AMERICAN ACADEMY OF PAIN MANAGEMENT

CRC Taylor & Francis
Taylor & Francis Group
Boca Raton London New York

Dedication to Richard S. Weiner, PhD

While standing upon the shoulders of giants helped advances to occur, the genius of Richard S. Weiner, PhD was that he could see the finished puzzle within the constituent pieces. He took pre-existing parts and ideas that others had overlooked, pulled them together in altered ways and created new results. He created harmony from the chaos others perceived. He did more than talk about the developing field of pain management; he walked the walk and co-founded the American Academy of Pain Management with Kathryn A. Weiner, PhD. Together, the Weiners created a new organization that finally met the needs of its pain practitioner members through pain-related education, practitioner credentialing, pain program accreditation, outcome measurement, and many other offerings. Bringing together leaders in the field of pain management to create the American Academy of Pain Management's textbook, *Pain Management: A Practical Guide for Clinicians,* was one of his greatest accomplishments and was a continuing source of pride for Richard. Revising six editions became his commitment to the advancement of the pain management profession.

For Richard editing each edition of the textbook was a challenging process that required more than a year of preparation. Richard weathered this process six times in 12 years to make certain that the American Academy of Pain Management's textbook was clinically useful, current, and the best source for multidisciplinary information about the assessment, evaluation, and treatment of pain. For Richard, this was his labor of love and he gave his very best to this process.

Many might say that authoring textbooks is just too much work. It is far more effort than most people would ever willingly take upon themselves. Richard never saw the textbook as too much work for himself. He looked forward to the revision process and the updating of the chapters with each new edition. He enthusiastically called authors, new and old alike, to talk with them about their submissions, suggested points to discuss, and then called up others to tell them about what he had learned in the new chapters when he received them. No matter how many hours or how many authors were involved, he treated each of the authors with consideration, excitement, and respect. He asked of the authors more than some knew that they had within themselves, but always knew what they could accomplish if properly motivated. Richard was the consummate manager, who not only managed ideas, but the people bringing the ideas to fruition.

Knowing that he was quite seriously ill in 2001, Richard began to consider future goals for the American Academy of Pain Management. He knew that in another couple of years the seventh edition of the textbook would need to be written to maintain the currency associated with the book. In his own amazing way, and in his attempt to find goodness and humor even in the worst of circumstances, he speculated that he wouldn't have to edit any more textbooks if he didn't respond to his anti-cancer therapies. He even tried to cheer up those who were so concerned about him by telling us that the chemotherapy was easier than editing the textbook. He helped to identify the principal editor for the seventh edition of the textbook before his death in May 2002.

Practitioners fortunate enough to have personally known Richard, continue to mourn his passing. His hundreds of personal friends and members of his immediate family remember all that he gave to our evolving profession. Always the gentleman in his dealings with others, he shall best be remembered as the man who gathered together the many disciplines that constitute the modern field of pain management to improve the treatment of pain for so many unfortunate sufferers he never met. He never wanted special recognition, but wanted the profession to mature and to see the "mainstreaming" of pain management services.

We miss Richard. Not a day goes by when we do not think about something he said to one of us, some lesson he taught us, or some opportunity he created for all of us who now follow in his footsteps. Few men pass through our lives and have as significant an impact as he did for each of us personally and for so many of our colleagues. While his life was far too short, his accomplishments more than filled his lifetime and left a permanent legacy for all of us. It is only fitting that this *Seventh Edition* be dedicated to the outstanding work and life of Dr. Richard S. Weiner.

Preface

PLEASE READ THIS PREFACE!

Few people ever bother to read the preface of a textbook, much less the preface of a book on the subject of pain management. This completely revised Seventh Edition is the most comprehensive rewrite of *Pain Management: A Practical Guide for Clinicians.* Unlike the previous six editions, every attempt has been made to offer evidence-based, clinically relevant information. This book is intended for pain practitioners and busy practitioners from other disciplines trying to provide relief for those suffering with pain.

Uniquely, the book unfolds the "story" of pain and its management just as those suffering present themselves to clinicians for help. Major perspectives and challenges are initially identified, leading to an appreciation of the various disciplines providing care. Common pain problems and diagnostic methods used in pain management next give "flesh" to the skeletal story. Treatment options unfold from least invasive to most invasive as we explore behavioral approaches, pharmacotherapy, procedural techniques and the integrative options. The needs of special populations, along with the legal aspects of care, belief systems and spiritual matters, and practice issues finally complete the book.

While no textbook is completely able to cover the entirety of a subject, the intent of this book is to give any reader the "fast take" on pain-related information needed for the next patient, the upcoming examination, or to satisfy some academic question. This book intends to be the "first and last" source for most clinicians needing to know something about pain management. The book has ample references to guide future self-inquiry, allowing readers to know the original source work and independently reach conclusions about the material presented.

The American Academy of Pain Management's textbook remains a work in continuous development. As the Seventh Edition becomes available, budgeting and planning begin anew for the eighth edition to follow in five years. No one holds all of the truth, and the leadership of the Academy expects that in years to come this book will continue to evolve from one editor to the next, always fresh and current in its presentation, and true to the original charge given to each of us practicing in pain management by our late, founding Executive Director, Richard S. Weiner, PhD.

Please enjoy the material included within these pages. Make note of areas that were covered superficially and need more detail. Be willing to help your colleagues "push the envelope" in future editions by writing chapters, providing peer review, and offering suggestions for continuous improvement.

About the Editors

Mark V. Boswell, MD, PhD is chief of pain medicine, director of the Pain Medicine Fellowship Program, and associate professor of anesthesiology at Case Western Reserve University in Cleveland, Ohio. Trained in interventional pain management, medical acupuncture and end-of-life care, Dr. Boswell has been actively involved in clinical pain management, pain-related research, and academic medicine for more than 15 years. Dr. Boswell is editor-in-chief for *Pain Physician*, the official publication for the American Society of Interventional Pain Physicians (ASIPP).

Dr. Boswell earned his PhD in experimental pathology and MD from Case Western Reserve University. He completed an anesthesia residency after a categorical surgical internship, a research fellowship in neuroscience, and additional training in interventional pain management. Dr. Boswell was named the Outstanding Clinical Teacher in Anesthesiology in 1992 from CWRU School of Medicine and received the Outstanding Educational Achievement Award from ASIPP in 2004.

Dr. Boswell was vice-chair of the School of Medicine of CWRU, serves on numerous committees at University Hospitals of Cleveland, including pharmacy and therapeutics, QualChoice Medical Policy and the Rehabilitative Services Advisory Committee. He is a frequent presenter at local, national and international meetings, an accomplished author, and committed member of his community, family, and church.

Dr. Richard S. Weiner personally asked Dr. Boswell to serve as the principal editor for the Seventh Edition of the American Academy of Pain Management's textbook. Under Dr. Boswell's editorial leadership the Seventh Edition has been revised entirely to embrace the evidence basis for pain diagnosis and management. Dr. Boswell has introduced many new sections and made this edition the most diverse in the disciplines involved, the most comprehensive in scope of practice, and the most clinically relevant.

Dr. B. Eliot Cole earned his undergraduate degree in bacteriology from the University of California, his medical doctorate from Wake Forest University School of Medicine, and his master's in public administration from the University of Nevada, Las Vegas. He performed residencies in psychiatry and neurology at North Carolina Baptist Hospital, and completed an anesthesia-based fellowship in pain management at the University of California, Los Angeles, Center for Health Sciences. The American Psychiatric Association awarded Dr. Cole Fellow status in 1995 and Distinguished Fellow status in 2002.

Dr. Cole has been active in pain management since 1985, as a pain management fellow, a clinician, and as an active member of many pain-related organizations. He served on the American Academy of Pain Management's Board of Advisors, Board of Directors, numerous committees, was the organization's President from January 1, 1994 until December 31, 1995, and was the Interim Executive Director from March 1 until December 31, 1998.

Currently, Dr. Cole is a consultant in pain management for the Hawaii Permanente Medical Group and for the American Academy of Pain Management, serves as the Executive Director for the American Society of Pain Educators, and vice-president for medical and scientific affairs for Aventine HealthSciences. Dr. Cole is the program dean for pain studies at the University of Integrated Studies. Dr. Cole enjoys lecturing and writing about pain management, care of the terminally ill, medical policy-making, and ethical issues.

Section I

Perspectives of Pain

Mark V. Boswell, MD, PhD, Section Editor

A Brief History of Pain from a Personal Perspective

B. Berthold Wolff, PhD

Pain — The Fifth Vital Sign? Pain is a natural phenomenon of all humankind. Yet, until recently, it has been a sadly neglected field of behavior and medicine. In 1958, when I started to study human pain behavior, I was amazed to find how little knowledge of pain and its treatment was available. At that time, most clinicians believed that "real" pain had an underlying physical or physiological basis. Therefore, treating this underlying cause by appropriate therapeutic methods would cure or at least control the basic problem and the patient's pain would be alleviated. Should the patient continue to complain of pain following "successful" treatment, except for malignancies, the patient was often told "it is all in your head" — or worse he would be called a malingerer. Actually, this may still occur occasionally.

In the 1950s, there existed no gate control theory, no real understanding of endogenous morphine-like substances (endorphins), no awareness of differences between acute and chronic (intractable) pain, and there was no generally accepted definition of pain. There also existed no national, international, or regional pain associations.

The ancient philosophers, such as Plato and Aristotle, placed pain together with pleasure among the passions of the soul. In his 1939 review, Dallenbach suggested that Aristotle's great influence on Western scientific thought delayed the recognition of pain as a sensation for almost two thousand years. Eventually, however, the 19th century permitted much research into the neurophysiological basis of pain. In 1884, both Blix and Goldscheider, independently of each other, finally established that pain was a sensation by demonstrating specific pain points in the skin.

In contrast, however, some other physiologists and psychologists believed that pain resulted from "overstimulation" of receptors (Wundt, 1874). Thus, at the end of the 19th century, three different "pain" theories co-existed. The old emotional (pain–pleasure) theory and two neurophysiological theories, the "specificity" theory (i.e., pain-specific receptors/fibers) and the "intensivity" theory (i.e., too much stimulation).

The early 20th century saw a shift toward specificity theory, such as Sherrington (1906), indicating that there are specific nerve endings for pain. Zotterman (1959) observed that in several "classical" experiments during the 1930s pain was apparently subserved by A-delta and C fibers. The faster-conducting A-delta fibers yield sharp and well-localized pain, whereas the slower C fibers yield dull and poorly localized pain sensations. This type of information led Lewis (1942; Lewis & Kellgren, 1939) to postulate the existence of two separate sensory pain systems, one transmitting pain from the skin and the other from deeper and visceral tissues. However, subsequent work by others, especially that of the Oxford group of anatomists (Weddell, Sinclair, & Feindel, 1948), indicated that the differences observed by Lewis, suggesting a two-pain system, could also be adequately explained in terms of pattern and density of innervation, which differ between skin and deeper tissue. Our own early work in my laboratory (Jarvik & Wolff, 1962; Wolff & Jarvik, 1961) demonstrated that two different pain responses could be elicited from the same tissue locus (gluteus medius muscle) and also tended to refute Lewis's two-pain systems theory. Further work by the Oxford group (Feindel, Weddell, & Sinclair,

1948) suggested that pain sensation may depend upon central analysis of space–time pattern of neural activity.

Eventually, this type of research led to the important gate theory of pain, published by Melzack and Wall in 1965, which revolutionized the field of human pain mechanisms. Simply stated, the gate theory postulated a "gating" mechanism that controlled the feedback of fast-conducting fibers from the central nervous system to advancing slower-conducting fibers either inhibiting or allowing progress through the "gate." Thus, a central nervous system analysis is required allowing both physiological and psychological influences. Four decades have passed since the introduction of the gate theory and like all good science, progress has been made and the theory further modified. However, this chapter is not concerned with current concepts but with a historical background from my personal perspective.

It is relevant at this point to mention an interesting problem. While our knowledge of pain and pain mechanisms has significantly increased during the 20th and early 21st centuries, we still lack a generally accepted definition of pain. A century ago, Sherrington (1906, p. 229) defined pain as "the psychical adjunct of an imperative protective reflex." Nearly all 20th-century pain researchers disagree with his definition, but they have eschewed defining pain themselves (Beecher, 1959). More recently, Merskey and Bogduk (1994) for the International Association for the Study of Pain defined pain as an "unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage" (p. 210). This definition, while passable, is in my opinion not completely adequate. Many years ago, I had the pleasure of personally discussing the problem of an adequate definition of pain with Dr. Harold Merskey and I applaud his courage and persistence in eventually coming up with a definition.

There are several problems. Pain, while almost always unpleasant, is not necessarily so. Occasionally, one pain may serve as a relief for another pain (e.g., counter-irritation). In an experimental study, we have observed that white noise is generally reported as more aversive than pain (Wolff et al, 1976). Another problem is that it is often difficult to communicate pain to others because we may lack appropriate words and may thus resort to analogy. This problem has recently been highlighted in a review by Schott. (2004). Both clinically and in the laboratory, pain tends to be defined operationally, such as withdrawal from a noxious stimulus, the patient or subject saying "pain," marking a point along a line, relaxing tense muscles. However, pain defined in this manner can strictly speaking only refer to the specific situation rather than act as an absolute. Consequently, it is yet premature to define pain in absolute terms.

My own work started in 1958, while I was a member of the New York University Rheumatic Diseases Study Group. Specifically the question was raised whether it is possible to (1) measure a patient's pain level objectively and (2) predict a given patient's ability to tolerate (clinical) pain during physical rehabilitation and postoperative exercises of an operated joint. Obviously, with that background and at that time, the emphasis was on deep somatic arthritic pain rather than on cutaneous or visceral pain. Consequently, I chose to utilize a strictly psychophysical approach to devise a technique and measure the patient's pain response. Pain threshold determinations had been made by earlier investigators, such as von Frey (1897), on the skin, culminating in the "heroic" studies of Hardy, Wolff, and Goodell (1952), who used themselves as guinea pigs to measure pain threshold and pain discrimination with radiant heat on the skin. They developed the Dol scale of pain and introduced the radiant heat dolorimeter. Their work can be regarded as the first major psychophysical study of human pain. However, at that time, less psychophysical information existed for deep somatic tissues.

Kellgren (1937–38, 1938) had published some studies on muscle pain although his work was not strictly as psychophysical as that of Hardy et al. However, Kellgren's studies served as a beginning for our own deep somatic pain research. After experimenting with several different body loci, we chose the gluteus medius muscle as the most suitable site (Wolff et al, 1961). We developed a single-blind psychophysical technique permitting the insertion of 32 hypodermic needles in rosette fashion through eight anesthetized blebs of the overlying skin. The muscle was stimulated at each different needle point with 0.2 ml of sterile iso-, hyper-, or hypotonic saline in randomized fashion and a lower and upper pain threshold was measured (Jarvik & Wolff, 1962; Wolff & Jarvik, 1951). We were able to demonstrate, as briefly mentioned previously, that the same body locus could produce two different pain responses, namely, well-localized, sharp pain intensity of short duration (from hypotonic saline and water) and a diffuse, dull ache after a relatively long interval of onset and long duration. This technique, while of scientific value, is rather cumbersome to be used routinely in a pain center. Therefore, few other studies had been published on human muscle pain until the 1980s (Capra & Ra, 2004).

Numerous studies involving experimentally induced pain in humans have been done during the second half of the 20th and the start of the 21st centuries. Different types of noxious stimuli have been employed, such as electrical, mechanical, thermal, and chemical. In the laboratory, attempts are usually made to have the noxious stimulus simulate clinical pain of some kind or other and then to investigate whatever parameter is relevant to the purpose of the experiment. In the mid-20th century a major stumbling block for experimentally induced pain studies in humans was the criticism that such laboratory pain was artificial and bore no resemblance to "real" (pathological) clinical pain, especially in terms of the emotional/psycho-

logical components of clinical pain, which were lacking in the experimental model. Dr. Henry K. Beecher (1959) of Harvard was one of the chief critics of experimental human pain and for years carried on a (published) dispute with the Cornell group of Hardy et al. on the latters' dolorimetric work with humans. At that time, Beecher was an important figure with great influence in the pain arena and clinical pharmacology, who, in my opinion, had a major negative impact on human laboratory pain work. Eventually, Beecher changed his mind and announced that he and Smith et al. (1966) had developed an experimental method — the submaximum effort tourniquet technique — which had validity for clinical pain and could be used to study analgesic agents. Consequently, with Beecher's "blessing," experimental human pain studies became "respectable" again.

In our own work with experimentally induced pain in humans, we focused on several pain response parameters and not only on the pain threshold. In psychophysical terms, the latter is the point at which pain is first reported 50% of the time; i.e., it is really a measure of minimal pain. We applied experimental procedures that also allowed us to collect reports of maximal pain tolerated by the subject — the pain tolerance level. (There is some confusion in the literature about terms such as *pain tolerance*, but we use this term to denote the upper threshold). A third parameter, which we called pain sensitivity range (PSR) is the difference between the pain threshold and the pain tolerance, i.e., pain tolerance – pain threshold = PSR. A fourth response parameter is the just-noticeable-difference between successive levels of stimulus intensity.

Hardy et al.'s Dol scale is based on these just-noticeable differences. In a number of experimental studies in our laboratory using several different pain-induction techniques, we were able to demonstrate that the pain tolerance is the most sensitive parameter for analgesic assays with both mild and potent drugs, such as aspirin and morphine; i.e., it is a valid tool (Wolff et al, 1969). Some investigators have used yet another response parameter, namely, the drug request point, i.e., the stimulus intensity level at which the subjects would have requested a pain killer, had it been clinical pain. Single dose, as well as cross-over designs, have been used in these experimental studies. While the latter are statistically more powerful than single-dose designs, they suffer from an interaction effect, such as order of presentation or expectancy. In recent years, experimental pain in humans has been used less frequently for drug (analgesic) studies but animal models are still widely used.

The important contribution of Dr. W. Crawford Clark (1969) should be mentioned at this point, as he was the first to introduce signal detection theory or sensory decision theory (SDT) to the field of human pain studies in 1969. Clark's approach originally was based on Swets's work (1961) who publicized SDT in 1961. SDT was developed to detect a weak signal above background noise and essentially challenged the sensory threshold of classical psychophysics. In turn, Clark criticized the classical pain threshold as being contaminated by both sensory and judgmental components, while SDT permits separation. SDT caused considerable excitement among many pain researchers resulting in numerous publications, both pro and con. I reviewed this area (Wolff, 1978) discussing classical as well as "new" psychophysical parameters.

In human pain studies, both clinical and experimental, differences in pain behavior have been observed between and within various groups. Frequently, observed differences have been ascribed to ethnic differences, Afro-American, Irish, Scandinavian, Jewish, etc. Unfortunately, such "ethnic" differences have implied "racial" (a dirty word) or "genetic" differences for some authors and are eschewed politically. A good and brief review has been published by Morris (2001) in which he questions the scientific validity of so-called ethnicity. Many years before this publication, I also was interested in ethnocultural factors of pain and published a review with an anthropologist (Wolff & Langley, 1968). On the basis of our own studies, as well as those of several other investigators, it is my belief that pain behavior and pain responses are largely learned responses, molded by many variables, especially sociocultural, and that so-called "ethnic" differences simply reflect such learned behavior. Consequently, it is possible to modify such response under appropriate conditions (Horland & Wolff, 1973). This is not to deny that physiological and genetic differences may exist, but more evidence is required. Within homogeneous groups, age and gender differences are often observed, but again how much is learned and how much (if any) is genetic? We have also noted apparent lateral dominance differences in the same individual. The nondominant side appears to be more sensitive to noxious stimuli than the dominant side, but the latter is more discriminative (Wolff et al., 1965).

In recent decades ethical considerations have played an increasingly important role in experimental and clinical pain studies — both human and animal. Strict standards have been set by both institutional and governmental bodies to guard the rights of animal and human subjects, and funded investigations require approval from various "independent" and "impartial" committees. This is most laudable in spite of greater "red tape." In the "old" days, many investigators paid little heed for the suffering of conscious animals being experimented upon. Now, the animal must be able to escape (avoid, terminate) the noxious stimulus. In laboratory human pain studies, it was considered appropriate for the experimenter to be his or her own first guinea pig, such as Hardy et al. in their radiant heat work, previously mentioned. In my personal experience, I was my first guinea pig when we tested various muscles for the hypertonic saline method. I well remember hobbling

around for a few days after we used the gastrocnemius muscle and obviously decided against this muscle. The ethical problem in general is that the experimenter is not the best judge of noxious procedures to be "inflicted" on human volunteers. Historically, the famous Dahlem Konferenzen sponsored a symposium on "Pain and Society" in November 1979 in Berlin to which I was privileged to be invited and selected to be the rapporteur of a small group of other invited pain mavens, including Drs. Ronald Melzack, Hans Kosterlitz, Sir Michael Bond, Kenneth Craig, Giancarlo Carli, Jane Dum, Hartmund Brinkhus, and Wei-ming Tu. In terms of ethics, our group recommended that the Golden Rule, which states, "Therefore all things whatsoever ye would that man should do to you, do ye even so to them," should be amended to "Do not do unto others what you would not have done to yourself, and do not do unto others what they would not have done unto themselves" (Wolff et al, 1980). It is only 25 years ago that such a statement had to be made, which may surprise many current pain specialists. Another major ethical problem in clinical studies is the use of placebo when there is pathology. A "good" experimental study with a new or untested treatment, e.g., an analgesic drug, should be double-blind and include placebo. Yet, if the experimental modality is therapeutically effective, what ethical right is there not to use it with the placebo group?

Historically, two animal techniques for measuring pain have been standard procedures in analgesic assays, namely, the Eddy hot plate method and the radiant heat tail flick method. In the former, the pain response is measured when the mouse lifts its hind paw and in the latter when the rat flicks its tail. In human experimental pain studies both verbal and nonverbal (e.g., withdrawal) responses are used. What about clinical pain? Obviously, both verbal (e.g., "I am in pain," "Ouch!") and nonverbal (e.g., wincing, rubbing, tensing) responses have been observed and are in daily use by the practitioner. However, for human analgesic studies, two methods have become standard, namely, a numerical rating scale (NRS) or the visual analogue scale (VAS). The former requires the patient to state his or her pain level along a numerical scale, usually from 5 to 10 points. Incidentally, many investigators consider a larger scale (e.g., 10 points) to be more accurate and discriminative than shorter ones. However, scaling has several inherent errors well known to psychophysicists, such as clustering, and therefore, a shorter (say, 5 points) scale may often be more valid because it is easier for the patient to do the ratings. The VAS has become very popular. I remember its being introduced into the field of human pain by Dr. E. C. Huskisson in 1974. It consists of a straight line, generally horizontal and 10 cm in length. One end represents no pain and the other the most extreme pain. The patient is requested to mark a point along the line to represent his or her pain level. An unmarked rather than a graded line tends to be more valid for human analgesic assays. There are many other measures of human pain, such as questionnaires, among which the McGill pain questionnaire is probably the best known.

