from the Neurosurgical Department, St Bartholomew's Hospital, probably in the 1950s)

neurosurgeons placed their patients in the lateral position. The sitting position fell out of favor. Recently however, the sitting position has again been used for awake placement of deep brain stimulators. Although the patient does not breathe spontaneously, air can easily be sucked into opened veins. As Professor Albin remarked "We should listen to the drumbeat of history [101]."

In 1972, only 6 anesthesiology training programs in the US and Canada had dedicated neuroanesthesia divisions or sections. Today, the Residency Review Committee requires that all programs provide training in neuroanesthesia. All academic centers have divisions of neuroanesthesia. In 1976, the American Society of Anesthesiologists recognized neuroanesthesia as a subspecialty society. In 1989, the *Journal of Neurosurgical Anesthesiology*, under the editorship of James Cottrell, grew out of the Newsletter of the Society of Neurosurgical Anesthesia and Critical Care. The journal was listed in the Index Medicus and Current Contents by 1993. It is the official journal of 10 societies of neuroanesthesia around the world (including the US) with an Impact Factor greater than 2.

Women in Neuroanesthesia

Female neuroanesthetists have a major presence in the specialty [102]. Hugh Cairns, who had trained with Harvey Cushing, realized the importance of a specialist neuroanesthetist. In 1933, he recruited Olive Jones, a 1928 graduate of the London School of Medicine for Women, as his anesthetist at the London Hospital. She was not only the first neuroanesthetist but also the first full time salaried anesthetist in

the UK. She remained as the sole neuroanesthetist in Oxford until 1967. At the initial meeting of the Neuroanesthetists Travelling Club in 1965, 4 of the 33 neuroanesthetists were women (Olive Jones, Aileen Adams, Betty Everett and Jean Horton). By 1993, 38 of the club's 140 members were women.

Credit must go to two Italian physicians from Milan, Marie Marrubini and Marina Rossande, for the development of neurologic intensive care and the management of severe head injuries. In Australia, anesthesiologists Nancy Edwards and Tess Brophy who worked with the neurosurgeon, Ken Jamieson, pioneered management of head injuries in the 1970s–1980s. Female contributors to advances in neuroanesthesia in the US include Jane Matjasko (a founding member of the Society of Neurosurgical Anesthesia and Neurological Supportive Care and the 10th president), Phillipa Newfield (14th president, 1987–8, of the Society of Neurosurgical Anesthesia and Neurological Supportive Care and author of her *Handbook of Neuroanesthesia*, now in the 4th edition), Betty Grundy, Judith Donegan, Elisabeth Abramowicz, Audree Bendo, Rosemary Hickey, Patricia Petrozza, Karen Domino, and Verna Baughman. As Aileen Adams noted, "one of the advantages of being a woman in a man's world is that you are noticeable [102]". I heartily agree.

A Reflection

Neuroanesthesia is less than 130 years old but the practice evolved over thousands of years. Advances resulted from collaboration with other specialists from different fields including surgery, physiology, pharmacology and radiology. Questions regarding precise monitoring of intracranial dynamics, brain survival after head injury, spinal cord regeneration, identification of serum markers of cerebral damage, and long term cerebral effects of anesthetic agents remain to be answered. If progress continues as it has in the past century, these quandaries may soon be solved.

George Gregory

Summary

Before anesthesia's discovery, children were forcibly restrained during surgery. The introduction of ether in 1846 and chloroform in 1847 quickly led to their use in children. Most nineteenth century pediatric surgery treated minor ailments. The first "giants" initiating development of pediatric anesthesia, emerged in Canada, the US and the UK after World War I. Robson, the father of pediatric anesthesia, became Anaesthetist-in-Chief at Toronto's Hospital for Sick Children. He defined the major problems extant in pediatric anesthesia—and their solutions. Betty Lank, chief Nurse Anesthetist at Boston Children's Hospital, gave anesthesia for several surgical firsts. Robert Smith became head of pediatric anesthesia at Boston Children's Hospital in 1945, noting that Lank "made me a pediatric anesthesiologist." In 1937, Ayre in the UK described his simple "T-piece" and in 1966, Jackson-Rees in the UK added an open-ended bag to Ayre's T-piece. The T-piece required high gas inflows, and thus, gradually gave way in the last half of the twentieth century to rebreathing anesthesia circuits with CO₂ absorption. The US adopted rebreathing circuits early.

In 1952, Deming showed that young children required more anesthesia than older patients, but as late as 1975, some surgeons might operate on infants (e.g., for PDA ligation) receiving little or no anesthesia, believing they felt no pain. In 1987, Redbook magazine put the lie to this belief and changed the practice.

Increasingly, surgery required better airway control. In 1882, New York surgeon O'Dwyer put a metal tube into the glottis to relieve airway obstruction in children with diphtheria. Budin of Paris developed the first neonatal intensive care unit (NICU) in the 1890s. In 1939, Gillespie invented a pediatric laryngoscope. Miller improved this design in 1946, and "Miller" laryngoscopes became fixtures. In 1963, Allen at the Children's Hospital in Adelaide, Australia, introduced nasotracheal intubation for croup, enabling prolonged airway management. To minimize deadspace, Soucek and Rendell-Baker made masks in 1962 that closely fit the faces of children of different ages. Later came the laryngeal mask airway designed by Brain in 1987. In the past 15 years fiberoptic devices facilitated tracheal intubation of infants and children.

The first Pediatric Anesthesia textbook "*Anesthesia in Children*" was published in the UK in 1923. "*Précis Clinique et Opératoire de Chirurgie Infantile*" followed in France in 1925. In 1948, Leigh and Belton wrote the first US book. In 1950, Smith wrote his comprehensive textbook, "*Anesthesia for Infants and Children*". Gregory's 1983 "*Pediatric Anesthesia*" was the first physiology-based textbook.

Societies formed to advance pediatric anesthesia. The Association of Paediatric Anaesthetists was established in the UK in 1973. The Anesthesia and Critical Care section of the American Academy of Pediatrics was established in 1966, and the Society for Pediatric Anesthesia in 1985 in North America.

Introduction

Several reports describe the early chronologies of pediatric anesthesia [1–3]. The present report attends briefly to these, but focuses more on advances that facilitated the modern surgical care of sick infants and children, advances that led to modern pediatric anesthesia.

Surgery Before and soon After the Discovery of Anesthesia

Before the discovery of anesthesia, most surgeries were quick, and brutal [4]; an amputation took a minute or two. Lucky children sucked whisky or poppy juice for pain relief. Unlucky children underwent trephination, extirpation of bladder stones, probing of an imperforate anus, inguinal hernia repair, and circumcision while forcibly restrained. Miraculously, longer procedures were done without anesthesia: cleft lips had been repaired as early as 390 CE. "Anesthetic" remedies for both adults and children were ineffective in the west. The use of scopolamine-like herbal preparations may

Table 65.1 Surgeries for which John Snow anesthetized infants and children

	General	Dental	Ophthalmologic	Orthopedic	Plastic	Urologic
Number (Percent)	35 (8.9%)	43 (10.9%)	24 (6.1%)	118 (30.0%)	133 (33.8%)	40 (10.2%)

Table 65.2 Deaths described in Snow's casebook. (From [6] with permission)

Patient age	Reason for anesthesia	Comment
3 yrs	Pertussis	Anesthetized for treatment of pertussis—died 1 day post anesthesia
2 yrs	Status epilepticus	Weak, rapid pulse during anesthesia. Died 1 hr after awakening from anesthesia, still in status
1 yr	Meningitis	Seizures and increased intracranial pressure pre-anesthesia. Died with fixed and dilated pupils
16 yrs	Above knee leg amputation	Hemorrhage during and after surgery. Died 4 days after surgery
17 yrs	Typhoid fever	Died post anesthesia—possibly from dehydration

have enabled Japanese surgeons to perform surgery, relying on sedation and amnesia.

Crawford Long (1815–1878) provided the first pediatric general anesthetic, giving ether in 1842 to an eight-year-old child for amputation of a toe. He also anesthetized several adults but waited seven years to report his discovery [5], thereby giving priority in the discovery of anesthesia to William Morton, a dentist who *publicly* demonstrated the anesthetic effectiveness of ether at the Massachusetts General Hospital 16 Oct 1846. The next year in Boston, approximately 80% of children undergoing surgery received ether [3].

James Simpson (1811–1870) discovered the anesthetic effects of chloroform in 1847, and John Snow (1813–1858) used both ether and chloroform (mostly chloroform). Between 1846 and 1858, Snow anesthetized 393 English children (Table 65.1), 186 of whom were less than 1 year of age [6]. Not surprisingly, none had thoracic or abdominal operations. Such procedures were rare at any age.

Amazingly, 98% of Snow's patients survived. Of the five who died, only one underwent surgery, and that death resulted from uncorrected hemorrhage and occurred several days after the surgery (Table 65.2). The other patients had anesthesia for reasons that we would smile upon today.

As Table 65.2 indicates, anesthetic failures joined successes. Shortly after the introduction of chloroform, 15-year-old Hannah Greener died during removal of a toenail under chloroform, the first reported anesthetic death in a child [7]. She had survived a previous anesthetic with ether.

John Snow's remarkable safety record overshadowed that of his peers, both because of his genius and because, in contrast to the occasional anesthetist, he practiced anesthesia nearly full time. Today, 6.5 children die per 100,000 anesthetics (excluding cardiac surgery) [8]. Under Snow's care, 20 per 100,000 died—in a less than friendly environment—mostly homes or surgeon's offices, and without monitoring, intravenous fluids, antibiotics, or postoperative pain relief [6]!

Like adults, children benefited from the introduction of anesthesia. Surgeons were not rushed by patient screams, and previously impossible surgical procedures were now possible: repair of congenital anomalies, gastrostomies, excision of tumors, and increasingly intricate orthopedic procedures. However, for a half-century, surgeons rarely entered the thoracic or abdominal cavities (e.g., see Table 65.1) because of unacceptable post-operative infection rates and pulmonary failure.

For more than a century after the discovery of anesthesia, ether or chloroform given by “rag and bottle” were the primary anesthetics administered to children. Ethyl chloride was a minor addition. It was introduced into Europe as a general anesthetic in 1894, and spread to Britain, the British Commonwealth, and the US in the beginning of the twentieth Century. It was commonly used for dental anesthesia, especially in children (Fig. 65.1). Although Snow recognized the great advantage of control over the concentration of anesthetic delivered, the general use of reliable versions of anesthetic delivery was delayed for a century. Precision vaporizers (e.g., the Copper Kettle) appeared in the 1950s, and radically increased the control over and safety of anesthetic delivery.

Ether stimulated ventilation, an advantage that Snow recognized [9] and Gregory et al. quantified 113 years later [10]. The adult ether masks commonly applied to children, imposed dead space and thus increased rebreathing and carbon dioxide (hypercarbia), and decreased oxygen (hypoxemia). Better to use ether than chloroform since the latter depressed breathing leaving the child more vulnerable to oxygen lack and rebreathing of carbon dioxide. In the 1890s, the concurrent administration of oxygen with ether allowed anesthetists to minimize hypercarbia and hypoxia. Frederick Hewitt (1857–1916) thought this especially helpful for children.

By the early nineteenth century, physicians recognized that children differed from adults in more than size. This recognition led to the development of Children's hospitals

Fig. 65.1 Rupert Hornabrook (Australia's first full-time anesthesiologist) produces anesthesia with a spray of ethyl chloride to a cloth held to a child's face. (Courtesy of Rod N. Westhorpe and the Geoffrey Kaye Museum of Anaesthetic History)

(Table 65.3) and associated specialties. Just as it took time for anesthesia to be recognized as a medical specialty in its own right, pediatric anesthesia did not develop as a subspecialty until the first half of the twentieth century. Until 1900, it was likely that the hospital physician, the surgeon's assistant, the family doctor or a nurse would administer the anesthetic given to a child.

Most pediatric surgery in the nineteenth century was for minor ailments. Intrathoracic and intra-abdominal surgery awaited the invention of antisepsis and asepsis, developments of the late 1800s. Asepsis and antibiotics were as important to the surgical care of children as they were to adults. Without control and treatment of infections, pediatric surgery (and hence anesthesia) could not advance, especially since the immune system of neonates and infants is less developed than that of older patients [11]. Before asepsis, infection-induced mortality of children following surgery sometimes exceeded 90%.

With the development of the subspecialty of pediatric anesthesia, it became clear that patients cared for by pediatric

anesthetists had fewer complications and fewer anesthesia-related deaths than patients cared for by adult anesthetists [12, 13]. Those caring for many patients with similar problems provided better results than those caring only occasionally for such patients. Today, children's hospitals in the United States, and elsewhere, are the backbone of pediatric care and research.

Adventurous Surgery

Two congenital anomalies awaiting anesthesia and asepsis for their successful repair were omphalocele (a large midline abdominal hernia) and gastroschisis (an intrauterine vascular accident that produces a large lateral abdominal hernia). For both anomalies the abdominal contents protrude through the abdominal wall at birth. These lesions are easily repaired and today more than 95% of such infants survive. In the early 1800s, William Hey (1749–1819) and James Hamilton (1749–1835) accomplished the first successful repair, doing so without anesthesia or antibiotics.

In 1889, Joseph O'Dwyer of New York City failed in his attempt to repair an infant's congenital diaphragmatic hernia (CDH). In 1905, Lothar Heidenhain (1860–1940) in Germany successfully repaired the CDH of a 9-year-old. Repair of CDH then and now exacted an invariant heavy price. Mortality exceeded 50% in 1925 and hasn't changed much since, despite Intensive Care Nurseries (ICNs), mechanical ventilation, and extracorporeal membrane oxygenation (ECMO) [14].

In 1939, William Ladd (1880–1967), in Boston, was the first to repair a tracheo-esophageal fistula (TEF; a connection between the trachea and esophagus), another usually lethal congenital lesion [15]. Ladd favored a two-stage approach (he first closed the fistula and fed the child through a gastrostomy until the child had grown. He later repaired the esophageal atresia). In 1941, Cameron Haight (1901–1970) of the University of Michigan ligated the fistula and did a primary repair of the esophagus as a single procedure [16], inventing the treatment used today. Ether or chloroform given via mask to spontaneously breathing patients supplied the anesthesia for early TEF repairs. Mortality exceeded 70%. Today nearly all these patients survive if they have no other congenital anomalies.

In 1946, Alfred Blalock (1899–1964), a surgeon, and Helen Taussig (1898–1986), a pediatrician at John Hopkins Medical Center, devised an operation to treat infants with Tetralogy of Fallot. Tetralogy of Fallot is a congenital defect that diverts blood flow from the lungs, limiting oxygenation of the arterial blood and resulting in a "blue baby" [17]. Merel Harmel (1917–) and Austin Lamont (1905–1969) anesthetized the first 100 of these patients [18], doing so with minimal monitoring (they felt the pulse, counted respiration

Table 65.3 Founders and founding years for early pediatric hospitals

Founded	Hospital	Founder(s)
1778	Hôpital Necker—Enfants Malades (Paris)	Madame Necker
1802	Hospital des Enfants Malades (Paris)	Conseil général des Hospices
1821	National Children's Hospital (Dublin)	Henry Marsh, Philip Crampton Charles Johnson

and occasionally measured blood pressure in most cases). Some patients breathed spontaneously via a facemask, even when the chest was open! Patients recovered in the operating room and were cared for on the ward after surgery. Mortality was remarkably only 25%, a testimony to the skills of the anesthetists and surgeons—and the resilience of young children!

For decades, surgeons sought to repair congenital abnormalities in utero [19], thinking it would improve outcomes. Target lesions included diaphragmatic hernias, teratomas, anomalies of the lung (e.g., cysts), and possibly cleft lips. In utero repair of cleft lips might have the great advantage of leaving no scars. But can we anesthetize the mother without excessive depression of the fetus? Biehl et al. showed that the maternal MAC was considerably greater than the fetal MAC (e.g., see Fig. 65.2) [20]. And fetal surgery may precipitate premature labor—a disaster at 20 weeks gestation because birth at this age is not compatible with extrauterine life. Fetal surgery remains a tantalizing possibility

for several lesions, and a success for others (e.g., twin-twin transfusion).

Giants Appear

With the end of World War I, came the appearance of the first giants in pediatric anesthesia, anesthetists who prompted the development of the discipline. These included Charles Robson (1884–1969), Betty Lank (1904–2002), Robert Smith (1913–2009), M Digby Leigh (1904–1975), M Kathleen Belton (1916–1980), C Ronald Stephen (1916–2006), Philip Ayre (1902–1980), and Gordon Jackson-Rees (1918–2001; Fig. 65.3). Beyond a focus on children, all of these clinically skilled anesthetists shared a love of teaching, and several advanced the science of pediatric anesthesia.

Robson, considered the father of pediatric anesthesia, returned from World War I to become Anaesthetist-in-Chief at the Hospital for Sick Children in Toronto. He defined the major problems extant in pediatric anesthesia—and their solutions [21]: children differed from adults in their physiology and their response to drugs (e.g., children “take more anesthetic ... than do adults” a fact later quantified) [22–24]. Children, he said, require anesthesia equipment designed for their needs (what a concept!), and in conflict with beliefs of some surgeons, he argued that operating on a child without adequate anesthesia was “vivisection”.

Robson advocated simple vital aspects of pediatric care, including recognition that induction of anesthesia with an inhaled anesthetic required maintenance of a patent airway. He claimed that “starvation” prior to surgery led to acidosis, and he fed children “strained gruel” up to four hours beforehand, withholding food after that to minimize vomiting, aspiration, and possible lung injury or death. He warned that “accident cases” and patients in pain took longer to empty their stomachs and were at greater risk of vomiting and aspiration. He suggested the insertion of a gastric catheter to relieve the gastric distention of patients who had pyloric stenosis (a constriction at the exit from the stomach). He administered ether as his anesthetic of choice, by open drop or by insufflation via an “ether hook.” (i.e., he “blew” ether into the mouth).

Fig. 65.3 Gordon Jackson-Rees (Courtesy of Rod N. Westhorpe)

He did not hesitate however, to use tracheal intubation, especially when using cyclopropane, a respiratory depressant, for complicated cases.

A little south of Robson, William Ladd (1880–1967) was busy in Boston Children’s Hospital developing Pediatric Surgery (he was its “father”). Betty Lank, the Chief Nurse Anesthetist at Children’s from 1936 to 1957, enabled Ladd’s success [25]. She adapted Riva Roca’s measurement of arterial blood pressure to children, initially making the blood pressure cuffs herself. She designed and had built, size-appropriate facemasks and breathing bags for children—later produced by Foregger [26]. She had anesthetic firsts to brag about: Ladd’s first patient for tracheo-esophageal fistula repair in 1939; Gross’ (1905–1988) first patient for ligation of a patent ducts arteriosus in 1938 [27], and his first patient for repair of a coarctation (narrowing) of the aorta in 1945 [28]. She was the first to administer cyclopropane to children in the United States. She usually gave ether or cyclopropane via mask, even to prone patients (something that would terrify today’s anesthetist).

Smith learned anesthesia in a three-month US Army course during World-War II. In 1945, he arrived at the

Fig. 65.4 Ayre’s “T”-piece consisted of a T connected to the tracheal tube at P and to a reservoir tube, R. Gas containing anesthetic entered the system through F. Intermittently occluding the otherwise open end of R caused ventilation of the patient’s lungs. (www.frca.co.uk/images/ayre1.gi. Accessed 31/03/2010)

Boston Children’s Hospital “knowing very little” about pediatric anesthesia (Personal communication), his previous patients having been soldiers. Smith said Lank “made me a pediatric anesthesiologist”. His first rate training program in Pediatric Anesthesia influenced the development of pediatric anesthesia worldwide.

Leigh, another early force in pediatric anesthesia, asked difficult, intriguing questions. He contributed a one-way valve that reduced the amount of carbon dioxide re-inspired by children during surgery. His textbook “*Pediatric Anesthesiology*,” written with Belton in 1948 [29] preceded Smith’s book (above) and contained much of what we “know” today, albeit based on an enormous amount of informed speculation.

A fourth early North American (another Canadian) pioneer of pediatric anesthesia—also a product of World War II—was Stephen. An outstanding teacher, he published a small textbook “*Essentials of Pediatric Anesthesia*” in 1954 [30]. He was among the first to (appropriately) raise concerns regarding the effects of operating room temperatures on patient well being. Like Leigh, he developed a valve to prevent carbon dioxide rebreathing.