The discovery of morphine-like opiates in the brain in the 1970s was another major advance in the second half of the 20th century. Endorphins, as these endogenous opiates were named, have been studied extensively since that time. A number of investigators in different laboratories across the Western world pursued this line of chemical investigation making it difficult to pinpoint the originator. Many of us in the pain field felt that this work deserved a Nobel prize, but perhaps there were too many researchers. The endorphins are involved in various aspects of analgesia and a variety of receptors have been identified. Pharmaceutical companies have and are studying a variety of potential drugs that may act upon such receptors or modify related chemical processes to produce better analgesics.

The use of opiates, such as morphine, for clinical pain has been practiced for a long time. They have been used for immediate postoperative acute pain as well as for palliative care in cancer patients. However, morphine or other opiates were not considered suitable for long-term treatment of nonmalignant intractable pain. In the mid-20th century, when I first started to study pain, many physicians were afraid to prescribe adequate doses of morphine for patients for fear they would become addicted. In fact, this fear also permeated the nursing profession and occasionally a nurse would question a doctor's prescription of morphine. In other words, patients were frequently undermedicated as far as opiates were concerned. Yet, the irony is that undermedication can still produce addiction under certain circumstances. Fortunately, in recent years, pain practitioners have attempted to change this medical attitude and insist that if morphine or other opiates are prescribed, it should be done in adequate doses to relieve pain properly.

A newer question relates to the use of opiates for long-term care of nonmalignant chronic pain. Some pain specialists advocate the use of opiates for such patients, claiming good results. However, other practitioners have seriously questioned such an approach. I like to mention aspirin at this point. This non-narcotic, nonsteroidal, anti-inflammatory drug has been around since the late 19th century. It has serious side effects; it can certainly burn holes in tissue because it is an acid and can cause Reye's syndrome in children. Yet, in spite of that, aspirin is an effective analgesic for many pain conditions. Acetaminophen is now used more frequently and tends to replace aspirin in pain management.

Historically, it is worth mentioning amitriptyline, a tricyclic antidepressant, which has been used by psychiatrists for a very long time to treat depression. In the 1960s and 1970s, several clinicians experimented with various psychotropic drugs including amitriptyline to control pain.

Amitriptyline in low doses appeared to have analgesic effects. Originally, many psychiatrists criticized pain physicians for using such low doses for pain management, well below the generally recommended doses for depression. In fact, I know some psychiatrists who refered to such low doses as producing nothing else but a placebo effect. It took several years for the analgesic effect of amitriptyline to be "officially" recognized, although many clinicians still prescribe the higher psychiatric doses rather than the lower analgesic doses. Other tricyclics for pain relief have also been studied and are used frequently. The American Pain Society publishes a short guide on "Principles of Analgesic Use in the Treatment of Acute Pain and Cancer Pain," at the time of writing already in its fifth edition, which is very useful for the practicing clinician.

I indicated at the beginning of this chapter that in the mid-20th century, we lacked knowledge in several areas. As stated before, at the time, pain was generally regarded as what we now call acute. Dr. John J. Bonica was one of the first to stress that acute and chronic pain must be differentiated. He termed chronic pain as a malefic state and said that it makes no sense to talk about "benign" chronic pain to separate it from cancer pain. While it may now seem obvious to classify pain into three major groups, namely, acute, cancer (or malignant), and chronic (or intractable) nonmalignant, it is Bonica who must be credited for promoting such distinctions. Many pain mavens call Bonica the "father of chronic pain," although I am not sure if he really would have liked that title. Recent and current research on pain based on neurophysiological and chemical investigations has demonstrated the plasticity of the brain and neural circuits involved in pain behavior. However, the above classification still has practical value.

I have always stressed the importance of communication both within and between professions for clinical practice and research. Initially, I worked in the field of arthritis and rheumatology and learned about the important contributions of nurses, physical therapists, orthopedic surgeons, and other health professionals in addition, of course, to the rheumatologists. In 1965, I was privileged to become a charter member and later president of the now-called Association of Rheumatology Health Professionals, joining forces with the rheumatologists in the American College of Rheumatology. As the name implies, the association brings together professionals from many fields working in arthritis and the rheumatic diseases. I considered this to be a good example for pain professionals. In 1964, just before the creation of the Association of Rheumatology Health Professionals, my colleague Dr. Thomas Kantor and I invited several pain "specialists" of whom we knew and who worked within a radius of about 100 miles from New York City to come to monthly luncheon sessions at New York University School of Medicine in order to network. We thus formed the New York Pain Group. It was disappointing, however, that only about 30 individuals, who were actively engaged in pain management and research, participated. Therefore, after 4 years of seeing each other, we stopped these meetings. It must be noted that at that time in the 1960s, there was still little interest in pain and the above group essentially comprised all then-active pain investigators in the greater New York City area. It was also a really interdisciplinary group with neurosurgeons, nurses, psychologists, physiatrists, rheumatologists, neurologists, statisticians, and others.

It was with great interest that I learned in 1973, that Dr. Bonica had invited many pain investigators to a meeting in Issaquah, Seattle, which eventually led to the formation of the International Association for the Study of Pain (IASP). This was indeed a very courageous and highly significant endeavor by Bonica to bring together pain clinicians and researchers from all across the world to exchange knowledge and communicate with each other. The first International Congress of IASP was held in Florence, Italy, in 1975 and was highly successful; other congresses are now held every 3 years in different countries. The IASP also publishes a journal, *Pain*, originally under the editorship of Dr. Patrick Wall, which has become the most influential scientific journal in the field of pain.

Stimulated by Bonica's success in forming an international pain organization, I decided to review what had originally been the New York Pain Group, especially after receiving enthusiastic support from many colleagues in the greater New York City area. Therefore, in 1974, I started the New York Pain Society, which almost immediately became the New England Pain Association following strong urging from Bonica. Rapidly thereafter, we enlarged to become the North-Eastern Pain Association and, as such, supported the IASP as one of its first chapters. Concurrently, the West Coast pain scientists formed the Western Pain Association and also joined the IASP as a chapter. In view of the steadily increasing interest in pain across the United States, both American societies enlarged, the Western including states west of the Rockies while the Eastern included states east of the Rockies. The latter again changed its formal name to Eastern Pain Association and has been functioning as such ever since.

In view of the rapidly rising interest in pain, I continued to feel that we should have a national pain organization in the United States in addition to the regional societies, a view shared by many of my Eastern colleagues. We considered it important that we have support for such a national U.S. organization from our Western U.S. colleagues as well as from the IASP. In 1975, during the First International IASP Congress, Dr. Pierre L. LeRoy and I discussed this issue with Dr. Bonica. The latter was concerned that an American pain organization might overshadow the IASP both financially and numerically and recommended that we wait some time until the IASP became a stronger organization. However, the success of the IASP, as well as the need to have a national society

that could represent pain scientists nationally rather than regionally, encouraged me to form a national U.S. pain organization. Therefore, I started informal discussions with Dr. Bonica, mainly by telephone, and we had Dr. Arthur F. Battista and Dr. B. Raymond Fink negotiate on our behalf — successfully. Thus, with Dr. Bonica's support, a national society could be started in the United States. In 1977, a meeting was arranged in Chicago to which Dr. Bonica and I invited 12 participants each, representing various interests. This meeting successfully supported the idea of a national organization and the American Association for the Study of Pain, shortly thereafter changed to the American Pain Society (APS), was formed, and I was elected as its first president. The Eastern and Western groups became chapters of the APS, which now has several regional chapters.

The APS has steadily grown and is representative of U.S. pain clinicians and researchers. The APS is truly multidisciplinary and includes all professions involved with pain. In view of its multidisciplinary structure, I decided that it could not have "trade union" functions but had to be predominantly scientific and educational. However, some physicians felt pain medicine had become important and that there should be a new specialty (or subspecialty) and eventually this led to the formation of the American Academy of Pain Medicine (AAPM). Fortunately, this did not pose a threat to the aims and goals of the APS. Furthermore, other professions can have pain specialists with their own guidelines within their profession. There always has been and still is concern that the APS is too scientific and research oriented and fails to cater to the practicing clinician while at the same time basic scientists often complain that the APS is too clinical. It is difficult to satisfy both views.

Because the APS gives no certificates or diplomas for proficiency in pain control, Dr. Richard Weiner years ago decided that there should be an organization to do so. Dr. Weiner had discussions with APS Board Members, including myself, and realized that this could not be a function for the APS. He thus formed the American Academy of Pain Management — the other AAPM — which focuses on the practicing health professional, provides education, and awards credentials of proficiency. It has now become one of the major pain organizations in the United States.

In this chapter, I have rambled along various historical paths often associated with my own functions and role. It is thus a little autobiographical although I hope not too boring. Detailed histories of pain may be found in other publications. Here I have cursorily reviewed the historical background leading up to the Melzack and Wall gate theory of pain and focused on the mid- and second half of the 20th century. In my opinion, the gate theory and the discovery and role of endorphins were the two most significant scientific contributions to pain in the latter half of the 20th century. Clinically, the realization that pain is a

specialty of its own and requires a multidisciplinary as well as multimodel approach should be regarded as another significant contribution. Associated with both the clinical and scientific contributions has been the much greater interest in pain, its mechanism, and management. Better communication and networking, largely due to the formations of regional, national, and international pain societies followed by the publications of several pain-oriented journals, have also contributed to our constantly increasing better understanding of pain — now often regarded as the Fifth Vital Sign.

Fibromyalgia: Patient Beliefs and Expectations

Lynne Matallana

Yes, when I see a healthcare professional, I am a fibromyalgia "patient," but more importantly I am a human being — a living, breathing, feeling person who must face, on a daily basis, a constellation of distressing symptoms that cause both physical and mental anguish. Like millions of others with fibromyalgia, not only do I have to live with the consequences and challenges that its chronic symptoms cause, I have to live with the fact that there are many people who give no credence to my condition, dismissing my suffering because they don't understand it or don't want to get involved with those of us who are seen as "difficult patients who constantly complain."

Ten years ago I believed that if you became sick, all you had to do was go to a doctor, get a diagnosis, be given the appropriate treatment, and within time (hopefully not a long period of time) you would feel better and your life would return to normal. Yes, a naive concept, but one that had been my experience. We live in a world that possesses more scientific medical knowledge than ever before. We place physicians on pedestals as they transplant hearts, cure cancers, and remove brain tumors. These acts are truly incredible, almost incomprehensible feats of accomplishment. So when only a few days after having had surgery for endometriosis I started to experience a variety of disturbing symptoms, including widespread body pain, unrelenting fatigue, migraine headaches, and the inability to easily organize my thoughts, I felt certain that a visit to my doctor would solve the problems. Instead, it marked the beginning of my passage into a new life. A journey that would mean learning to live well despite chronic pain, one of the most desperate of human conditions, yet one that still in many ways remains challenging and mysterious to the medical community.

Although it took me some time to come to accept the fact that doctors don't possess a magic wand to make pain disappear and that my expectations of their "God-like" ability to cure me was not only unfair but silly, I couldn't accept their conclusion that there was nothing wrong with me and that there was nothing that could be done to help. Was there truly no hope for my future? Although even at times I questioned my sanity, wondering if my pain was "real," I believed that no matter what the cause of my suffering, I deserved to be treated with respect as a human being and that my experience could not and should not just be dismissed because others didn't understand it. My pain didn't fit into their reality, but my pain was very much my constant reality.

When I first became ill scientific *proof* of my condition lagged behind my state of misery, but I believed that *I* shouldn't be seen as a pariah, a nuisance to the medical community and valueless to humanity. However, that is how I felt. I wanted and needed help, so that I could regain my worth and continue to contribute to society. Pain is not new, so how could the medical community not accept my pain as real or help treat it as something that truly existed? Was I naïve to also think that a physician should be *compassionate* to my distress no matter what the illness? Was it simply because the *type* of pain that I experienced did not yet have evidence of organic pathology, unlike pain from a broken limb or a cancerous growth, that made it unworthy of concern? Without empirical evidence, my pain was invisible to everyone except me. And my frustration with the situation made me frantic, and I turned into that "difficult and constantly complaining patient." I hated what I had become. I hated the looks of frustration on the faces of my family and doctors. I felt like the little baby who cries and cries, trying to let others know that there is something wrong, but no one can figure out the reason for the screams. I couldn't imagine a life

where I was supposed to just quietly disappear. Like the women of my grandmother's generation whose complaints were dismissed as one of those "middle-age women's things," which left them retreating to their beds for days, weeks, and years at a time. I valued life too much not to fight for a life of quality, despite fibromyalgia. I tried to be understanding of the frustrations that everyone around me was feeling. I felt guilt because *I* had caused them distress and yet angry that they couldn't take away my pain.

I remember as a child the first time I looked through a microscope and a drop of water from a pond turned into a world of small invisible creatures that hadn't existed in my reality a few seconds earlier. Even though my fibromyalgia pain weighed me down with frustration, fear, disillusionment, guilt, and even anger, I wanted to fight the temptation to believe the cluster of preconceived negative assumptions that were attached to *my* illness. I wasn't crazy, I wasn't just stressed, I wasn't lazy, or just a negative person. Why was I supposed to suffer because of other people's ignorance and lack of acceptance? Of course it was easier to just turn away than to try to make sense out of something that didn't fit into the way the medical community *currently* looked at and accepted things. But we *can't* be reluctant to look through the microscope and discover new truths, to recognize that we can't *see* everything easily, so we must take a closer look, refusing to turn a blind eye, especially when it involves a large community of people who are truly suffering.

Unlike most patients with fibromyalgia who do not have the circumstances that allow them the opportunity to keep searching for answers, I had the emotional and financial support that allowed me to continue to seek out help. Although there were times that I began to lose faith, my pain urged me on, a constant reminder that there was no room for self-doubt. My pain was real and it wasn't something that could be ignored. It wasn't just the medical community that had left me feeling stranded and isolated; it was friends, employers, and society who questioned my pain and fatigue. Even the media talked about a *new* illness that was thought to affect people who were "lazy and out of physical condition." What had I done that was deserving of *abandonment and judgment*? I kept telling myself — I did nothing wrong. This was an *illness*, not a punishment. So there had to be answers and there had to be people out there who *did* care. I just had to find them.

Unfortunately, today and even more so ten years ago, knowledgeable physicians on fibromyalgia are rare. Thirty-seven doctors and two years later, I found my compassionate, open-minded, knowledgeable doctor. I came to understand that my quality of life was going to be influenced by our doctor–patient relationship. I realized that it was going to take time to build this relationship and that we both had to make a commitment to working hard and doing our part as *a team*. I couldn't have expectations that my doctor was going to cure me, and my doctor couldn't expect me to not share my suffering with him. I trusted him to keep me informed of the most recent treatment options available to people with fibromyalgia, and he trusted me to try to keep a positive attitude and to be willing to take his medical advice while making personal life-style changes that would help improve my overall symptoms. We both made a commitment — he to treating and encouraging me to the best of his ability, and I to being a pro-active patient, implementing a multidisciplinary self-management plan, working to achieve both physical and mental balance. Even though much of the "responsibility" did fall on me, the patient, his willingness to diligently keep up with new research findings that led to the implementation of new treatment options encouraged me and resulted in treatments (both pharmacological and alternative) that helped reduce my symptoms.

When asked, most individuals with fibromyalgia express above all else the need to feel "normal" and understood. Living with an "invisible" illness can strip away people's self-confidence and make them feel isolated and alone. All need and feel better when they receive validation, whether it is for what they have accomplished, what they think, or what they feel. When you are told that what you are feeling is not real, it is like being told that *you and your feelings* have no value. We as individuals need our lives to have value, a purpose, without which we feel cast out, alone, and even abnormal. Pain that is not validated causes one to feel guilt, fear, and hopelessness, which in turn can even become disillusionment and depression. Referring to fibromyalgia as being a "waste basket" diagnosis alludes to the fact that the diagnosis has no value, again discrediting and belittling the personal experience. It is evident that even before pursuing efforts to reduce their symptoms, people with fibromyalgia can greatly benefit from acts of compassion, acceptance, and the gift of hope.

In pain states that are caused by injury, the treatment protocol is to treat the injury, thereby eliminating the problem that is causing the pain. However, fibromyalgia is a condition of central sensitization and neuroendocrine dysfunction, so the pain experience becomes chronic. For a person living with constant pain it is an ongoing challenge to find ways to achieve a better quality of life. The actions taken and avenues pursued by a person with fibromyalgia are based specifically on the chronic nature and idiosyncrasy of the syndrome. Each individual's personality affects the way in which he or she approaches the problem. With the lack of reliable treatment options, the individual can feel that there is nothing available to help and can become depressed and withdrawn, while others spend hours searching for solutions, becoming overwhelmed with a countless selection of unreliable treatments touted to "cure" or help relieve symptoms. Desperation can sometimes outweigh common sense and one can

become compulsive in the attempt to find relief. Those of us who were once independent and self-sufficient can find ourselves needy and desperate for others to concentrate only on our dilemma, at times not even recognizing that our neediness can actually push others away.

In that fibromyalgia is a syndrome of multiple symptoms and overlapping conditions, the extent of the complaints can seem questionable to those on the "outside," and patients often find themselves trying to explain, as well as understand, a myriad of ever-changing ailments. One day you'll be suffering with a burning pain sensation all over your body and the next day you'll experience cognitive dysfunction, dizziness, and anxiety. Then you'll find yourself gaining confidence as things slowly start getting better, and then the next day you'll be experiencing nagging unrelenting pain that seems to come from nowhere. Living in a world where we look at things in relationship to cause and effect, people with fibromyalgia can become disheartened by the inability to find this type of relationship when it comes to their pain and symptoms.

Overanalysis of the situation can lead to nothing but confusion, and therefore, it is important to realize that with our current limited understanding of central sensitization, it is often impossible to predict a cause/effect relationship when it comes to symptoms. In those situations where one can identify a "trigger" for a specific symptom, a small sense of control can emerge, helping one to better self-manage the condition. However, when one expects a certain reaction, for example, spending several days in bed in order to relieve pain and exhaustion, and that result does not occur, the sense of control becomes elusive and the ensuing frustration is not surprising.

It is important to realize that our "cause and effect" expectations are based on our existing experiences and knowledge of the reactions of a healthy body or one with a specific disease or trauma. But in the case of fibromyalgia, we are learning that the problem is "system failure," or in other words, symptoms that are caused by disordered sensory processing at a central level. For a person experiencing "pain amplification," the existing cause-and-effect "rules" do not apply. It is only with additional research that we will be able to assist the person with fibromyalgia by better understanding the cause(s) of this illness. We as patients will experience more control over symptoms when we come to understand the new relationship of cause and effect, which produces fibromyalgia symptoms.

It is at this point that one realizes yet another challenge confronting those of us living with fibromyalgia. Not only must we adapt to living with disruptive, disabling symptoms for which there is often little relief, but we must also live with an illness that produces symptoms that don't "react" like our preconceived expectations. Besides the physical pain that must be endured, this lack of control

and resulting feelings of abnormality cause extreme emotional suffering. Until we understand the cause(s) of the "system breakdown," and we can find ways to correct that problem, patients must find ways to feel a sense of control over their illness through limited existing avenues — usually consisting of options that involve extensive self-motivation and patience. In the past, the focus has been on the patient's learning to accept and live with the pain (and other symptoms) through means of counseling, cognitive behavioral therapy, biofeedback, etc. These are excellent ways to deal with the situation, but they are not solving the actual problem so as to eliminate the symptoms. For years patients have had to learn ways to adapt and adjust to their illness rather than have options that will "fix" them. Today, there are more options available to help people with fibromyalgia cope with their symptoms. But the continuous waxing and waning cycle still robs certain individuals of the freedom to plan daily activities and move forward with their life.

Fibromyalgia obviously affects the patient in numerous ways, but it must be pointed out that fibromyalgia also affects the lives of all who share the patient's life. As with any chronic illness, individuals find themselves in roles that they are not comfortable with or even refuse to accept. Spouses and family members must become caregivers, employers are asked to make work accommodations, physicians are asked to treat patients with exceptional needs, and friends are relied upon to provide support and assistance. When one or more of these people decide that they cannot or will not accept the responsibilities that go along with their new role in their relationship with this person, more emotional trauma ensues. Often fibromyalgia can make a person dependent on others for various aspects of their livelihood. When an individual becomes chronically ill there are people around that person who will not be able to cope and will remove themselves from the situation. In the case of a person who is chronically ill with fibromyalgia, an "invisible illness" that is difficult at best to understand and doesn't have the "credibility" of other chronic illnesses, the chances of disassociation become even greater. Living with fibromyalgia all alone is something that far too many people have to face.

Fibromyalgia is not just a problem that affects a specific group of people. It is a health condition that touches the lives of millions and millions of people every day. The negative implications of this illness are far reaching and must be given the attention necessary to ensure that we will find the answers that will allow us to eliminate the suffering caused by this disorder. Education is the key to providing a future that guarantees hope for those who live with fibromyalgia. As a patient, I can live with an illness that causes pain, but as a person, I can't live with the knowledge that others have dismissed this pain and find it unworthy of their concern and acceptance.

The Neuroscience of Pain and Analgesia

James Giordano, PhD

By definition, pain is a noxious sensation that evokes perceptions of dysphoria and illness. The linkage of sensory phenomena with cognitive processes is important to the strong avoidant motor reflexes, autonomic events, and emotional responses that are co-terminal with both the pain experience and its expectation (Cazzullo & Gala, 1987). The scientific perspective has evolved to characterize pain as a heterogeneous entity that may be classified by temporal (i.e., acute, chronic), mechanistic (i.e., nociceptive, inflammatory, neuropathic), and phenomenologic (i.e., eudynia, maldynia) factors. Far from being mutually exclusive, these classifications are both overlapping and interactive and can be useful when elucidating the qualitative, quantitative, and pathologic variables that contribute to a particular clinical pain syndrome (Woolf & Max, 2001). The neural substrates that are involved in processing noxious input contribute to both the sensation and cognitive–emotional phenomena of pain.

NOCICEPTORS

The first step in the nociceptive sensory pathway is the transduction of noxious thermal, mechanical, or chemical stimuli to a relevant neural electrophysiologic signal. In cutaneous, muscle, and visceral tissues, free nerve endings of nocisponsive primary afferents are responsible for this transduction step. Cationic channels on free nerve endings respond to noxious stimuli directly and to evoked changes in the innervated tissues.

Two nonselective cation channels, molecularly similar to vanilloid receptor-1 and vanilloid receptor-like protein 1, are responsive to noxious heat (>45°C) and thermal sensitization (Davis, 2000). A related cation channel, the cold- and menthol-receptor-1 (CMR1/transient receptor potential M8) is responsive to noxious cold (8 to 25°C) and menthol (McKemy, Neuhausser, & Julius, 2002). In both cases, thermal change produces an ungating of the channel(s) to induce cationic flux.

Noxious mechanical input (i.e., compression, shear, tensile distortion) is subserved by a nonspecific cation channel that is gated by mechanical linkage to bridging elements of the free nerve ending membrane and the matrix of surrounding tissue (Mannsfeldt, Carroll, Stucky, & Lewin, 1999). Transduction occurs as these stimuli distort the mechanical field of the neural membrane, transforming channel configuration and producing an inward Na^+, K^+, or Ca^{2+} current. The receptor potential for free nerve endings appears to be a graded response, with time- and intensity-dependence of the membrane polarity. Once the conductance threshold for Na^+ is achieved, activation of voltage-gated Na^+ channels occurs, leading to a propagation of the depolarization along the membrane of the primary nociceptor. As well, the influx of both Na^+ and Ca^{2+} elevates the concentration of intracellular Ca^{2+} that activates a variety of intracellular signaling systems capable of producing short- and long-term changes in neuronal function (and perhaps microstructure; *vide infra*).