The first textbook of Pediatric Anesthesia “*Anesthesia in Children*” was published in Great Britain in 1923 [31]. The next such book, “*Précis Clinique et Opératoire de Chirurgie Infantile*” was published in France 1925 [32]. Following the publication of Leigh and Belton’s book, in 1950, Smith wrote the first comprehensive textbook on “*Anesthesia for Infants and Children*” and therein, concisely described how to provide anesthesia for infants and children undergoing various surgical procedures [33]. Gregory’s textbook “*Pediatric Anesthesia*” was the first physiology-based pediatric anesthesia textbook [34].

The increasing interest in pediatric anesthesia was not confined to North America. The Englishman, Philip Ayre, invented a simple system for delivery of anesthesia to children undergoing craniofacial surgery [35]. His “T”-piece (Fig. 65.4) avoided the imposition of increased resistance to breathing, particularly important for infants having cleft lip and palate surgery, and allowed him to get his hands out of the surgical field.

Ayre was a master pediatric anesthetist. Like many of his patients, he had a cleft lip and palate, badly repaired, and he

spoke with a “honking” sound that adults found difficult to understand. But his voice apparently mesmerized children, especially during induction of anesthesia, distracting them from the vapors they breathed.

Electronic versions of Ayre’s simple device underlie many modern pediatric ventilators. Gordon Jackson–Rees (1918–2001) added an open-ended bag to Ayre’s “T”-piece; the bag could be used to control or assist ventilation [36]. We used this modification to provide Continuous Positive Airway Pressure (CPAP) and improve the outcome of premature infants who had hyaline membrane disease (HMD) (See below) [37].

Control of Breathing

Anesthetists recognized early on, that airway obstruction commonly occurred with induction of anesthesia, particularly due to the tongue falling to the back of the oropharynx, and collapse of the upper airway. In 1847, Francis Sibson (1814–1876) applied a jaw thrust (lifting the jaw at its angles) to treat this problem [38], and Snow also suggested maintaining light anesthesia and jaw thrust. In 1908, Frederick Hewitt made an oropharyngeal airway roughly similar to those used today to treat this problem [39].

The increasing demands of surgery, particularly surgery of the chest, abdomen, and cranium, required better control of the airway and a need to protect the airway from contamination with blood, pus, and gastric contents. It required that the anesthetist ensure adequate ventilation and oxygenation. The solution lay in passage of a tube into the trachea, and in this, both surgeons and anesthetists led the charge. In 1882, Joseph O’Dwyer (1841–1898), a New York surgeon, used one of the first “tracheal tubes” (really a tube into the larynx) when he inserted a metal tube into the glottis of children to bypass the pseudo membranes of diphtheria that caused glottic obstruction and death [40]. He adapted the positive pressure artificial respiration apparatus developed by his colleague George Fell, by replacing Fell’s mask with O’Dwyer’s glottic tube. He was thus able, when necessary, to ventilate the patient’s lungs with air supplied by a foot-operated bellows (Fig. 65.5).

After initial failure with a spring-loaded device intended to insert his tube into the glottis of children, O’Dwyer placed the tube blindly by lifting the epiglottis with a finger, sliding the tube along that finger and into the glottis, a technique still occasionally used today (Fig. 65.6).

The Scottish surgeon William Macewen (1848–1924) was the first to use tracheal intubation to deliver anesthesia. He inserted a tube into the trachea of a patient with tongue cancer in 1878, to facilitate excision of the mass [41]. In the early twentieth century, surgeons Charles Elsberg (1872–1948) of New York and Rudolph Matas (1850–1967) of New Orleans,

Fig. 65.5 The Fell-O’Dwyer apparatus. The O’Dwyer tube was held in the operator’s hand and passed into the glottis. To ventilate the patient’s lungs, a bellows was compressed with the foot and the opening on top of the tube occluded with the thumb. During exhalation, the thumb was removed and gas exited the lungs through the opening in the top of the tube. (Courtesy of AATS: Founders)

used blind tracheal intubation and manual ventilation of the lungs to facilitate thoracic surgery. At approximately 1920, Ivan Magill (1888–1996) and Stanley Rowbotham (1878–1979) developed laryngoscopes that allowed anesthetists to visualize the glottis of children [42]. Despite the availability of laryngoscopes and tracheal tubes, neonates and infants seldom underwent tracheal intubation until the advent of pediatric thoracic and cardiac surgery, and even then many were anesthetized with open drop ether! Early tracheal tubes were stiff, often made of hard rubber or latex covered spiraled wire, thick-walled devices that increased resistance to gas flow and caused airway damage.

Cole seemingly solved the resistance problem by making tracheal tubes with a short, narrow distal end that inserted into the trachea. This short end connected to a wide bore, low resistance tube [43] (Fig. 65.7). The shoulder at the junction of the larger and smaller tubes sat on the vocal cords and reduced the incidence of bronchial intubation. However, in

Fig. 65.6 In the “digital” method of tracheal intubation, the index finger was passed into the mouth and the epiglottis was lifted (note identity to the approach used with the MacIntosh blade). A tracheal catheter was passed along the finger and into the trachea. The author was taught this method of tracheal intubation as a medical student before a full time anesthetist (Sol Shnider—1929–1994) directed anesthesia in the delivery room at UCSF and taught us to use a laryngoscope to visualize the glottis for tracheal intubation. (<http://www.hmc.org.qa/mejem/mar2002/comm/comm1.htm>. Accessed 31/03/2010)

1969, Bernard Brandstater (1929–) reported that downward pressure could force the upper wide portion of the tube between the vocal cords and damage the larynx [44].

Brandstater was one of the pioneers of prolonged intubation in infants. While working at the American University in Beirut in the late 1950s, he achieved encouraging results in 40 infants with tetanus, intubating the trachea with soft polyvinyl chloride tubes, and ventilating their lungs with room air. He used a Harvard sine wave pump from the research laboratory, carefully covering the plaque, which read “For use in laboratory animals only”. In 1963, Tom Allen (1923–2011) at the Children’s Hospital in Adelaide, Australia, introduced prolonged nasal intubation as an alternative to tracheotomy for croup, and his paper with Ian Steven (1926–2006), published in 1965, paved the way for prolonged airway management in children [45, 46].

Thin-walled plastic tracheal tubes replaced Cole tubes in the 1970s. These low resistance tubes tempted practitioners to leave tubes in the trachea for protracted periods to facilitate mechanical ventilation and avoid tracheotomy. Early on, however, practitioners discovered yet another problem: plasticizers in the tubes damaged the trachea and caused subglottic stenosis (narrowing of the trachea) [47]. Removing the plasticizers allowed safer prolonged tracheal intubation.

In 1939, Noel Gillespie (1904–1955) developed a pediatric laryngoscope. Robert Miller (1906–1976) improved on this design in 1946 [48], and “Miller” laryngoscopes became fixtures

Fig. 65.7 The Cole tube had a wide (low resistance) upper part and a short narrower (higher resistance) lower portion; the short portion was placed into the trachea. The beveled portion rested on (and could distend) the vocal cords. (old.cvm.msu.edu/services/aneth/docs/cat-intu/. Accessed 31/03/2010)

in delivery rooms, neonatal intensive care units, and operating rooms throughout the world. Other designs specifically tailored to pediatric practice were subsequently introduced. In the past 15 years, newly developed fiber optic intubation equipment has proven useful for guiding tracheal intubation of infants and children with upper airway anomalies.

The T-Piece

Before 1937 it was difficult to ventilate the lungs of neonates undergoing head and mouth surgery because the anesthetist competed with the surgeon for airway space. As noted earlier, Ayre solved this problem with his T-piece (Fig. 65.8). He achieved induction of anesthesia via a mask and then intubated the trachea and attached his device to the tracheal tube, thereby removing his hands from the surgical field and out of the “cranky surgeon’s” way [49]. Ayre believed this approach decreased pallor, tachypnea (rapid breathing), and respiratory distress during and immediately after surgery. His elegantly simple device imposed little resistance to spontaneous breathing. The T-piece had another virtue—it could be used to ventilate the lungs of patients by intermittently obstructing the gas outflow from the T-piece. In 1963, Keuskamp (1915–1992) of Amsterdam, devised the first pediatric ventilator, the LOOSCO, using a solenoid to intermittently “thumb” the gas outlet from what effectively was an Ayre’s T-piece [50]. People called this machine the “electronic thumb”. Some modern infant ventilators use this T-piece principle.

Jackson-Rees (1918–2001) modified Ayre’s T-piece by adding a bag to the expiratory tube so that he could ventilate

Fig. 65.8 The upper picture is a drawing of the Jackson–Rees modification of the Ayre’s “T”-piece. We added an under water “pop off valve” which set an upper limit to the pressure that could be applied and thus minimized the incidence of pneumothorax. The lower picture shows this device applying CPAP to a preterm baby

System for applying CPAP through an endo-tracheal tube

Infant with HMD treated with CPAP

the children’s lungs by squeezing the bag. This modification of the Ayre’s T-piece facilitated hyperventilation, which was part of Jackson-Rees’ “Liverpool Technique” (see below). We used Jackson-Rees’ modification of the Ayre’s T-piece to create positive end-expiratory pressure while applying CPAP to the lungs of premature infants (Fig. 65.8) [37].

Like all of the Mapleson rebreathing non-absorption circuits (A to E), versions of the Ayre’s T-piece (Mapleson E, and the Jackson-Rees modification, often referred to as Mapleson F) are generally used with high gas inflows, often at least twice the patient’s minute ventilation, in order to prevent accumulation of CO_2 . This wastes potent inhaled anesthetic and carrier gases (air, oxygen, N_2O). And, unless the gases are scavenged, they contaminate the operating room with anesthetic. The relatively recent application of end-tidal gas monitoring allows anesthesiologists to administer the minimum fresh gas flow needed to maintain the desired end-tidal CO_2 , thereby reducing some of the gas wastage.

Today, in most major pediatric centers in developed countries, anesthesia circuits used in children, even in tiny premature babies, are of the “circle” or rebreathing type. The circuits are incorporated into complex modern anesthesia machines with accurate monitoring, largely eliminating wasted gas. The Jackson–Rees modification of the T-piece and the “Liverpool Technique” are still commonly used, however, in developing countries that cannot afford anesthesia machines. They also cannot afford end-tidal CO_2 monitors. Consequently they use

high gas flows, and waste large volumes of fresh gas and anesthetic, which they also cannot afford.

Children’s Masks

The use of traditional adult masks for delivery of anesthetic to children, even when reduced in size, resulted in a large volume of “dead space” within the mask. When the child was anesthetized and breathed spontaneously, this could lead to inadequate oxygenation and accumulation of carbon dioxide. In 1960, two pediatric anesthesiologists were requested by a newly appointed pediatric surgeon to anesthetize his neonatal patients for inguinal hernia surgery, without intubation. The inadequacy of the available masks led Donald Soucek (1935–) and Leslie Rendell Baker (1917–2008) to make alginate casts of the faces of children of different ages, while intubated and anesthetized, and develop the pediatric anesthesia mask that became used universally [51]. The advantage of these masks was that they had very little dead space and reduced rebreathing and hypercarbia.

Anesthesiologists sought ways to avoid intubation of the larynx and trachea, because of the “delicacy” of these structures. Archie Brain (1942–) accomplished this in 1987 when he introduced the laryngeal mask airway (LMA) as an alternative to tracheal intubation. The mask fits over the glottis (the opening to the larynx), and connects to a wide tube [52].

These devices minimize stimulation of the trachea but in the lightly anesthetized patient still can cause laryngospasm. One day I wondered what the dead-space (volume of inhaled gas that does not take part in alveolar ventilation) was for LMAs of different sizes so I took LMAs and determined the amount of water the mask and connecting tube could contain. The volume of the mask and tube in infants and young children was large. Thus, these devices impose significant amounts of dead-space, making their use less desirable in patients with increased intracranial pressure or respiratory failure. Another problem with the smallest size masks is that they are merely a small version of the adult mask and do not take into account the anatomical difference in the larynx of neonates and young children. This makes seating the masks properly over the larynx uncertain.

Monitoring

In the 1850s, John Snow taught anesthetists to feel the pulse of patients and to observe their skin color, and breathing patterns and rates to detect anesthesia-induced depression of the cardiovascular and respiratory systems [9]. He appreciated that a smaller margin of safety existed for infants, and that it was easier to over anesthetize them and produce apnea, especially when using chloroform. It was this recognition and his exceptional care that allowed him to have excellent outcomes. For the next century, monitoring consisted of palpating the pulse and counting respirations. By the 1960s, anesthetists consistently measured arterial blood pressure (although Cushing advocated such measurement a half century earlier). Betty Lank and Robert Smith were early advocates of doing so during pediatric surgery. Smith and Stuart Cullen (1909–1979) also suggested taping a stethoscope to the chest of patients to monitor heart rate, heart tones, and breathing [53]. Introduction of esophageal stethoscopes by John Inkster (1924–2011) in the 1970s, made it easier to monitor heart tones, breathing, and temperature, but the widespread use of electronic monitors and the increased noise in modern operating rooms have made esophageal stethoscopes obsolete, except in developing countries lacking other forms of monitoring.

Early textbooks made no mention of monitoring, but in the second edition of his book (1959), Smith recommended monitoring the “usual case” with a stethoscope, a sphygmomanometer, and a thermometer [33]. For cardiac surgery, he recommended intra-arterial pressure and ECG measurement. Increases in cardiac and thoracic surgery cases in the 1940s–1960s and the development of intensive care units in the 1960s increased the need for invasive monitoring. Oxygen saturation and end-tidal gas monitors became available in the late twentieth century, and their use decreased anesthesia-related

injuries and deaths [54]. The advent of ICUs (see below) increased the need for monitoring and these devices were routinely used in the operating room by the early 1970s.

Infants don't feel Pain, do they?

As late as 1975, some surgeons might operate on infants who were receiving but a small dose of morphine, paralyzed with drugs, and whose lungs were mechanically ventilated. Fearing circulatory depression, anesthetists excused this barbarism, in the belief that infants barely felt pain [55–57]. “And even if they felt pain, no matter, they would not remember it.” These notions have now been disproven [58, 59]. I (and countless other parents) knew they were untrue. Once, after I changed my 3-month-old son's diapers, he became inconsolable. I had accidentally stuck a safety pin through his scrotum. Calm returned with removal of the safety pin. Clearly babies feel pain. In 1987, an article in *Redbook* magazine described surgery in an infant lacking sufficient anesthesia [60]. The resultant publicity caused this practice to change. Infants in developed countries are now appropriately anesthetized, and provided with post-operative pain relief. However, in some developing countries in which I have worked, infants still receive little or no anesthesia, or medication for postoperative pain relief by the local anesthesiologists or anesthetists.

The “Liverpool Technique” commonly used to anesthetize infants and children provided a subtle variant on the “no anesthesia” problem. Originally the technique consisted of “heavy sedation”, intravenous induction of anesthesia, muscle paralysis and hyperventilation with oxygen and nitrous oxide [36]. However, many practitioners reduced the technique to hyperventilation with 70% nitrous oxide and muscle paralysis—and no sedation. Anand and Aynsley–Green [58, 61] showed that term and preterm infants anesthetized by this technique had greater hormonal and metabolic stress responses than infants receiving the same “anesthesia” plus fentanyl (a narcotic) [62]. Infants anesthetized with nitrous oxide, muscle paralysis, and hyperventilation alone had approximately nine times more complications after surgery than infants anesthetized by the same technique plus sufentanil. Similarly, administering anesthesia during cardiopulmonary bypass decreased mortality [58].

Despite contrary antique beliefs, young children require more anesthesia than older patients. In 1952, Margery Deming (1914–1998) showed that infants and children had greater concentrations of cyclopropane in their blood than adults, when anesthetized [22], and Snow [9] and Robson [21] intuitively knew that children require more anesthesia. In 1969, Gregory et al [24] and Nicodemas et al [23] showed that minimum anesthetic concentrations (MAC values) for

halothane in infants and young children exceed those of adults (Fig. 65.2).

Intravenous Fluids, Blood, and Blood Products

Hemorrhage caused Snow's single surgical death in a child. Both adults and children benefited from advances in intravenous fluid delivery. Anesthetists maintain the internal milieu of the patient during surgery by such administration, and delivery of sterile fluids to maintain intra and extra vascular volumes enabled surgeons to undertake more ambitious surgery. Children may have benefited more because of their smaller fluid volumes, and the fact that smaller fluid losses lead to hypovolemia; children may require seemingly astronomical volumes of fluid to survive some types of surgery.

The invention of plastic intravenous catheters minimized the number of insertions for intravenous infusions, a particular blessing to children and infants who detest needle-sticks, and in whom it is often difficult to find a vein. We are grateful to David Massa (1923–1990), who while an anesthesia resident at the Mayo Clinic, invented the insertable plastic catheter in 1950 [63].

James Gamble (1883–1956) described the fluid compartments of the body and their changes from dehydration, showing that these are not simply proportionate to size in children versus adults [64]. Application of this information improved a child's chance of surviving. Adding to this, Malcolm Holliday (1924–) and William Sager (1898–1951) defined the fluid and glucose requirements of different aged children [65]. It isn't always a perfect world of advances, however. In the 1960s, Tom Shires (1925–2007) described the shifts in extracellular fluid volume occurring during surgery in adults [66]. Misapplication of these findings to infants and children often resulted in fluid overload and congestive heart failure, especially in septic children. Today, fluid is more accurately and safely administered to the smallest infant using infusion pumps. Measurement of electrolytes and serum osmolarity *during* surgery on small volumes of blood (micro liters) guides today's administration of appropriate amounts of fluid.

The ability to transfuse blood, platelets, fresh frozen plasma, and individual clotting factors, makes major pediatric surgery possible. In a premature infant, who may have a blood volume of 80 ml, a loss of 8 ml of blood may be dangerous, and 16 ml disastrous. Transfusion may be needed to sustain life. Without clotting factors and platelets (e.g., as in clotting-factor deficient patients), bleeding from surgical wounds and needle sticks would be excessive. Like John Snow's patient, many would die. The development of safe transfusion was indispensable to the advancement of pediatric anesthesia, and the management of infants and children in pediatric and neonatal intensive care units.

Postanesthesia Care Units

As with transfusions, the development of post anesthesia care units (PACUs) has been essential to the advancement of pediatric anesthesia. PACUs improved outcome for both adult and pediatric patients. The invention of PACUs came earlier than most people realize. In 1801, in an attempt to reduce postoperative complications, English surgeons developed the first PACUs and located them near the operating room [67]. Soon after Morton's demonstration, it was recognized at the Massachusetts General Hospital, that residual anesthetic effects plus longer, complicated and traumatic surgery increased the need for careful postoperative observation, and the first PACU in the United States was built there. Johns Hopkins Hospital had a PACU by the 1920s [68].

But PACUs were not the norm. Well into the early 1940s patients might have surgical procedures, e.g., tonsillectomy, at home, and their parents provided the postoperative care. Into the 1960s, most hospitalized patients, including pediatric patients, received postoperative care on the ward. Beecher (1904–1976) and Todd's (1918–1998) report in 1953, documented fewer deaths in hospitals that had PACUs [69]. Initially infants and children were cared for in adult PACUs in most hospitals. By the 1960s and 1970s, it was realized that it would be better to care for these patients in pediatric PACUs because the problems of children were different from those of adults, and pediatric PACUs became common

Pediatric Intensive Care Units (PICUs)

PICUs enabled the pursuit of complex and traumatic surgery and thus underlay progress in pediatric anesthesia. Anesthetists built and ran the first ICUs in Copenhagen, Denmark, and in Uppsala and Stockholm, Sweden in the 1950s, to care for adults and children suffering from polio (Fig. 65.9).

Drinker tank-type ventilators, which were commonly used for these patients, had considerable limitations. Moreover, during the 1952 polio outbreak in Copenhagen, too few machines existed to meet the needs of the hundreds of patients who required artificial ventilation. Physicians, medical students, and nurses were recruited to manually ventilate these patient's lungs, a heroic but sometimes flawed solution, given human frailties. Positive pressure ventilators were developed to provide a better, more constant and controllable solution. But these early crude devices could cause complications, especially when used to ventilate small children's lungs. Because they were designed to inflate the lungs of adults, they sometimes delivered excessive volumes that ruptured the lungs (pneumothorax), or perversely might inadequately ventilate the lungs of babies who had "stiff" lungs. In the early 1960s, about 30% of babies with stiff lungs receiving mechanical ventilation developed a pneumothorax.