In addition to the direct action of noxious stimuli upon nociceptors, high-intensity input may incur local tissue disruption or membrane damage to evoke the release of fatty acids and free ions from cell membranes. The enzyme phospholipase-A2 catalyzes free membrane fatty acids to produce the omega-6, arachidonic acid, that then serves as the initiative substrate for (latent) induction of the isoenzyme cyclooxygenase 2 (COX-2) to induce the inflammatory cascade, subsequently mediated by the for-

TABLE 3.1
Algogenic Substances/Stimuli and Substrates Mediating Effects

Algogenic stimulus	Substrate(s)	Effect(s)
H^+ ion	VR1 receptor	Na^+, Ca^{2+} influx
Protons	Acid-sensitive ion channel (ASIC)	Na^+ influx
Noxious heat >45°C (and capsaicin)	VR1, VRL-1 receptor proteins	Na^+, K^+, Ca^{2+} influx
Noxious cold 8–25˚C (and menthol)	CMR1/trpM8	Na^+, K^+, Ca^{2+} influx
Mechanical distortion	Nonselective cation channel	Na^+, K^+, Ca^{2+} influx
BDNF	Trk-B receptor	MAPK activation–transcription effects
Prostaglandin-E_2	Prostanoid receptor	Metabotropic activation of protein kinase
Serotonin	5-HT$_3$ receptor	Na^+ influx
		NK-1 receptor sensitization
		NO production
Adenosine (or ATP)	A_2 purinoreceptor	Sensitization of Na^+ channels
Glutamate	AMPA receptor	Na^+ influx
	NMDA receptor (GluR)	Ca^{2+} influx
	mGlu receptor	Phospholipase-C-induced rise in intracellular Ca^{2+}
		Protein kinase-C phosphorylation/sensitization of trk-B
Bradykinin	Bradykinin B_2 receptor	Cationic influx

mation of biologically active prostaglandins, most specifically prostaglandin synthase–generated prostaglandin-E2. Prostaglandin-E2 acts upon the free endings of nociceptors to produce a receptor-mediated increase in adenyl cyclase to elevate cyclic adenosine monophosphate (cAMP) and engage specific protein kinases. Protein kinase A and C can phosphorylate membrane proteins to affect the sensitivity of prostanoid, kinin, or amine receptors as well as increase the sensitivity and/or modify the configurational state of ion channels (McClesky & Gold, 1999). Such changes can produce a leftward shift in nociceptor membrane thresholds, which can sensitize the affected primary afferents to subsequent stimulation by increasing the number and frequency of nociceptor depolarizations produced by both noxious stimuli (e.g., contributing to hyperpathic responses) and perhaps innocuous stimuli (i.e., allodynia; Gold, Levine, & Correa, 1998; Ji, Kohno, Moore, & Woolf, 2003). Table 3.1 presents an overview of noxious stimuli and the substrates that transduce their neural activity.

Subsequent to transduction, the nociceptive signal is conducted from free nerve endings in the periphery (or viscera) along the membrane of primary nociceptive afferents via depolarization induced by sodium influx subserved by $Na_v1.8$ and $Na_v1.9$ subtypes of Na^+ channels, that are specific to nociceptor membranes (Amaya et al., 2000). There are two types of primary nociceptive afferents, A-delta and C-fibers. These subtend distinct types of noxious input (e.g., thermal, mechanical, polymodal) and are strongly contributory to the differing subjective sensory qualities of fast (i.e., "first") and slow (i.e., "second") pain, respectively (Ochoa & Torebjork, 1981).

PRIMARY AFFERENTS

A-Delta Fibers

These fibers are small, thinly myelinated neurons, 1 to 5 μm in diameter, with conduction velocities in the range of 5 to 30 m/s. The rapid rate of conduction is responsible for the initial sensation of pain, "first pain," typically described as sharp, localized, and well defined. A-delta fibers have small receptive fields and are relatively modality specific. This latter quality is a function of specific, high-threshold ion channels on the free endings of A-delta afferents that are differentially activated by distinct high-intensity thermal or mechanical input (Julius & Basbaum, 2001). A-delta thermosponsive fibers respond to extremes of temperature. One population is activated by noxious heat, with an initial response threshold in the range of 40 to 45°C. Response function increases directly, although not necessarily linearly, as a consequence of temperature elevation, with maximal responses occurring at temperatures of 46 to 53°C. These responses subserve both the rapid, demonstrably painful response to an initial presentation of noxious heat and the ability to quickly discriminate extent of thermal pain as a function of heat intensity. A second population, high threshold cold afferents, responds to cold temperatures at or below a threshold of approximately 8°C, with increasing cold sensitivity to temperatures less than 25°C (Price & Dubner, 1977; see Table 3.1).

A-delta mechanoreceptive afferents are activated by high-intensity mechanical stimulation (deep pressure, stab, pinch, stretch), although these fibers may be sensitized by, and become secondarily responsive to, noxious heat. Unlike A-delta thermal afferents, sensitized A-delta mechanoreceptive afferents respond to suprathreshold heat (usually in excess of 50 to 55°C) and/or repetitive presentation of noxious heat, rather to a singular exposure to a heat stimulus at or above the nociceptive threshold (Kumazawa & Perl, 1976). The sensitization of this second population of nociceptive A-delta afferents may contribute to the hyperalgesia observed following heat and mild to moderate burn injury.

C-Fibers

C-fibers are small, unmyelinated afferents with broader receptive fields than A-delta fibers. C-fiber diameters range from 0.25 to 1.5 µm, and the absence of myelin leads to slower conductance velocities that vary from 0.5 to 2 m/s. This slower conductance together with the broad receptor fields subserve clinical "second pain," a diffuse, poorly localized burning, throbbing, or gnawing sensation that follows and that is temporally and qualitatively distinct from the initial sensation of "first pain" (Torebjork, 1974). Numerically, C-fibers constitute the majority of primary nociceptive afferent innervation of cutaneous tissue. C-fibers are polymodal, and can be activated by thermal, mechanical, and chemical stimuli. This latter quality reflects the direct engagement of C-fibers by specific chemicals that perfuse the neuronal microenvironment of C-fiber free endings following cellular disruption. Free H^+ ion (i.e., lowered pH), protons, and adenosine triphosphate (ATP) are all capable of activating C-fibers. H^+ acts by sensitizing the VR1 vanilloid receptor (that is also responsive to noxious heat) and enhancing Na^+ and Ca^{2+} influx (Caterina et al. 1999). Protons stimulate C-fibers by acting at an acid-sensitive ion channel to evoke an inward Na^+ current (Waldman & Lazdunsky, 1998). Adenosine, liberated from ATP by hydrolysis, binds to an A_2 purinoreceptor, to sensitize Na^+ channel excitation (Gold, 1999; see Table 3.1).

In addition to responding to noxious (thermal, mechanical, and chemical) stimuli, C-fiber polymodal afferents may be sensitized by substrates of the inflammatory cascade (e.g., prostaglandin-E2, bradykinin) that are released following thermal or mechanical insult (Gold et al., 1998; Levine & Reichling, 1999). Once sensitized, these C-fibers can be activated by certain types of non-noxious, low-intensity stimulation. This may account for the persistent second pain and hyperalgesia that occurs following burn injury or other inflammatory states (Rowbotham & Fields, 1996). In this light, C-fibers may contribute to multiple sensations from a painful region.

C-fibers also innervate muscle tissue, localized to the intrafibril matrix, tendons, and areas surrounding the vascular walls (Iggo, 1974). C-fiber muscle afferents are polymodal and are responsible for the nociceptive response to intense mechanical stimulation (Jones, Newham, Obletter, & Giamberardino, 1987) that produces numerous substances as a consequence of both aerobic and anaerobic metabolism. C-fibers innervating muscular tissues are activated by H^+ ions as a constituent of the acidic postmetabolic environment (Mills, Newham, & Edwards, 1982) as well as end products of inflammation due to exercise-induced micro- or macrotraumatic insult (including bradykinin, histamine, and 5-HT; Vecchiet, Giamberardino, & Marini, 1987), mechanical distention of microedema (Newham & Jones, 1985), and heat (Mense, 1977). Although not directly activated by muscular contraction or the stretch reflex, intramuscular C-fibers can be sensitized (under ischemic conditions) to respond to even small myofibril contraction and may respond vigorously to excessive stretch (Vecchiet et al., 1987). It appears that ischemia yields an increased concentration of free adenosine that acts at A_2 purinoreceptors to produce G protein–mediated modulation of Na^+ channel thresholds (Gold, 1999). This sensitization helps to explain the diffusely painful response to both passive and active movement of over-exerted, traumatized, or ischemic skeletal muscle.

Visceral Primary Nociceptive Afferents

Numerous stimuli are capable of producing visceral pain (see Gebhart, 1995, for review). Distention, compression, and chemical and tactile irritation of several visceral structures have all been shown to elicit distinct and quantifiable pain responses in humans (Willis, 1985), that are often accompanied by reports of localized somatic and cutaneous pain. The diversity of response to various types of noxious stimuli suggests the presence of afferents with polymodal qualities. Taken with the diffuse, poorly localized quality that often accompanies visceral pain, such findings implicate the involvement of C-fiber-type innervation (Dubner, 1985; Gebhart, 1995). C-fiber-type afferents innervate several visceral structures, even though studies have also demonstrated presence of A-delta fibers with polymodal sensitivity, particularly in the testes and structures surrounding the heart (Paintal, 1972; Uchida & Murao, 1974). As well, a small, unmyelinated J fiber has been identified in the parenchyma of the lung (Paintal, 1972). J fibers have structural properties, receptive fields, and conductance velocities similar to C-fibers and respond to high-intensity mechanical changes in lung volume (i.e., distention and compression), inflammation, and exogenous chemical irritants (e.g., acidic and basic substances; Coleridge, Coleridge, & Luck, 1965).

TABLE 3.2
Physiologic and Neurochemical Properties of Primary Afferent Nociceptors

Type	Stimulus	Anatomy	Diameter	Conduction/Properties	Chemistry
A-delta fiber	High threshold Mechanical Thermal (>45°C) (<20°C) Mixed-sensitized	Free endings Myelinated Punctate fields	1–5 μm	10–30 m/s Fast; First pain; Well localized	Glutamate Substance-P CGRP (?) VIP Postsynaptic activation of AMPA receptors Short-term NK-1 receptor activation
C-fiber	High threshold Polymodal Thermal Mechanical Chemical	Free endings Unmyelinated Diffuse receptive fields	0.5–1.5 μm	0.5–2 m/s Slow; Second pain; Chronic; Poorly localized; Sensitized	Glutamate Substance-P CGRP Postsynaptic activation of NMDA, Glu receptors Potentiated NK-1 receptor activation May induce neural plasticity

Nociceptive afferent innervation of visceral structures has several characteristics that are markedly distinct from those in cutaneous and muscle tissues. First, nociceptive afferent innervation of the viscera is relatively sparse, with considerable diffusion at projection sites at second-order neurons within the spinal dorsal horn (Cervero & Iggo, 1980). Thus, nociceptive input from the viscera may not evoke strong, well-localized volleys of excitation capable of spatially or temporally summating at spinal relays. Second, the nature of visceral afferents is such that sensitization by chemical mediators and/or sympathetic activity (see below) appears to be required for their sustained firing. Given the sparse distribution of these fibers throughout the viscera and the diffuse connections with nociceptive units of the spinal cord, it appears that this sustained firing is responsible for the activation of second-order spinal afferents and, ultimately, the transmission of visceral nociceptive signals. The perception of visceral nociception is vague, becoming more intense (and better localized) as increased painful activity in the innervated structure(s) sensitizes the involved afferents (Dubner, 1985). Third, nociceptive afferent innervation of the viscera is often structurally co-localized with sympathetic afferent (and perhaps efferent) neurons. Noxious stimulation from the viscera can lead to concurrent excitation of both visceral nociceptive afferents and sympathetic innervation, capable of producing retrograde sympathetic outflow and sympathetically maintained regional hyperalgesia and altered autonomic tone. However, such sympathetic alterations are not exclusive to visceral pain; sympathetic effects are strongly contributory to the constellation of nociceptive, vasomotor, and sudomotor features of complex regional pain syndromes (CRPS) that can affect somatic innervation, as well. In such cases, excessive stimulation of sympathetic axons or endings (either by ephaptic transmission from adjacent nociceptive afferents or directly by peripheral tissue insult) can induce increased synthesis of high-affinity adrenoceptors, thereby perpetuating the cycle of peripheral adrenergic sensitivity, sympathetically-maintained pain, and alterations in peripheral autonomic regulation (Campbell, Meyer, & Raja, 1992, for an overview). Last, visceral nociceptive afferents are often anatomically integrated with somato-cutaneous nociceptive afferents within dorsal root ganglia or within the aggregate of primary afferent synaptic fields at second-order afferents of the spinal cord (Willis, 1985). Reciprocal sensitization within the dorsal root ganglion and the overlap of second-order receptive fields for both visceral and somato-cutaneous input subserve the somatic referred component that is characteristic of much of visceral pain. It is clinically relevant to understand the convergence of visceral and somato-cutaneous afferents when attempting to predict involvement of visceral structures in patterns of referred somatic pain.

PROJECTIONS TO THE SPINAL DORSAL HORN

Although a small number of nociceptive afferents synapse within the ventral spinal cord, the vast majority of somato-cutaneous and visceral nociceptive primary afferent fibers project to defined areas of the superficial dorsal horn (Gobel, 1976). This area has been anatomically distinguished into discrete zones, the laminae of Rexed. The laminae are numbered consecutively from dorsal to ventral regions (Rexed, 1952). Both A-delta and C-fibers terminate on specific populations of second-order spinal neurons in laminae I, II, IIa, and V that are the origin of the ascending spinal pathways critical to pain transmission. Specifically, A-delta fibers terminate in laminae I, II, and to a lesser extent, IIa (Gobel, 1976), while C-fibers project to laminae II, IIa, and V (Torebjork, 1974). The anatomic, physiologic, and neurochemical properties of primary nociceptive afferents are presented in Table 3.2.

NEUROCHEMISTRY OF PRIMARY AFFERENT PAIN TRANSMISSION

The principal neurochemical mediator at the synaptic cleft between primary afferent nociceptors and dorsal horn cells is glutamate. Postsynaptically, glutamate is capable of binding to two types of discrete receptors (Woolf, 2004). The first, the AMPA (alpha-amino-3-hydroxy-5-methyl-isoxazole-4 propionic acid) receptor, appears to be the initial or first molecular target for glutamate binding. Glutamate-induced AMPA receptor activation evokes a ligand-gated sodium current in postsynaptic second-order neurons of the dorsal horn that produces a rapid depolarization. AMPA receptor-mediated depolarization modulates glutamate-induced activation of the second class of receptor, the N-methyl-D-aspartate (NMDA) receptor, by allosteric modulation of magnesium binding to a shared or cooperative domain of the NMDA receptors. With persistent AMPA receptor activation, the rise in intracellular sodium displaces a magnesium "gate" from the NMDA receptor, thereby increasing its sensitivity or releasing it from an inaccessible configuration to actively bind glutamate (Woolf & Salter, 2000).

There are two types of NMDA receptor: a fast-on, slow-off, ionotropic, Ca^{2+} channel site (GluR) that subserves a durable calcium influx and a metabotropic, G protein–coupled receptor (mGluR). Of the eight identified mGluR sites, three are positively coupled to phospholipase-C (PLC). In nociceptive neurons, one type of mGluR engages PLC to induce inositol triphosphate (IP3) to release calcium from intracellular stores. These effects elevate the level of intracellular calcium; this activates a Ca^{2+}-sensitive protein kinase-C (PKC) to phosphorylate serine and threonine residues in the submembrane pool of NMDA and AMPA receptors, thereby inducing post-translational changes that subsequently increase the number and sensitivity of these receptors (Luo et al., 2001; South et al., 2003). Metabotropic glutamate receptors can also act through intracellular diacylglycerol (DAG) to activate PKC to phosphorylate the tyrosine kinase-B (trkB) receptor for brain-derived neurotrophic factor (BDNF; Kerr et al., 1999). BDNF, a secretory protein, is produced and released by primary nociceptive afferents (McMahon & Bennett, 1999). The action of BDNF at postsynaptic trk-receptors initiates mitogen-activated protein kinase (MAPK) capable of affecting gene transcription (Friedman & Greene, 1999).

Taken together, these glutamate-dependent reactions may be responsible for the sensitization of second-order afferents to input from nociceptors. There is further evidence to suggest that prolonged activation of newly synthesized NMDA receptors may instigate PKC-mediated activation of transcription factors to affect genomic elements to facilitate ongoing alteration of cell membrane components (e.g., sensitized ion channels, additional upregulated receptors) and produce durable changes in second-order nociceptive afferent function (Stubhaug, Breivik, Eide, Kreunen, & Foss, 1997).

While brief, suprathreshold primary nociceptor activity causes the release of glutamate, prolonged and/or intense C-fiber activation induces the release of the undecapeptide tachykinin, substance-P (Cao et al., 1998). Initially, substance-P binds postsynaptically to neurokinin-2 (NK-2) receptors on second-order dorsal horn neurons. However, with more prolonged excitation, substance-P also binds to NK-1 receptors to activate G protein–mediated, metabotropic, slow onset, durable shifts in membrane potential (Woolf, 2004). The continued activation of NK-1 receptors induces DAG-dependent activation of protein kinase (A and C) to phosphorylate NMDA receptors, leading to enhanced intracellular calcium levels (Thompson, Dray, & Urban, 1994). Latent (i.e., 30 to 60 min) calcium-mediated phosphorylation of transcription elements stimulates production of the early-phase proto-oncogenes, *c-fos, c-jun,* and *Krox-24* (Jin et al., 2003; Lanteri-Minet, Isnardon, de Pommery, & Menetreu, 1993). The induction of these proto-oncogenes produces protein products that both act as metabolic regulatory units and produce late-gene effects that may be responsible for transcribing and translating novel (and perhaps aberrant) proteins involved in functional and microstructural remodeling of second-order neurons that are actively processing chronic pain (Jin, Zhuang, Woolf, & Ji, 2003). According to Doubell, Mannior, & Woolf (1999) such remodeling characteristically results in a reduced firing threshold, increases in durability and frequency of response, expansion of the functional postsynaptic region (i.e., the receptive field), and a suppression of inhibitory potentials (subserved by both downregulation of receptors for inhibitory transmitters and a loss of inhibitory synapses). These processes are similar to long-term potentiative (LTP) and depressive (LTD) mechanisms, respectively, and it is likely that they play a role in central sensitization and directly contribute to neuropathic pain syndromes (Ji et al., 2003; Randic, Jiang, & Cerne, 1993).

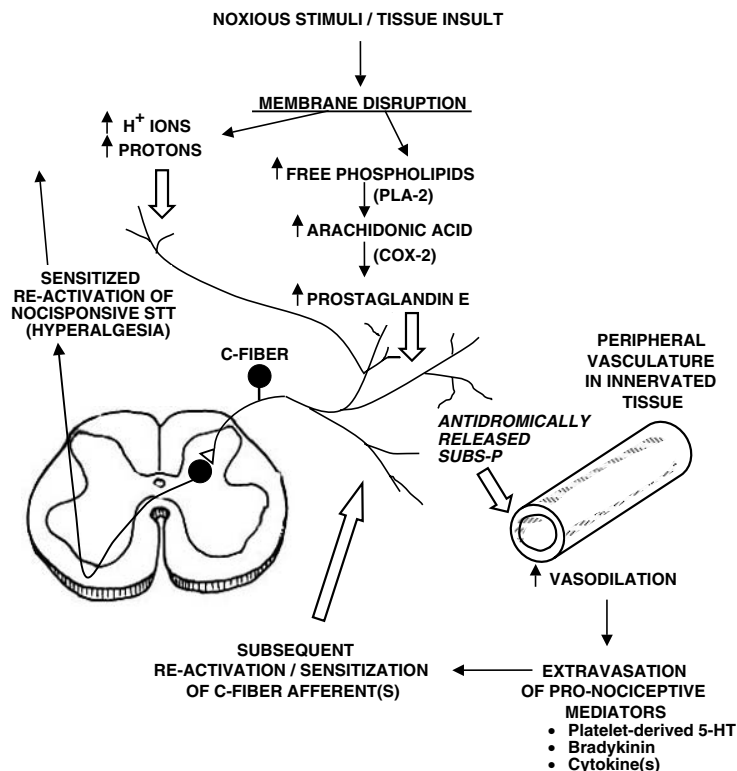
Additionally, sensitized primary afferents are capable of antidromic or retrograde release of neurochemical mediators of the inflammatory response (Fitzgerald, 1989). Substance-P provokes degranulation of mast cells in peripheral tissue leading to the release of several potent vasoactive and proinflammatory mediators including histamine and serotonin (Holsapple, Schnur, & Yin, 1980). Substance-P may also act directly as a vasodilator. In addition to antidromic release of substance-P, primary afferent nociceptors release calcitonin gene-related peptide (CGRP) from terminal branches to affect distal peripheral (and/or visceral) tissues. CGRP activates the enzyme NO (nitric oxide) synthase from


FIGURE 3.1 Schematic depiction of mechanisms subserving inflammatory pain and subsequent neurogenic inflammation. Although noxious stimuli (e.g., heat, high-intensity mechanical stress, and/or chemical irritants) can act directly at nonselective cationic channels on free nerve endings, such stimuli can also disrupt membrane integrity and evoke the formation of prostaglandin-E_2 (via initiation of the arachidonic acid cascade) and liberation of H^+ ion and protons. These substances induce depolarization of C-fibers, causing both an orthodromic and antidromic release of substance-P. Antidromically released substance-P acts as a vasodilatory agent, both directly and through nitric oxide–mediated mechanisms. Extravasation of blood-borne substances (e.g., 5-HT, bradykinin, cytokines) stimulate and/or sensitize C-fibers, perpetuating both nociception and inflammation. PLA-2: phospholipase-A2; COX-2: cyclo-oxygenase-2.

the vascular endothelium leading to an increase production of NO and ultimately vasodilatation. Taken together, the effects of histamine, mast cell–derived serotonin, substance-P, and CGRP produce potent peripheral vasodilatory effects that lead to extravasation of chemical mediators that both propagate the neurogenic inflammatory response and are directly pro-nocispuosive (Figure 3.1). These include vasoactive intestinal peptide (VIP), bradykinin, and platelet-derived serotonin (Gupta & Bhide, 1979; Handwerker, 1976). Of particular interest is the effect of rising concentrations of serotonin in extravascular tissue from mast cells and degranulated platelets. As peripheral serotonin concentrations rise, serotonin 5-HT$_3$ receptors on terminals of C-fiber primary afferents are engaged to produce a rapid Na$^+$ influx, depolarizing C-fibers and leading to continuity of this cycle (Giordano & Dyche, 1989; Sufka, Schomburg, & Giordano, 1992). Additionally, locally concentrated free serotonin appears to sensitize both 5-HT$_3$ and NK-1 receptors on C-fiber afferents, thereby increasing subsequent responsivity to serotonin and substance-P (Giordano & Gerstmann, 2004).