Fig. 65.9 This picture of a child in a Drinker “Iron Lung” exemplifies the devices used to provide ventilation for thousands of patients who could not breathe adequately due to polio. Such artificial ventilation might continue for years. (<http://pathmicro.med.sc.edu/lecture/vaccines.htm>. Accessed 31/03/2010)

Better ventilators and better understanding of lung diseases decreased this life-threatening event to less than five percent, even in premature infants.

Two factors led anesthetists to develop early PICUs (Table 65.4). First, training in the operating room provided the required knowledge of respiratory and cardiovascular physiology. Second, anesthetists closely observed patients for protracted periods, learning to quickly interpret and act on what they observed. The invention of safer endotracheal tubes, mechanical ventilators, and monitors, and the education of dedicated nurses who understood technology and the physiology of small patients, made possible the PICU care we now take for granted.

New gadgets progressively advanced care [70]. In the 1960s, results from Severinghaus’ blood gas and pH electrodes guided changes in mechanical ventilation. Plastic catheters inserted into arteries facilitated the drawing of blood and measurement of arterial blood pressure. Pressures obtained from central venous catheters guided fluid administration. Sometimes a step backwards accompanied a step forward. In 1972, the Swan–Ganz catheter, introduced for adults, was used in pediatric cardiac patients to measure pulmonary artery pressures and cardiac output [71]. Although the derived information improved understanding of

the cardiovascular function of ill children, the catheter could cause infections, thrombosis, and lung infarction. Pediatric heart rate and blood pressure monitors became available in the mid 1970s, making possible the ongoing diagnosis and treatment of cardiovascular abnormalities at the bedside. The introduction of echocardiography into PICUs in the 1990s, advanced the diagnosis of congenital heart disease at the bedside, and allowed immediate determination of the effectiveness of treatment. It also decreased the need for cardiac catheterization and provided previously unavailable information about the heart’s function and pulmonary vascular resistance.

Neonatal Intensive Care Units (NICUs)

Pierre Budin of Paris (1846–1907) developed the first NICU in the 1890s [72]. Working with a chicken equipment manufacturer, he constructed incubators for premature babies that maintained a relatively constant environmental temperature. Budin appreciated the need of premature babies for warmth, frequent feedings (often only 3 ml at a time), and protection from infection (three hallmarks of modern NICU care). He also recognized the need for specialized nursing care. One of his pupils, Martin Cooney (1870–1950), a German physician, exhibited ‘incubator babies’ at fairs, first in France and then in England and the United States, doing so until 1940 and World War II. Babies of similar size and gestation to those cared for by Cooney died in most nurseries around the world, but about 85% of Cooney’s babies survived. Most pediatricians ignored Cooney’s work, and between 1940 and 1960 the outcomes of most sick premature babies remained dismal.

Advances Underlying Modern Neonatal Anesthesia and Intensive Care

The period from 1940–1960 laid foundations for great advancement. Geoffrey Dawes’ (1918–1996) book “Fetal and Neonatal Physiology” summarized landmark studies carried out at Oxford and in the Caribbean in the 1960s, that defined the circulatory changes that allowed the fetus to move from intra-uterine to extra-uterine life, thereby facilitating the rational resuscitation of troubled neonates [73]. Adamsons et al found that administering glucose and buffers (to correct acidosis) improved resuscitation of acidotic, asphyxiated fetuses [74]. Kenneth Cross (1916–1990) and co-workers showed that the neonate might fail to respond to hypoxia (after all, such an environment was what the neonate faced for 9 months) indicating why asphyxiated neonates require help with their breathing [75].

John Clements (1923–) demonstrated that the low surface tension in the lining of normal alveoli prevented

Table 65.4 Early pediatric intensive care units

1965	Washington, DC	Cheston Berlin

atelectasis [76]. Mary Ellen Avery (1927–2011), a pediatric resident at Harvard, suggested that inadequate quantities of surfactant in the lungs might cause the impaired breathing in preterm infants who had hyaline membrane disease (HMD). Surfactant, a special kind of natural soap, was what induced the low surface tension. Using a Wilhelmy Balance (a device to measure surface tension), she and Jerry Mead (1921–2009) demonstrated that the lungs of infants with HMD lacked surfactant (i.e., lacked the ability to lower surface tension) and indicated that this lack caused the atelectasis and impaired breathing [77]. In an epic 1964 study in Singapore (Singapore because a hospital there had 24,000 births per year), Clements et al insufflated nebulized surfactant into the trachea of these infants in an attempt to improve their outcomes. He also created devices to measure pulmonary blood flow and ventilation while in Singapore (personal communication). Clements and associates documented the predicted decrease in lung volumes (atelectasis), but to their surprise found abnormally low pulmonary blood flows [78]. The infusion of acetylcholine increased pulmonary blood flow. This information added another important piece to the HMD puzzle—in addition to inadequate ventilation, HMD was also associated with reduced pulmonary blood flow.

In 1967, pediatricians William Tooley (1925–1992), Roderic Phibbs (1930–), and Joseph Kitterman (1936–) invited me, an anesthesia resident, to join them in their newly developed NICU at UCSF. They hoped my experience in mechanically ventilating the lungs of adults could be applied to improve the respiratory care of neonates. William Hamilton (1922–), the new Chair of anesthesia allowed me to work in the NICU full time for a year, an adventure that has lasted more than 35 years. Here was the picture in our NICU in 1967. Pediatric ventilators were inadequate, and we were without most neonatal monitors (e.g., heart rate, blood pressure, hemoglobin oxygen saturation monitors) available today. John Severinghaus (1922–) and Freeman Bradley (1932–) (inventors of the CO₂ electrode) [79] made a set of oxygen, CO₂, and pH electrodes for our NICU (Fig. 65.10). Each set of measurements required more than 1 ml of blood,

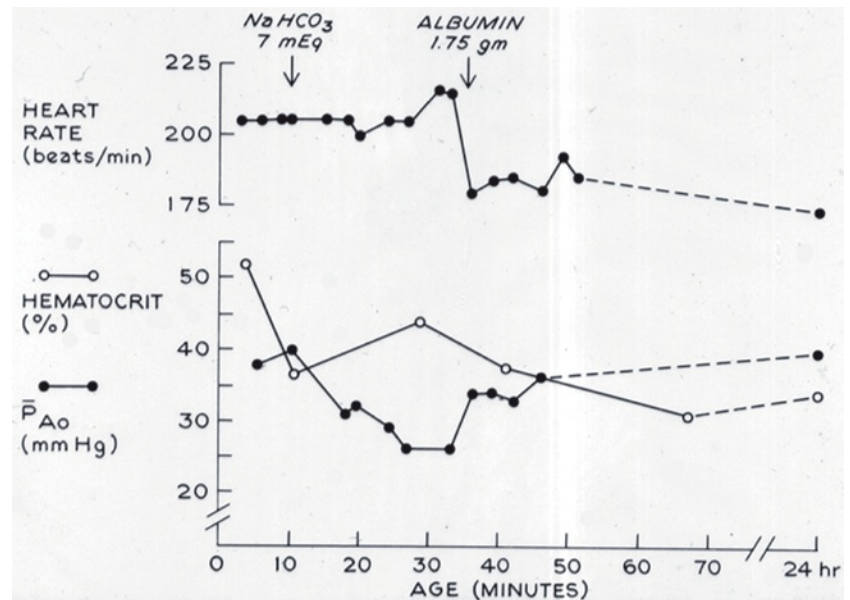

Fig. 65.10 The blood gas and pH electrodes built by Severinghaus and Bradley for use in the ICN at UCSF. (Courtesy of Joseph Kitterman, MD)

Fig. 65.11 Mean arterial pressure, heart rate, and hematocrit changed in a 1.75 Kg infant during resuscitation. Administration of bicarbonate decreased mean arterial pressure (PAO) and hematocrit, demonstrating that the baby had a low blood volume. Administering albumin and fluid returned the pressure to normal. The hematocrit data indicated a startling 30% volume deficit. (Courtesy of Joseph Kitterman, MD)

a blood loss necessitating blood transfusion for many infants! Today these analyses plus electrolyte determinations require <100 micro liters of blood. Residents and faculty made the measurements and repaired the electrodes when they failed. Calibrating standards weren't available, so if the blood gas and pH values conflicted with the patient's clinical picture, I drew blood from my radial artery, and if my measured values differed significantly from what I knew they should be, we changed the electrode membranes (so much for complicated electronics). Since there were no neonatal monitors, we employed the eight-channel Grass Recorder™ used by Clements, et al in Singapore, and measured and recorded arterial and central venous pressures from umbilical artery and venous catheters, doing so at least every five minutes.

We quickly learned what “normal” blood pressures of sick infants were [80], and what constituted hypotension; we used this information to determine whether measures used to correct hypotension were effective or not [81]. While such measurements are routine today, it was new and exciting at the time, because normative data were not available. It was part of the era of phenomenological research. We used arterial pressure determinations to judge the amounts of fluid needed to correct hypovolemia (Fig. 65.11).

We learned that hyperventilation often caused hypotension, and that the combination of hypotension and hyperventilation could be detrimental to the brains of neonates. Such measurements, and others, promoted the care of infants based on physiology, not guesses, and this improved outcomes (Fig. 65.12).

Earlier, I noted some of the problems (e.g., pneumothorax) for sick babies, particularly premature babies, associated with the first commercially available mechanical ventilators. In addition, weaning from the ventilator required

discontinuation of ventilation for progressively longer periods of time to allow spontaneous ventilation. This could precipitate collapse of the lungs (atelectasis) and hypoxemia. In 1968, a report by Harrison et al. led me to devise a way to manage these problems [37]. Harrison et al described the effects of tracheal intubation in infants who had HMD. Before tracheal intubation, these infants grunted during expiration. It was clear to me that they grunted to keep their lungs from collapsing during expiration, and to improve oxygenation. Tracheal intubation prevented grunting, and, instead of making the babies better, made them worse; their oxygenation (PaO₂) decreased, the level of carbon dioxide (PaCO₂) in their blood increased, and their acidity increased. Removing the tracheal tube made them better.

I combined these thoughts with ones expressed by Hamilton about the “tight bag”, a technique for imposing an increased pressure in the airway, and I had an “aha” moment. Why not maintain positive pressure during expiration when the babies were breathing through the tracheal tube (apply “continuous positive airway pressure” or CPAP) and allow the babies to breathe spontaneously? This might improve oxygenation and survival. That night, we tested this proposition in a new patient with a frighteningly low PaO₂ of 30 mm Hg (normal is 60–80 mm Hg). After tracheal intubation, we applied an end-expiratory pressure of 8 mm Hg and the PaO₂ immediately increased to 88 mmHg. Over the next hour it rose to 230 mm Hg, a remarkable increase, and this very sick infant survived in contrast to those treated previously by us and by others [82]. Of the next 20 patients treated with CPAP, 16 survived! Prior to this therapy, half of such premature babies weighing 1,800 grams at birth had died. Many of the initial babies we cared for were smaller than this, making their odds of survival even smaller. After introducing CPAP,

Fig. 65.12 The percent mortality of preterm infants greatly decreased during a recent 35-year period, probably because of therapies introduced into the ICN. The Y-axis indicates percent mortality and the X-axis, the approximate years for the indicated value. (Courtesy of Joseph Kitterman, MD)

more than 98% of our 1800 g babies survived, without lung injury. Amazingly, none of the original babies treated *only* with CPAP developed chronic lung disease, a finding later confirmed by others [83]. During the same period, Daily [84] reported that those babies surviving mechanical ventilation often developed bronchopulmonary dysplasia (BPD), a newly defined and severe and often fatal form of neonatal lung injury [85].

In the spring of 1970, we presented the effects of CPAP on the outcome in premature infants, at the Society of Pediatric Research. The results prompted Robert Kirby (1938–), an anesthetist at Wilford Hall Hospital at Lackland Air Force Base in San Antonio, Texas, to develop the Baby-Bird Ventilator™. This machine allowed babies to breathe spontaneously between ventilator breaths, and to maintain positive end-expiratory pressure (PEEP). In effect, this machine was both a mechanical ventilator and a means of delivering CPAP. It made separation from the ventilator easier and advanced neonatal mechanical ventilation. However, BPD continued to occur in mechanically ventilated premature babies, and remains a major problem today [86]. Consequently most premature infants are now treated with nasal CPAP when possible. If the patients develop pulmonary hypertension (high blood pressure in the arteries of the lungs) they are now treated with nitric oxide to dilate the pulmonary arteries.

The methods devised in ICNs for the care of preterm infants were subsequently used to care for infants during and after surgery, an example of translational research. Anesthetists improved the outcomes of preterm infants and then applied the information gained in operating rooms. The

Liverpool technique of ventilation had unwittingly provided positive end-expiratory pressure (PEEP), and the good outcome of the patients reported by Nesbit (1926–) and Wilson (1927–1981) in 1958 probably resulted from inadvertent PEEP. Of note, they thought that inadvertent PEEP was detrimental and recommended using zero pressure during expiration [87].

Outreach

During the past 40 years, increasing numbers of anesthetists and surgeons traveled to developing countries to correct lesions, usually congenital anomalies. Among the first to do this was the plastic surgeon Donald Laub (1935–) who, other surgeons, anesthesiologists, and nurses from Stanford University, made weekend trips to Mexico to repair cleft lips and cleft palates. Laub had been moved by Antonio, a 13 year-old boy from Mexicali, who went to Stanford University for cleft surgery. Before surgery Antonio rarely attended school and did poorly when he did attend. After surgery he regularly attended school and did well. Believing that many children like Antonio could benefit from surgery, in 1969 Laub established Interplast (now ReSurge International), an organization dedicated to providing free reconstructive plastic surgery for children in developing countries. Within a few years Interplast had expanded into Vietnam, China, India, Laos, and other countries. Similarly focused organizations, including Operation Smile (1982), Smile Train (1999), and many others have been established. In parallel developments,

hundreds of organizations in Europe and the United States now provide free cleft surgery, orthopedic surgery, cardiac surgery, ear nose and throat surgery, eye surgery, and dentistry. These organizations are both large (e.g., Doctors without Borders) and small (sometimes consisting of only two or three people).

The well-known aphorism “if you give a man a fish, he eats for a day while if you teach him to fish, he eats for a lifetime” arose as an issue. At the International Plastic and Reconstructive Surgery Organization meeting in 1990, Ortiz–Ministerio of Mexico, and other surgeons from developing countries requested education that would permit them to perform the surgery themselves. This makes sense because they can do a much better job of preoperative evaluation and follow-up care than groups present for only a week or two. Some organizations responded to this request with outreach programs by the parent group that pay indigenous surgeons, nurses, and anesthesiologists to perform the surgery—once it was clear that the local team can effectively and safely do the repairs. In one-year, Nepalese outreach groups performed nearly 2000 cleft repairs, whereas a traveling surgical group could have performed 75 at most, during their two-week stay. One group, Smile Train, has as its primary goal, the funding of groups to establish outreach programs. This is a daunting task in places lacking consistent electricity and running water and that frequently have no anesthesia machines, monitors, blood pressure cuffs, tracheal tubes, or even stethoscopes.

Societies

Several societies formed to advance knowledge and science in pediatric anesthesia. The Association of Paediatric Anaesthetists was established in Great Britain in 1973. The Anesthesia and Critical Care section of the American Academy of Pediatrics was established in 1966, and the Society for Pediatric Anesthesia in 1985, both in North America. Beyond their educational mandate, these groups address government and other public concerns affecting pediatric patients requiring anesthesia, surgery, and intensive care. Board examination/certification for pediatric anesthesia will begin in 2013 in the US. This will advance the status of pediatric anesthesia and improve patient care, as has specialization and certification advanced critical care.

Conclusions

Pediatric surgery developed in parallel with advances in pediatrics, surgery, and anesthesia. Each group learned from the other and prospered. The ability to safely anesthetize nearly any child allowed the imagination and daring of surgeons to

soar. They attempted surgical procedures that they had only dreamt of in the past. The discovery of anesthesia allowed the invention of new operations in adults and children alike. It took half a century and more, for surgery to demand significantly more of anesthesia. Pediatric anesthesiologists evolved through several steps, first developing safe approaches to anesthetic delivery, modifying advances in techniques and drugs to infants and children. With these approaches codified, pediatric anesthesiologists expanded development of ideas focused specifically on problems in infants and children. Superimposed on this information, are present research programs investigating basic mechanisms underlying pediatric pathophysiology specific to anesthetic concerns.

In parallel with these developments, the desire to solve new and more complicated problems made it crucial to construct child-centered environments (hospitals) in which surgeons, anesthesiologists, nurses, and others could work together to improve the care of children. It also allowed those working there to interact and to learn from one another. This interaction advanced knowledge of the differences between children and adults. Anesthesia care benefited greatly from the development of blood banking, antibiotics, electronic monitors and intensive care units. Anesthesiologists gained from, contributed to and continue to contribute to these advances.

Acknowledgment I thank Felicia Reilly of the Wood Library-Museum for her unflagging help in finding references and birth and death dates. Her help, kindness, and expertise are much appreciated.

Some Examples of Industry Contributions to the History of Anesthesia

66

Richard Leazer, David Needham, John (Iain) Glen and Paul Thomas

Summary

Anesthesia evolved through joint contributions by clinicians, investigators, and industry. For example, physician Squibb formed Squibb Pharmaceutical in 1858, to make a purer form of ether. High pressure cylinders made in the late 1800s enabled the economical use of N_2O and O_2 . Dentist-manufacturers developed reducing valves and metering devices, tubing, fittings, and masks—and thus the anesthesia machine.

Shukys at Ohio Chemical/Airco synthesized the first commercial fluorinated inhaled anesthetic, fluroxene, in 1953. In parallel, Suckling, at Imperial Chemical Industries (ICI), synthesized halothane, the anesthetic of the 1960s. Safety required precise control of its concentration. Foregger's support of Morris' 1953 development of the Copper Kettle made this possible. In the 1950s, Edmonson and Jones organized Cyprane Ltd to make the Fluotec, the first variable bypass vaporizer directly indicating the concentration of anesthetic. Ayerst donated the Fluotec to US hospitals to capture the market for both halothane and the Fluotec.

In the mid 1960s, Eger became the de facto "Medical Director" for Airco, illustrating the effective relationship between industry and academia in that era. By 1970, enflurane displaced halothane in the US, but it could produce seizures and (rarely) injure the liver. Isoflurane seemed to have neither problem and became the anesthetic of the 1980s. By 1975, Cyprane produced an estimated 85% of the world's calibrated vaporizers. The 1991 introduction of desflurane challenged vaporizer design. Enter the Tec 6, a vaporizer structured unlike any previous vaporizer. In 1998, the Datex-Ohmeda Anesthesia Delivery Unit (ADU) machine was released, a new form of the variable bypass vaporizer, one that accommodated desflurane.

In 1965, ICI began a search for a replacement for thiopental. In 1973, Glen and James detected hypnotic activity in propofol (2,6-diisopropylphenol), but the vehicle Cremophor EL caused anaphylactoid reactions. In 1981, use of a lipid emulsion formulation, and clinical evaluations allowed launch in May 1986.

In 1981, Schwilden introduced the concept of target-controlled infusion (TCI). UK approval for TCI of propofol by the 'Diprifusor' was given in 1995. Approval has been obtained in most countries of the world, but not in the US.

In the early 1980s, Ohmeda supported a "Safety in Anesthesia" symposium directed by Nick Gravenstein. From this meeting came the Anesthesia Patient Safety Foundation (APSF). Led by Pierce in 1985, the American Society of Anesthesiologists and industry provided financial support. The National Academy of Sciences/NIH cited the APSF for improving quality of care. Industry members also partnered with ASA in the 1986 design and funding of the Foundation for Anesthesia Education and Research (FAER). Dollars given to FAER recipients generated several-fold more dollars in NIH awards.

Introduction

Although private sector scientists, engineers and companies have discovered or developed products that advanced anesthetic care, these contributions of industry to the history of anesthesia are rarely considered or recorded. To construct this chapter, I (RL; Fig. 66.1) and special and findable colleagues reviewed selected industry-sourced contributions and added our own recollections. This essay follows an "exemplar" format providing noteworthy examples of successful interactions between industry and our specialty. Through

Fig. 66.1 Richard Leazer. (From RL)

this abbreviated—and fragmented (only a small fraction of many tales can be told)—statement of industry contributions, we hope to add information and texture not otherwise available—and perhaps stimulate further chronicles.

The history of industry's contributions to anesthesia, particularly the early history, differs somewhat from that of many other industries because physicians often both invented and used the products. This provided a closed loop guidance system for early manufacturing, arguably accelerating improvements in anesthesia care more than in typical industry models.

Many products, including vaporizers, breathing circuits, anesthesia machines, muscle relaxants, gas analyzers, and inhalation anesthetics, provide examples of joint discovery or invention by physicians and dentists, often stimulated by patient need. More recently, several factors, most notably the increasing demands of regulatory approval, have changed this physician-industry relationship. In addition, as science and technology have become more complex, discoveries and advancements have originated from sources outside the operating room.

In the Beginning...Ether and Nitrous Oxide

An early illustration of the physician-industry interaction arose in the second half of the nineteenth century. Ether had been discovered by Lully in 1275 CE and Morton in 1846 demonstrated its anesthetizing effect. At the time, Jackson cautioned Morton to use a pure ether [1]. Physician Edward Squibb noted this need for ether and other medicines, leading to the 1858 formation of Squibb Pharmaceutical (see uab.edu/Reynolds/cwfigs/squibb). Squibb's contribution (so they said) was to make ether more pure "using an improved production method".

Another early example of a contribution by industry followed progress in the iron and steel industry and the invention of the high pressure gas cylinder in the late nineteenth century. Today, we take for granted the availability of compressed gases for anesthesia, but this was not the case for several decades following the discovery of ether anesthesia. US industrial gas companies were started in the early 1900s, stimulated by the French discovery of new methods of producing various gases at lower cost. Some of these gas companies subsequently developed and manufactured anesthesia equipment and accessories (e.g., Air Products, Puritan Bennett, Airco-Ohio Chemical and Surgical Equipment, and National Cylinder Gas.) In Great Britain, Coxeter and Sons were the first to supply compressed nitrous oxide in steel cylinders. Later, they developed high pressure cylinders for oxygen and until about 1950, were a significant manufacturer of anesthesia equipment of all types.

High-pressure gas cylinders (tanks) solved the problem of storing large amounts of gas in a conveniently small space, but imposed a new problem: how to deal with the huge pressures within the tanks. A full tank of oxygen might have a pressure of 2,200 pounds per square inch, the pressure produced at nearly a mile's depth in the ocean. The development of the tanks also prompted the development of reducing valves and metering devices. To these, manufacturers added tubing, fittings, and masks, all eventually leading to the anesthesia machine.

Along the way, manufacturers realized the necessity of standards and regulation to make devices safe, consistent, and interchangeable. Standards associations, and groups such as the National Fire Protection Association (formed in 1896), Food and Drug Administration (1906), US Compressed Gas Association (1913), and American Standards Institute (1918) "fit it all together". The chaos of World War II galvanized the effort to improve safety via standards. Anesthesia equipment sent to war zones agonizingly illustrated the dangerous incompatibility of equipment provided by different manufacturers. To preclude operating room fires and explosions, the National Fire Protection Association specified guidelines that would prevent sparks and ignition of flammable inhaled

anesthetics in 1941. These developments illustrate the inability of industry and the anesthesia profession to separately deal with joint problems, and the need for such associations and regulatory organizations.

On the other hand, the Pin Index Safety System and Diameter Index Safety System, developed in the 1950s, exemplify successful industry-sourced safety efforts. These systems prevented misconnection of gases to equipment. Prior to their introduction, patients had been killed or injured by mistakes such as connection of a tank of nitrous oxide to a fitting intended for oxygen. Wayne Hay and Harold May invented these safety systems while employed at Ohio Medical and Surgical Equipment Company. The patents were donated to the Compressed Gas Association, thereby facilitating universal use by all manufacturers.

The history of nitrous oxide illustrates the early role of industry in the world of anesthesia. We take the availability of this useful anesthetic for granted, but it wasn't until near the end of the nineteenth century, that industry supplied the wherewithal needed for the practical delivery of nitrous oxide. Large-scale production of nitrous oxide was a daunting task, especially so in the decades prior to sophisticated process control systems. The widely used and economical method involves heating ammonium nitrate to 200 °C, a potentially dangerous process because the process is exothermic (generates heat), and at a somewhat greater temperature, the ammonium nitrate explodes. In 1947, the French registered vessel, SS Grandcamp, with approximately 2,300 tons of ammonium nitrate aboard, caught fire in the port of Texas City. The resulting explosion and onshore fires destroyed Texas City, killing nearly 600 people [2].

Similarly, explosions have occurred at nitrous oxide manufacturing facilities, in some cases causing loss of life. In the 1950s, an explosion occurred at an Ohio Chemical and Surgical Equipment-Airco plant in Montreal, fortunately at night—thus sparing loss of life and injury. However, in the 1980s, an explosion occurred at an Air Products nitrous oxide production facility, resulting in a few fatalities. Ohio Chemical had located a nitrous oxide manufacturing facility at the corner of 10th and Mason in San Francisco, but the San Francisco city fathers remembered the great Texas City explosion. No nitrous plants in the city! An abbreviated daily production system was employed, until the facility relocated to an industrial site in the intrepid town of Berkeley.

The commercialization of nitrous oxide manufacturing required industry to manage the cost and deployment of heavy steel cylinders. Fortunately, nitrous oxide compresses to a liquid at moderate pressures. A cousin of Edgar Allen Poe converted this knowledge into a commercial process in the late nineteenth or early twentieth century in Trenton, New Jersey, but a half-century passed before the implementation

of bulk delivery/storage of nitrous oxide at large hospitals. Some hospitals used nitrous oxide in such large quantities that it was economical to take it from the production plant in a bulk tank truck, in liquid form, and transfer it to a bulk liquid storage tank at the hospital, much like the liquid oxygen systems used today.

The memoirs of the dentist, Jay Heidbrink, read at the American Dental Society of Anesthesiology in 1957, testify to the challenges of administering nitrous oxide anesthesia to dental patients in the early 1900s. Heidbrink describes patients who fought with him, one for three bouts, before being subdued or anesthetized! Stimulated by such events he tinkered with an anesthesia machine purchased from Charles Teter in Cleveland, in 1903. The machine apparently provided an inaccurate mixture of oxygen and nitrous oxide, and Heidbrink made improvements to correct the problem. Local Minneapolis physicians and dentists asked him to make machines for their practices. A local machine shop quoted a price of \$600 per unit for Heidbrink's device. A second shop asked for \$1.00 per pound or \$32.00 total. This machine was called the "Model A," and the Heidbrink company was "off and running." His company later became part of "Ohio Chemical and Surgical equipment," with numerous company names to follow.

Of note was the contribution of Elmer McKesson, an anesthesiologist who in the 1910s developed the "McKesson" anesthetic machines, machines particularly devoted to administration of high concentrations of nitrous oxide [3]. McKesson advocated induction of anesthesia with 100% nitrous oxide. When cyanosis became profound, McKesson machines allowed use of a flush valve that would add enough oxygen to prevent death. The combination of nitrous oxide and transient hypoxia was sufficient to anesthetize patients for brief procedures (e.g., dental extractions). The flush valve was McKesson's lasting contribution to anesthesia. McKesson is an example of the physician-industrialist of a different era. McKesson ran courses for visiting anesthetists, to teach them how to use his machines and learn basic engineering skills, so that they could repair the machines.

Halothane: The First Successful Modern Inhaled Anesthetic

In 1951, Charles Suckling, a chemist at Imperial Chemical Industries (ICI) in Cheshire, England, began work leading to the synthesis of halothane and the world of modern inhaled anesthetics [4]. Pharmacologist James Raventos (1905–1982; Fig. 66.2) tested halothane in animals, finding that it had the desirable properties needed for an inhaled anesthetic—absence of flammability, absence of pungency, high

Fig. 66.2 James Raventos (on left) and Charles Suckling were the key players in the discovery of halothane. (Courtesy of AstraZeneca, Wilmington, DE, USA)

potency, and no obvious toxicity (unlike chloroform, its non-flammable competitor) [5]. Halothane became a smash hit, making millions for ICI, and changing the face of anesthesia from the late 1950s. It wasn't perfect however, as suggested by increasing numbers of reports of hepatotoxicity, starting in the 1960s [6]. The story goes back now to Ohio Chemical.

And Then Enflurane and Isoflurane

In 1906, Justin Scholes founded Ohio Chemical Corp in Cleveland, Ohio. The company developed or manufactured ether and other anesthetic compounds for several decades, with cyclopropane and nitrous oxide being the mainstays for much of its early history. Research at Ohio Medical led to the discovery of several widely used inhaled anesthetics. Around the time of World War II, Airco bought both the Heidbrink Company and Ohio Chemical. The combined entity, Ohio Chemical and Surgical Equipment, continued the develop-

ment of anesthesia apparatus and inhalation products. Today, GE Medical owns much of the equipment portion of Ohio Medical.

Julius Shukys, at Ohio Chemical, synthesized fluroxene, an ethyl vinyl ether in the late 1940s. It was released commercially in 1953, before the introduction of halothane [7]. Another early fluorinated ether discovered by Ohio Chemical, was Indoklon, a convulsant hexafluorodiethyl ether, marketed in the late 1950s as a substitute for electro-shock therapy. However, a convulsant anesthetic is hardly saleable to most anesthetists, and fluroxene couldn't compete with halothane. Other fluorinated ethers had more promising characteristics. These were developed in the 1960s by fluorine chemist Ross Terrell and his small group of colleagues working in Airco's Central Research Laboratories in Murray Hill, New Jersey, rather than at the Ohio Chemical facilities in Cleveland. Terrell et al. would synthesize more than 700 compounds in their search for the perfect inhaled anesthetic. They never found that, but they came close enough, producing the dominant inhaled anesthetics from 1970 to the present [8–10].

A key element in Terrell's program was the establishment of a means to measure the quality of the anesthetic effects produced by his compounds. Accordingly, Ohio Chemical developed a relationship with John Krantz, the chair of Pharmacology at the University of Maryland. One of his graduate students, Freida Rudo (1924–1996) became expert in "screening" the experimental compounds discovered by Terrell and his team. Terrell's program was small in staff and budget, so having an economical means of preliminary animal testing was critical to success. Great expertise at bargain basement price was needed. Each mouse tested was a noted budget expense, and did double duty by serving as a meal for the University of Maryland's snake collection.

Rudo was a favorite with her University and Industry colleagues. She had reportedly won first place in a Miss Puerto Rico beauty contest. Add her personal presence, her statesmanship and her pipe smoking, and she was a memorable personality. She evaluated each new putative anesthetic by placing a few drops of the compound in a one quart Mason jar containing one scrambling mouse. She then observed respiratory and cardiovascular responses (Did the mouse stop breathing? Did it die?), the ease and rate of induction, rigidity and convulsions. She recorded her data on 3 × 5 note cards, an effective if now antiquated data and lab notes management system.

Terrell became an industry legend for his record of successes in inhalation anesthetic discoveries. He synthesized, and Rudo tested, enflurane, isoflurane, sevoflurane and desflurane, in addition to several hundred undeserving compounds. A success rate this great is rare in the pharmaceutical world.

Ohio Medical's clinical and regulatory expertise was modest, especially at the time of the development of their first anesthetic, enflurane. At the outset, Ohio looked for

guidance from members of the anesthetic community. In the 1960s, James Vitcha (see below) sought out a surprised Edmond Eger, asking him if he wanted to be involved in Ohio's studies of new anesthetics. Eger remembers that he (Eger) quickly wrote a stellar grant for several hundred thousand dollars and was rewarded with a dinner at Toots Shor's, where Vitcha diplomatically told him that his application was rejected. Eger got it anyway; it just took much longer than he had expected. Eger became involved in the clinical trials for all of the anesthetics that Ohio brought to the market. He was especially effective in arguing for the development of desflurane, noting the need for faster acting anesthetics in a world increasingly focused on ambulatory anesthesia/surgery. The anesthesia community, and especially Eger, played the role of "Medical Director." This was possible in the regulatory world of the last half of the twentieth century, again illustrating the effective relationship between industry and physicians and academia in that era.

James Vitcha had long worked for Ohio Medical, in various capacities in the anesthetics programs, and took on the role of coordinating the clinical studies and preparing in large part, the New Drug Applications for enflurane and isoflurane. He organized clinical anesthesia researchers effectively, created a strong information base for the products upon market introduction, and provided the FDA with information needed for approval reviews.

Vitcha's real role at Ohio Medical/Ohio Chemical/Anaquest, was that of the grain of sand in the oyster leading to the formation of a pearl. Ohio Chemical was poorly equipped in both technical and business experience, to deal with the pharmaceutical world. Jim often threw caution and career future to the wind in arguing for the inhaled anesthetic program, persuading many doubters within the Ohio Medical management team. He followed that with a clinical studies program and FDA submissions effort that was impossible by later standards. Were it not for his unique persistence internally, important inventions might never have seen the market place, or would at least have been delayed for several years.

Although the road from laboratory to marketplace for new compounds was shorter in the 1970s than in the twenty-first century, some unanticipated obstacles impeded progress. The obstacle with halothane was its rare capacity to injure the liver [6]. Enflurane, the 347th compound made by Terrell, had minimal hepatotoxic effects [11], and that advantage gave it a competitive edge over halothane. By 1970, enflurane had largely replaced halothane in the US. However, enflurane had its own problem, the capacity to produce seizures [12]. The incidence of seizure activity with enflurane was low and the number of patients exhibiting seizures was small. Moreover, there were no reports of residual damage from the seizures. The FDA chose a middle of the road solution to this situation. They approved enflurane for sale, on the condition that the package literature fully describe the

risk, and that a "phase 4" study comprising a complaint form be included in the package literature, to be used by anesthesiologists for reporting seizure incidence.

It was clear that the FDA was anxious to have an alternative to halothane, and apparent that they had confidence in the physician's ability to observe and report the condition, to the extent that it was a limitation. This study did not provide alarming findings, and enflurane continued to be widely used.

As indicated above, enflurane largely replaced halothane in the US and some other developed countries (except for anesthesia in children) because enflurane had fewer effects than halothane on the liver. But enflurane was also attacked for its capacity to injure the liver, albeit with a much lower incidence than occurring with halothane [11]. Isoflurane was also tarred with this brush [13]. Anaquest asked Eger to examine each of the rare reported cases of hepatic injury, finding in some patients, that the injury resulted from an infection by a herpes virus [14, 15]. Overall, we were impressed with the small degree of metabolism of isoflurane, and therefore decided to fully investigate and resolve reports of 'toxicity' in patients as they arose, thinking that other causes would most likely be ruled in and isoflurane toxicity ruled out. At worst, no specific cause would be proven or found, and as such, the overall results would keep the product in good stead in the eyes of clinicians. I suppose we were thinking that one patient did not a side effect make.

Sebastian Reiz's 1983 suggestion that isoflurane caused "coronary steal" was a larger concern [16]. This issue had been studied by prominent investigators and was added to the package label. We asked Eger and Cahalan to visit Reiz in Umea, Sweden. Eger remembers it being one of the coldest places he'd ever been, and that Reiz offered him some wild mushrooms to eat (Eger declined). My recollection is that "steal," while not completely irrelevant, did not significantly influence isoflurane usage. The millions of patients, seemingly safely given isoflurane, continued to pile up and significant side effects from any one cause became statistically more remote.

But we've gotten ahead of our story in telling of isoflurane's development. Enflurane was good, but far from perfect, and Terrell and his group searched for something better. In initial trials with compound 469 (isoflurane), made by preparatory chromatograph (personal communication, John Wynne), Rudo found that isoflurane seemed superior in its overall properties. However, a problem in its manufacture nearly killed it. Several hundred pounds were required for additional animal testing, toxicology, and eventually human trials. Wynne was assigned to the process and scale-up work, but was unable to purify the crude final isoflurane to more than 97% by normal distillation. The problem was the boiling point of a contaminant compound, 1-chloro-2,2,2-trifluoroethyl monochloro difluoromethyl ether, which at 53 °C was too close to that of isoflurane at 48.5 °C, to enable

separation by simple distillation. Louise Speers saved the day, finding that isoflurane forms a high boiling azeotrope with acetone and has a lower volatility, while 1-chloro-2,2,2-trifluoroethyl monochloro difluoromethyl ether forms a low boiling azeotrope with acetone which can be distilled from isoflurane. As an aside, note that two women, Rudo and Speers, led the way forward in this history of inhaled anesthetics, doing so during an era when female scientists were much less prominent.

Spears took pleasure telling of her interviews for jobs after completion of her PhD in chemistry at Columbia University. During that era, young single women needed a proper escort for their interview travels. Spears' mother filled that role as best she could (I don't think she attended the interviews, themselves). Fortunately for the anesthesia world, her trip from Columbia University to Murray Hill, New Jersey to be interviewed by Terrell was less than 50 miles, causing her to choose a career in anesthetic synthesis and azeotrope distillations!

The submission of the New Drug Application, for approval of isoflurane for clinical use, was a family business. Eger remembers Vitcha proudly talking about several feet of documents on his dining room table, he and his wife sorting and stacking. Isoflurane was his baby.

Towards the mid 1970s, it looked like clear sailing to an approval of isoflurane by the FDA, which had provided a preliminary "approvable" status letter. The celebrations inside Ohio Medical began. Human clinical testing had been well orchestrated by Vitcha and Eger (the shadow Medical Director-Consultant). Vitcha was a friend to numerous investigators in the anesthesia world, investigators providing input to the inhalation anesthetics program. His vigor outside the company was also used inside the company, to argue fiercely for additional funding for the anesthetics program. He usually got what he asked for (although complaining that it never was enough).

And then, isoflurane had an enormous setback. Tom Corbett, at the University of Michigan, had studied the potential of various compounds, particularly alpha chloro ethers to cause cancer [17]. Prompted by this, by considerable intelligence, and by a crusader's zeal, Corbett had conducted a small test on mice which suggested that isoflurane (an alpha chloro ether) had carcinogenic properties [18]. Vitcha, Terrell, and Eger visited Corbett at his laboratory. Convinced that although Corbett's study was fatally flawed (insufficient controls, absence of blinding, inadequate statistical analysis, and failure to use a comparator anesthetic), Airco had no alternative but to stop the release of isoflurane. Corbett had acted with the best of intentions, and with his findings in print there was naught to do but repeat what he had done, eliminating the flaws. Nonetheless, for a time Airco dithered on whether to challenge Corbett, eventually realizing that they would fight a losing battle. In the meantime (and unknown

to us), Eger and Wendell Stevens—with Corbett's help—set about duplicating Corbett's study but correcting the flaws in that study. After several months of indecision, and discussions with the FDA, Airco finally asked Eger and Stevens to conduct the study that they had already set in motion.

So on went the experiment, while Airco and the FDA mused a bit more. And then Eger wryly remembered trouble. Vitcha called and said that the FDA and Anaquest would like to make a minor modification to the protocol—to extend the survival period after anesthetic exposure from 15 to 18 months. However, modification was not possible. The mice were in formaldehyde. There was no way they could grow for an additional three months. It was *mea culpa* time. So Eger and Stevens met with us and confessed their sins, adding that the data seemed to indicate that no inhaled anesthetic caused cancer. Eger remembers being embarrassed at having deceived me but tickled that he had gotten away with it until we asked for the modification. The final answer came after two years of study; isoflurane was exonerated [19].

A few interesting things resulted from this saga. The FDA enacted and then rescinded a rule specific to isoflurane—to withhold approval based on a flawed study. It was probably a stretch of their authority at that time to enact such rules, and it was discriminatory to isoflurane, relative to rules applied to inhaled anesthetics that followed. Faced with this rule stretching, and its effect to delay the release of isoflurane, we acted to extend isoflurane's patent life. We engaged in lobbying, and I (RL) testified at a congressional hearing conducted by Congressman Kastenmeyer's sub-committee on intellectual property. The life of only 2 patents had previously been extended. One was Ronson lighters; a bribed judge had ruled against their patent. Imagine this, he was in New Jersey! That happened in the first half of the twentieth century. The other patent extension applied to a sweetener that, like isoflurane, had been accused of causing cancer. Legislation extending the isoflurane patent life eventually was bundled into the legislation by Waxman and Hatch, restoring patent life of pharmaceuticals for the amount of time they spent in regulatory review. There was a *quid pro quo* for that legislation, making it legal for generic manufacturers to use patented processes in preparation for the generic production of products ahead of patent expiration. Prior to that, it was not legal for generic manufacturers to use a patented process ahead of its expiration. Waxman was anxious to have generic competition as early as possible, and manufacturers were anxious to have patent extension for testing period delays.