SECOND-ORDER AFFERENTS

The dorsal horn of the spinal cord is a critical site for the convergence and neural processing of nociceptive information from peripheral primary afferent fibers. A-delta and C-fibers form synaptic connections on wide dynamic range (WDR) and nociceptive-specific (NS) neurons within the spinal cord whose functional properties contribute to both spatial and temporal transformations of the afferent input. As depicted in Figure 3.2, the majority of these second-order neurons aggregate in the dorsal horn, project contralaterally, and ascend within the anterolateral quadrant(s) as the spinothalamic tract (STT) to sites within the brainstem, midbrain, and thalamus. The unique physiologic characteristics of WDR and NS neurons encode specific qualities of intensity, modality, and localization to the nociceptive signal that is transmitted to supraspinal targets.

Wide Dynamic Range Neurons

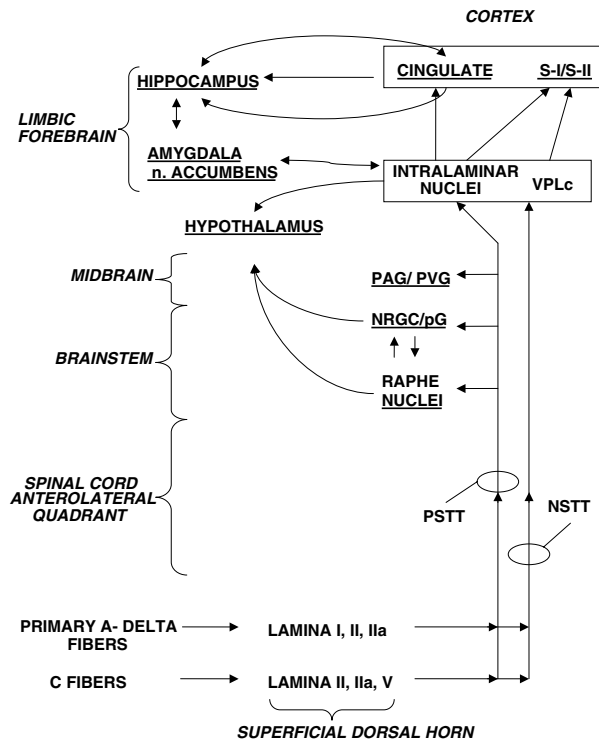
WDR neurons are localized with highest concentrations in laminae I, II, V, and VI, with greatest numbers found


FIGURE 3.2 Diagrammatic depiction of afferent pathways subserving nociception. Primary afferent (A-delta and C) fibers synapse upon second-order neurons in the superficial laminae of the dorsal horn. These units decussate and ascend in the contralateral anterolateral column as the spinothalamic tract(s). The NSTT is a relatively direct pathway that projects to the VPLc nucleus of the thalamus. Thalamo-cortical projections from VPLc are predominantly to S-I, subserving stimulus discriminatory functions. The PSTT comprises the spinoreticular pathway, which projects to monoaminergic nuclei of the brainstem, and the spinotectal pathway that projects to the midbrain PAG. The PSTT projects to thalamic intralaminar, medial, and latero-dorsal nuclei. Connections among the brainstem, intralaminar nuclei, and hypothalamus mediate autonomic and neuroendocrine responses to nociceptive input. Projections from the intralaminar nuclei to the cingulate and from the cingulate bilaterally to S-II and the hippocampus are involved in associative and evaluative domains of pain processing. Refer to text for further description of afferent processing of pain sensation and cognition. NRGC: nucleus reticularis gigantocellularis; NRpG: nucleus reticularis paragigantocellularis; NSTT: neo-spinothalamic tract; PSTT: paleo-spinothalamic tract; PAG/PVG: periaqueductal/periventricular gray; S-I/S-II: somatosensory cortices I and II; VPLc: ventroposterior laterocaudal nucleus of the thalamus.

in the latter levels. Although WDR neurons receive input from low-threshold cutaneous mechanoreceptor afferents (A-beta type), they are also a site of convergence for both A-delta and C-fiber nociceptive afferents. WDR neurons that are driven by nociceptive input are hierarchically organized within the dorsal horn, with the majority of primary A-delta and C-fiber afferent input occurring in

laminae V (Maixner, Dubner, Bushnell, Kenshalo, & Oliveras, 1986). The size and responsivity of WDR neuron receptive fields increases progressively from laminae I to V: WDR units in laminae I and II have smaller receptive fields that are sensitive to gentle mechanical stimuli; those of laminae V have larger, overlapping receptive fields with graded sensitivities containing small, discrete regions excited by non-nociceptive input and broad regions that are maximally sensitive to high-threshold nociceptive stimulation (Mayer, Price, & Becker, 1975).

WDR neurons are not individually sensitive to specific types of stimuli. Rather, individual WDR neurons, based on response properties within their receptive fields, function to discriminate stimulus intensity. Increases in stimulus intensity activate coexistent areas of receptive fields of numerous WDR neurons. This pattern of engagement would involve slight differences in temporal activation, with individual WDR responses becoming phase shifted. The activation of greater numbers of WDR neurons by high-intensity nociceptive stimuli would therefore result in both spatial and temporal summation of these responses (Hayes, Price, & Dubner, 1979).

NOCICEPTIVE-SPECIFIC NEURONS

In contrast to the anatomical distribution of WDR neurons, NS neurons are found in highest concentrations in laminae I and II, with lesser numbers in laminae V (Dubner & Bennett, 1983). NS neurons receive excitatory input from A-delta fibers and polymodal C-fiber afferents. Generally, NS neurons have small, non-overlapping receptive fields with a well-defined, center-surround organization. The central region is maximally excited by high-intensity stimuli, while the outer region is differentially excited by frequency-based repetitive stimulation. This outer region may be inhibited by non-noxious input. The homogeneity of input from nocisponsive primary afferents and the small size and nociceptive selectivity of their receptive fields provide evidence that NS neurons appear to function in localization, and perhaps qualitative discrimination of particular types of noxious input (i.e., noxious pressure and heat; Willis, 1979).

Although painful sensations and responses can be evoked by WDR neuron excitation alone, both WDR and NS activity appears to be necessary for the constellation of spatial and temporal qualities ascribed to pain (Mayer et al., 1975). This becomes apparent when the convergent inputs of A-delta and C-fibers upon WDR and NS neurons are considered. The unique properties of the primary afferents and the second-order neurons essentially "assemble" the neurologic pain signal. For example, the sensation of first-pain as punctate, well localized, and temporally well defined is a function of the response characteristics of both rapidly conducting A-delta primary afferents and their excitation of WDR and NS neurons. In contrast, second-

pain, a more diffuse, long-lasting nociceptive sensation that follows the initial stimulus, is the result of the threshold, firing, and conduction properties of C-fibers sustained by local tissue damage and/or chemical change, as well as patterns of temporal and spatial summation of C-fiber inputs by WDR and NS neurons (Mayer et al., 1975; Price & Dubner, 1977). Both WDR and NS neurons are capable of after-responses that persist as a consequence of the number and frequency of nociceptive afferent volleys (Willis, 1979), factors that are related to nociceptive stimulus intensity and continuity.

The anatomic and physiologic properties of second-order afferents also subserve the phenomenon of referred pain. As previously discussed, primary afferent innervation of visceral and deep muscular structures is organized so that these fibers converge upon WDR and NS neurons that also receive input from primary nociceptive (and non-nociceptive) afferents from specific somato-cutaneous regions (Selzer & Spencer, 1969). The convergence of visceral and cutaneous afferents from a given somatotome upon second-order WDR and NS neurons underlies patterns of referred pain. Thus, sensory information from the viscera is often subjectively interpreted as afferent information from a cutaneous structure within the corresponding somatotome.

SPINOTHALAMIC TRACT(S)

The majority of WDR and NS neurons project contralaterally within the spinal cord and ascend within the anterolateral quadrant, forming the spinothalamic tract(s) (STT). A minority of fibers remain ipsilateral and ascend outside of the STT within the ventrolateral white matter to supraspinal sites that correspond to the contralateral anterolateral quadrant projections (Appelbaum et al., 1975). Anatomically, axons from second-order neurons in the superficial dorsal horn (laminae I and II) are segregated from those of deeper laminae (lamina V). This provides anatomical separation between the neospinothalamic (NSTT) and paleo-spinothalalmic (PSTT) tracts. While both the NSTT and PSTT may be considered "labeled-lines" for the transmission of pain signals, the differential localization of NS neurons to laminae I and II, in contrast to a greater abundance of WDR neurons in lamina V, subserves functional distinctions in the type of nociceptive information that is transmitted in these pathways (Giesler, Yezierski, Gerhart, & Willis, 1981).

The NSTT projects directly to the ventroposterior lateral (VPL) nuclei of the thalamus and is composed predominately of NS neurons from lamina I and II (Kenshalo et al., 1980). WDR neurons are in smaller numbers within these laminae, and they comprise only a minority of NSTT fibers. NS neurons receive almost completely homogeneous input from A-delta and high-threshold polymodal C-fiber afferents, and encode stimulus localization and

modality. Therefore, the main role of the NSTT appears to involve transmission of these signal qualities to the thalamus (Price, Hayes, Ruda, & Dubner, 1978).

The PSTT is composed of axons from second-order neurons arising in lamina IIa and V of the spinal cord. WDR neurons constitute the majority of cells from this lamina, with only a smaller number of NS neurons contributing to the axonal pool of the PSTT (Appelbaum, Beall, Foreman, & Willis, 1975). Heterogeneous input to lamina V WDR neurons from both nocisponsive and non-nocisponsive primary afferents contributes to the transmission of some non-nociceptive signals along the PSTT. WDR neurons of lamina V also send axons ipsilaterally to ascend within the dorsal column medial lemniscal tract (Boivie, 1980; refer to Figure 3.7 later in the chapter). This latter pathway is responsible for the transmission of light touch, vibration, and other low-threshold stimuli. Given the role of lamina V WDR neurons to encode noxious stimulus intensities, the co-localized transmission of both nociceptive and non-nociceptive afferent information within the PSTT appears to serve a stimulus discriminatory function (Price & Dubner, 1977). This is further supported by the properties of PSTT WDR neurons to accumulate strong after-responses following nociceptive input. Such after-responses override weaker impulses evoked by non-nociceptive afferent stimuli and produce temporally summated volleys within the PSTT. These events are correlated to, and appear to subserve, the qualities and subjective characteristics of second-pain.

Unlike the NSTT, the PSTT is not a direct thalamic pathway. PSTT fibers project to several supraspinal sites that are involved in (nociceptive) sensory processing and that exert pain modulatory control. The PSTT is divided into spinoreticular, spinotectal, and ultimately spinothalamic projections. Spinoreticular pathways project to areas of the brainstem reticular formation. These include the raphe nuclei of the rostro-ventral medulla and the nuclei reticularis gigantocellularis (NRGC) and paragigantocellularis (NRpG) of the caudal pons (Basbaum & Fields, 1978).

Spinotectal projections terminate within the tectum and periaqueductal gray (PAG) region of the midbrain (Beitz, 1982). The spinoreticular and spinotectal circuits function in centrifugal pain control, and ascending neurons from these sites serve as relays between spinal pathways and higher centers that mediate the cognitive and affective dimensions of pain. Of particular note are defined tracts from the reticular formation to several regions of the limbic forebrain, and a reciprocal neuraxis involving the PAG, periventricular gray region (PVG), hypothalamus, and brainstem (Guilbaud, Bernard, & Besson, 1994). Thalamic projections of the PSTT differ from those of the NSTT; PSTT fibers project diffusely to the thalamus, with terminations at the intralaminar nuclei (Ralston, 1984), the centro-median parafascicular complex, and the latero-

dorsal and the mediodorsal nuclei (Mancia et al., 1987). (Refer to Figure 3.2 and Figure 3.6, later in the chapter).

BRAINSTEM NOCICEPTIVE NEURAXES

As depicted in Figure 3.2, PSTT neurons differentially project to specific sites within the brainstem. Some stimulus-specificity exists in PSTT activation of raphe and/or NRGC/NRpG neurons. Input from NS and/or WDR units excited by thermosponsive primary afferents appears to evoke greater excitation of raphe circuitry, while WDR and NS neurons driven by mechanosponsive input elicit somewhat greater activation of the NRGC/NRpG (Giordano & Barr, 1988; Kuraishi, Hirota, Satoh, & Takagi, 1985). Both circuits are apparently engaged by chemosponsive or polymodal C-fiber afferent activation of WDR or NS neurons. It has been suggested that such stimulus specificity is maintained at the midbrain level and may be involved in the differential activation of PAG-raphe or PAG-NRGC centrifugal analgesic systems (as described further in this chapter). Whether these distinctions actually subserve modality specificity or reflect differential activation based upon stimulus intensity remains speculative (Craig, 2003). Of note is the existence of specific cells that respond differentially to PSTT input. One group of brainstem cells, "on" cells, depolarizes in response to PSTT input driven by noxious stimulation. These cells appear to augment transmission of pain via facilitation of spinal afferent output. Another group, the "off" cells, hyperpolarizes upon PSTT activation and reduces nociceptive transmission along spinally originating PSTT pathways (Heinricher, Morgan, Tortorici, & Fields, 1994). The net actions of these cells appears to augment or suppress the pain signal and may play a role in frequency-dependent or intensity-dependent encoding for given types of noxious stimuli. Additionally, PSTT excitation of "on" cells activates hypothalamic, cingulate, insular, and septal systems involved in pain-related aversive and arousal responses (Kalivas & Barnes, 1993).

MIDBRAIN NOCICEPTIVE MECHANISMS

There is anatomical evidence to demonstrate that PSTT fibers project to the midbrain PAG both directly and through interneuronal pathways from the reticular formation. The PAG is somatotopically and perhaps stimulus-specifically organized. Somatotopic organization corresponds to the ascending hierarchy of PSTT afferents from progressively rostral somatotomes: the posterior PAG receives input from PSTT fibers of the caudal spinal cord while the anterior PAG receives PSTT projections from more rostral regions.

Stimulus-specific organization of the PAG seems to be a function of characteristics of populations of PSTT

WDR or NS neurons that are selectively excited by mechanical, thermal, or polymodal primary afferents. While it is difficult to determine whether absolute stimulus-specific organization exists, it is likely that regions of the PAG respond to somatotopic innervation of the periphery and would thus be maximally excited by input from a particular modality or intensity.

Although the function of the PAG in centrifugal pain control is clear, the role of the PAG in afferent processing of the nociceptive signal remains more enigmatic. Pathways exist between the PAG and hypothalamus and several structures of the forebrain, including the septal nuclei and amygdala (see Figure 3.2). Stimulation of the PAG or fibers within this pathway elicits an array of arousal and behavioral activation responses that have distinct aversive or frightening emotional content (Cailliet, 1993). Such responses have significant conditioning potential, primarily by activating "upstream" neuraxes involving the mammillo-thalamic tract, anterior thalamic nucleus, and subsequent involvement of the cingulatum and ultimately the hippocampus (Ploghaus et al., 1999). It is not completely understood whether the PAG can evoke these responses alone or acts in concert with the reticular system, cingulate gyrus, insula, and frontal cortex.

THE THALAMUS

The NSTT and PSTT project to different regions within the thalamus. NSTT neurons project to a caudal area of the ventroposterior lateral nucleus (VPLc). Nociceptive inputs from the NSTT are arranged in columnar zones that are somatotopically organized. Thalamic neurons within these zones retain many response characteristics of WDR and NS units. Thalamic wide-range neurons have center-surround receptive fields with distinct, small areas sensitive to low-threshold excitation and a broad area that is excited by high-threshold nociceptive input. Thalamic NS neurons, like their spinothalamic counterparts, have smaller receptive fields that are excited by high-intensity mechanical or thermal input (see Albe-Fessard, Condes-Lara, Sanderson, & Levante, 1983, for review).

Both WDR and NS neurons of the VPLc summate responses as a function of stimulus frequency and intensity (Gerhart, Yezierski, Fang, & Willis, 1983). Slow temporal and spatial summation is accompanied by a prolonged firing phase that exceeds the actual noxious stimulus and primary and secondary afferent discharges. It is probable the temporal aspects of pain *perception* reflect serial processing of afferent information from the peripheral to the thalamic levels, with progressive extension of after-discharges along the pathway (and perhaps subsequently to cortical sites; see below). It is temping to speculate that such effects may "match" sensory, arousal, and environmental cues in establishing conditioned responses to circumstances surrounding painful stimuli.

The PSTT projects to the intralaminar thalamic nuclei, the dorsal nucleus centralis lateralis, and medialis dorsalis (see Figure 3.6). Most of the neurons within these thalamic areas are of the wide range type, sensitive to both nociceptive and non-nociceptive activation and with extensive overlapping input from cutaneous and visceral innervation (Curry, 1972; Dong, Ryu, & Wagman, 1978). These units do not have the adaptive properties of neurons of the VPLc; intralaminar neurons summate responses, but response patterns do not reflect direct spatial or temporal transformation of increments in stimulus frequency or intensity (Guilbaud, Caille, Besson, & Benelli, 1977). Unlike neurons of the VPLc, intralaminar neurons appear to be arranged in a "looser" somatotopic pattern and project diffusely to S-II, as well as the anterior and posterior cingulate gyrus regions of the cortex, and a reciprocal pathway to the amygdala has been described (Burton & Jones, 1976; see Figure 3.6). The response patterns of individual intralaminar neurons, together with their anatomic distribution to cortical and amygdalar projections, suggest that PSTT-intralaminar thalamic pathways act to engage these systems in behavioral activation, aversive-emotional, and nocifensive responses.

CORTICAL PROJECTIONS

Neurons from the NSTT project to the VPLc of the thalamus; thalamo-cortical fibers from this region terminate in S-I (and to a lesser extent S-II areas) of the somatosensory cortex. Thalamo-cortical fibers from the intralaminar, lateral, and medial dorsal nuclei, driven by the PSTT, project more diffusely, with a smaller number terminating in S-I, while the majority project bilaterally to S-II (Figure 3.6) (Albe-Fessard, 1983). The somatotopic organization of the thalamus is preserved in S-I and to some extent S-II; nociceptive input contributes to distinct regions of somatosensory activation within the cortex (i.e., the sensory "homunculus," the spatial representation of bodily structures across the cortical sensory field).

Somatosensory cortical regions are arranged in vertical dominance columns in which hierarchical processing of afferent input occurs. Only a small percentage of nociceptive input constitutes each given cortical column (Kaas, 1993). Nociceptive thalamo-cortical input is differentially distributed within each column. Superficial cortical layers receive thalamic input from non-nociceptive pathways, while WDR- and NS-activated inputs are concentrated throughout the deeper cortical layers (Kaas, 1993). Thus, for any given bodily region represented in a cortical column there is an array of non-noxious information (relayed through medial lemniscal tracts) and nociceptive information (relayed through the STTs) that creates the "depiction" of sensations that determine the subjective sensory experience (Ralston & Ralston, 1994). The integrity of the pain signal and unique qualities of its duration and intensity are a function of additive transformation of afferent volleys from primary nociceptors through multiple processing ultimately terminating in cortical neurons. The slow adaptation, long after-discharges, and highly modifiable spatial and temporal summation of cortical S-I and S-II neurons contribute to the subjective, temporospatial, discriminative dimensions of pain sensation (Mayer et al., 1975).

As depicted in Figure 3.6, there are projections from S-II to the anterior cingulate via the insula and to the posterior cingulate through a direct, reciprocal pathway (Vogt, Finch, & Olson, 1992). The role of the anterior cingulum in pain sensation and pain-related behavioral responses is well documented (Devinsky, Morrell, & Vogt, 1995), such that the superior, anterior cingulate is commonly referred to as the nociceptive cingulate area (NCA). Anterior cingulate–hypothalamic projections mediate components of neuroendocrine and autonomic responses to pain sensation (Bromm & Desmedt, 1995). The involvement of the hypothalamus is initiative in engaging multiple, non-opioid, hormonally mediated forms of pain modulation (Bodnar, Kelly, Steiner, & Glusman, 1978; Lewis, Cannon, Stapleton, & Liebeskind, 1980; Lewis, Chudler, Cannon, & Liebeskind, 1981; see Watkins & Mayer, 1982, for review). Diagrammatic depiction of putative hormonal mechanisms of pain modulation is shown in Figure 3.3. Additionally, Losel et al. (2003) suggest that the nongenomic action of steroid hormones on neurotransmitter receptors may be a mechanism that alters hypothalamic function to affect the activity of other supratentorial structures. This may subserve distinctions in pain presentation and responses that occur in various neuroendocrine (and perhaps psychiatric) states (e.g., premenstrual disorder, depression; Kalin & Dawson, 1986).

Efferent connections that project from the anterior cingulate to the caudate, putamen, and nucleus accumbens mediate motor responses to pain (Kalivas & Barnes, 1993) and may be involved in repetitive and/or stereotypical behaviors observed in (chronic) pain states. Afferent pathways from the hippocampus via the subicular complex and entorrhinal cortex (together with efferent input from the posterior cingulum) mediate cognitive and memory-based aspects of pain (Vogt et al., 1992).

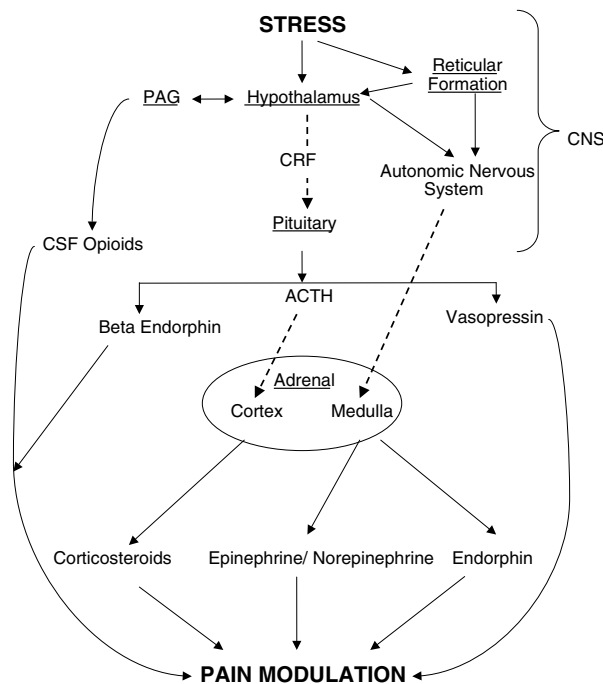
Afferent and efferent connections exist between the posterior cingulate, the lateral dorsal thalamic nucleus, and the amygdala. As well, the posterior cingulum receives efferent input from the inferior temporal, mediotemporal, and inferior parietal cortices. These pathways appear to subserve the higher cognitive-emotional dimension of pain sensation (Bromm, 2001). The anatomy of these pathways well illustrates that the subjective experience of pain may vary according to myriad combinations of extero- and, perhaps, interoceptive circumstances for each individual.