And Then Desflurane

In 1981, the Ohio Medical Division of BOC placed its anesthetics business in a new division called Anaquest. Anaquest/Ohio Medical had one considerable success, enflurane, and

another about-to-be success, isoflurane. These scientific, clinical, and financial achievements prompted and supported the 1983 commitment of BOC, to enormously expand the Research and Development arm of the general anesthetic business, then headed by Ross Terrell, a pioneer in the development of volatile anesthetics. The vision was to become the resource for all the major drugs used to provide the anesthetic state, specifically to invent premier opioids, local anesthetics, neuromuscular blockers and reversal agents. These would compliment Anaquest's inhaled anesthetic offerings, meet the increasing demands of ambulatory surgery, and improve the care of anesthetized patients. It was an extraordinarily ambitious goal.

This goal radically changed Anaquest's drug development program. The small, extremely productive activities of Terrell's team of Speers, Halpern and a few others would be expanded several fold. Experts in pharmacology and toxicology would occupy a wing of rooms at BOC's Murray Hill site in New Jersey. By 1984, it housed fifty scientists plus an accredited animal facility to evaluate new chemical entities (NCEs), including new volatile anesthetics. Ted Spaulding, from Hoechst-Roussel Pharmaceuticals joined with Terrell to head this endeavor, particularly to perform in house validation of the efficacy and safety of intravenous therapeutics. It was thought important to bring biology in close proximity to the expanded synthetic chemistry program. Even with this expansion, Richard Wynn, Frieda Rudo, and Paul Thut continued to test some NCEs in the Pharmacology Department of the School of Dentistry at the University of Maryland. Their experience with inhalation anesthetic and muscle relaxant pharmacology, their enthusiasm for the expanded program, and their role as "biology" teammates were crucial to the advancement of the program.

A parallel move was afoot. In 1984, Eger was asked to review the 700+ compounds that Terrell had made in the 1960s, to see if any might have desirable anesthetic qualities that had been overlooked. Consulting with Terrell (who had no memory of their discussions), Eger searched among a subgroup of ether molecules that were halogenated solely with fluorine atoms, believing that these would have the requisite properties of stability, low solubility, and good anesthetic profile as suggested by the tests performed by Rudo. He found 4 molecules worthy of further testing, but only one passed the test of stability—desflurane. Desflurane had been set aside because it had been dangerous to make, had a relatively low potency, and had a saturated vapor pressure near one atmosphere, making its delivery difficult. Fortunately, Anaquest had thought so little of desflurane that they had not published on its properties, or attempted to patent it. That meant that a new patent and exclusivity for 17 years were possible. Terrell gave Eger all the desflurane that Anaquest had kept on the shelf for 2 decades, approximately 10 ml. Because of the limited availability of compound, Eger recap-

tured the desflurane at the end of each experiment by condensing the gas phase with liquid nitrogen. With careful use, Eger and colleagues conducted several experiments in 1985 and 1986. Anaquest became aware of the possibility that desflurane might supply a desirable alternative to isoflurane.

By late 1986, the synthetic efforts within Ken Spencer's chemistry group had resulted in numerous patents, and first-time-in-human testing of intravenous analgesics and a neuromuscular blocking agent. Because of the development time associated with these new chemical entities (NCEs), efforts to in-license¹ both products and newer technologies in drug delivery systems for its small molecule program were also undertaken. It was hoped that these initiatives would rapidly lead to a portfolio of products supplementing the company's major product isoflurane, whose patent expiry in 1993 was imminent. Times' winged chariot hurried near.

In 1987, Anaquest had taken a year's option with Baxter Laboratories for the right to license sevoflurane. At the same time, as noted above, Eger had explored the properties of desflurane. For several months, Anaquest management debated which agent to pursue. Either choice meant a major financial commitment. The decision to develop the next generation of inhaled anesthetics was a difficult and nuanced choice between desflurane and sevoflurane. In retrospect, Paul Thomas (then product manager, later President of Anaquest) summed up the considerations as follows:

"The context of these deliberations included a need to have an anesthetic with a faster recovery than that from isoflurane, ideally with a lower incidence of postoperative nausea and vomiting, and particularly with minimal or no capacity to irritate the airway (especially relevant in children and with the growing popularity of laryngeal mask airways). It was also important to have an anesthetic that could be safely used with lower flow rates (1–2 l/min) because of potential clinical benefits and cost savings. These thoughts informed our analysis of the relative advantages of desflurane and sevoflurane."

"Desflurane had the lowest—better—blood/gas partition coefficient [20, 21], and this plus tests in rats pointed to a recovery that might be faster than with sevoflurane [22]. Desflurane had the edge in safety, its metabolism producing little fluoride ion, and it didn't break down in soda lime [23] or produce Compound A. Thus desflurane passed muster, but the data for sevoflurane were alarming. And the market's experiences with halothane and methoxflurane made the Anaquest team gun shy of instability and decomposition issues. We feared that the worst-case sevoflurane decomposition scenario would weigh heavily on clinicians, if not the FDA. The patent life advantage went to desflurane (16 yrs) since sevoflurane had only Waxman Hatch protection (5–7 years). And Anaquest owned desflurane, but not sevoflurane. Initial studies in animals did not reveal evidence of airway irritation, but transfer of such evidence to humans is unreliable. Still, this plus the lower blood/gas partition coefficient gave us hope that induction in humans would be more rapid."

¹A business practice of granting a patent license to an invention made by one company for the purpose of further development and commercialization by the company taking the license. One party out-licenses and the other in-licenses.

“But sevoflurane offered counterbalancing advantages. Its lesser MAC [24] meant that sevoflurane would require roughly a third the consumption of desflurane, producing a cost advantage. Sevoflurane could be delivered from a conventional flow vaporizer versus the much more costly vaporizer needed for desflurane. Anaquest would provide vaporizers to anesthesiologists using either anesthetic, imposing an additional cost with desflurane of tens of millions of dollars. Capital costs—for a plant to manufacture desflurane—were approximately 80 million dollars more than for sevoflurane. And lack of airway irritation in humans was a known fact favoring sevoflurane [25].”

Thus, when it came time to choose between desflurane and sevoflurane, patent life, pharmacology, production costs, licensing fees and more were on the table. There were human data for sevoflurane [25] (a seemingly good clinical anesthetic) but not even preliminary human data for desflurane. Before deciding, should Anaquest commit millions of dollars to get into human trials? Expensive decisions had to be made on limited data. At the decision meeting, probably in 1986, all the information and arguments were presented to an Anaquest management team. Sifting and winnowing swayed to and fro for a couple of hours. Finally I (RL) suggested that the non-sevoflurane favoring group was biased because sevoflurane was “invented there” whereas desflurane “was invented here.” In his usual low-key manner, Terrell said “No, sevoflurane had been ‘invented *here*’ and discarded years ago for the same reason that was of concern now, instability in the presence of soda lime.” Those prosaic words seemed to provide a good point for polling of the seven present; not a vote, but a poll because I wanted to reserve the right to act contrary to the majority, to weigh product performance more heavily than financial and business considerations. The result was not unanimous but favored desflurane. I announced we had reached a good consensus and asked that we proceed with desflurane. Thus, the path forward leading to an FDA application for human clinical trials began.

In August 1987, Terrell moved from his executive role to the position of Senior Scientist and Advisor, and Hollis Schoepke joined Anaquest as Vice President of Research. With the emphasis now on product development and regulatory approval leading to market, Schoepke brought to Anaquest the experience of managing pharmaceutical R&D in three major pharmaceutical companies.

Paul Thomas commented regarding the launch of desflurane in October of 1992:

“The market introduction of desflurane and loss of patent protection for isoflurane occurred concurrently, and led to intense generic competition from Abbott Laboratories. The profit impact was profound with the selling price for isoflurane declining in a year from approximately \$100 to about \$60 per bottle, greatly decreasing profitability on isoflurane.

“In the late 1980s and early 1990s, several factors forced a dramatic decrease in research and development. These included the in licensing of nitric oxide, and the acquisition of recombinant albumin and the associated development costs for both products. The anticipated steep profit decline for isoflurane, and

the increased expenses associated with the development and launch of desflurane added further to the pressure on the NCE program, and resulted in elimination of the clinical trials. We sharply decreased our basic research efforts seeking improved anesthetic agents. These efforts had found it difficult to improve upon agents such as rocuronium and fentanyl. The recombinant albumin project became more difficult and expensive to pursue than anticipated. Accordingly, we sold our interest in this enterprise. As part of the project shuffling, we protected our development of inhaled nitric oxide for Persistent Pulmonary Hypertension of the Newborn, which turned out to be the correct decision given the subsequent significant clinical and commercial success of the drug. Unfortunately, inhaled nitric oxide’s success was several years later than needed and desired!”

The desflurane project imposed major demands on people and finances at Anaquest. Several nitty-gritty problems had to be faced. Animal and human studies required development of a vaporizer, no small challenge given the saturated vapor pressure of desflurane. Clinicians would also expect to have a monitor that would tell them how much desflurane was being given. It was one thing to produce quantities of desflurane for experimental purposes, but quite another to scale these up for commercial production. A vendor qualified under Good Laboratory Practice guidelines to evaluate safety in animals had to be found. A small group of toxicologists and pharmacokineticists were charged with conducting safety studies, including by this time, studies of mutagenicity. In sum, these studies would be more expensive and comprehensive than those Anaquest had previously undertaken with anesthetics such as enflurane and isoflurane.

Eger presented the safety and efficacy results of desflurane to the NDA Advisory Committee in late 1991. Like presenters at today’s Advisory Committee meetings he had hundreds of slides at his disposal, but these were in numerous carousels. He magically knew the location of the one slide needed to answer each committee member’s questions. The NDA was approved in 1992.

This delay in new products available for marketing, the increased costs associated with the in-licensed products, coupled with generic isoflurane availability resulted in BOC’s exit from the business. The BOC Group was primarily an industrial gas company, much more in tune with global strategies for capital intense industries rather than the intense research and regulatory nature of the pharmaceutical industry. BOC decided to divest itself from the health care business. The anesthesia equipment and monitoring businesses (Ohmeda) were sold to Datex Instrumentarium (subsequently GE). The inhalation anesthetics business was sold to Baxter Laboratories. Anesthetic musical chairs!

The BOC decision was similar to those made by Air Products and NCG. Decades earlier it had been cost effective for gas suppliers to make and sell the equipment that delivered gases to patients. As each of the business areas became more complex, specialization became more competitive and cost effective. A single management team found it increasingly

difficult to be expert at several major tasks (e.g., equipment manufacture, cryogenics, and development of pharmaceuticals). The economic advantages of specialization overtook the economic advantages of consolidation. For a time, Vitcha's enthusiasm convinced us that we could and should do both equipment manufacturing and pharmaceutical development at the Divisional level, and much more at the corporate level, but ultimately, the forces of specialization won out.

Two decades later, in 2011, Paul Thomas commented on Anaquest's experiences with the introduction of desflurane, saying that:

"the introduction was modeled after Hernando Cortez's strategy upon arrival in the New World. He burned all of his ships to convince his crew that there was no turning back (i.e., to isoflurane). The New World needed to be conquered (i.e., we needed to convince anesthetists of the value of desflurane). We devoted substantial resources to the desflurane launch (vaporizer placements, clinical support, marketing efforts, sales force commissions) and priced it aggressively to support conversion of the market from isoflurane to desflurane. We were partially successful in our efforts but never fully replaced the profitability lost due to generic isoflurane competition. And then there was the competition that came from the launch of sevoflurane."

"Our assumptions concerning the safety of sevoflurane and our hopes regarding a lack of laryngospasm with desflurane were in hindsight misplaced. Both anesthetics found a place in anesthesia practice. I don't know if BOC would have supported the simultaneous development of both drugs but clearly we should have pushed for this option!"

And Sevoflurane

Just as had Terrell, Bernard Regan at Baxter independently synthesized sevoflurane, and Richard Wallin (also Baxter) performed several studies of its anesthetic and physical properties [26]. Baxter offered to license sevoflurane to ICI. One of us (JG) was asked to evaluate it.

"I liked its anaesthetic properties as seen in animals, but noted its marked degradation to a toxic product on contact with soda lime. We were able to show in an experiment in a dog that the degradation product was adsorbed onto soda lime, and changed the colour of the indicator dye, but did not appear to accumulate in the circuit. However, I was concerned that all CO₂ absorbents might not behave in the same way and felt that the degree of chemical instability observed would not be acceptable in a modern anaesthetic. I recommended rejection of the licensing offer in 1977."

So no one wanted this orphan, sevoflurane, until a small fearless Japanese company, Maruishi reopened the issue in the 1980s and successfully brought sevoflurane to market in Japan. In the early 1990s, Maruishi offered to license sevoflurane to Abbott Laboratories who accepted and were enormously successful in sevoflurane's development and sale.

Industry Contributions to Safety

A more recent example of the relationship between industry and the anesthesia specialty is the formation of two US-based anesthesia foundations in the 1980s. The early 1980s were challenging years for anesthesia equipment manufacturers, malpractice insurance companies, and anesthesiologists buying malpractice insurance. Owing to the joint and several liability laws, manufacturers could be held responsible for 99% of a malpractice award even if their equipment was only 1% responsible. New machines had safety features that old machines lacked, and manufacturers were sometimes held accountable for human errors resulting from absent safety features in the older machines. For example, in the early 1980s, the TV program 60 Minutes aired an exposé of morbidity and mortality due to adverse anesthesia incidents. This highlighted manufacturers, hospitals and clinicians who failed to develop, obtain and use systems with oxygen monitors. The manufacturer with the oldest equipment in the field (i.e., the one at greatest risk because its equipment might lack specific safety features), Puritan Bennett-Foregger, left the anesthesia business.

In the early 1980s, Ohmeda (formerly Ohio Medical Products) organized a preliminary "Safety in Anesthesia" symposium led by Nick Gravenstein. From this meeting, a commitment was made to create the Anesthesia Patient Safety Foundation (APSF). In 1985, led by Ellison (Jeep) Pierce (1928–2011), the American Society of Anesthesiologists (ASA) and industry members provided financial support for the APSF. This first multi-disciplinary organization, created to improve patient safety in the context of anesthesia, has succeeded in its purpose, as confirmed a decade later by the National Academy of Sciences/National Institutes of Health, who recognized the APSF as a model for improving quality of care within a medical specialty [27].

In 1986, the ASA formed the Foundation for Anesthesia Education and Research (FAER), to expand opportunities for education and research in anesthesia, especially at the post residency level. Funding for basic research from agencies such as the NIH and the National Science Foundation had increased dramatically post World War II, but funding for research in anesthesia had not undergone a commensurate increase. It was intended that FAER would help narrow that gap and thereby ensure the growth of anesthesia as a worthy academic endeavor.

The ASA asked Bill Hamilton to obtain industry support for FAER. He invited me (RL), and Clifford Parrish from Burroughs Wellcome, to a joint discussion in Portland, Oregon. We quickly agreed that education and research were laudable labels and the FAER title was born. Fund raising progressed at a good pace but received a major shot in the arm when the ASA president, Howard Zauder, learned of funding needs and, on the spot, announced a doubling of

refresher course fees, from \$5 to \$10 with the increased proceeds devoted primarily to FAER.

FAER has succeeded, as reflected in the return on investment. Every dollar spent by FAER on recipients has generated several-fold greater amounts from the NIH and other granting agencies. Once again, industry members were full partners in the design, funding and implementation of FAER.

Development of Calibrated Anesthetic Vaporizers

Halothane was a game-changing anesthetic. The positives were that it was nearly without pungency, didn't stimulate the circulation, and had a solubility far less than that of diethyl ether, the main potent volatile anesthetic competitor. The negatives were that it was nearly without pungency, didn't stimulate the circulation, and had a solubility far less than that of diethyl ether, the main potent volatile anesthetic competitor. That is, it could induce anesthesia in a thrice and kill patients in two thrices. Its safe use would depend upon precise control of the delivered concentration. Thus, the introduction of halothane by ICI in 1956 prompted development of a calibrated, temperature compensated, and flow-controlled vaporizer. With the exception of the Copper Kettle, invented by Lucien Morris in 1953 (see chapter 39), competing vaporizers offered limited to poor control over the delivered anesthetic concentration. An additional important safety factor of the new vaporizers was that they were positioned outside the anesthetic circle (breathing system) making their output independent of ventilation.

Two entrepreneurs, Bill Edmonson and Wilfred Jones had been employed by Coxeter, a UK manufacturer of anesthetic equipment acquired by British Oxygen Corporation (BOC). Dissatisfied with their new situation, they left BOC in 1949 to found a small company in the north of England. Initially, the entrepreneurs toyed with a new dispensing system for cyclopropane, accordingly coining the name Cyprane Limited for their company. Cyprane never made a cyclopropane dispenser, starting instead with a hand-held inhaler for trichloroethylene, the Cyprane Inhaler, used for analgesia during childbirth (it is still used for that purpose). Concurrently, ICI, based in the northwest of England was developing the new anesthetic, halothane. Only the Pennine hills between Yorkshire and Lancashire separated Cyprane Limited and ICI.

Working closely with ICI, Edmonson and Jones modified a vaporizer that they originally had designed for trichloroethylene (the Tritec). The vaporizer accepted the total flow of delivered gases and produced in these gases the concentration of anesthetic precisely indicated on a control dial, a concentration that nominally was not altered by changes in the flow rate or agent temperature. As halothane had been branded Fluothane by ICI, the vaporizer calibrated for halo-

thane was called the Fluotec, and was used in the clinical evaluation of Fluothane. The Tritec and Fluotec were the world's first fully calibrated vaporizers, devices producing a known anesthetic concentration that was mostly independent of inflow rate and fully compensated for temperature variation. They were the first variable bypass vaporizers.

A minor incident reflects the seriousness and professionalism of the industry. Early in the life of the Fluotec, a clinical report suggested that the control knob had loosened, resulting in delivery of an incorrect, potentially hazardous, concentration. Wilf Jones was devastated by the thought that such a failure was possible. He was convinced that the vaporizer had been dismantled and incorrectly reassembled, but Cyprane recalled all Fluotec vaporizers. Following modification, the vaporizer was re-issued as the Fluotec Mark II.

In the US and Canada, ICI partnered with Ayerst Laboratories and released halothane as Fluothane. In parallel, Cyprane appointed as its agent, Fraser Sweatman Inc, a small supplier of medical equipment which bore the name of its larger-than-life founder. It had a head office in Toronto and a subsidiary in Buffalo, New York. A talented marketing entrepreneur with an infectious enthusiasm for business, Sweatman built a close working relationship with the Cyprane founders. He persuaded Ayerst to offer the Fluotec free to hospitals ordering a minimum annual quantity of halothane. The result successfully promoted both halothane and the Fluotec. Fraser wanted the Fluotec to become the gold standard in the US and promoted its sale to competing producers of anesthesia machines in order to maximize penetration of the Fluotec into the US market. The approach in the US served as a model for the later release of enflurane, isoflurane and desflurane and their corresponding vaporizers in the US.

The Fluotec II was good enough, especially with the marketing plan assembled by Fraser-Sweatman, to capture most of the market. Its primary competitor—and that only in the US—for a flow and temperature compensated vaporizer was the copper kettle. But the copper kettle required calculations to define the concentrations that it produced, and this made it less popular with mathematically challenged anesthetists. Still, the Fluotec II vaporizer was less than precisely accurate, and it failed to compensate for the effect of back-pressure from the breathing circuit. In 1966, Draegerwerk, a German manufacturer of medical equipment, seized on these limitations in its introduction of a vaporizer (named "Vapor") for halothane. For the first time, Cyprane had a serious competitor.

By now relatively wealthy, the Cyprane founders decided in 1967 to sell the business, giving Fraser Sweatman time to produce a financing proposal before seeking other buyers. Sweatman assembled a buy-out financed by a £500,000 equity investment from Industrial and Commercial Finance Corporation (ICFC), a consortium of High Street banks set

up by the UK government to promote new start-up businesses. ICFC later became 3i, a noteworthy venture capital firm.

In 1967, Cyprane, with Wilfred Jones, developed the Fluotec III, but the output concentration was not consistent over the design flow range, and the vaporizer was difficult to calibrate, a problem that Sweatman attributed to a lack of consistent internal laminar flow. Jones was not convinced. A determined Sweatman tracked down the designer of the Vapor, Peter Schreiber, and recruited him to join Sweatman's US team.