FIGURE 3.3 Representation of certain stress-induced analgesic mechanisms. Exogenous stress can engage the reticular system and hypothalamus to heighten the activity of the autonomic nervous system. As well, hypothalamic involvement in the stress response can engage the hypothalamic–pituitary–adrenal axis. Together, these mechanisms synergistically lead to a systemic increase in glucocorticoid and epinephrine/norepinephrine level(s). The pituitary, adrenal medulla, and midbrain periaqueductal grey region (PAG) release opioids, which act on populations of opioid receptors in the central nervous system (CNS) and periphery. These opioid and non-opioid pain modulatory systems can be engaged together or distinctly, dependent upon the type, intensity, and duration of the provocative stress(or). It is interesting to note that prolonged or acute disturbance of this system may be contributory to altered patterns of pain modulation and an alteration in pain sensitivity (see text for details). ACTH: adrenocorticotropic hormone; CRF: corticotropin releasing factor; CSF: cerebrospinal fluid.

The assemblage of sensory input together with memory, emotional response(s), and cognitive state creates conscious experience of pain that contributes to its perception. However, there is a considerable philosophical debate whether pain can be completely defined as a perception (Wikler, 1979). The complexity and strongly subjective nature of pain strengthen the hypothesis that the hierarchical neural processing that expands the sensory signal into an aggregate of combined awareness of internal state, circumstances surrounding the event, and memory and emotional components that impart contextual "meaning" to the experience qualifies pain as a discrete event of consciousness. This becomes significant in light of the involvement of nonsensory central nervous system structures in nociceptive processing. Thus, it may be that the experience of pain represents both a conscious interpretation of the sensory experience caused by activation of neural pathways and an epiphenomena of higher-order consciousness resulting from the change in brain state.

PAIN MODULATING SYSTEMS

INTRASPINAL PAIN MODULATION

Pain modulation can occur through the activation of local circuits within the spinal dorsal horn. Interneurons that receive collateral projections from primary A-delta and C-fibers are found in laminae I, II, and V. These interneurons form reciprocal synapses upon primary afferent(s) and, in certain cases, second-order WDR and NS neurons. The majority of such interneuronal connections are found within a given horizontal section of the spinal cord, although Willis and Coggeshall (1991) have shown that some interneurons have terminal fields that are trans-segmental. Pharmacologic and electrophysiologic evidence has demonstrated that these interneurons are inhibitory; many produce and release the inhibitory transmitter gamma amino butyric acid (GABA), as well as the opioid peptides dynorphin and leu- and/or met-enkephalin (Fields, Heinricher, & Mason, 1991). Acting at postsynaptic $GABA_B$ receptors on primary and second-order afferents, GABA induces a chloride ion flux to produce hyperpolarization. Dynorphin binds post-synaptically with kappa-opioid receptors (Corbett et al., 1982). There is some heterogeneity in kappa receptor populations; however, most found in the spinal cord are negatively coupled to N-type calcium ionic channels. Dynorphin binding at these kappa sites on primary or second-order afferents closes the calcium channel, thereby producing a hyperpolarizing inhibitory current, essentially "tuning down" or "shutting off" the transmission of nociceptive information along this neuraxis (Han & Xie, 1982). In contrast, leu- and met-enkephalin act at delta, and to a lesser extent mu opioid, receptors to engage G protein–mediated kinases to phosphorylate and open K^+ channels, enhancing K^+ influx and producing graded hyperpolarization (Duggan & North, 1983). Recently, endogenous cannabinoids, including anandamide and 2-arachadoylglycerol, have been shown to exert spinal anti-nociceptive effects by acting at type-1 cannabinoid (CB1) receptors in the dorsal root ganglion and superficial spinal cord (Hohmann & Herkenham, 1999; Pertwee, 2001; Rice, 2001). Cannabinoid CB1 receptors are also expressed in cortical and subcortical brain regions where anandamide (and exogenous *cannabis sativa* and 9-tetrahydrocannabinol) exerts pain modulatory effects, as well (Rice, 2001).

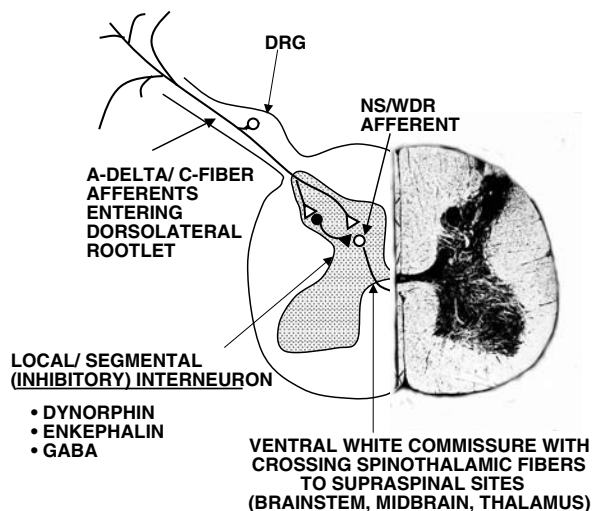
This local circuit inhibition modulates firing of primary A-delta and C-fibers afferents; a particular frequency pattern of primary afferent firing may excite populations of local interneurons to exert recurrent inhibition. Simi-


FIGURE 3.4 Local/segmental inhibition producing pain modulation within the dorsal horn of the spinal cord. A-delta and C-fibers synapse upon interneurons that release dynorphin, enkephalin, or gamma amino butyric acid (GABA) to postsynaptically suppress/modulate the activity of second-order nociceptive specific neurons (NS) and wide dynamic range neurons (WDR) afferents. As well, the endogenous cannabinoid anandamide may act at specific cannabinoid (CB1) receptors to inhibit nociceptive transmission within the dorsal root ganglion and superficial dorsal horn (not illustrated). The level of local spinal inhibition may be dependent on the spatial and frequency intensity of incoming nociceptive afferent volleys. Increased primary afferent activity is capable of overcoming local inhibition. As well, these spinal inhibitory interneurons can be driven by descending bulbospinal activation. Complete description of these mechanisms appears in text. (*Note*: Not to scale.)

larly, primary afferent activity may evoke local spinal inhibition of certain populations of second-order WDR and NS neurons to limit the "gain" of mild nociceptive input (Figure 3.4).

BULBOSPINAL PAIN MODULATION

Projections from the (P)STT synapse upon neurons in the rostro-ventral medulla and ventromedial pons (Basbaum & Fields, 1978). In the rostro-ventral medulla, the projection fields include neurons of the raphe nuclei, including the nuclei raphe alatus, dorsalis, and raphe lateralis. These sites are combined when referring to the nucleus raphe magnus (NRM). In the caudal pons, the PSTT projects specifically to the subcerulear nuclear group, consisting of the nucleus reticularis gigantocellularis, nucleus reticularis paragigantocellularis, and the nucleus paragigantocellularis lateralis (NpGL). These sites are often referred to as the reticular magnocellular nuclei (RMC). The NRM and RMC also receive efferent input from the PAG as well as this afferent input from the PSTT. Both neuraxes are capable, either alone or in concert, of exciting NRM or RMC neurons to elicit centrifugal or bulbospinal pain

modulation, respectively (see Fields & Basbaum, 1999, for review). Mixed inhibitory and excitatory connections between these groups of brainstem nuclei exist (Stamford, 1995); this inter-brainstem inhibition appears to determine the relative participation of NRM, RMC, or both groups in bulbospinal analgesia. Moderate levels of activity within the RMC inhibit the NRM. In contrast, higher levels of RMC activity excite certain NRM neurons. The NRM maintains tonic modulation of the RMS, and phasic, "burst" activity of NRM cells can engage activity within the RMC (Fields, 2000).

As previously discussed, two distinct subtypes of neurons exist throughout the rostral medulla. These are referred to as "on" or "off" cells, with reference to their electrophysiologic response patterns to noxious afferent input. "On" cells become active with noxious afferent stimulation and appear to potentiate afferent transmission. "Off" cells become quiescent in response to afferent noxious input, and the lack of facilitatory input to the spinal cord decreases the frequency and duration of nociceptive transmission. "On" cells suppress "off" cells; thus, once sensitized, "on" cells can potentiate nociception by driving volleys of transmission within the spinal cord. Opioid projections from the PAG inhibit the activity of "on" cells, and thereby eliminate their capacity for facilitating the pain signal and also disinhibit "off" cells to exert an analgesic effect (Fields & Basbaum, 1999; Heinricher et al., 1994.)

Axonal projections from the NRM and RMC descend in the dorsolateral funiculi (DLF) of the spinal cord and terminate in dense synaptic fields within laminae I, II, and V of the dorsal horn (Basbaum & Fields, 1979). Synaptic connections within these layers involve polysynaptic circuits of multiple spinal interneurons, as well as monosynaptic contacts with WDR, NS, and primary afferent neurons. Spinal interneurons receiving efferent projections from the brainstem synapse on WDR and NS second-order neurons as well as the terminals of primary afferent fibers. As previously described, these interneurons are neurochemically heterogeneous, releasing the inhibitory transmitters GABA, enkephalin, dynorphin, and/or anandamide. These interneuronal contacts provide selective, multifocal inhibition of specific groups of nociceptive afferents.

Synaptic connections between bulbospinal and WDR, NS, and perhaps primary afferent neurons exist in laminae I, II, and V (Fields et al., 1991). A single fiber from the brainstem may synapse on several second-order afferents within a given lamina. The differential projection of NRM or RMC terminals onto discrete populations of mechanosponsive, thermosponsive, or polymodally driven WDR and NS neurons in laminae I, II, and V further suggests that some stimulus or modality specificity may exist in the analgesic axis that originates from these brainstem nuclei (Abbott & Melzack, 1982; Giordano & Barr, 1988; Kuraishi, Harada, Aratani, Satoh, & Takagi, 1983; Kuraishi et al., 1985).

Midbrain Pain Modulation

There is considerable evidence to show that the midbrain PAG is a principal site for endogenous pain control. Efferent projections from the cingulate gyrus, limbic forebrain structures, and hypothalamus are capable of exciting opioid (i.e., endorphinergic, enkephalinergic, and orphaninergic) neurons of the PAG, as do inputs from the PSTT (Fields & Basbaum, 1999). The PAG exerts pain modulation by centrifugal inhibition of the spinal second-order afferents that comprise the PSTT and NSTT. This effect primarily involves disinhibition of bulbospinal projections from the NRM and NRGC/NRpG (Fields, Bry, & Hentall, 1983). Defined pathways from the PAG to the raphe nuclei and NRGC/NRpG are activated by high-threshold, high-frequency afferent volleys from the PSTT. Mechanical, thermal, or polymodal nocisponsive units of the PSTT appear to differentially stimulate discrete areas of the PAG to activate the raphe nuclei, NRGC/NRpG, or both (Fields et al., 1983; Fields & Basbaum, 1999). It is not fully understood whether selective PAG engagement of raphe-spinal or NRGC/NRpG spinal neuraxes is dependent on the modality, frequency, or intensity of the evoking afferent input (Abbott & Melzack, 1982; Giordano & Barr, 1988; Kuraishi et al., 1985).

The former system involves a release of opioids from the PAG that enhances the output of serotonergic cells of the raphe nuclei, thereby causing an increased turnover and release of serotonin in pathways that descend in the dorsal lateral funiculi (Fields & Anderson, 1978). These serotonergic fibers synapse heterogeneously in lamina I, II, and V, where serotonin may postsynaptically bind to heterogeneous populations of serotonin ($5-HT_1$, $5-HT_2$) receptors on processes of primary and/or second-order nociceptive neurons (LeBars, 1988, see also Fields & Basbaum, 1999, for review). As well, serotonin may bind to postsynapic $5-HT_3$ receptors on an interneuron pool in several laminae of the dorsal horn to evoke the release of the inhibitory transmitters GABA, dynorphin, and enkephalin to produce graded inhibition of second-order pain transmitting afferents (Giordano, 1991). PAG-NRGC connections involve a release of opioids from the periaqueductal gray that suppress GABAergic interneurons, thereby disinhibiting noradrenergic neurons of the reticular formation (whose axons similarly descend in the dorsal lateral funiculi) to evoke a release of norepinephrine in lamina II and V. Norepinephrine binds to postsynaptic $alpha_2$ receptors on primary (and perhaps second-order) neurons to produce a graded hyperpolarizing inhibitory current, thereby "toning down" these neurons and producing a reductive modulation of volleys from nociceptive primary and second-order afferents (Dostrovsky, Shah, & Gray, 1983; Dubuisson & Wall, 1980).

The described connections between the PAG and brainstem are polysynaptic, involving pools of both excitatory glutaminergic and inhibitory GABAergic interneuronal relays. Tonic glutaminergic excitation of the brainstem produces low-level modulation of STT volleys and appears to have a "band-pass filtering" effect upon the nature and extent of low-level noxious sensory input that is transmitted to higher centers (Behbehani & Fields, 1979; Fields & Basbaum, 1999). In contrast, spatially or temporally summated high-frequency volleys from PSTT cells activate opioid systems of the PAG that suppress the tonic activity of inhibitory GABAergic interneurons that terminate upon descending neurons of the RMC and/or NRM (Dostrovsky et al., 1983). This suppression of tonic inhibition releases (i.e., disinhibits) the brainstem, thereby facilitating descending inhibition of nociceptive afferent transmission within the spinal cord. Such "volume control" is a function of the nature of the afferent nociceptive stimulus, the extent of PAG activation of PSTT (and perhaps cortical, hypothalamic, and mesolimbic) neurons, and the relative degree of excitation or inhibition of specific neural circuits to the brainstem. Thus, the PAG can discriminably recruit (or suppress) bulbospinal substrates whose net output determines the extent and properties of centrifugal pain modulation (Figure 3.5). These subcortical pain modulatory systems are summarized in Table 3.3.

Cortical Inhibitory Processing

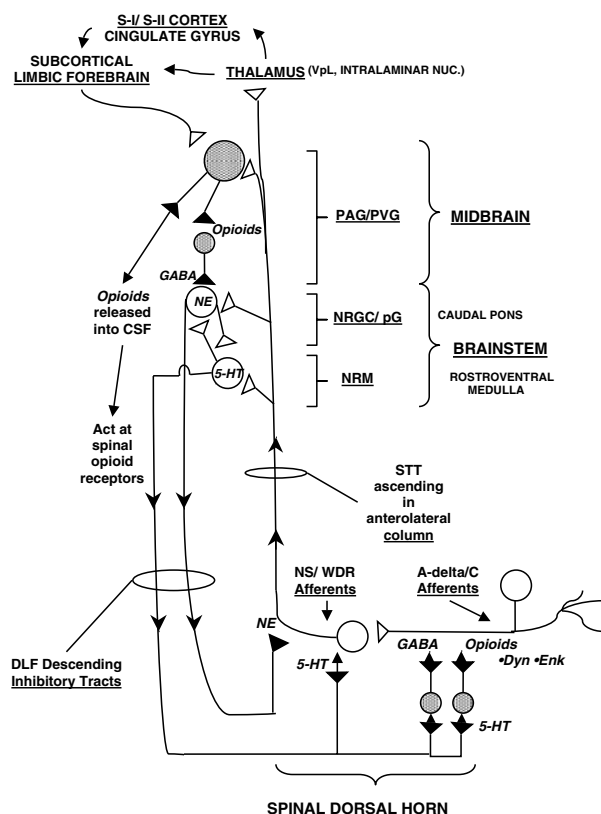
The pathways through which cortical pain modulation occurs are presented in Figure 3.6. Neurons of the sensory cortex are capable of inhibitory control over the thalamo-cortical units of STT origin that project to them (although cortico-thalamic inhibition can also occur over neurons of the medial lemniscal tract that are non-nocisponsive). The extent of inhibition appears to vary with frequency and intensity of thalamo-cortical input. For nociceptive input that is both rapidly temporally and spatially summating, there is a greater level of inhibition (Guilbaud et al., 1994). Sensory cortical inhibition involves "normalization" or "stabilization" of afferent volleys. This compensates for differences in response characteristics between thalamic and cortical neurons and ultimately enhances the input–response function of thalamically driven, nociceptive cortical inputs. In this way, a more direct transformation of the incoming sensory signal is generated without oversummation. Cortical neurons can also excite both thalamo-cortical fibers and STT units directly. This inhibition and excitation serves a modulatory role over afferent information that affects cortical circuitry. Thus, cortical neurons can discriminately amplify or reduce the extent of nociceptive input (Sawamoto et al., 2000). Such modifications strengthen the signal-to-noise ratio of particular afferent volleys and facilitate discrimination of sensory input. This alternate excitation/inhibition may also subserve changes in the nociceptive sensorium as a consequence of levels of cortical activity (e.g., sleep, hypnosis, biofeedback), and


FIGURE 3.5 Representation of pathways involved in bulbospinal and centrifugal analgesia. Afferent volleys from the STT can activate 5-HT and/or NE systems of the brainstem and cause the release of these monoamines within the dorsal horn. Postsynaptically, 5-HT can directly inhibit the activity of nociceptive afferents and may act by stimulating inhibitory interneurons within the superficial cord to (indirectly) suppress nociceptive afferent output. NE acts directly to inhibit the firing of nociceptive afferents. Both 5-HT and NE systems can be engaged by the release of opioids from the PAG (through suppression of GABAergic inhibition of bulbospinal output). Opioids are also released into the cerebral spinal fluid and act at spinal opioid receptors to produce antinociception. Descending influences from the limbic forebrain can also stimulate the PAG. A complete description of brainstem and midbrain pain modulatory systems is provided in the text. Excitatory synapses are depicted by open endings/icons. Inhibitory synapses/neurons are depicted by shaded icons. CB1: cannabinoid-1 receptor; CSF: cerebrospinal fluid; Dyn: dynorphin; DLF: dorsolateral funiculus; Enk: enkephalin; GABA: gamma amino butyric acid; 5-HT: serotonin; NE: norepinephrine; NRM: nucleus raphe magnus; NRGC/pG: nucleus reticularis gigantocellularis/paragigantocellularis; NS: nociceptive specific neurons; NUC: nucleus; PAG/PVG: periaqueductal/periventricular gray; STT: spinothalamic tract; VpL: ventroposterior lateral nucleus of the thalamus; WDR: wide dynamic range neurons.

may be contributory to the elicitation of pain by cognitive expectation or anticipation (Fields, 2000).

It is of interest to note that changes in higher-order consciousness (i.e., cognitive changes) can alter the appre-

ciation, extent, or contextual "value" of sensory phenomena. While the pain-modulatory role of acute sympathetic arousal has long been known (Pribram & McGuinness, 1975), more recent studies have revealed that events that engage cortical and limbic areas to produce alterations of first- and second-order consciousness may have significant pain suppressive effects as well (Hugdahl, 1996; Lou et al., 1999). The long-held "placebo response" is better described as a patient-centered response, in which the participation in some event (e.g., relaxation, types of patient–clinician interaction, meditation, prayer) induces neurochemical change(s) in reticular and mesolimbic/cortical areas (d'Aquili & Newberg, 1993; Levine, Gordon, & Fields, 1978; Saver & Rabin, 1997). Such changes can affect neuraxes to alter nociceptive processing, as well as other physiological events (e.g., immune function, autonomic tone; Amanzio & Benedetti, 1999; Petrovic, Kalso, Petersson, & Ingvar, 2002). This concomitantly activates higher-order consciousness to interpret the interoceptive state (and its effects) and circumstantially "frame" this interpretation relative to environmental, behavioral, and cognitive events that are temporally antecedent and/or coincident. The pairing of these phenomena can have profound conditioning effects. In this way, such inductive events (and awareness of their biological effects) assume both salutogenic value to the patient and "noetic" value that is rich in subjective interpretation of the event itself (Giordano & Engebretson, 2004; Newberg, Tashner, both in this volume).

Dorsal Columnar Pain Modulation

Low-threshold mechanosponsive dorsal column afferents, driven by A-beta mechanoreceptors, also exert modulatory influence over WDR and NS neurons that make up the STT. Interneurons in laminae IIa, III, and IV with synaptic fields linking the dorsal columns and STT evoke brief inhibitory postsynaptic potentials (IPSPs) in STT cells following dorsal column excitation by low intensity mechanical stimuli (Lee, Chung, & Willis, 1985). These IPSPs persist after termination of the low-intensity stimulus and cause a short-lasting, rightward shift in both the time- and threshold-based stimulus response function of the affected WDR and NS cells within the STT. In other words, low-level mechanical stimulation of the dorsal column tract is capable of "overriding" or "de-sensitizing" WDR and NS activity within the STT. As well, the dorsal column projects to the nuclei cuneatus and gracilis of the medulla, and as the medial lemniscal pathway, decussates to terminate in the VPL of the thalamus (Willis, 1985; Figure 3.7).

Continuous, low-level phasic or high-frequency repetitive stimulation of the medical lemniscal pathway can produce selective activity within the VPL that can suppress STT-induced input(s) and reduce thalamo-cortical transmission of nociceptive information (Campbell, 1982; Sweet & Wepsic, 1968; Willis, 1985). These phenomena

TABLE 3.3
Physiologic and Pharmacologic Properties of Selected Pain Modulating Systems

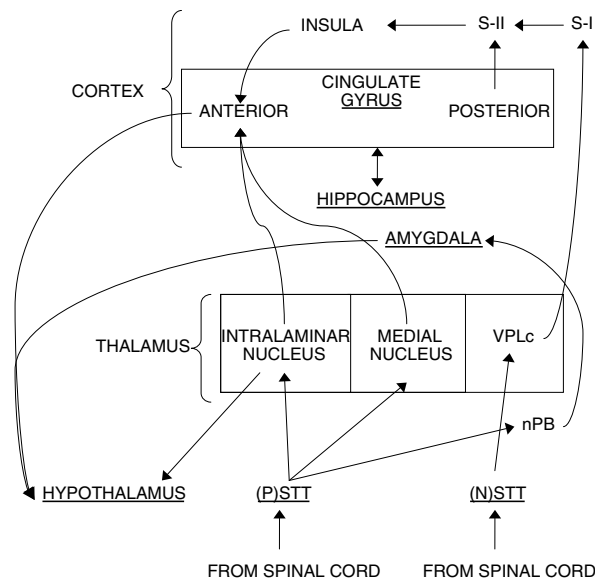
System	Anatomy	Chemistry	Physiology/Properties
Intraspinal Segmental	Interneurons, laminae II, V Synaptic contact with recurrent processes of A-delta fibers	Opioid Dynorphin Leu/met-enkephalin GABA Anandamide	Acts upon κ-receptors Acts upon δ (and perhaps μ) receptors Acts upon GABA$_B$ receptors: potentiates chloride flux hyperpolarization Acts upon CB1 receptors
Bulbospinal NRM	Descending fibers from NRM of medulla Fibers descend via DLF Mono- and polysynaptic contacts with primary and second-order units of dorsal horn Synapse upon interneurons	5-HT	Acts on postsynaptic 5-HT$_{1b}$ receptors on (presynaptic) primary afferents and (postsynaptic) second-order neurons Hyperpolarizing; inhibitory Acts on postsynaptic 5-HT$_3$ receptors on GABA and opioid spinal interneurons; excitatory; evokes release of inhibitory modulators
RMC	Descending fibers from NRCG/NRpG of pons Fibers descend via DLF Mono- and polysynaptic contacts with primary and second-order afferents of dorsal horn	NE	Acts on postsynaptic α$_2$ receptors on (presynaptic) afferents and second-order afferents Graded hyperpolarization, inhibitory
Midbrain PAG PVG	Multilevel connections: inputs from hypothalamus, limbic system, cortex Activated by STT Polysynaptic contact with brainstem to disinhibit centrifugal modulatory systems	Opioid Leu/met-enkephalin Endorphin Orphanin	Acts on μ and δ sites Acts on μ-receptor subtypes Some direct opioid release into CSF Graded slow hyperpolarization; inhibitory


FIGURE 3.6 Schematic diagram of projections from the spinothalamic tract and thalamus to higher centers mediating the emotional, executive, and cognitive dimensions of pain processing. As described in the text, the PSTT diffusely projects to the intralaminar and medial nuclei of the thalamus. Projections from these nuclei to the anterior cingulum subserve emotive aspects of pain. The anterior cingulum also receives input from the posterior cingulum and S-II associative cortex, both via the insula. Reciprocal connections exist between the cingulum and hippocampus. The integrative role of the cingulate gyrus becomes evident in light of these pathways. The PSTT engages the amygdala via the parabrachial nucleus. Hypothalamic activation by the PSTT occurs both through this pathway and by a PSTT-intralaminar nuclei neuraxis. This neural circuit is involved in activational and arousal dimensions of pain. The NSTT projects to the VPLc thalamic nucleus, from where thalamo-cortical pathways project to both S-I and S-II. This pathway is primarily involved with sensory discriminative aspects of the pain signal. However, the interaction of S-I and S-II, and the contribution of S-II input to the cingulate (via the insula) play a synergistic role in cognitive–emotional dimensions of pain consciousness. nPB: parabrachial nucleus; (N)STT: neospinothalamic tract; (P)STT: paleospinothalamic tract; S-I/S-II: primary and associative somatosensory cortex; VPLc: caudal ventroposterior lateral nucleus of the thalamus.
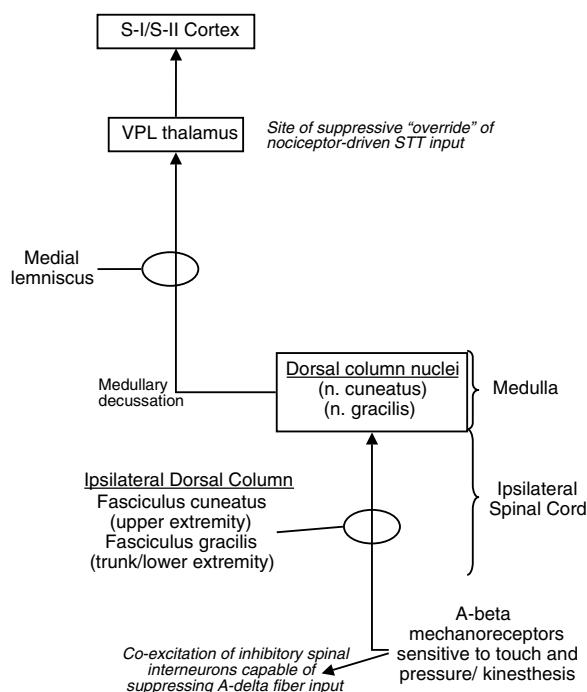

FIGURE 3.7 Schematic depiction of the dorsal column/medial lemniscal pathway and its role in pain modulation. As described in text, A-beta mechanoreceptors can excite inhibitory neurons within the dorsal horn to suppress low-level A-delta nociceptive fiber activity. As well, A-beta mechanoreceptor input can stimulate medial lemniscal pathways from the dorsal column nuclei. Lemniscal projections to the VPL nucleus of the thalamus can modulate coterminal nociceptive input from the STT.

subserve the clinical efficacy of dorsal column electro-stimulation (DCS) and help to explain the somewhat beneficial effect of rubbing a painful area. The effects of dorsal column stimulation, however, seem to be relatively temporally limited in circumstances of long-standing, durable, or progressively increasing pain. With continued A-delta and C-fiber activity, the function (and perhaps microstructural architectural re-modeling) of the STT and/or supraspinal nociceptive neuraxes enhances the transmission of the pain signal, thereby overcoming the viability of spinal or thalamic suppression by dorsal column input (Erickson & Long, 1983). Augmented dorsal column stimulation is then required to regain suppression over STT input, and clinically there appears to be an asymptotic (i.e., ceiling or plateau) pattern to the relative efficacy of serially incremented DCS against progressive neuropathic pain.

SUMMARY

The anatomical and physiologic systems that subserve pain and analgesia are complex. Heterogeneous populations of neurons from the periphery, through the spinal

cord, brainstem, thalamus, and ultimately cortical and limbic systems, with discrete neurochemical and physiological properties all contribute to the amalgam of sensations and the cognitive phenomena known as pain. By understanding the structure and function of this system, we may develop enhanced therapeutic approaches for chronic pain that target these substrates more effectively and selectively, thereby reducing deleterious side effects while facilitating an enhanced quality of life.

Overview of Pain: Classification and Concepts

James W. Woessner, MD, PhD

Pain is generally described as an unpleasant sensation. Pain, as a concept and symptom, is discussed and described throughout professional and lay medical literature. Pain is the reason for initial contact with any physician for the vast majority of medical problems, e.g., abdominal pain, chest pain, limb pain, low back pain. As such, pain *condition* classification is very sophisticated and advanced, as demonstrated by the IASP Chronic Pain Classification system (Merskey & Bogduk, 1994) and others (Derasari, 2000; Waldman, 2003).

The foundation for the history of physiological pain (mechanism) classification essentially started with Descartes (Melzack & Wall, 1965) in the 17th century but has not been framed in these terms until recently (Thienhaus & Cole, 1998, 2001). The history of pain condition classification is synonymous with the history of pain in humankind.

Only recently have physician neuroscientists and medical doctors begun to focus on pain mechanisms that are the foundation for understanding pain conditions and, therefore, for pain classification (Dallel & Voisin, 2001). This effort should proceed rapidly because much information is already available. However, this progression is hindered by the difficulties of transferring scientific knowledge to medical practice.

The main reason to classify (i.e., label or name) clinical presentations of symptoms centered around pain is to facilitate communication between patient and doctor for better pain care outcomes. The goal of therapy is to reduce suffering and increase function, which is the overriding purpose for practicing pain management and is at the core of this textbook and of medicine itself (Fields & Martin, 2001).

THE PRESENT STATE OF PAIN THEORY AND THOUGHT

Pain is described in a myriad of ways:

- In temporal terms: chronic pain, subacute pain, and acute pain
- In characterizations: intermittent pain, intractable pain, lancinating pain, referred pain, burning pain, and dull pain
- In medical diagnoses: phantom pain, cancer pain, vascular pain, arthritic pain, nerve pain, muscle pain, fibromyalgia, myofascial pain, sympathetically maintained pain, and complex regional pain syndrome
- In mechanistic/etiologic terms: neuropathic and nociceptive pain
- In anatomic perceptional terms: headache, back pain, neck pain, facial pain, limb pain, abdominal pain, etc.
- In source or origin terms: central pain as originating in the spinal cord or brain, or peripheral pain
- In psychiatric/psychogenic terms: psychosomatic ("all-in-the-head") pain, etc.

Caudill (1995) analyzed pain from different angles to emphasize its complexity:

- Biologically — Serves as a signal that the body has been harmed.

- Psychologically — Is experienced as emotional suffering.
- Behaviorally — Alters the way a person moves and acts.
- Cognitively — Calls for thinking about its meaning, its cause, and possible remedies.
- Spiritually — Serves as a reminder of mortality.
- Culturally — Tests a people's fortitude or forces their submission.

DSM-IV-TR PAIN DISORDERS

Pain Disorders are coded for their medical conditions in the *DSM-IV-TR* (American Psychiatric Association, 2000; First and Pincus, 2000) as follows:

307.80 Pain Disorder Associated with Psychological Factors
307.89 Pain Disorder Associated with Both Psychological Factors and a General Pain Condition

Elsewhere, the *DSM-IV-TR* (First & Pincus, 2000) attributes neural dysfunction to pain. Again, these are only descriptive categories and do not provide insight into underlying pain mechanism. Suffering, or the affective component, is not separated.

PAIN CLASSIFICATION CHARACTERISTICS

Pain has been classified by anatomic location, body system, duration, severity, frequency, and etiology (Cole, 2002). Merskey and Bogduk (1994) have done a prodigious job of compiling numerous pain conditions, basically all pain conditions mentioned in modern medical literature. Refer to Table 4.1 for a summary of the characteristics of this and other current systems of pain classification.

To add complexity, many factors, such as culture, personality, psychosocial stressors, nutritional status, and other disease states, can be involved to influence the degree of perceived pain and to confound understanding of the causal factors of the pain.

Healthcare professionals and the general public tend to think of location first for most pain classification systems. Waldman (2002, 2003) did so in listing and describing many locations for both common and uncommon pain conditions.

The simplest traditional categorization of pain has been "acute" and "chronic." Acute pain is usually just a result of the stimulation of a normally functioning pain detection system and serves to allow us to avoid or minimize tissue damage. Chronic pain merely means that pain is perceived over a long period of time, which is often arbitrarily set at 3 to 6 months.

However, while the chronology of pain has further subdivided pains basically into "acute" and "chronic," there is a mechanistic relationship, i.e., acute pain is simple nociceptive pain and chronic pain is a complex mix of pathologies along the neural pathways. Dr. Lippe (1998) has suggested the useful terms, *eudynia* (good pain) and *maldynia* (bad pain). As a generalization, many would describe eudynia as acute, and maldynia as chronic, although actual, individual cases tend to be more complex in both cases.

"Biopsychosocial" considerations are one step up from the "traditional" classification. The "pathogenetic"

TABLE 4.1
Pain Classification Systems

Categories	I	II	III	IV	V
Traditional	Acute	Subacute	Chronic		
Biopsychosocial	Acute	Recurrent acute	Cancer related	Chronic nonmalignant	
Pathogenetic	Primary	Secondary	TX. Effect (chemotherapy, tissue trauma, edema, etc.)		
ICD-9[a]	Disease process	Pain location	Secondary		
Dickerson (special case adapted by Brookoff, 2000, who elaborates the various subtypes)	Neuropathic	Inflammatory	Long-term		
IASP[b,c]	Region	System	Chronology	Intensity	Etiology

Note: The "traditional" classification scheme addresses chronology, location, and gross mechanisms.

[a] International Classification of Diseases, 9th edition.
[b] International Association for the Study of Pain.
[c] Merkey & Bogduk, 1994.

TX = therapy; Effect = therapy effect.

system grossly indicates the cause, primary or secondary, as major disease classifications. Inflammatory and long-term designations can involve both nociceptive and neuropathic pain. The IASP system provides a more detailed description of the pain, but fails to approach the cause, except generally in Etiology; the IASP definition of pain avoids linking pain to a specific stimulus.

The biopsychosocial model includes four categories: acute, recurrent acute, cancer-related, and chronic non-malignant pain. The first two categories deal with timing issues; the latter two categories speak to whether cancer is involved. Although useful in incorporating the issue of suffering, we suggest that these categories bear little relationship to mechanisms of pain. Except, perhaps, for vascular headaches, identifying the location of the pain is not necessary to basic understanding. The basic pain mechanisms are the same — whether for arm, leg, abdominal, or ear pain. Further, we think that the mechanisms of pain and pain pathways are the same, whether or not cancer is involved.

The most advanced concepts are expressed by Craig (2002), who states that pain is just one manifestation of the mind–body homeostasis system. From the patient's point of view, the spectrum of pain control spans temporary treatments (usually pharmaceutical) in suppressing pain to permanent remission or cure of underlying pathology/disease.

Obviously, these are all very useful concepts; but, are still generally academic in nature and do not provide much practical help to a physician. Concepts of pain pathophysiology, and thus classification, are abundantly available in the scientific and medical literatures. There is a need to refine and clarify all of this information and apply it as simply as possible to the treatment of pain in the physician's office.

Pain and Suffering

Pain is an unpleasant sensation appreciated as suffering. Most of the present pain classification systems actually include suffering as an essential part of the pain condition described. If suffering is removed, then, theoretically, pain can occur without suffering and would then logically seldom come to medical attention.

Suffering, as a separate life experience, may remain in the psychopsychiatric realm and not be objectively measurable for some time. There is an implied linkage between pain and suffering, which we disconnect here.

PAIN IS A MICROSCOPIC EVENT

Certainly, the first step is to understand that nociceptive pain is not a psychological event; it is a microscopic physical, chemical, or thermal event.

Acute, noxious stimulation of nociceptive pain (detecting something at the pain nerve ending), which may also precede neuropathic pain (hypersensitive transmission pathways), occurs at microscopic pain nerve endings as a signal that something is wrong, physically, chemically, or thermally. The neurotransmitters across synapses and endogenous and exogenous neurotoxic substances are microscopic. The upstream normally functioning peripheral and central neurons are microscopic. Then, neuropathic pain is, by definition, pathology of neurons. Because neurons are microscopic, peripherally or centrally, neuropathic pain can be likewise nothing but a "microscopic" event.

The presence of macroscopic pathology may or may not explain local pain, nociceptively or neuropathically. Macroscopic pathology, in other words, is not necessary, and may even be unrelated, for pain to occur or pain to be perceived. However, many patients and clinicians seek macroscopic pathology as *the* explanation for pain and suffering, e.g., most low back pain patients think of a "slipped disc" first, even though at least 85% of low back pain is nonspecific and, indeed, microscopic.

Functional MRI (Coghill et al., 1994) or PET scans (Iadarola et al., 1995) can show characteristic areas of activation in response to noxious stimuli in both nociceptive and neuropathic pan states. While not yet used in daily clinical practice, this information illustrates that pain is measurable in that it cuases physiological brain phenomena akin to "perception." Suffering is likely to be manifested in different patterns, sometimes with the areas activated by pain, and sometimes without the coincidence of pain. Thus, there are some cases that theoretically could have pain without suffering. Lepers have no pain and no direct suffering (Brand, 1993).

PAIN MECHANISMS

It has been known in medical science for decades that evolutionally advanced somatic A-delta fibers and primitive sympathetic C-fibers transmit pain signals under specific circumstances. In addition to transmitting cold information, the A-delta fibers also transmit thermal and mechanical pain information relatively quickly and with precise locational information to the central nervous system. The C-fibers, on the other hand, transmit thermal and mechanical pain information relatively slowly and rather imprecisely to the central nervous system, i.e., warm pain and achy/burning pain are seen by the central nervous system as "through fogged glass."

Perception may be defined as the localization and quantification by the central nervous system of signals from the A-delta and C-fiber pain pathways. Present pain *condition* classification systems are helpful, but these classification systems are complex and do not seem to be organized to provide the practicing physician with handles

TABLE 4.2
Peripheral Nerve Fiber Types/Characteristics

Class\Units	Stimuli/Function	Perception	Conduction Velocity (m/s)	Diameter (microns)	Myelinated
A-alpha fibers	Motor contraction Efferent transmission	None direct	30–85	12–22	Yes
A-beta fibers	Vibration, pressure Afferent transmission	Vibration, pressure	30–70	5–12	Yes
A-delta fibers*	Cold sensation, pain Fast pain, localized touch Afferent transmission	Cold sensation, pain Localized touch	5–30	1–5	Yes
C-fibers**	Hot sensation, pain Slow pain, generalized touch Afferent transmission	Hot sensation and pain Generalized touch	0.5–2.0	0.3–1.3	No

Note: Based on Haines, 1997; Cousins & Bridenbaugh, 1998; Ganong, 2003.

* Spinal laminas I and V.

** Spinal laminas I and II.

*** C-fibers can still be clumped and embedded in other nonconducting tissue.

that can help the physician more effectively treat those patients presenting with pain — particularly chronic pain. Medical doctors depend on knowledge of the pathophysiology, or at least a diagnosis, to decide on treatment. Thus, to maximize likelihood of a correct and effective treatment and a positive outcome, physicians need to understand where and what the pain mechanism is and how the pain is perceived.

A relatively recent trend has been to look at basic mechanisms of pain (Dallel & Voisin, 2001). By doing so, we are seeking to look one level deeper at the underlying mechanisms so treatment can be facilitated. Dallel and Voisin (2001) recognize the need for a clear roadmap: "Once pain-generating mechanisms are known, it becomes possible to establish the appropriate treatment of pain." We suggest that refining these concepts is a giant step in the right direction and propose to present a simple, clear pathophysiologically based classification model. We contend that pain treatment should primarily focus on reversing pathologic mechanisms that cause the pain in the first place.

Any one or combination of the microscopic mechanisms can contribute to pain: nerve pain ending/"sensor" stimulation, neural "wire" misfiring, and central nervous system/"perceptron" dysfunction (Woessner, 2002a).

RELEVANT NEUROANATOMY AND NEUROPHYSIOLOGY

It appears that the locational patterns of disease, including neuropathology, and the mixture of these mechanisms that are dynamic over time make understanding the basic neuroanatomy and neurophysiology important.

Nerves, or neurons, are long tubes of protoplasm (rather than a series of sausage links), which may, or may not, be surrounded by poorly conducting myelin (insulation). Nerves generally come in various sizes and characteristics and have numerous branches to other neurons. Neurons interact/communicate via numerous electrical (gap junction) and chemical synapses. There are motor (efferent) neurons, which primarily carry signals from the brain to muscles, and sensory (afferent) neurons, which primarily carry signals from the periphery to the brain.

The primary focus for investigation by pain practitioners should be the small sensory nerves, which carry unpleasant signals to the brain that may or may not be perceived by the brain. Descartes depicted a noxious stimulus causing information to flow along a pain pathway to the brain that is then perceived as pain in his famous illustration of a boy's foot touching the edge of a fire (as in Melzack & Wall, 1965). Characteristics of nerve fibers, including classification and conduction velocities, are listed in Table 4.2.

There are three types of fibers that carry pain signals to the brain — A-beta, A-delta, and C-fibers. The first two are evolutionarily modern fibers that are myelinated (insulated) and carry nerve impulses rapidly to the cortical regions of the brain (Haines, 1997).

Neural signals are conveyed by sodium and potassium ions moving out and into neurons via voltage-gated channels in specific patterns to form a relatively slow (see Table 4.2; not 186,000 mi/sec) moving wave of information to, from, and within the central nervous system. These voltage-gated channels are concentrated in "holes" in the myelin (nodes of Ranvier) of the somatic nerves (A fibers),

but are more evenly distributed in the more primitive, unmyelinated nerve fibers (C-fibers).

In the absence of neural wire damage, there is a continuum across various numbers of synapses (switching stations) from the source or place of stimulation to the site of perception. At the distal end of sensory nerves, there are various types of nerve endings. When it comes to pain nerves, those endings are so-called "free" nerve endings. At the proximal end are the perceptor areas of the brain (Haines, 1997).

The A-beta fibers are probably reserved for deep, lancinating pain; certainly these carry vibratory signals. The A-delta fibers are somatic, myelinated fibers that have primary connections to the cortical regions of the brain. These fibers convey sharp, lancinating, easily localized pain signals; these pain sensations usually pass quickly unless constant or recurrent stimulation occurs.

Then, a more generalized, burning/aching pain sensation is perceived in the brain. This latter pain takes longer to pass. The C-fibers are relatively primitive and are not covered by myelin and conduct rather slowly to the subcortical part of the brain (Haines, 1997). Thus, when one experiences a paper cut, one quickly appreciates a "zing" followed by a "burning" pain. You know exactly where the "zing" comes from (A-delta pain pathways), but the brain "sees" the burning pain through "fogged glass" (C-fiber pain pathways).

Now that we know generally how these small nerves work, we need to know where these nerve endings and small pain nerves reside. Our standard anatomy books often do not depict or describe these networks of nerves. Dr. Fishman (2000), an insightful pain doctor, has described in his book entitled *The War on Pain* that these nerve fibers cover and line most of the tissue plane surfaces throughout the body.

HOW PAIN IS MEASURED

If pain is separated from suffering, it is easy to understand that pain is then measurable physiologically. As indicated in Table 4.2, neurophysiologists have assigned identifiable physiological functions to different nerve types. As with large-fiber functional testing, the small fibers, i.e., the A-delta and C-fibers, can be tested electrically and thermally. Measurement of small pain fiber function by preferred frequency transmission measurements (= current perception threshold [CPT]) has been clinically available for more than ten years. Thermal testing is as old as neurology itself; the basic physical examination includes qualitative testing with the handle of a reflex hammer as is for comparative cold sensation and heated for comparative warm sensation. In the laboratory, neuroscientists have been able to quantify thermal nerve, i.e., A-delta and C-fiber, function for decades. Machines are available now to test the function of pain nerve pathways in clinical settings. Testing pain

nerves thus provides valuable information for diagnosis, and more effective treatment (Woessner, 2002b).

Imaging of pain perception has also been accomplished with transcranial magnetic stimulation (Gale, 2004), positron emission tomography (PET) (Iadarola, et al., 1995), single photon emission computed tomography (SPECT), functional magnetic resonance imaging (fMRI) (Coghill, et al., 1999) and near infrared spectroscopy techniques (NIRS) (Cope, 2000). "Research in diagnostic imaging of neuronal activity is … endemic at many academic medical centers. … The ability to map transmission of pain and other disorders not only to block but to alter and reprogram neurotransmission is now a very active and ever-changing research area (Cope, 2000)."

An interesting question arises from this research: Can a human being perceive pain without suffering? My clinical experience indicates that this is exactly so. Most clinicians, indeed, do understand that patients suffer for a variety of reasons. Thus, what medicine really needs is Suffering Relief Specialists rather than Pain Medicine Specialists per se. With the proper mindset, a pain specialist should be able to tackle the broader, and sometimes separate, issue of suffering. Thus, measuring and understanding physiological pain and comparing the results to perceived pain allow the clinician to more precisely treat "pain patients."

PROPOSED PHYSIOLOGICAL PAIN MODEL

This physiological pain model (Woessner, 2002a) focuses on underlying causative mechanisms, as opposed to the pain condition classification systems listed in Table 4.1. To review terms, nociceptive pain is merely normal functioning of the neural sensor/wire/perception system. This system serves useful purposes in alerting the brain to bodily injury. Neuropathic and central pain, however, is a manifestation of true dysfunction and can be the "disease" itself.

If we consider a bundle of axons, neuropraxia, axonotmesis, and neurotmesis represent points along a complex continuum of damage to axons and nerves. The three possibilities for individual axons are normal function, hyperfunction (hyperesthesia, hyperalgesia, hyperpathia, and allodynia), and hypofunction (hypoesthesia, hypoalgesia, and conduction block). Hyperfunction can also be thought of as sensitization or irritation. The ultimate hypofunction is axon death without regrowth. Free nerve endings can also be sensitized or irritated, which is considered here to be in the neuropathic category.

Understanding neurophysiology of pain pathways is helpful. Further, we propose that all pain can be understood by considering problems of stimulation of sensors, conduction along nerves, and/or perception in the spinal cord and brain. The perception then may involve feedback, either positive or negative (i.e., release or not of native painkiller, e.g., endorphins). If negative, the result

is, by and large, a dysfunction that conceptually could stand alone.

Haines (1997) describes an electronic schematic of the nerve cell membrane and forms the basis of concepts discussed below. A key concept is that the neural pain system follows basic electrochemical principles.

The analogy of the neural net in complex electrical circuitry seems to be an accurate one. The pain sensors (free nerve endings) are relatively simple. The wires (peripheral nerves) are even simpler. The central nervous system is incredibly complex. We are discovering that the spinal cord is not just a transmission device; complex interactions can occur here also. Finally, the complexity of the brain is difficult to imagine with millions of neurons and billions of synapses (Haines, 1997).