But Schreiber and Sweatman combined could still not convince the Cyprane design team that there was a problem with the Fluotec III (particularly with laminar flow), and interest turned to another important area, the design of a Safety system to prevent filling of vaporizers with the wrong drug. Meanwhile, reluctant to put at risk his reputation and market position, Sweatman delayed launch of the Fluotec III in the US.

At this point in 1967, in London, Sweatman fortuitously met socially with David Needham (Fig. 66.3), an Imperial College post-doctoral research fellow in laminar flow, albeit at hypersonic speeds. Sweatman persuaded Needham to test his theory. Needham proved Sweatman correct and, better yet, Needham came up with a solution. Needham continued to consult for Cyprane and in 1969 joined the board as technical director, becoming the managing director in 1971. Schreiber then left Fraser Sweatman to form Draeger North America in partnership with his previous employer, thus becoming a direct competitor of Cyprane. Fraser Sweatman replaced Schreiber with Al Bickford, the designer of the Foregger Fluomatic.

Musical Chairs or Incest?

Meanwhile, Abbott Laboratories had developed methoxyflurane (Penthane), an inhaled anesthetic with strong analgesic properties. Cyprane produced a calibrated vaporizer for Abbott, the Pentec, just in time for clinical trials and an anticipated international launch.

Also in the 1960s, Airco Inc's subsidiary, Ohio Medical Products, turned to Cyprane to produce the Enfluratec for the US launch. Meanwhile, problems of renal toxicity derailed methoxyflurane, and to fill the gap, Abbott licensed the distribution rights for enflurane outside the US from Ohio, and Cyprane supplied the Enfluratec vaporizers.

The possible launch of two new anesthetic agents and an associated possible demand for anesthesia machines capable of dispensing enflurane, halothane or methoxyflurane raised the potential of a disastrous filling of a vaporizer with the wrong anesthetic. This threat prompted development, in approximately 1966, of the safety filling system in which the filler port on the vaporizer and the bottle neck were each uniquely coded for a specific agent.

Fig. 66.3 David Needham. (From DN)

The prospect of a worldwide market for vaporizers made Cyprane an acquisition target, and in 1972 the company was sold to the BOC Group, from whom its founders had escaped some 25 years earlier.

Eger's and Stevens' successful experiments "resurrected" isoflurane (now branded Forane), and FDA approval arrived earlier than expected. Ohio's hopes of launching Forane with an in-house vaporizer were dashed when the decision was taken to go to market in the early 1980s. Once again, Cyprane reacted quickly to produce a vaporizer calibrated for isoflurane, named the Fortec, doing so in barely sufficient quantities to support the US launch. (Eger remembers many complaints of delays in receipt of sufficient supplies of vaporizers). DN remembers the struggle at Cyprane to divert common components from the Fluotec line to produce more Fortecs, and the resulting speculative ordering which generated a two-year backlog. All this was against a backdrop of grim economic conditions in the UK with the confrontation between Margaret Thatcher and the striking miners unions, and a government-enforced three-day week to conserve energy stocks. It was, as they say, character building.

Despite these stresses, the company maintained production that met demands, and in the 1970s and 1980s, controlled an estimated 85% of the world market for calibrated vaporizers. The BOC Group now brought together all of its worldwide subsidiaries in medical equipment and consumables, including Cyprane, under the umbrella of a new

company, the Medishield Corporation. In 1976, BOC made a successful acquisition bid for Airco Inc., which was immediately blocked by the Federal Trade Commission (FTC) on anti-trust grounds, citing in particular, the combined (Fraser Sweatman-Cyprane) dominance of the anesthesia vaporizer business in the US. Four years later, the FTC objection was removed on the condition that Medishield divest itself of its Fraser Sweatman business in the US, helping to establish Fraser Sweatman as a viable competitor to Cyprane.

1981 and later saw the birth of two new important names in the world of anesthesia, and the end of two others. BOC commenced the task of integrating the Medishield and Ohio Medical businesses under the global name BOC Health Care, thereby creating a \$650 million enterprise. The medical equipment companies were brought together under the name Ohmeda, and the Cyprane vaporizer was upgraded to produce the Ohmeda Tec 4 range in 1985. These vaporizers continued to use the basic design of the Fluotec III. The pharmaceutical side of the business emerged as Anaquest and continued the pursuit of new anesthetic agents, particularly desflurane. In the late 1990s, the group was split up and sold to new owners.

Vaporizers continued to be calibrated for each newly introduced anesthetic. Engstrom marketed an anesthetic machine in the mid 1980s, where the bottles of anesthetic agent (halothane, enflurane and isoflurane) were screwed on to indexed ports in a compartment on the rear of the machine. Having selected a concentration to be delivered, the selected agent was electronically and accurately injected into the gas stream. With this exception, the basic vaporizer mechanism remained largely unchanged. Desflurane was a challenge because its saturated vapor pressure of nearly an atmosphere at room temperature precluded the use of the Tec 4 variable bypass technology. An entirely new approach seemed to be required. Enter the Tec 6, a truly new vaporizer, with a structure unlike that of any previous vaporizer. The concept was simple: convert desflurane into a gas (by heating the desflurane) and then meter the gas into a diluent flow of oxygen with or without other gases (e.g., nitrous oxide or air). The concept was simple, but implementing it so that the functional result was the same as with the familiar variable-bypass vaporizer was a challenge. The device had to give an indicated concentration at any diluent inflow rate and at any ambient temperature (within reason). The challenge was met.

The story ends with a return to the future. Through the 1990s, the variable bypass vaporizer had been marginally improved following its release in the 1960s. Accuracy had increased over a wide range of flow rates and temperatures, and a key lock prevented filling with the wrong anesthetic. But it was expensive and could not accommodate desflurane because of the proximity of desflurane's vapor pressure to one atmosphere. In 1998, the Datex-Ohmeda Anesthesia Delivery Unit (ADU) machine was released. It separated the

sump holding anesthetic from a control unit. There were different sumps for different anesthetics. Each sump was coded to inform the control unit of the identity of the sump contents. The control unit was programmed to adjust the flows through and past the sump, to produce the concentration indicated on the control knob of the vaporizer. It worked at more than one atmosphere and thus could accommodate desflurane as well as anesthetics with lesser vapor pressures. It was more efficient because the control unit could deal with several cassettes (sumps). General Electric bought the rights to the vaporizer which is now widely used.

The Discovery and Development of Propofol

Around 1965, the search for a novel, short-acting intravenous anesthetic began in the Pharmaceuticals Division of ICI. Thiopental was the standard agent used for induction of anesthesia. ICI sought a new agent reproducing the quality of anesthesia provided by thiopental, but more rapidly metabolized, such that rapid recovery could be obtained if anesthesia were maintained by repeated bolus injections or an infusion. New compounds were screened in mice, and those showing hypnotic activity and an acceptable safety margin were taken forward in other species.

A tension exists for two properties of an intravenous anesthetic: water solubility is needed to facilitate intravenous injection, but access to the brain requires lipophilicity. One solution to this problem is to use compounds that are salts of a weak acid or base. Such salts are soluble in water (blood), but able to dissociate back to the free acid or base needed to enter and act in the brain. Sodium thiopental made into a salt by adding sodium hydroxide is an example. By the end of 1971, the ICI team had studied over 2000 of these compounds but no candidate drug emerged.

A second solution to the solubility problem is to dissolve the putative anesthetic in some lipid-like substance that can be injected safely into blood. In 1972, I (JG; Fig. 66.4) joined the Biology Department at ICI, becoming responsible for the pharmacological evaluation of new compounds. Back in the 1960s in Europe, Bayer Laboratories had introduced the eugenol derivative, propanidid (Epontol), as a short-acting intravenous anesthetic. Propanidid was hydrophobic and was dissolved with the aid of a surfactant, polyoxyethylated castor oil (Cremophor EL), which Bayer also manufactured. This solubilizing agent allowed poorly water-soluble compounds to be injected. Roger James, one of the ICI chemists selected a number of poorly soluble compounds synthesized before 1965 and held in the ICI compound collection, as these could now be tested using this approach. I (JG) did the testing.

In early 1973, hypnotic activity was detected in ICI 43117 (2,6-diethylphenol). No further work was done with

Fig. 66.4 J (Iain) B Glen. (From JB Glen)

this compound because induction of anesthesia in rabbits was slow, but it provided a lead for James to follow. He submitted about 150 related alkylphenols for testing and later that year, I demonstrated the anesthetic activity of propofol (ICI 35,868; 2,6-diisopropylphenol, with the trade name of Diprivan). Many of these compounds had hypnotic activity [28], but propofol had the optimum balance of properties in secondary tests designed to predict rate of onset, duration of effect, rate of recovery, freedom from excitatory effects, absence of accumulation after repeated injection, and clinically acceptable effects on respiration and circulation. Thirteen years elapsed before ICI first marketed propofol, the delay principally reflecting the difficulty in obtaining an acceptable formulation of this highly lipophilic oil.

Around 1972, Glaxo Research Laboratories introduced the combination of two steroids (alphaxalone/alphadolone acetate), named Althesin, again formulated with Cremophor EL, as a new short-acting IV anesthetic. The clinical acceptance of this new agent and Epontol prompted the trial of propofol in Cremophor EL. However, by 1975–76, several severe anaphylactoid reactions had been reported with both Althesin and Epontol. The contribution of Cremophor EL

to these reactions was uncertain; no animal model revealed a deleterious effect of Cremophor. Nevertheless, clinicians began to regard Cremophor with suspicion. It was agreed to proceed to clinical trial of propofol with the Cremophor preparation on the understanding that an alternative non-Cremophor formulation would be developed before marketing the product. No Cremophor-containing agent ever became available in the US.

Brian Kay, an anesthesiologist from Derby in the UK, conducted the first clinical trial, with a formulation containing 2% propofol in 16% Cremophor EL and 8% ethyl alcohol, while visiting George Rolly's department in Ghent, Belgium in 1977 [29]. Kay was a quick worker and three days later he telephoned ICI to report that he had already studied 22 patients. Induction of anesthesia was rapid and smooth, and recovery prompt. However, two unexpected results were obtained: first, anesthetic potency appeared to be greater than had been anticipated, with 1.0 mg/kg being an effective dose in these nominally unpremedicated patients. The one page record forms provided by Kay provided limited information and many years later when I approached George Rolly requesting a copy of the anaesthetic record of the first patient to receive propofol, I discovered that these patients had in fact been premedicated with fentanyl and droperidol. Second, several patients reported pain on injection into the smaller veins of the hand. As the pain was thought to relate to the free aqueous concentration of propofol in the preparation, the propofol concentration was decreased to 1%. Because it was no longer needed to solubilize the propofol, the alcohol was also removed. Benefit from these maneuvers was confirmed in further clinical studies. A dose of 2.0 mg/kg induced anesthesia with this second formulation.

An important step forward occurred with our development of an animal model in pigs, in which Cremophor produced an anaphylactoid response resembling that seen in patients [30]. Cremophor EL or Cremophor-containing anesthetics produced no effect on first administration, but a second injection given 1–2 weeks later produced an anaphylactoid response in almost 100% of test animals. In this model, a synthetic polyoxyethylene/polyoxypropylene surfactant (Synperonic PE39/70) made by ICI produced no adverse response. This was one of about 100 alternative solubilizing agents that we examined, and agents with satisfactory pharmaceutical properties were taken forward for animal testing in a cascade of tests. Although rats and dogs tolerated the Synperonic formulation well, in 30-day toxicology tests, histological evaluation detected minor, unexplainable hepatic changes. Human studies were never conducted with the formulation.

Clinical studies continued with the Cremophor formulation in Europe, in more than 1,000 patients, until several anaphylactoid reactions were encountered, and studies were halted. Cremophor was thought to be responsible for these reactions. Because the clinical profile continued to

look promising, a decision was taken in 1981 to develop an emulsion formulation of propofol. Two years of study were required to identify constituents for a final suitable preparation. A formulation containing soybean oil with purified egg phosphatide was selected, and a formulation with these materials containing 1% propofol produced less pain in rats than did the Cremophor formulation [31]. The emulsion formulation did not alter the anesthetic properties, and did not produce an anaphylactoid response in pigs.

Ron Stark (an enthusiastic and well-organized ICI physician) coordinated the clinical evaluation of the emulsion formulation, and I was transferred to the Medical Department at ICI to assist with the international trials. The first study began in July 1983, and a full clinical evaluation, including repetition of dose finding and pharmacological compatibility studies, was completed by the end of 1984. Many anesthesiologists were involved in clinical trials and it is difficult to single out individuals. In the UK most of the major academic centers took part in studies with the Belfast department led by the late John Dundee prominent in early induction studies, while the Bristol department with Cedric Prys-Roberts and John Sear investigated continuous infusion techniques for maintenance of anesthesia. In Germany, Alfred Doenicke in Munich, and Juergen Schuttler in Bonn were early investigators. Elizabeth Gepts in Brussels and Frederique Servin in Paris, working in collaboration with Ian Cockshott at ICI performed pharmacokinetic studies. Patrick Ravussin in Switzerland and Hugo Van Aken, at that time in Belgium, conducted studies relevant to neuroanaesthesia.

The first regulatory approval was obtained in 1986 and I had the pleasure of participating, together with John Dundee from Belfast, in the first launch meetings, in Auckland and Rotorua, New Zealand, in May of that year. Clinical trials in the US followed the European development program. One of the first of these was done in Chicago by Bob Fragen, who had used the drug while on sabbatical leave in Holland. Paul White in St Louis studied its use in outpatient anesthesia. As opportunities in maintenance of anesthesia were further explored, Steve Shafer at Stanford, Jerry Reves and Peter Glass at Duke, and Carl Hug and Peter Sebel at Emory, became involved. Propofol received FDA approval in 1989.

With further clinical trials, approvals were extended to long-term maintenance, sedation for local-regional anesthesia and intensive care, use in children and use in specialized areas such as neuroanesthesia. In most countries a 2% formulation was introduced to limit the fat load associated with prolonged use for anesthesia or sedation. In the US, some instances of misuse of the standard formulation in an effort to economize, led to bacterial contamination and several cases of postoperative fever. A modified formulation containing 0.005% ethylenediamine-tetraacetate (EDTA) to limit bacterial growth (if accidental bacterial contamination occurred) was introduced, first in the US in 1997. Sodium

Fig. 66.5 The Ohmeda 9000 infusion pump produced by BOC Health Care in the UK in 1990 was the first of a new generation of computer controllable syringe drivers with the ability to deliver a maximum infusion rate of 200 ml/h and ‘bolus’ rates of 300, 600 or 1200 ml/h. (Courtesy of JB Glen)

metabisulphite was tested by Zeneca, but did not prevent bacterial growth at the pH specified in the formulation of Diprivan. However, by altering the pH specification, a bacteriostatic effect was achieved and a generic propofol formulation containing this additive was developed by Gensia Sior and marketed by Baxter in the US.

In combination with opioids, propofol is now frequently used to produce total intravenous anesthesia (TIVA). An initial barrier to the wider use of propofol for maintenance of anesthesia by infusion was the lack of suitable equipment. Volumetric pumps were bulky and not ideal for a one or two-hour procedure. Most syringe pumps available in 1986 had a maximum delivery rate of 99 ml/h. The Ohmeda 9000 pump (Fig. 66.5) was the first of a new generation of syringe pumps with an extended dynamic range, a range sufficient to allow induction as well as maintenance of anesthesia by infusion [32]. Similar devices followed from Graseby Medical, Cardinal Health, and Fresenius-Kabi in Europe, Terumo in Japan and Bard, Medex and Baxter in the US.

Fig. 66.6 Delegates invited to attend a workshop on ‘Target Controlled Titration in Intravenous Anaesthesia, co-sponsored by ICI Pharmaceuticals and Janssen Pharmaceutica in Holland in 1992 included Academicians from the US (Julie Barr, Peter Glass, Carl Hug, Christina Mora, Jerry Reves, David Watkins, Steve Shafer, Don Stanski), from the UK (Michael Halsey, Cedric Prys-Roberts, Gavin Kenny, Martin White), from Germany (Juergen Schuttler), from Belgium (Elisabeth Gepts, Alain D’Hollander), from France (Frederique Servin), from Australia (David Crankshaw, Laurie Mather), from South Africa (Johan Coetzee), and a representative of the FDA in the US (Dan Spyker). (Courtesy of JB Glen, who organized the workshop)

Many infusion schemes were proposed for maintenance of anesthesia, one of the most popular being the Bristol scheme where infusion was successively decreased from 10 to 8 to 6 mg/kg/h to accommodate decreasing redistribution of propofol [33]. In 1981, Helmut Schwilden, a mathematician and anesthesiologist at the University of Bonn, introduced the concept of target-controlled infusion (TCI), whereby a pharmacokinetic model is incorporated into the pump software, and the pump controls the infusion rate, to achieve a desired target drug concentration. After extensive discussions with academic groups with an interest in this area (Fig. 66.6), ICI (now Zeneca) decided in 1993 to commercialize the system developed by Gavin Kenny and Martin White in Glasgow. The clinical utility of this approach, and their system, had been demonstrated, and Zeneca conducted an extensive 3-year program which involved software design and validation, regulatory discussions, the development of delivery performance specifications and clinical trials [34]. Following completion of this program, approval for the administration of propofol by Diprifusor TCI was obtained in the UK in 1996. This technique, which facilitates titration of propofol during maintenance of anesthesia or sedation, is now available in most countries of the world, but not to date in the US. See Chapters 26 and 33 for more details on the history of TCI.

Educational Support by Industry

For more than a half century, industry in the US and elsewhere has supported education of members of the anesthesia community. This has taken the form of grants for educational purposes, as support of speakers dedicated to conveying information concerning a specific device or drug, and as

distribution of educational materials and at times support for publication of proceedings of meetings, the subject of which may be a specific pharmaceutical or device. Support might underwrite a meeting or construction of written or electronic resources such as the books and videos produced for the Distinguished Professors Programs, underwritten by Baxter Healthcare. These might consume hundreds of thousand of dollars—for example the program that resulted in the textbook Eger wrote with James Eisenkraft and Richard Weiskopf on the Pharmacology of Inhaled Anesthetics [35], and the video that accompanied the book. Teaching programs in the US and abroad, particularly student nurse anesthetist programs, have used tens of thousands of copies of the book and associated DVD. As noted earlier, industry contributed to the organization and funding of FAER and continues financial support of the WRSA, APSF, and the AANA Research Foundation.

There is an obvious self-interest, of promotion by industry in the support of programs that focus attention on the virtues of products and devices. Selection of materials and speakers may create an unbalanced presentation of information. Industry has been accused of “buying” members of the anesthesia community by providing gifts, sometimes trivial handouts such a pens or flash drives, and sometimes far fancier attractions such as a meeting at a fancy resort. But one member of industry (private communication) suggests that there are positive reasons for industry’s support of clinicians. By partnering with specialists, industry can better appreciate the decision-making processes of clinicians and better appreciate their frustrations and unmet needs. Such an appreciation enables a more effective approach to those issues over the long haul. I think steps taken to safeguard against favoritism as a result of commercial incentives to customers have merit. But I also believe that ways will be found to get

a company's message to customers for it has an incentive to do so. Anesthetists may be safeguarded against undue influence from such messages because they immediately see the effects of products on patients.

Regardless of where the truth lies, there has been an increasing concern by educational institutions, professional societies, and government organizations that industry's "educational" ventures distort the process of selecting the best drug for individual patients. Sometimes the response to these concerns was "I can't be bought by a gift of a pen or a book bag or even a one time trip to Miami." But that may not be true. When someone is nice to you, you may wish to return the favor, even for something as trivial as a pen or book bag. The salesman has become your friend, and friends help friends. Evidence suggests that repeated contact from, and advertising by, pharmaceutical companies can affect physician choice.

The resulting advocacy by those opposed to such support is sometimes farcical. One of the editors of this book (LJS) was at an ASA meeting and as Editor of *Anesthesiology*, was carrying a huge volume of material for discussion at various ASA business meetings. He was and is adamantly opposed to industry providing gifts and anesthetists accepting them. Still, he found himself in need of a book bag to carry materials and despite his principled position, accepted a book bag from a vendor advertising the merits of the vendor's offerings. LJS arrived with his materials in the book bag, having concealed his indiscretion by turning the bag inside out. Unfortunately, another one of the editors of this book (EIE) saw LJS carrying the bag. EIE has far fewer scruples than LJS and has never since missed an opportunity to tease LJS for his fall from grace.

Over the past decade, the voices arguing that educational support by industry distorts the selection of drugs and devices have prevailed. Gone are the pens and most book bags. Gone are the free lunches. Speakers underwritten by industry cannot now speak at universities, and pharmaceutical representatives are now banned from distributing "educational materials" at most teaching institutions. Some departments of anesthesia forbid residents to attend industry sponsored dinners or meetings. Pharmaceutical companies have responded to the pressures by scripting the material that can be used by speakers that they support.

One can debate whether more has been lost than gained in this process, but the purpose of this book is to tell a story, not to judge. I (RL) remember standing on a balcony overlooking the commercial exhibits at the San Francisco convention center, with an unnamed ASA officer. He said he thought the ASA needed to allocate more break time for the exhibits because more education was going on there than at the scientific sessions. Correct or incorrect, I am sure what he said was not for attribution.

At present, the focus of industry on educational support in the US has markedly diminished. In part this has resulted from the pressures brought to bear on industry by academic institutions and the implied threat of regulatory action by government agencies. In part, it results from the loss of patented positions and thus the loss of an incentive to compete with a privileged product. And the rise in generic competition has decreased the amount of "discretionary funds that industry has available to support educational ventures.

These perceptions and changes may differ from those in other parts of the world. Since the mid 1980s, Australia-New Zealand has had an Anaesthesia Industry Liaison Committee of representatives from the specialty and industry. The committee oversees involvement of the industry in major scientific meetings, assuring the achievement of mutually agreed objectives, including ensuring that exhibitors are reasonably treated (e.g., have adequate space near to delegates). One result is that morning and afternoon tea breaks and lunches are held in the exhibition space. This relationship has been an effective one, one built on the principle that industry and the specialty are in the same business and can learn from and educate each other. (personal communication, Rod N. Westhorpe).

Some Conclusions

The profit motive that drives and enables industry has been part of the history of anesthesia from its beginning. Dreams of financial gain animated Morton's demonstration of the anesthetic effects of ether. Without that incentive, the discovery of anesthesia would have been delayed.

We have presented exemplars of historical and ongoing contributions of industry to the advancement of anesthesia. In concert with clinicians, industry has supplied the specialty with anesthetics and anesthetic adjuvant drugs and the means to deliver and analyze them. Anesthetists have expressed their needs and worked with industry to generate these new and better products. Industry has recognized a responsibility beyond the supply of better products. It has materially advanced the specialty by its support of societies, foundations, and national and local educational ventures. It has been and is a symbiotic relationship in which everyone wins, especially the patient.

The History of the Anesthetist as a Perioperative Physician

67

Marlene R. Meyer and Jeanine P. Wiener-Kronish

Summary

This essay provides exemplars contributing to the evolution of anesthesia from empiricism and technical skill to a present focus on evidence based medicine.

John Snow (1813–1858) fathered modern epidemiology. He devised principles used to assess anesthetic depth, and made vaporizers that reliably controlled ether and chloroform vaporization. His analysis of anesthesia-associated deaths provided the first perioperative outcome study.

Arthur Guedel (1883–1956) revived Snow's signs of anesthetic depth, and with Waters constructed the modern oral-pharyngeal airway.

In 1927, *Ralph Waters* (1894–1979) initiated the first academic department of anesthesia based on research, teaching, and administration.

John Lundy (1894–1973) developed the anesthesia department at the Mayo Clinic, helped establish the American Board of Anesthesiology, created the first blood bank, and encouraged the AMA to recognize anesthesia as a specialty.

Gertie Marx (1912–2004) brought modern anesthesia into the labor ward. She championed epidural anesthesia, providing maternal pain relief while minimizing the risks of newborn aspiration and death from deep sedation.

John Bonica's (1917–1994) articles and textbook inspired new techniques for treating pain. In 1960, he initiated a multi-modal approach to pain management.

Bjørn Ibsen's (1915–2007) use of artificial ventilation to support breathing during Copenhagen's 1952 polio epidemic, led to today's Intensive Care Units.

Peter Safar (1924–2003) promoted closed-chest cardiopulmonary resuscitation. He established the first residency in intensive care medicine (ICM).

In 1952, *Henry Beecher* (1904–1976) suggested the use of placebo controls in human studies. His 1954 study showed the lethality of unantagonized muscle relaxants. In 1966, he developed principles of informed consent for patient care and human experimentation. In 1968, he used brain death to define death, itself.

Charles Robson (1884–1969) was the first pediatric anesthesiologist, serving as chief of Anesthesia at Toronto's Hospital for Sick Children from 1919 to 1950.

In 1953, *Virginia Apgar* (1909–1974) published the "Apgar Score" that became the international standard used to assess a newborn's physical status.

Goran Haglund (1915–2007) used Ibsen's approach to manage the 1952 polio epidemic in Sweden, developing the paradigm leading to pediatric ICUs. He also designed a pediatric ventilator.

Introduction

Today's anesthesiologist assesses the perioperative risk of patients who are to undergo anesthesia. This has become complicated, given the increasing diversity and severity of illnesses, the increasing extremes of patient age, and the myriad procedures requiring anesthesia care. This risk assessment requires acquisition of pertinent information about the patient and their medical history, and additional investigation where necessary to guide the care plan.

At times the anesthesiologist may be called in consultation and at other times may seek consultation from other medical

specialists. With the needed information in place the anesthesiologist discusses the anesthetic plan with the patient and their family. The discussion will include explanation of risks and benefits, describing the post-procedure care, answering the patient's questions, and obtaining their consent to the plan. The anesthesiologist as a perioperative physician plans the pre-operative medical management, intra- and immediate post-operative care, pain management and, when indicated, intensive care or other interventional therapy.

Anesthesia as a medical specialty had humble beginnings. A surgeon might ask anyone to "give ether". In Britain and the antipodes such "etherizers" might give chloroform and be called "chloroformists". The more than century-long evolution from etherizers to physicians practicing a medical specialty required the acquisition of scientific thinking and the development of a considerable body of knowledge, culminating in today's anesthesiologist as a perioperative physician who supplies more than anesthesia.

Many contributed to this evolution. A few individuals created the basis for the specialty and led the anesthesiologist beyond the operating room to further benefit patients. This essay will describe notable individuals or exemplars whose interests, expertise, and leadership created diverse models of patient care. They may apply to special patients (e.g., children, parturients, patients having suffered a heart attack), areas within hospitals (Intensive Care Units, Post Anesthetic Care Units), new services (blood banking, pain management, preoperative assessment clinics), or a consideration of ethics in medicine (informed consent, when is a patient dead?) Such individuals moved the specialty from empiricism and technical skill to a present focus on evidence based medicine extending the reach of anesthesia far beyond the operating room. We will use the ground-breaking contributions of "exemplars" to explore the development of the practice of anesthesia from "etherizer" to anesthesiologist and perioperative physician.

In the Beginning....

Anesthesia is the only medical specialty that can claim a "birth date". On 16 October 1846 William Morton demonstrated the anesthetic properties of sulfuric ether before an audience in the surgical amphitheater of the Massachusetts General Hospital, prompting the surgeon, John Collins Warren, to exclaim, "Gentlemen, this is no humbug." [1] One of the men organizing the demonstration, Henry Bigelow, fearing the results could not be reliably replicated, observed a series of cases demonstrating the anesthetic properties of ether before publishing the news in the 18 November 1846 issue of the *Boston Medical and Surgical Journal* [2].

The reports of sulphuric ether's anesthetic properties spread from Boston to England through letters, newspaper

clippings, and a copy of the *Boston Medical and Surgical Journal* article brought by Edward Warren (brother of John Collins Warren) to an American physician-scientist living in London, Francis Boott [1792–1863] [3] Edward Warren departed Boston on 3 December, aboard the paddle steamer "Acadia". Boott received the news on 18 December, the day after the Acadia made port.

Boott quickly sent the letter and the newspaper report to the *Lancet* and with his neighbor, dentist James Robinson, experimented with the new agent. On 19 December Robinson and Boott gave the first anesthetic in England at Boott's home. Soon after, other demonstrations were given. On 28 December, Boott and Robinson gave another demonstration in Boott's home. Present was the physician-scientist, John Snow [4, 5].

John Snow [1813–1858], the First and Greatest Anesthesiologist, Laid the Foundations for the Safe Delivery of Clinical Anesthesia

During his remarkable career, Snow published more than 100 articles, books, and pamphlets while carrying on a busy medical practice in Victorian England [6]. He was a "complete physician", outstanding in every aspect. Through meticulous record keeping and a keen analytical mind, he proved that cholera spread via contaminated water, doing this before the discovery of bacteria or the existence of the idea of "infection". This work is popularly known as the "Broad Street Pump" story. Snow's studies led him to conclude that the Broad Street well was the source of the contagion, and he helped quell the epidemic by advising removal of the handle of its pump. It is a foundation study in the fields of epidemiology and public health [7].

Not only did Snow "father epidemiology", he was also the first specialist anesthesiologist. At the time of his death at age 45 from a stroke (autopsy showed renal disease), he had given more than 5,000 anesthetics, all the while continuing his general medical and obstetric practice and undertaking research. His casebooks served as the basis for his publications and testify to his keen powers of observation.

His origins were humble. Snow's father could only afford a private primary school education for his son (there were no public schools). Snow served a series of apprenticeships, first qualifying as an apothecary, then as a surgeon. Finances forced him to take classes one by one until he completed the requirements needed to take the examination to become a physician. Perhaps it was fortunate that he could not attend a "proper" university. By avoiding the "philosopher" theories of medicine, his mind remained open to scientific discoveries.

Snow avidly attended medical meetings, presented papers, and debated medical issues. Being "well known"

in London medical circles, on 28 December 1846 he was among the friends Boott invited for a demonstration of “The Yankee Dodge”, as the surgeon Robert Liston called ether. Liston was the first surgeon to operate on an “etherized” patient at the London University Hospital, doing so on 19 December 1846 [7].

Because of his exposure to obstetrics and the associated problem of asphyxia of the newborn, Snow developed an interest in respiratory physiology. He did not accept the varieties of treatments and theories used to resuscitate the newborn. Practices such as immersing the infant in cold water, warm water, or even electrical stimulation were among the methods advocated. In 1841, he published an elegant article describing the components needed to successfully resuscitate the “still-born” child. Included in this publication were the results of his experimentation, using diverse animal subjects to validate his recommendations for successful resuscitation [8].

With this insight into the physiology of respiration, he had the tools to conduct experiments using first ether and then chloroform. Both drugs, liquids with low boiling points, became gases (vapors) when exposed to air at room temperature. Inhalation of these vapors produced the state soon called “anesthesia”, a state freeing the patient from pain.

After seeing the ether demonstration, Snow devised experiments to reliably demonstrate the effects of ether in all test species, including himself. In a lecture given on 17 May 1847, he provided the first scientific analysis of the physiology and pharmacology of ether, presenting a basis for its safe administration as an anesthetic. He devised a vaporizer that minimized variations in the delivered concentration of the inhaled anesthetic, especially those due to changes in the temperature of the liquid. The principles he applied are those found in modern vaporizers. In 18 articles “On narcotism by the inhalation of vapors” published in the *London Medical Gazette* [1848–1851] he provided a guide for the safe administration of both ether and chloroform to alleviate the pain of surgery. He described physical signs to guide the “etherizer” or “chloroformist” that might prevent lethal overdosing.

His fame as an “anaesthetist” with a busy obstetric anesthesia practice caused Queen Victoria to seek his services for the birth of Prince Leopold in 1853. This muted early objections to painless labor [9].

Reports of deaths associated with chloroform appeared within weeks of its introduction for anesthesia. Snow analyzed the causes of these deaths. In one patient he had anesthetized with chloroform, autopsy showed a “fatty heart,” but no observation to suggest anesthetic overdose [10]. The patient was known to have had heart disease. In his preoperative assessment of the patient’s fitness for anesthesia, Snow had expressed reservations concerning the patient’s ability to withstand the effects of anesthesia and surgery but proceeded because the patient had previously undergone the procedure without difficulty.

Snow’s analysis provided one of the first models of perioperative care. He had assessed the patient’s medical status, provided care, and studied the cause of the patient’s death. He determined that the anesthetic drug was probably not the sole cause of death. Snow had recognized the risk the patient brought to the procedure and had informed the patient of the risk. Snow’s sudden death in 1858 left a great void.

The Last Half of the Nineteenth Century: Little is Demanded of Anesthesia

The discovery of anesthesia was such a colossal advance that it took nearly a century for surgery to catch up, and there was little need for advances in anesthesia until that happened. Some viewed specialization in medicine—a practice solely devoted to anesthetic delivery—to be a form of quackery. In major cities, a few physicians chose to focus their practices on surgery or obstetrics. Rarely did a physician become interested in anesthesia.

In Britain, medical students, dentists, and physicians administered anesthesia. The practice in the US was a step lower, and porters (orderlies) and secretaries sometimes gave anesthesia. Soon after the introduction of ether, nurses were recruited to administer it. Nurse anesthetists, along with nurse midwives, were the pioneers in advance practice nursing.

Surgeons supervised the administration of anesthesia well into the twentieth century, even when the anesthetist was a physician. As surgery progressed, becoming more complex and technically demanding, the surgeon needed to focus on the procedure, leaving management of intra-operative and immediate postoperative care to the anesthetist.

The Twentieth Century: The Age of Science and Medicine

Many individuals contributed to the tools and techniques, and to the intellectual growth of anesthesiology. The focus of this essay is the evolution of anesthesia as it became a “medical specialty”. The individuals we have selected represent those who either laid the foundations for the clinical practice and academic basis of anesthesiology, or brought the anesthesiologist out of the operating room. They provided care before and beyond this boundary.

The pace of scientific discovery during the twentieth Century rapidly added to the understanding of diseases. Application of scientific principles led to the development of effective medications. The practice of anesthesia benefited from improved methods of anesthetic delivery, new technologies for monitoring, and new drugs. By 1939 the knowledge and technical skills required to practice anesthesia prompted the

American Medical Association to recognize anesthesiology as a medical specialty [11].

The pace of change accelerated after World War I and then further after World War II. By the end of the twentieth Century, anesthesiology had itself given rise to sub-specialization in obstetrics, pediatrics, cardiothoracics, neurosurgery, intensive care, and pain management.

Arthur Guedel [1883–1956]. The Motorcycle Anesthesiologist

The “artists” of anesthesia catalogued patients’ responses to anesthetics and incorporated their perceptions into an organized representation for their private use. There was a need for a system that could be easily learned and remembered, a system that could be broadly applied by diverse etherizers. Guedel supplied this, unknowingly reviving observations made by Snow. In the era before Index Medicus, PubMed, and Google, retrieving information from old publications was a tedious and difficult task not routinely undertaken. Old discoveries were often lost and then rediscovered.

Guedel began his career as a general practitioner, becoming fascinated by anesthesia during his internship, when his training required him to administer anesthetics. He built an extensive anesthesia practice before serving with the American Expeditionary Forces in France during World War I.

In France, he found himself confronted by soldiers with massive injuries requiring surgery. His responsibilities required him to move quickly from field hospital to field hospital in order to guide the delivery of ether by a wide range of etherizers. The motorcycle became his favored mode of transportation, giving rise to his fame as the motorcycle anesthesiologist.

As the only anesthesiologist in his region, he needed to quickly train nurses, secretaries, orderlies and others to safely administer ether anesthesia. Using observations from almost a decade of anesthesia practice, he devised a chart of the signs and stages of ether anesthesia, and trained personnel to follow it. The steps in the progression of patient responses as anesthesia deepened became known as Guedel’s stages. The safety record resulting from the use of this guide proved its value. First published in 1920, [12] the guide quickly became the universal standard for conducting ether anesthesia. Others added details to the guide.

Guedel returned to private practice and later became an “academic” anesthesiologist. He invented several airway devices during his career, always looking for better ways to care for patients [13]. His oropharyngeal airway is used today.

The idea of connecting a drug dose to a predictable response was poorly understood in the early twentieth century. Anesthesia was “dangerous” when administered by unskilled people. Guedel’s stages of anesthesia (the depth of anesthe-

sia) express the neurological and cardiovascular changes reflecting “doses” of ether. Like Snow, Guedel used easily observed physiologic changes to construct a dose-response relationship applicable to all patients. By using his clinical observations he created a useful tool for the safe administration of inhaled ether. It became one of the elements that led to the establishment of anesthesia as a specialty within the practice of medicine.

Unfortunately, the introduction of new inhaled anesthetic drugs presented a problem: Guedel’s signs and stages for ether did not directly translate for different anesthetics. How did one quantify the correct concentration to administer when each drug produced its own profile of observable changes? In addition, opioids and sedative drugs used in conjunction with the inhaled drugs changed the observable signs.

The ability to measure the exact dose present in the patient’s central nervous system and know the dose required to safely proceed with surgery would improve patient care. Edmond Eger [1930-] described the method for assessing the amount of volatile anesthetic drug needed to produce a crucial clinical endpoint, MAC (the minimum alveolar concentration required to suppress movement in response to a noxious stimulus such as surgery in 50% of subjects) in 1965 [14].

MAC provided a standard applicable to all inhaled anesthetics. It quantified Snow’s qualitative findings. Using MAC, Eger’s group and other investigators compared the relative effects of all commonly used anesthetics on the physiologic responses to clinically relevant anesthetic concentrations. With this information, and the breath-by-breath analysis of anesthetic concentration provided by present technology, today’s anesthesiologist has the knowledge needed to administer the exact dose required by each patient throughout the surgical procedure.

Ralph Waters [1894–1979]. Father of the Academic Specialty of Anesthesia

Waters transformed the art of anesthetic administration into a scientific medical specialty. With Henry Beecher, Waters is acknowledged as the father of modern academic anesthesia in the US. He began medical practice, including occasional surgery, in 1913. He and his fellow surgeons aided each other by administering anesthesia. As a medical student and intern he taught himself to administer ether—to be an anesthetist, the term used for anyone who provided anesthesia.

By 1916 he decided to limit his practice to anesthesia. Over the next decade, he progressively increased contacts and friendships with anesthetic pioneers and those interested in respiratory physiology. In the 1920s, the new medical school at the University of Wisconsin changed the paradigm for medical education by creating full time clinical profes-

sors. In 1927, the university invited Waters to become the first full time professor of anesthesia. His academic appointment gave him entree to an academic milieu that allowed the development of anesthesiology as a medical specialty, a specialty devoted to patient care that was based on scientific principles.

Underlying Waters' approach to anesthesiology was his belief that an understanding of the science of medicine was essential for competency in a physician. Waters was uncompromising in his scientific integrity [15]. His interests in respiratory physiology raised questions that he believed could best be answered in a medical school where there was collaboration between basic scientists and clinical faculty.

John Snow was Waters' hero. Writing a biographical paper on Snow in 1936, he concluded that "We need not hesitate to say that John Snow was and remains the greatest anaesthetist as well as the first". Like his hero, he investigated methods for resuscitation [16]. He advocated tracheal intubation for cases of difficult airway management, and mouth to mouth respiration during resuscitation.

He had a prolific career, authoring many scientific papers and encouraging residents and staff in their academic development. Through his example and generous spirit he literally created the next generation of academic anesthesiologists. He led the way in professionalizing anesthesiology [17]. His protégés called themselves the "Aqua-Alumni".

John Lundy [1894–1973]. Developer of the Recovery Room, Blood Banking, Anesthetic Certification, and New Anesthetics

Lundy practiced anesthesia before it became a medical specialty. He sensed the limitations in those pursuing a career in anesthesia at the time: "There was a tendency for only those physicians who were incompetent in general practice or in other branches to limit themselves to the practice of anesthesia." [18] His life contributed mightily to changing that tendency.

Lundy met William Mayo in 1924 at a meeting in Seattle. Lundy's enthusiasm and knowledge of anesthesia so impressed Mayo that he invited Lundy to establish an anesthesia department at the Mayo Clinic. Before this appointment, nurses provided all anesthesia under the direction of surgeons. Mayo saw the opportunity to relieve surgeons of this responsibility.

Lundy championed anesthesia education, developed regional anesthesia, and created the first blood bank. The latter achievement occurred at a time when donors were called to contribute blood on an "as needed" basis. Venous access could be technically difficult because of the type of needles available in the 1930s, and it was common for the vein to be exposed surgically, the venous "cut-down". Most transfu-

sions at the Mayo Clinic occurred in the operating rooms. Lundy had established his professional credentials as an expert in intravenous fluid administration, and had the technical expertise to procure and administer blood.