Stimulation of the sensors is nociceptive or eudynia. Malfunction of the wires and perceptron is neuropathic. Note that neuropathic pain is divided into central and peripheral parts of the pain nervous system because, while relatively little is known about either, these two parts of the pain pathways are clearly distinguished from each other.

Essentially no pain condition is unifactorial. For the actual pain conditions that the practicing physician encounters, it is useful to assess the pain using a conceptual framework. This approach is useful as a tool in assessing an individual patient's pain and deciding on treatment within the conceptual pain model.

STIMULATION OF PAIN SENSORS (NOCICEPTION)

Normal stimulation of pain sensors is the "good" pain described in *The Gift Nobody Wants* (Brand, 1993). It is termed "eudynia" in that the free nerve endings of pain pathways are working perfectly and normally — giving good information to the body and brain that tissue is being damaged — or is about to be damaged — and that the body needs to do something about it. Impact on mechano(noci)ceptors, heat or cold stimulation of thermo(noci)-ceptors, or caustic chemicals on chemo(noci)ceptors start the process of perception of pain. In other words, this type of pain is based on mechanical, thermal, and/or chemical stimulation of normally functioning pain nerves; nerves that detect pain as a signal indicating impending or active tissue damage.

MISFIRING OF WIRES (NEUROGENIC OR NEUROPATHIC PAIN)

During the normal transmission of neural signals to the central nervous system, any damage to the neural pathway itself may manifest itself analogously to "static" in radio transmissions. This neural "static" alters the neural signal and is then perceived as pain. Nerves can be damaged just

as any soft tissue, in which these nerves occur, can be damaged. Neuropathic pain, therefore, is a result of damaged and malfunctioning wires/nerve fibers. One can also conceive of similar damage to nerve fibers in the central nervous system. As long as those fibers are not the end of the pathway, the phenomenon is the same. Damaged nerve fibers follow a course of anatomic and physiologic change involving irritation (hyperactivity) and dysfunction/death (hypoactivity) (Iadarola et al., 1995). Upon nerve death, of course, signals can no longer be transmitted along the neural pathway.

Mechanisms of hypersensitive or pain neuropathology include "rapid repriming" of sodium channels or "electrical bursting in pain signaling neurons." These sodium channels are specific to the "spinal sensory neurons" (Waxman, 2001, p. 382). Waxman et al. (2001) provide significant detail of this mechanism without indicating the nerve type; we assume that a similar mechanism works for both the A-delta and C-fiber pain nerves and, at least, is related to local microscopic mechanical and chemical occurrences.

DYSFUNCTION OF PERCEPTION (CENTRAL PAIN)

The most complex, and very difficult to study, part of the pain pathway(s) is in the central nervous system and occurs at the end of the neural pathway, where these signals are interpreted. Perception and consequences can occur in the dorsal horn. If central neurons malfunction in any part of the pain perception pathway, one possible consequence is that the brain perceives "pain." The environment of the central nervous system can also play a part. This complex system can be considered together to be a *perceptron* (Woessner, 2002a). This word has been chosen to convey the true complexity and computer-like nature of these central nervous system phenomena. If the "perception" is the cause of the perceived pain, this pain pathology can also be called central neurogenic pain.

ANTINOCICEPTIVE DYSFUNCTION

The human body possesses antipain (antinociception) systems including endorphins, enkephalins, etc. that are utilized as natural pain killers and neural feedback modulation to reduce perception of pain and the quantity of pain signals arriving at the "perceptron." In normal function, the human body releases these painkillers to modulate or mollify pain. At the very least, if these chemicals are not released or do not arrive at the affected receptors, the perceptrons will appreciate pain or greater pain, in the presence of pain signals (Craig, 2002).

Pain experts have also recognized that pain is nociceptive and/or neuropathic (Abrams, 2000), which are

commonly thought to be equivalent to "acute" and "chronic," respectively. The difficulty is that most acute and chronic pain conditions are a combination of both nociceptive and neuropathic pain, which can and do change over time. An acutely damaged nerve can result in acute neuropathic pain, and chronic arthritis can result in a chronic recurrent nociceptive pain.

Antinociceptive dysfunction (Brookoff, 2000) occurs in the perceptron (brain and/or spinal cord) and can worsen both nociceptive and neuropathic pains; antinociceptive pain, in other words, is dysfunction of the natural pain modulation system (Heinricher, 2002). Then, externally delivered painkillers are antinociceptive, as well.

Then, there are natural pain modulations that can malfunction resulting in more pain (hyperalgesia) or even pain without a noxious stimulus (allodynia). In this physiological manner, pain can be better understood. Each possible mechanism is dynamic in anatomical location, along pain pathways, and over time; each mechanism is individual and unique according to the underlying pain condition.

COMPLEX PAIN FROM A MIXTURE OF MECHANISMS

Over time and with the presence of widespread and/or severe causal factors, more than one aspect of the pain perception system may be malfunctioning at the same time. For example, it is common for patients to develop pain in a limb due to trauma that injures small pain fibers in addition to the other soft tissue. One can have stump pain along with phantom pain, possibly not coincidentally. Central sensitization can develop over time in a patient with ongoing peripheral disease. Dysfunctional efferent reflexes or reactions can change the physical and chemical environment of pain sensors, which then causes nociceptive pain as in complex regional pain syndrome (CRPS).

REFERRED PAIN AND NONTENDER SYNDROMES

Likewise, clinicians should be aware of pain perceived in body areas that are not tender on palpation. In other words, referred pain is pain that is perceived separately from the true pain generator and was first discussed in publications by Sturge (1883), Ross (1887), and others (Bonica and Loesser, 2001; Coda & Bonica, 2001). Local acute pain is relatively easy to understand, and physicians usually appreciate radicular pain, which is one type of referred pain. The concept of referred pain can be difficult for clinicians and patients alike.

Physicians strive to achieve the best possible understanding of pain conditions and try to find an acceptable label or diagnosis, even for conditions and presentations that are uncommon and/or difficult to understand. As the patient's presentation becomes more complex and as pain conditions become more chronic, physiologically legitimate presentations may not be understood.

Understanding referred pain requires specialized and diverse knowledge along with wide clinical experience. Suggesting that complaints are "non-anatomic" or "non-physiologic" may very well be a clear indication of the diagnostician's ignorance rather than a negative reflection on the motives of the patient. Individual variations in the presenting pain patterns complicate interpretation. Even well-known and classic pain patterns may be difficult to diagnose in the face of complex disease and multiple causes of pain. There are other complex, and poorly understood, pain conditions defined below.

REFERRED PAIN MECHANISMS

Kosek and Hansson (2003) have specifically found that "referred pain is most likely a consequence of misinterpretation of the origin of input from the stimulated focal pain area, due to excitation of neurons somewhere along the neuraxis with projected fields in the referred pain area … [this] suggests that the divergence of the input is not reciprocally arranged."

The best-known referred pain patterns may originate from viscera and myofascial trigger points. Each type is presented below. Other pain syndromes, with different names, however, also fall within this general category with the broad definition given above, where the pain is perceived at a site separate from the pathology.

Ombregt et al. (2003) have provided more precise principles limiting and defining referred pain:

1. Radicular pain is directly related to spinal segments.
2. The perceived pain site and causative pathology are usually on same side of midline.
3. The main pain is usually felt deeply.
4. The referred pain is referred distally within a dermatome, but not necessarily throughout that dermatome.
5. Referred pain may be contiguous with or may be separated from pathology.

The author proposes a sixth principle (Woessner, 2003): that the site of perceived pain is not tender, whereas the site of pathology is tender. Central pain phenomena do not necessarily fit completely within these general principles, but it is still useful to understand the similarities.

Selzer and Spencer (1969) suggest five underlying mechanisms involved with referred pain:

1. "Convergence-Projection" describes one neuron receiving impulses from two sources; i.e., peripheral neurons, resulting in the central path-

ways not being able to distinguish between the sources (Ruch, 1960).

2. "Peripheral Branching of Primary Afferent Nociceptors" involves the fact that single neurons are very long narrow tubes that may have various branches that come from different peripheral sources, again making it impossible for central pain pathways to distinguish the source.

3. "Convergence-Facilitation" is ephatic transmission that occurs where nerves from two different body areas are in close proximity and results in signals from the viscera being transmitted along an associated spinothalamic tract to be perceived in the brain as coming from various skin areas (originally proposed by Ruch, 1960).

4. "Sympathetic Nervous System Activity," which is suggested to restrict blood flow to an area causing pain in that area or by releasing substances that sensitize nerve endings in the area of perceived pain such that hyperesthesia or allodynia occurs. Except as illustrated elsewhere, this possibility does not make much sense.

5. "Convergence or Image Projection at the Supraspinal Level" describes ephaptic transmission in central locations rather than at the dorsal root, or some similar mechanism to be perceived as being pain in one area while the stimulation comes from another.

There are, of course, other possibilities and/or contributing factors to referred pain:

1. Note that when nerve root pathology affects only the nerve root surface pain nerves, we expect local pain to be perceived and local tenderness to be elicited. For more severe pathology that extends physically as pressure and chemically to the pain nerves inside the nerve root, we expect that the brain would perceive the pain more distal to nontender locations in the feet or hands, understood as "radicular" pain. This mechanism is likely for all non-central syndromes considered here.

2. Mistransmission or ephatic transmission solely in the central nerve system, as in the phantom pain phenomenon discussed in the labeled section below.

3. The embryologic relationship of the internal organs to spinal levels, which is then directly related to sympathetic chain levels. The importance of the embryologic levels must reflect organization in the central nervous system. In addition, the main nerve fiber type of the sym-

pathetic nerve system is the C-fiber, the primitive, unmyelinated pain fiber, emphasizing that ontogeny follows phylogeny.

4. Along these pathways, neuropathic pain can also be referred and, in some cases, may indicate that the nerve is "trying" to normalize, to heal. Certainly, dead neurons do not transmit pain signals or any other impulse.

5. Central pain syndromes could very easily fit into the same category as phantom pain. Deafferent pain syndrome is consistent with "total body amputation" from the head/brain and represents a pain syndrome without nerve impulses of any sort coming from the periphery. In other words, the pathology or dysfunction is in the neurons of the central nervous system, but not necessarily just in the brain.

6. Wide dynamic range (WDR) neurons and interneurons of the spinal cord represent neuropathic dysfunction that could by specific, complex mechanisms end with the perception of pain where there is no pathology; the pathology, in this case, is in the spinal cord.

7. Sympathetic chain pathology is the same as the spinal cord pathology. We may eventually identify WDR neurons of the sympathetic chains; we will probably come up with a different name.

8. Patchy brain modulation of pain, i.e., antinociception, could well leave the brain appreciating pain where there is no pain with or without a reason, i.e., nerve impulses of any kind coming from elsewhere.

Certainly, more than one or all of these phenomena could occur together to form the various widespread and complex pain problems that a physician must manage and try to cure.

EMBRYOLOGY AND REFERRED PAIN

Various authors (Marcus, 1998; Ombregt et al., 2003) discuss the embryologic basis for referred pain. Certainly, the referred pain mechanisms must have a relationship to nerve pathways and networks. These pathways and networks are geometrically and positionally related to where the precursor structures occurred in early ontogenic stages and how these structures migrate during growth and maturation. Thus, referred pain patterns have an evolutionarily ancient (phylogenic) and developmentally individual relationship (ontogenic) to dermatomes, myotomes, sclerotomes, viscerotomes, etc. Central pathway and network pathology can probably be understood in the same way.

Factors Causing Referred Pain

Ombregt et al. (2003) described factors that predispose to referred pain. Stronger central and/or proximal deep (vs. superficial) stimuli more likely cause the perception of pain beyond the pathology. Sclerotomal referred pain is more likely than myotomal referred pain, and much more likely than bone pain. This order of occurrence may be generally inversely related to intensity and pain-related dysfunction.

Marcus (1998) adds and states differently that "tenacious" pain stimulation is more likely to be referred; superficial pain is more likely to be localizable (less likely referred), deep (excluding bone) is more likely referred; soft tissue referred pain is less localizable, i.e., more likely referred; and distal pathology is more localizable than proximal.

Viscerotomes

Visceral referred pain is probably the most widely recognized, while still being the least understood of all the referred pain patterns. Head (1893) noted disturbances of sensation arising from visceral disorders. Cousins (1987) refers to these patterns as "viscerotomes." Lingappa and Farey (2000), in fact, describe "referred pain" as "the phenomenon in which injury to internal organs causes pain that localizes, in part, to surface structures or other organs clearly distinct from the site of primary injury. Typically, the pain is referred to other structures that have the same embryonic origin" (pp. 798). There are established patterns of referred pain from internal organs. Drewes et al. (2003) have provided a detailed description of the various referred visceral pain distributes, providing basic information to understand the complexities of viscerotomes.

Ephatic transmission is analogous to electrical shorting out. Via these shorts, "many different afferent sensory nociceptive neurons synapse with the same ascending fibers in the spinal cord," which causes the brain to mistake the origin of the pain signals; in other words, the pain feels like it is coming for some typical locations on the skin or nearby subcutaneous tissues and possibly deeper structures, rather than the actual internal organ from which the pain signals are coming (Lingappa & Farey, 2000, pp. 798–799). These scientists also suggest that the brain generally will have more recent memory of surface/subcutaneous pain and will "ignore" deep pain until an inciting event occurs.

With A-delta pain fiber involvement, a skin injury is easily locatable. Visceral pain is difficult for the human brain to locate because the pain is "referred" to the skin and involves sympathetic C-fibers, which subserve poorly localized pain.

Angina pectoris is well known to cause left arm pain, alerting to the possibility of impending myocardial infarc-

tion. Abdominal pain that becomes rapidly generalized implies perforation and leakage of fluid into the peritoneal cavity, irritating the parietal peritoneum. Biliary pain can radiate to the right inferior scapula. Pancreatic and abdominal aneurismal pain may radiate to the back. Ureteral colic classically is referred to the groin and thigh (Haist & Robbins, 2002).

The areas of the body to which visceral pain is referred are described in narrative rather in schematics. Note that we expect that each patient will display variations on these generalizations. Word descriptions may actually represent reality better than the various published schematics because each viscerotome schematic is different and inconsistent, with individuals and populations being unique and different to some degree.

Common Pain Radiation Patterns (Woessner, 2003)

Lungs: Pain is referred in a collar-like band completely around the neck from about C6 to T3 levels.

Diaphragm: Pain is referred in a pattern similar to the lungs.

Heart: Pain can be referred to around the mouth, but is more commonly referred over the left chest and contiguously down the anterior left arm and directly to the mid-back between the scapulae from T4 to T7.

Gallbladder: Pain is referred to superior and lateral right shoulder, offset superior similar in size and circular shape to the superficial distribution of the axillary nerve.

Liver: Pain is referred in a similar pattern to the heart, but only on the right hemi-body.

Stomach: Pain is referred just to the right of midline in the epigastric area and to the mid-back, just below the referred angina from T7 to T9.

Ovaries: Pain is referred to the skin area immediately over the ovaries anteriorly and directly posteriorly, but more lateral.

Appendix: Pain is referred to the umbilicus and then to McBurney's point in the right hypogastric area when parietal peritoneum becomes inflamed.

Kidneys: Pain is referred to the skin area somewhat below the kidneys, posteriorly only, and medial to the posterior referred ovarian pain; there is also an area half way down the right lateral thigh, the right chest just to the right of the lower sternum.

Ureters: Pain is referred to an anterior band across the pelvis, including the groin and the genitals, but not extending to the back.

Bladder: Pain is referred to a continuous area encompassing the sacrum from S2 down to the upper medial thighs.

RADICULAR PAIN

Radicular pain originates at the nerve root, cervical, thoracic, lumbar, or sacral, and typically radiates or is referred along a dermatome. Dermatomal pain suggests nerve root involvement from a herniated disc or other physical or chemical irritation at the nerve root exiting from the spinal canal.

Consistent with the definition, there can be various pathologies at the nerve roots, which include (1) nerve root compression from a herniated disc, (2) foraminal stenosis from bone spurs or arthritis irritating the nerve root, (3) nerve root pressure from mass lesions, (4) chemical changes at the nerve roots secondary to diabetes, (5) scarring from previous spinal surgery or chronic disc pathology, and (6) all other nerve root injuries. The radiating component is technically "referred pain." This type of "referred pain" is not a nociceptive process; it is neuropathic, even if momentary. Pain with such a specific distribution seems unlikely to even be central.

Thinking of the distribution of pain nerves in the cross section of a nerve root is instructive. If the pathology is minor, the pain on this surface of the nerve root is most affecting, and thus local pain is appreciate (Woessner, 2002a). With more compression the pain nerve pathways/axons deeper in the nerve root are affected and "fool" the brain into thinking that the painis located more distal toward the limb involved.

OVERLAPPING DISTRIBUTIONS

The nerves that innervate dermatomes interdigitate at the borders to some extent, making the boundary edges fuzzy. In addition, the sensory distributions, which characterize and define dermatomes, may not be identical to the pain patterns. Therefore, exact determinations of pain perception distributions are not "cut and dried" (Bonica & Loeser, 2001).

REFERRED MUSCULAR PAIN

Referred muscle pain in voluntary muscles is most often accompanied by secondary hyperalgesia and hypotrophic changes. A schematic of these referral distributions is shown in *Bonica's Management of Pain* (Coda & Bonica, 2001).

"Myotomal" pain involves problems with the fascial tissue planes that surround muscle groups. While "myotomal" may not be the correct description, when muscles were injected with hypertonic saline, which is an experimental substance known to produce pain, mapped patterns of referred pain emerged (Coda & Bonica, 2001). While we would expect that these would be the same referred pain patterns as myofascial trigger points, gross inspections reveal no clear congruence or overlap.

SCLEROTOMES

Pain referred from tendinous and/or ligamentous interfaces with bone surfaces has no specific, well-recognized name (Hackett, 1958). Sclerotomes are pain referral patterns from sites of enthesopathy, i.e., pathology of the collagenous attachments (tendons, ligaments, cartilage, etc.) to bones generated by inflammation (Bonica & Loeser, 2001).

DURAL PAIN PATTERNS

Bogduk (2003) has recognized that the spinal dura is innervated. Cailliet (1988) has further shown that the dura is innervated by sympathetic C-fibers. Ombregt et al. (2003) and Butler (1991) have postulated that certain pain perception patterns occur when the pain nerves on the dura are stimulated.

Certainly, these diffuse patterns do not even vaguely resemble dermatomal distributions. They are much more widespread than the limited zones of referred trigger point pain. For instance, dural nerves stimulated by scar tissue in the lumbar region may result in perceived pain and discomfort throughout the legs.

Kernig's and Brudzinski's signs, i.e., the meningeal signs (Gerard & Kleinfield, 1993), are reminiscent of this same phenomenon. By definition, these are consistent with meningeal irritation, i.e., dural irritation, where A-delta and C-fiber pain nerve endings occur, anteriorly and laterally (Cailliet, 1988).

THERMATOMES

There are thermal patterns of pain, which are probably related to the distribution of sympathetic C-fibers nerves and with sympathetic chain pathway components, without shorting, crossing over, emphatically to the A-delta fiber pathways.

Hooshmand (2000) has coined the word *thermatomes* to describe referred pain patterns related to the circulatory distribution of sympathetic C-fiber nerves. These relatively amorphous distributions are consistent with the observation that these C-fiber nerve pathways end up seeing pain "through fogged glass."

If we think of the possible evolutionary origin of the sympathetic chains, which in lower animals transmit all efferent and afferent nerve impulses, those pathways should be able to reestablish transmission pathways in compensation, much like collateral circulation.

FACIAL REFERRAL PATTERNS

Pain referral patterns in the innervation of the face and anterior neck are not completely appreciated by healthcare professionals.

Guyton & Hall (2000, pp. 558–560) show that:

Nasal sinus and eye aches radiate to a wide area around the eyes from below the nose and up to mid-fore.

Cerebral vault aches occur frontally to parietally at the ear.

Brainstem and cerebellar vault aches occur from the ear through the entire occiput.

PHANTOM PAIN (WOESSNER, 2003)

Phantom sensations and pain are well-described phenomena, which means that the brain perceives the existence of a body part, from which no nerve impulses could possibly be emanating.

In a sense, phantom pain is the ultimate "referred pain." Perceived pain location is obviously not where the pain is originating because there cannot be peripheral pain nerve stimulation. Stump and neuroma pains are separate pain phenomena and are not referred pain, and therefore, these pains are not phantom pain. There is surprising confusion about these, i.e., stump and neuroma pains versus phantom pain.

REFERRED PAIN DUE TO HEALING PAIN NERVES

Healing nerves and tissue cause pain by the following:

1. Inflammation is part of the healing process; the natural chemicals involved are caustic to pain nerve endings. The treatment dilemma here is if you stop the pain with anti-inflammatory medications, do you not also stop the healing?
2. Consequent muscle spasms occur. Spasm or cramping muscles change, usually decrease circulation; ischemia causes pain by causing a caustic microenvironment around nerve endings. In addition, the spasm/cramping muscles are causing pressure on the A-delta and C-fibers that occur in the myofascial tissue planes.
3. Improper healing of any tissue can reasonably contort it and cause pain and dysfunction; such nociceptive pain is caused by pressure on and/or caustic chemical environment around the nerve endings; neuropathic pain would come from the changed neuroanatomy, thus changed neurophysiology, and also from the changes in the chemical microenvironment.

HOW, IN THE END, DOES PAIN AND REFERRED PAIN CLASSIFICATION HELP?

For nociceptive pain, the primary goal is to resolve ("cure") or remove the stimulant, i.e., the causative pathology, while covering up the pain. For neuropathic pain, the goal is to stop the irritation and promote rebuilding the damaged nerves or normalization of their function. For central pain, the goal is to employ techniques to change the central nervous system neural environment. For antinociceptive pain, the goal is to normalize pain perception and reestablish natural painkiller production and function.

The ultimate approach for effectively treating pain is individualizing and balancing the various approaches for optimal results in complex chronic pain cases. By understanding the underlying mechanisms, physicians clearly have a better chance of effectively serving their patients with better pain relief. Suffering is probably the most difficult part of pain to quantify and treat. However, it is expected that suffering will improve as we improve our abilities to treat pain.

SUMMARY

Pain classification depends on the understanding of pain mechanisms. The more we know about these mechanisms, the more likely we are to apply the appropriate terms to the pain conditions that we see in our clinics. We cannot abandon the time-honored names that we are using.

Basically, there are two categories, i.e., nociceptive and neuropathic pain. Eudynia and maldynia, respectively, may actually be more useful terms because the accepted terminology may be limited by the historical processes involved in pain (condition) classification. Accurate consideration of these basic concepts should be applied to every pain condition encountered by the practitioner in order to plan appropriate treatment of the pain.

Referred pain is neuropathologic, i.e., not nociceptive. Referred pain is important because it may have diagnostic value. Referred pain adds another layer of complexity to the process of making a diagnosis. Making the diagnosis by artfully and systematically combining the findings obtained from the clinical history and physical examination allows the clinician to formulate a coherent treatment plan.