In 1934, citrated blood was occasionally kept in the ice-box for as long as 14 days. It was noted that this "stored" blood could be infused safely. Lundy was put in charge of transfusions in 1934, and set up a system for the storage of citrated blood in the laboratory of WC MacCarty at the Mayo Clinic. Thus the Blood Bank was born. He also worked on techniques for the rapid infusion and freezing of blood [19].

In 1929, he formed the Anaesthesia Travel Club, one of the forerunners of the professional societies for promoting education and exchange of information. Lundy lobbied the American Medical Association for recognition of anesthesia as a specialty within the Association, and in 1939 the AMA recognized anesthesia as a section within the Association [20, 21].

He contributed to the clinical introduction of thiopental sodium, a drug administered intravenously for general anesthesia, as well as the anesthetic gas, cyclopropane. He championed the use of local anesthetics and techniques for regional anesthesia [22]. He pioneered the concept of "balanced anesthesia", the combined use of intravenous drugs, such as thiopental and opioids, with inhaled anesthetics.

He created a specialized section within the department of anesthesia that managed ventilators and supplied techniques for supplementing inspired oxygen [23]. In 1942, Lundy opened the world's first post anesthesia recovery room, now called the Post Anesthesia Care Unit, or PACU. This development recognized that surgery and anesthesia created conditions that could lead to adverse outcomes. Prevention of such outcomes required close observation in a specialized area near the operating suite by specially trained nurses. The anesthesiologist became the responsible physician for directing patient care in the PACU.

Gertie Marx [1912–2004]. The Grande Dame of Obstetric Anesthesia

Although Nathan Keep anesthetized Fanny Appleton (Mrs. Henry Wadsworth) Longfellow in 1847, [24] and Snow famously anesthetized Queen Victoria in 1853, [7] for their deliveries, prejudice against using anesthesia in obstetrics remained well into the mid-twentieth Century. Despite these well-publicized demonstrations, the benefits of analgesia for the ordinary woman in labor were not routinely available until the 1960s–1970s.

Marx was the "Grande Dame" of obstetric anesthesia [25]. Nazism forced her to leave Germany once she had completed medical school at the University of Bern, Switzerland. She immigrated to the US in 1937, obtaining a rotating internship at New York Beth Israel Hospital only after a male candidate

chose not to attend. Originally planning a career in pediatrics, she discovered anesthesia while an intern.

At the time, laboring women might receive no anesthesia, heavy sedation, or general anesthesia, all choices potentially detrimental to mother and child. Marx championed epidural anesthesia because it provided pain relief for the mother while minimizing the risks of aspiration and possible death from deep sedation. In addition, the small amount of local anesthetic absorbed from the epidural space did not depress the newborn's respiration. Some thought epidural anesthesia would delay labor and thereby increase the incidence of Caesarean sections. Marx proved these critics wrong, winning the gratitude of mothers worldwide [26].

Marx's relentless efforts also changed the care of pregnant patients by introducing the anesthesiologist into the obstetric care team. Her clinical research in regional anesthesia improved patient care, increasing the use of epidural anesthesia during labor and for the management of post-operative pain. She is an exemplar because she brought anesthesia beyond the operating room into the labor ward.

John Bonica [1917–1994]. Founder of the Multidisciplinary Chronic Pain Clinic and Pain as a Subspecialty

After completing his residency in anesthesia during World War II, Bonica joined the US Army and was placed in charge of the anesthesia service at Fort Lewis, Washington. During his service, he supervised the anesthesia care of over 10,000 soldiers. He taught himself regional anesthesia techniques, something that had been absent from his anesthesia residency. He noted that regional anesthesia sometimes relieved both acute and chronic pain, stimulating a lifelong interest in the alleviation of pain.

After the war, Bonica became director of anesthesia at the Tacoma, Washington Hospital in 1947. There, he founded the first residency with formal training in regional anesthesia. In 1960, he assumed the Chair at the University of Washington, establishing a balanced program of general and regional techniques that stressed patient care and clinical research. His numerous articles and his massive textbook on pain inspired new techniques for treating pain. Perhaps his greatest contribution was the initiation of a multi-modal approach to pain management. On assuming the Chair, he founded a clinic that focused the combined efforts of anesthesiologists, neurologists, surgeons, psychologists, and physical therapists on pain management. It was a revolutionary concept that is now used worldwide [27].

Ironically, pain was no stranger to Bonica. He worked his way through school as a professional wrestler, and the resulting physical insults left him crippled with pain at the end of his life.

Most anesthesia residencies now have a pain clinic and a consultant service to manage perioperative pain. Because of Bonica's vision, the anesthesiologist-pain specialist takes the practice of anesthesia well beyond the operating room.

Bjørn Ibsen [1915–2007]. Father of Intensive Care Medicine

Wars and epidemics in the twentieth Century conspired to advance anesthesia practice and patient care. Ibsen completed medical school at the University of Copenhagen in January 1942, anticipating a career in thoracic surgery. Although Germany occupied Denmark in April of that year, Ibsen managed to continue his training and earned a prize in biochemistry in 1944 [28].

At the end of World War II, the tattered European economies offered few openings for research. Henry Beecher seized this opportunity to recruit eager young European physicians seeking research training. Ibsen went to the Massachusetts General Hospital in 1949 as an assistant resident for a year-long course, returning to Denmark in 1950 [29].

Although the Danish government established departments of anesthesia to care for "patients during the operation and postoperatively", [30] Ibsen could not secure a permanent appointment. He was working as a free-lance anesthesiologist when a devastating polio epidemic struck in 1952 [30]. Among Copenhagen's population of just over a million, 3,000 had polio; 1250 had some paralysis and 345 required respiratory support [31].

The (Blegdam) Fever Hospital, the hospital caring for most of these patients, was overwhelmed, and standard practices produced dismal results. Based on his work with Beecher and his experiences managing ventilation outside of the operating room, Ibsen proposed long term controlled or assisted ventilation for patients with impaired swallowing or respiration. He was invited to apply his suggestions, in particular a plan to ensure proper oxygenation while keeping the level of carbon dioxide within tolerable limits. To do this he created a cadre of specialized care providers, coordinating care within one space [32]. His plan dramatically improved survival, relative to the medical paradigm that had focused on diagnosis and causal therapy. His model corrected the physiological disturbance that the illness created.

Ibsen's genius created a collaborative team that worked in an integrated setting separated from the general medical patient population. This innovative concept was soon applied to patients with complex medical and surgical problems. Ibsen's creation, the Intensive Care Unit (ICU), now exists in all major medical centers. Today, anesthesia training includes intensive care rotations and opportunities for additional training and subspecialty certification.

Peter Safar [1924–2003] Invents CPR

Perhaps the Prophet Elijah performed the earliest successful resuscitation when he revived a dead boy, “putting his mouth upon the child’s mouth.” [Bible, 2 Kings 4:34]. Similarly, Peter Safar created a simple algorithm that could restore cardio-respiratory function and could be taught to the general public, increasing its life-saving potential.

Nominated three times but never awarded the Nobel Prize in Medicine, Safar was a prolific writer, educator, and consummate clinician. His passion was to “save the hearts and brains of those too young to die”. Safar graduated from the University of Vienna, immigrated to the US in 1949, and completed an anesthesia residency at the University of Pennsylvania in 1952.

Most of us know that CPR stands for cardiopulmonary resuscitation—Safar’s consuming interest. In 1956, Safar began his studies of unexpected sudden death, and in 1961, demonstrated that closed chest cardiac massage without ventilation described by Kowenhoven et al in 1960 [33] did not provide adequate tidal volume and recommended that “closed-chest cardiac massage should be preceded and accompanied by pulmonary ventilation”. [34] The techniques were simple to learn and were widely taught to the public. In the 2000s, the timing and even the application of artificial ventilation became more complex than suggested by Safar. Resuscitation now began with chest compression followed by opening the airway and might or might not then be followed by artificial ventilation [35].

Safar pioneered the role of the anesthesiologist in emergency medicine, developed the first intensive care unit in the US, and established the first residency-training program for intensive care medicine. He made intensive care medicine a medical sub-specialty in anesthesia.

Henry Beecher [1904–1976]. Ethicist and Scientific Leader

Born Harry Unangst, Beecher was a scientist-clinician. Although his first loves were physiology and chemistry, he enrolled in Harvard Medical School, graduating with honors in 1932. He completed two years of training in the department of surgery at Massachusetts General Hospital, after which Edward Churchill, the chairman of the department of surgery, selected Beecher to develop the anesthesia department, at that time a division of surgery. He was sent to Denmark to work in the laboratory of the Nobel Laureate, August Krogh. On his return in 1936, he was appointed Anesthetist-In-Chief at the Massachusetts General Hospital. In 1941, Beecher became the Henry Isaiah Dorr Professor of Anesthesia Research, the first endowed chair in anesthesia in the US [36].

He is one of very few chairmen appointed to lead a department of anesthesia who had no specific training in anesthesia. His research contributions are considerable, including one of the first important outcome studies, his investigation of nearly 600,000 patients that showed the dangers of the use of curare, used to provide muscle relaxation in the absence of reversal of residual neuromuscular blockade at the end of surgery [37].

Patients must give their consent to receive medical care. What information did the patient need to know in order to give consent? In the 1940s, the traditional idea that “the doctor knows best” limited the information provided to patients concerning options, risks and benefits. The decision to treat was, in fact, the physician’s. The patient’s choice of a specific physician implied acceptance of the proposed care.

The Nuremberg trials documented human experimentation that horrified the medical community, but that community was reluctant to examine its own practices. Beecher’s landmark publication in 1966 [38] revealed the systematic failure to tell patients the details of proposed treatments, including risks or benefits or the unproven nature of some proposed remedies.

Physicians must now obtain a patient’s informed consent before embarking on a care plan. The once common practice of relying on a combined surgical and anesthesia consent form obtained by the surgeon, or the use of documents stating only the name of the operation and that anesthesia was provided, were clearly insufficient. Beecher’s work expanded and codified the anesthesiologist’s responsibility to educate each patient about the anesthesia plan and to obtain consent.

Beecher’s protégé, Ibsen, raised a crucial problem that Beecher attacked: when was a patient dead? By the 1960s, ICU physicians could mechanically support respiration and maintain circulation with drug therapy and mechanical devices. How did one know if such a patient was alive or dead? The answer to the question required a consensus definition of the word “death”. In 1968, a panel of physicians and ethicists led by Beecher published the “Harvard Criteria for Brain Death”. [39] “Death” shifted from cessation of breathing and absence of cardiac activity to loss of discernable brain function and absence of the possibility of regaining function. Beecher’s work in ethics and his credentials as a respected scientist added credence to the Committee’s report and its acceptance by medical and legal communities, world-wide.

Beecher created a world class research program but is best remembered for two monumental contributions: the development of the principles of informed consent for patient care and human experimentation, and the definition of brain death as a criterion for determining a patient’s demise.

Charles Robson [1884–1969]. First to Lead a Pediatric Department of Anesthesia; Advocate for Anesthesia in Infants

Children received anesthesia as early as 1842 when Crawford Long gave ether to a “Negro boy”. Snow had extensive experience anesthetizing children, correctly identifying physiologic differences between children and adults. Advances in technology and measurements a century later supported Snow’s observations and deductions [40]. Despite Snow’s genius and guidance, anesthesia for children remained risky. Equipment used in anesthetic practice was poorly adapted for children, especially younger ones. Slowly, during the 1930s, surgical techniques and knowledge of pediatric physiology progressed, and it was recognized that the safe pursuit of complex surgical procedures on ill children required an anesthesia care team approach.

Robson was the first anesthesiologist to devote his practice exclusively to pediatric care. He graduated from McGill University School of Medicine in 1913. After a one-year internship at Montreal General Hospital, he joined the Canadian Expeditionary Forces during World War I where he developed his anesthesia skills, becoming the senior ranked anaesthetist. On returning to civilian life, he was appointed chief of the Department of Anaesthesia at the Hospital for Sick Children, Toronto, where he served from 1919–1950.

Snow’s observations notwithstanding, the differences between the physiology of the developing child and the adult were not well understood when Robson began his career as a pediatric anesthesiologist. He used his keen powers of observation and inventiveness to develop equipment and airway management techniques appropriate for the differences in the anatomy and physiology found in children. He believed that infants experienced pain and required anesthesia for surgical procedures, a view that many of his contemporaries did not share. He championed better ways of approaching the frightened child. He pioneered the use of tracheal intubation during surgery in infants [40]. He was the first to recognize the importance of fasting a for few hours before surgery to lessen the risk of aspiration during anesthesia.

Virginia Apgar [1909–1974]. Care of the Newborn

Worldwide, “the Apgar” means the tool used to assess a newborn’s physical status at birth. Few know the origin of the term and Apgar’s remarkable story. She is a select member of a fraternity of physicians whose names are part of the vocabulary of medicine.

Although a gifted musician and athlete, Apgar chose medicine as a career while still a young child. Coming of age in the Great Depression, she worked her way through college

and medical school, aided by scholarships and loans from family members [41]. After graduating fourth in her class from the College of Physicians and Surgeons at Columbia in 1933, she was accepted into the surgical training program at Columbia Presbyterian Hospital.

Although the chairman of the department of surgery, Allen Whipple was convinced of Apgar’s talent, he believed that prejudice against women in surgery would hinder her capacity to earn a living as a surgeon. After she completed three years of surgical residency, he persuaded her to take up anesthesia. Perhaps because it paid poorly and attracted few men, there was no bias against women in the practice of anesthesia [42]. Being in debt and with dim prospects of financial success as a surgeon, Apgar followed his advice. Her training was typical for the time. She worked with nurse anesthetists for a year, learning the art of anesthesia delivery, and then spent a year with Waters in Wisconsin learning the science. She continued her anesthesia training under Emory Rovenstine at Bellevue Hospital in New York.

On returning to Columbia in 1938, she was appointed director of anesthesia in the department of surgery. In this role, she laid the groundwork for a subsequent department of anesthesia. She educated medical students to facilitate their later recruitment as anesthesia residents. She provided patient care beyond anesthesia and contributed to the development of an anesthesia research program.

One morning, during the anesthesia breakfast discussions that she held each day, a question by a medical student prompted the birth of the Apgar Score: “How do you evaluate a newborn baby?” “Easy”, she replied, jotting down five things to assess. Legend has it that she wrote these observations on a napkin for the student. She rushed off to start her day in the obstetric unit. During that day she thought about what she had written from a scientific perspective, and recruited colleagues to validate her observations. The rest is history. The five things were skin color, pulse, reflex irritability, muscle tone, and respiration, each scored as 0, 1, or 2 (best).

The Apgar Score was published in 1953 [43]. Its enormous value lay in its simplicity (it required no technology and was easy to learn and apply), and in its considerable predictive value (e.g., a value of 5 indicated an infant in trouble).

Later in her career, Apgar became involved with the problem of birth defects. Leaving Columbia in 1959, she went to Johns Hopkins University and earned her PhD in public health. She became the director of the division of congenital malformations for the National Foundation, also known as the March of Dimes, helping it refocus its activity after vaccines had solved the ravages of polio in the US. Apgar received the ASA Distinguished Service Award in 1961 and was posthumously honored by the United States Postal Service with a stamp bearing her image in 1994.

Goran Haglund [1915–2007]. Pediatric Intensive Care

The man who created modern anesthesiology in Sweden, Torsten Gordh, trained under Waters at the University of Wisconsin, returning shortly before the World War II blockade of Sweden. After the war, anesthesiologists interested in additional training turned to Waters' protégés in the US.

After completing medical school at the University of Lund, followed by two years of training in surgery and anesthesia, Haglund went to the US in 1949. He worked under the direction of Allen Conroy, one of the “aqua alumni” at the University of Chicago. On returning to Sweden in 1950, Haglund was one of three anesthesiologists in Gothenburg. In 1951 he accepted an appointment to the Children's Hospital [44].

His experiences in the US led him to conclude that problems with respiration and circulation in critically ill patients were better managed if the patients were concentrated in one location. The surgeons agreed to try his idea. Then the polio epidemic struck Sweden as it had Denmark [45]. The epidemic and its management fostered the development of the care paradigm that would underlie the pediatric intensive care unit [46].

Because there was no equipment designed for respiratory support for children, he constructed a ventilator of his own design [44]. By 1955 his plans for a pediatric intensive care unit were fully implemented. The pediatric anesthesiologist thus joined his anesthesia colleagues who were in the early phase of developing the subspecialty of intensive care medicine, extending their scope of practice beyond the operating room.

Besides his busy clinical practice, research, and teaching duties, Haglund was renowned for his classical education and knowledge of music. In addition to his many talents he possessed a fine sense humor. For several years, he and a friend hosted a popular Swedish radio program that showcased their humor and knowledge.

There are Many Exemplars

Our essay cited some of the most famous exemplars of the anesthesiologist as a perioperative physician, noting the contributions of each. We could have detailed the lives of many more. Meyer Saklad, for example, who devised the ASA Physical Status and was instrumental in the evolution of the American Board of Anesthesiology certification examination. Or Ellison (Jeep) Pierce whose leadership led to the formation of the Anesthesia Patient Safety Foundation. Or Lee Fleisher [47–51], who has influenced guideline development with the American College of Cardiology and the

American Heart Association. He has worked with Medicare [CMS] as a member of the team involved with the surgical care improvement project [SCIP initiative]. Through Fleisher's efforts, anesthesiologists are now integrated into healthcare reform and quality initiatives. Or Michael Roizen [52, 53, 54], who found that the results of a patient's history and physical examination could obviate the need for (and cost of) many specific preoperative tests. He expanded preoperative assessment to include all of medical and wellness assessment, leading to his present career focused on improving wellness in patients. Or Daniel Sessler and Harriet Hopf (among others) who showed that what we do to our patients in the operating room—how much oxygen we deliver and how well we maintain our patient's temperature, whether we use epidural analgesia—can affect the postoperative well-being of our patients and can affect the incidence of infection or healing of wounds [55–57]. And Emory Rovenstine, much as Ralph Waters, was instrumental in the explosive growth in anesthesia, particularly academic anesthesia [58]. And John Severinghaus, developer of the blood gas electrodes we use every day [59]. There are many more anesthesiologists whose contributions reach beyond the operating room and the delivery of anesthesia, but space limitations force us to those we have chosen for detailed examination, exemplars of the exemplars.

Reprise

Diethyl ether was synthesized in the 1200s, rediscovered in the 1500s, and first publically used for anesthesia in humans in 1846. The demonstration of anesthesia occurred when society had evolved sufficiently to promote progress in surgery and science. What began as an act of administering a drug grew into a specialized branch of medical science called anesthesiology.

John Snow, the first and perhaps greatest anesthesiologist, set a standard of practice that we admire today. He was devoted to providing the best care for all of his patients, combining clinical observations with scientific experimentation to validate his observations. His care of a patient began with a pre operation assessment of the patient's ability to “survive” the planned surgery and anesthesia. He monitored the patient's responses to anesthesia, made adjustments to anesthetic doses accordingly, and remained with the patient until the patient was judged fit to be cared for by others. When necessary, Snow investigated intra operative fatalities to determine if the anesthetic was the cause of the death.

The generations of men and women who followed Snow, added to the knowledge and skills necessary to be an anesthesiologist. Many anesthesia departments include “Perioperative Medicine” in their title, denoting their expanded roles in

patient care. Departments of Perioperative Medicine consist of individuals trained as “anesthesiologists” but whose training and interests extend beyond those focused on the traditional care of patients in the operating room. These expanded roles include preoperative assessment and testing intended to determine a patient’s fitness for surgery, and intraoperative care of patients of all ages, sizes, complexity and illness. They include immediate and long-term care in PACUs and ICUs, acute pain management for surgical patients, and out-of-hospital pain management for patients with chronic pain (e.g., consequent to cancer or orthopedic problems). The perioperative physician offers educational assistance to nurses, other medical and non-medical professionals, including those delivering hospice care and home health infusion therapy. Finally, the increasingly diverse roles played by the perioperative physician include direction for institutions in the increasingly important and complex area of health care management and financing.

In a sense there is no perioperative physician since no individual can embrace all the functions that might be undertaken. But there can be Departments of Anesthesia and Perioperative Medicine that contain individuals whose combined talents provide the diverse functions of the perioperative physician.