Culture and Pain

Margie Rodríguez Le Sage, LMSW, PhD

INTRODUCTION

The growing attention that is given to understanding the influence of culture on pain stems from a number of factors that go beyond intellectual curiosity. Growing public interest in the treatment and palliation of pain, advanced technology to manage symptoms, and an increasingly diverse consumer base all combine to prompt culturally mediated issues of whether to relieve pain, for whom, with whom, how, when, and under what circumstances. The national commitment to eliminate disparity in health care outcomes along with the fact that most persons suffering health inequity are culturally and linguistically distinct compels further understanding of the relationship between culture and pain. As evidenced by emerging research, policies, and professional statements on diversity and pain, it is clear that scholars, policy makers, and clinicians are hopeful that advancing understanding of how culture informs pain experiences will contribute to optimal pain-related interventions.

The complexity of both concepts, culture and pain, has encouraged variable interpretations. Although pain is considered systemic, context dependent, multidimensional (e.g., biological, cognitive, emotional, social, and spiritual) and substantially affected by personal values and cultural traditions (Morris, 1998), culture implies an ongoing multilayered dynamic process of accepted ways of seeing, experiencing, interpreting, and expressing experiences affected by social processes and historical epoch (Moore, 1994; Shore, 1996). Models that attempt to explain pain relationship to culture generally assert that (1) pain is more than a simple neurological response to physiological injury and disease; (2) pain has mental-emotional, cultural, spiritual, and historical dimensions;

(3) pain can be influenced by personal values and spirituality as well as multiple layers of context including cultural traditions and social dislocation or disharmony; (4) pain is subjective and can only be defined by the individual; and (5) pain can be partly fabricated out of imagined lives and possible social exigencies (Bates, 1987; Glucklich, 2001; Jackson, 1994; Kleinman, 1994; Melzack & Wall,1983; Moore, 1994; Shore, 1996).

In line with current discussions that resist "ethnizing" culture, that is, limiting culture to ethnicity alone, a broader definition offered by the Office of Minority Health (Meadows, 2001, p. 1) is used here: *Culture* refers to integrated patterns of human behavior that include the language, thoughts, communications, actions, customs, beliefs, values, and institutions of racial, ethnic, religious, and social groups. A related concept, *cultural and linguistic competence*, refers to a set of congruent behaviors, attitudes, and policies that come together in a system, in an agency, or among professionals that enables effective work in cross-cultural situations. In turn, *competence* implies having the capacity to function effectively as an individual and an organization within the context of the cultural beliefs, behaviors, and needs presented by consumers and their communities (Meadows, 2000, p. 1).

The focus of this chapter is not to review the broad and complex topic of culture and pain or the accumulated findings on how culture influences pain, as that would require a book of several thousand pages, even for the parsimonious writer. Instead, this chapter focuses on addressing topics that are elementary yet important to current discussions of culture and pain, particularly in terms of appropriate and just responses to pain across cultures and linguistic traditions. This chapter encourages a broader understanding of culture and pain by briefly

addressing current thinking in the analysis of culture and pain and select challenges encountered when attempting to understand culture. Potential areas for cross-cultural tension are considered in this chapter, as is research that points to disparate outcomes on pain relief across socio-cultural groups. Other topics addressed in this chapter are the importance of language when addressing culture and pain, standards for cultural and linguistic competence, and multilevel cultural and linguistic competencies that can help anticipate, mitigate, and perhaps prevent cross-cultural tension. Finally, the chapter concludes by considering challenges and opportunities to advance the effectiveness and equity in the treatment or care of pain across cultures. The choice of topics is driven by two notions: (1) better understanding of culture in an increasingly culturally and linguistically diverse world contributes to appropriate and just clinical outcomes; and (2) equity in the treatment of pain requires multilevel cultural and linguistic competencies. While the discussion in this chapter points to classic and current sources, it does not represent the extant literature that addresses culture and pain.

TOWARD A BROADER UNDERSTANDING OF CULTURE OF PAIN

Our understanding of culture and pain has advanced steadily over the last 52 years since Zborowski's classic work (1952) opened the study of pain to cultural comparisons, now regarded superficial in theory and method (see Delvecchio Good, Brodwin, Good, & Kleinman, 1994, p. 2). Our current level of analysis of culture and pain has moved beyond cultural comparisons and explorations of how meaning shapes pain experiences to one that addresses pain as a deeply personal feature of lived experience of individuals in the context of their social world and historical era. Individuals experiencing pain are not regarded as passive to the potential influence that culture can have on their perception and response to pain, but are seen as active in mediating (i.e., accepting, rejecting, modifying) cultural messages and other levels of social context that may or may not be within their control (Janes, 1999). In addition, current thinking on the influence of culture and pain considers all clinical encounters as cross-cultural, relational, and affected by imbalances of power. The multiplicity of factors, including personal values and cultural traditions that influence the attitudes about, perceptions of, and responses to pain take on special significance in clinical settings where pain becomes an interpersonal experience between the consumer and clinician and where therapeutic control is vested in the clinician (Farber Post, Blustein, Gordon, & Dubler, 1996). Current understanding of culture and pain has rediscovered the relationship between culture and voluntary pain. Current thinking

reminds us that the experience of pain, whether observed through the athlete who endures, the person who elects to undergo tattoos, the woman who elects child birth without analgesics, can signify something other than disintegration (Glucklich, 2001). Finally, current thinking does not limit culture to ethnicity but considers it to emerge from other sociocultural categories such as age, gender, religion, ablement, sexual orientation, race, national origin, linguistic tradition, and socioeconomic status.

Our broader and deeper understanding of culture and pain has encouraged developments that are certain to enhance the treatment and palliation of pain. This broader understanding of culture and pain discourages the temptation to overassign importance to cultural descriptions of groups, particularly those that are elevated above person, time, and situation and void of culture-bound information on sociocultural categories across the diversity spectrum. Current emphasis on the distinctive intimate experience of pain-in-context prompts clinicians and their sponsoring institutions to acquire multilevel competencies to best understand personal cultures and serve persons-in-their-pain experience. The renewed attention to voluntary pain and the premise that pain can be regarded a good thing that can enable a sense of belonging or connectedness challenges clinicians to think and prepare broadly to respond competently to diversity. Current thinking on culture and power that interact in clinical encounters to produce disparate outcomes has advanced commitment to explore the sources of inequity in pain relief. The emphasis that current thinking places on the complexity of culture in relationship to pain encourages clinical and scholarly engagement across disciplines, interdisciplinary rather than multidisciplinary, to more holistically and appropriately respond to pain.

Despite the advances made in our understanding of culture and pain, this field of study is in an early stage of development. Routes, patterns, and end points of cultural influence are considered complex and to reflect the multifaceted exchanges between culture and individual pain-related cognition, emotion, behavior, and spirit remains a challenge. Deeper understanding of what culture and pain mean and the processes that shape their meaning remain in development. The recent commitment by at least 15 National Institutes of Health (NIH, 2001) to support research on the social and cultural dimensions of health communicates the importance of advancing our understanding of culture and counters the tendency to use the term superficially and mechanically. While better information on how culture influences pain is being obtained, applying what is known can help allay cross-cultural misunderstandings. The following section discusses select aspects of culture that are known to challenge our grasp of its nature and influence.

CHALLENGES IN UNDERSTANDING CULTURE

A number of factors can make our understanding of cultural influences on pain particularly challenging. Understanding some of these factors permits a more accurate understanding of cultural diversity that guards against blind spots in our assessment and response to cultural difference. First, there are a great many cultures and within each single general culture, except for certain minority religious or ethnic groups (Yazar & Littlewood, 2001), there is substantial intracultural of variation, often related to other subcultural categories such as gender, age, religion, race, ablement, national origin, linguistic tradition, sexual orientation, and socioeconomic location (Miller & Eskin, 2001). The value that a specific Latina places on pain, for instance, may not be entirely a function of her ethnicity, but related to the cultural underpinnings of her religion and age, as well as the cultural construction of womanhood that assigns meaning to some of her pain. In contrast, this Latina woman's sister, who is agnostic, 10 years younger, resentful of culturally mediated messages of womanhood, and relatively removed from her Latina origins, considers all pain dehumanizing and requiring relief.

Second, due to its dynamic nature, culture changes across time. For example, discourse on the history of pain reminds us that pain lost much value after anesthetics were invented and applied in the 20th century (Cusick, 2003; Glucklich, 2001; Morris, 1991). In most general terms, this cultural shift transformed pain into a medical problem, of physical matter, and one devoid of meaning and function, thus relegating voluntary pain to deviant status.

Third, cultures intersect and persons acculturate. Defined as a multidimensional, multidirectional, developmental, interactive, and adaptive process of cultural adjustments experienced by individuals (Cuellar, Arnold, & Maldonado, 1995; Padilla & Perez, 2003) and groups (Berry, 1997; Berry & Sam, 1996), acculturation blurs cultural boundaries and creates variants of all aspects of culture. Individuals, particularly if presented with alternate forms of viewing phenomena, may reject, accept, or adapt culturally mediated messages related to pain (Johansen, 2002), not always in a definable pattern.

Once pain is suffered, it may be experienced differently by the same individual over time. For instance, a Mexican laborer who migrates from a small village in Mexico to the United States confronts an assessment of his pain that is contrary to his own. While in his native village his pain is regarded as a necessary part of living and spiritual transformation, in migration he experiences a society where pain is considered something that should be avoided. This can lead to a transformation of the pain experience, from necessary and meaningful to unnecessary and even destructive. Johansen (2002) shows, from her study of pain associated with infibulation among

Somali immigrants in Norway, that the contexts in which pain is originally suffered and subsequently remembered can affect the pain experience and its management. The implication is that not everyone from every culture group conforms all the time to a set of expected behaviors or beliefs, particularly in the face of acculturation. Cultural stereotyping (e.g., assuming that a person of Chinese heritage is stoic about pain) can contribute to inaccurate assessment and treatment of pain.

Fourth, not all behaviors are culturally based. For instance, a First Nations person who remains nonverbal during a clinical interview may not be signaling a cultural or linguistic tendency, but rather his or her resistance to the clinician's poor interviewing skills. Responses related to overwhelming pain may be void of culture as well. Intolerable pain with its mortifying character, referred to as "unmaking" of the world (Scarry, 1985), is considered a noncultural or even an anticultural experience (Jackson, 1994). The "unmaking" or counterpoint to culture that insurmountable pain may evoke is said to be due to the duration, intensity, and meaninglessness of the experience. Developing competencies to skillfully engage and interview for accurate assessment and corroboration across cultures and linguistic traditions guards against inaccurately assigning cultural significance to behavior.

Finally, in the midst of deterritorialization, the character of modernity whereby ethnic groups and communities, among other social formations, operate according to principles that transcend territorial boundaries and identities (Appadurai, 1991), it is increasingly hard to make specific local cultural assignments. Appadurai suggests that in our deterritorialized world, intertwined by the effects of media, technology, migration, tourism, and global markets, individuals belonging to what were once circumscribed local communities now are invited to imagine and envision alternative lives. Given this aspect of our postmodern world, Appadurai (1991) posits that the notion of symbolic pain may become more extraordinary both for the observer and participants. Among the many implications of Appadurai's forecast, greater cultural variation will require more attention to skillful assessment of personal cultures during clinical encounters. *Personal culture* has been defined by Pack-Brown and Braun Williams (2003) as the "organized, dynamic totality of an individual's identity … comprised of historical, political, and economic dimensions, including religion, work experience, parental status, sexual orientation, gender and so forth" (pp. 230–231).

Understanding culture and its relationship to pain assumes special significance in clinical settings where pain becomes an interpersonal and cross-cultural experience between the consumer and clinician. The culture of Western medicine, prominent and powerful in clinical settings, provides the principal basis for the cross-cultural nature of clinical encounters. The following section briefly

discusses medicine as a culture and potential areas in which cross-cultural tension can arise.

WESTERN MEDICINE AS CULTURE AND POTENTIAL CROSS-CULTURAL TENSION

Most clinical encounters responding to pain can be expected to be cross-cultural and thereby hold the potential for cross-cultural tension. This assertion is more obvious if Western medicine is viewed as the prevalent culture operating in clinical encounters and one that is at odds with those of consumers. Cultures of health care providers, growing in number as many cross national boundaries to fill labor shortages, operate in clinical encounters as well. This section briefly discusses medicine as culture and potential cross-cultural tension as it relates to culture-bound principles.

While some of Western medicine's core values, metaphors, beliefs, attitudes, and themes are not found problematic by some persons, particularly those receiving Western medical training and indoctrination, they may be considered challenging, if not threatening, by persons who are ill and in pain. Persons in pain, feeling highly dependent on others and in-the-present with their pain, may have difficulty accepting medicine's value orientation, which favors activity, mastery over nature, individualism, and future mindedness (see Stein, 1990, for an ethnographical account of American medicine). The potential for tension between clinicians and consumers is appreciated further when key components of Western medicine's world view are considered:

> (1) the "basic sciences": anatomy, physiology, biochemistry; microbiology, pathology; (2) the belief that medical science is and should be based upon rational, scientific, dispassionate, objective, professional judgment; (3) the belief that disease and its attendant suffering are ultimately to be understood in terms of pathological entities, organic in nature, and that treatment optimally consists of a technological procedure or interventions that results in a cure; (4) the belief that medical knowledge and skills are best organized by creating specialties around "organ systems." (Stein, 1990, p. xiv)

Comparing medicine's worldview with that of other groups, particularly those who encounter a disproportionate burden of inequity in the treatment and care of pain, demonstrates that the potential for cross-cultural conflict is substantial. Western medicine's tendency to distinguish illness into distinct mental and physical spheres can lead to conflict with individuals who integrate mind and body with social and natural universes (Ulusahin, Basaglu, & Paykel, 1994). Moreover, the holistic system that is frequently associated with an integrated system of prevention and healing that attributes psychological distress to

physical imbalance and conversely assigns the cause of physical illness to spirits or the evil eye challenges Western medicine's world view (Avila with Parker, 2000; Mirdal, 1985). Similarly, religious medicine across cultures that are grounded in beliefs that pain can be spirit-imposed and that the sacred word or touch can lead to healing (Glucklich, 2001; Littlewood and Dein, 1995) is in direct contrast to Western medicine's worldview. Medicine's worldview as outlined is even at odds with the widely held understanding that pain is a subjective experience influenced by multiple factors that fall outside the basic sciences.

The potential for cross-cultural tension is compounded when values and beliefs that surface in clinical encounters involve major philosophical commitment to what is "good" and what is "bad." For this reason, the potential for cross-cultural tension is considered in relationship to select ethical principles that operate in clinical settings, namely, in decision making. The principles that are considered here include those that hold the most potential for generating cross-cultural tension: autonomy, beneficence, nonmaleficence, and fidelity (for discussion on ethics across cultures, see Braun, Pietsch, & Blanchette, 2000; Farber Post, Blustein, Gordon, & Dubler, 1996; Pack-Brown & Braun Williams, 2003).

Autonomy

Autonomy is a central principle in Western cultures that reflects the core values of individual rights, independence, and self-control (Zaner, 1988). Autonomy receives widespread support publicly, administratively, and legally, yet can be at odds with individuals who are family and group oriented. There is growing evidence that a number of groups, distinguished by age, gender, and ethnicity, prefer alternate models of decision making, models that subscribe to communitarian or hierarchical standards. Autonomy in these groups may be shared with their "families" or transferred to others, including clinicians who may be viewed as holding the knowledge and power needed to make the best decisions. Family-centered models of making decisions have found support in a number of studies (Blackhall, Murphy, Frank, Michel, & Azen, 1995; Morrison, Zayas, Mulvihill, Baskin, & Meier, 1998).

An associated cultural script, that of filial responsibility (Berger, 1998), which refers to the expectation that family members are expected to assist in some manner, may also come into conflict with the principle of autonomy and those who support it. Filial responsibility can cue family members to assist the patient in self-care functions that clinicians desire the patient to do on his or her own. Patients and families who prefer to be together for protective, instrumental, or supportive purposes can be regarded as disruptive and interfering by clinicians who endorse autonomy. Culturally competent clinicians

addressing the relief of pain not only assess the patient's and family's moral basis for making decisions, they assess the role that the family assumes in the treatment and care of pain.

BENEFICENCE AND NONMALEFICENCE

While beneficence refers to the principle to do good, non-maleficence refers to the principle to cause no harm. Because notions of what constitutes "good" and "harm" are value driven and culturally bound, we can expect certain interventions considered "beneficial" by Western standards to be viewed as harmful by some culturally distinct groups. Instances of conflict between varying perspectives of what is "good" and "not harmful" to the consumer system (patient and family) often underlie consumer choice not to take prescribed pain medication or to resist treatment altogether. The clinical challenge is to establish a working relationship built on trust and to rely on strong foundational interviewing skills to accurately assess consumer perceptions of "goodness" and "harm," as well as the basis for their choice to reject treatment. Much research has been committed to examine differing perceptions of what is regarded as "good" and "harmful" treatment (Carrese & Rhodes, 1995; for interesting and detailed account of cross-cultural conflict between Hmong consumers and Western medicine, see Fadiman, 1997).

FIDELITY, VERACITY, OR TRUTH-TELLING

A perceived fundamental duty of clinicians in Western medicine contexts to disclose information of medical status supports values related to self-determination and informed consent (Zaner, 1988). The culture-bound value of "accepting" diagnoses and prognoses, which requires full disclosure of medical status, has encouraged unflinching disclosure by clinicians. Direct disclosure can engender conflict with culturally distinct groups whose members may consider disclosure as inflicting unnecessary pain, such as Latinos (Blackhall et al., 1995), Hmong (Fadiman, 1997), Navajos (Caresse & Rhodes, 1995; McCabe, 1998), and Japanese (Kalish & Reynolds, 1976). Cultural competency calls for accurately assessing consumers' moral code on disclosure (e.g., who determines whether to disclose "truth," when is it shared, who shares it, with whom is it shared, how is it shared, and how much is shared?), in a timely manner. An institutional-level competency related to truth-telling encourages policies that dually protect a consumer's right to determine his or her own moral code on disclosure and the institution's need to guard against potential charges of negligence to disclose.

Attention to the interrelational, cross-cultural, and tension-prone nature of clinical encounters can help anticipate, mitigate, and prevent consumer–clinician conflicts. More importantly, attention to potential cultural misunderstanding and misuse of therapeutic control can help avert inequity in clinical outcomes. The following section summarizes research that addresses inequity in pain relief.

DISPARATE PAIN RELIEF OUTCOMES ACROSS SOCIOCULTURAL GROUPS

A growing body of literature that addresses potential inequity in clinical outcomes related to pain has been evolving and providing evidence that group-based differences, associated with culture, are related to pain-related clinical outcomes. Although this body of literature uses language and ethnicity to reference culture and ignores gender and age as cultural subcategories, its findings are worthwhile noting. A caveat when interpreting these studies is that factors that could help explain disparate outcomes are unknown (e.g., pain attitudes and perceptions, understanding and expectations of treatment, and the nature of patient–clinician interaction).

Select findings from this body of scholarship show that disparities in the treatment of pain by sociocultural categories are not due to chance alone and are evident in fracture treatment (Jones, Johnson, & McNinch, 1996; Todd, Deaton, D'Adamo, & Goe, 2000; Todd, Lee, & Hoffman, 1994; Todd, Samaroo, & Hoffman, 1993), postoperative pain following limb fracture (Ng, Dimsdale, Shragg, & Deutch, 1996), cancer pain (Bernabei et al., 1998; Cleeland, Gonin, Baez, Loehrer, & Pandya, 1997), migraine, and back pain (Tamayo-Sarver, Hinze, Cydulka, & Baker, 2004) and for persons in long-term facilities (Won et al., 1999).

In a particularly notable series of studies, Todd and associates (Todd et al., 1993, 1994, 2000) demonstrated that African Americans and Latinos were significantly less likely to receive analgesia in emergency departments for isolated bone fractures than were Whites, even though physicians rated patients' pain as similar in severity. Findings from a larger-scale study using 1997–1999 National Hospital Ambulatory Medical Care Surveys and involving a substantial sample size ($N = 67,487$) did not show differential administration of analgesics for long-bone fractures in emergency departments, yet revealed that Black patients with back pain and migraines were less likely to receive opioids in comparison with their White counterparts (Tamayo-Sarver et al., 2004). Relevant research suggests that not only may physicians have more negative perceptions of minority patients, but opioids may raise physician concerns that the patient may be seeking opioids in order to satisfy addiction or to sell them (van Ryn & Burke, 2000). Another study that did not find potentially unjust medication patterns for long-bone fractures in an emergency department suggests that hospitals serving larger ethnic minority populations may be best prepared

to address cultural and linguistic difference (Karpman, Del Mar, & Bay, 1997.)

In a study that examined analgesic administration with patients treated surgically for limb fracture (Ng et al., 1996), significant differences by ethnicity in analgesic administration were found. Based on data gathered from chart reviews, the researchers found that while White patients received 22 mg/day of morphine equivalents, their Black and Hispanic counterparts received 16 and 13 mg/day, respectively. The researchers (Ng et al., 1996) suggest that patient–provider interaction during clinical encounters may partly explain differences in analgesic administration.

Findings from studies that focus on cancer-related pain are equally noteworthy. One study reported that 65% of the patients referred to as minority did not receive guideline-recommended analgesic prescriptions for their cancer-related pain compared with 50% of nonminority patients (Cleeland et al., 1997), with Latino patients at primary risk. Another study reported that older persons of ethnic minority groups who have cancer were at risk of receiving less medication or even no medication for daily pain (Bernabei et al., 1998).

Disparity according to age has been reported as well. In one study that examined analgesic administration with patients with fractures, it was found that persons aged 70 and older received less medication and had to wait longer than patients aged 20 to 50 (Jones et al., 1996). A study involving nursing home residents reported that persons older than 85 years, males, or members of non-European White group were less likely to receive pain medication even when pain was acknowledged in the patients (Won et al., 1999). Pain Management Index scores in a study that examined outcomes of pain management and predictors of patient satisfaction in hospitalized Latino patients reporting pain revealed less effective pain management with older persons (McNeill, Sherwood, Starck, & Nieto, 2001).

Disparity in pain management has also been found to vary according to gender. In a study that assessed pain management across groups (Breitbart, Rosenfeld, Passik, McDonald, Thaler, & Portenoy, 1996), it was found that besides patients with less education and those with histories of drug abuse, women were most likely to be undertreated. In another study, women were given analgesics less often and sedatives more often than men by physicians and nurses because they were seen more emotionally labile and prone to exaggerating pain symptoms (Calderone, 1999).

Inequity in pain relief at the community level has been documented as well. A study that examined the distribution of pain medication in neighborhoods (Morrison, Wallenstein, Natale, Senzel, & Huang, 2000) reported that only 26% of pharmacies in predominantly ethnic minority neighborhoods in comparison with their European American counterparts had sufficient opioid analgesics for someone with severe pain.

Although research examining group-based inequality in the treatment and care of pain is at an early stage of development, findings show that disparate outcomes in pain relief are widespread. The commitment to eliminate inequity in pain treatment outcomes directs our attention to multilevel approaches that can contribute to this goal. The following section briefly addresses the importance of language to the topic of culture and pain and provides resources that support efforts to advance cultural and linguistic competency.

THE IMPORTANCE OF LANGUAGE TO CULTURE AND PAIN

Although it has been proposed that pain is uniquely private, subjective, and beyond the construction of language (Daniel, 1991; Scarry, 1985), prevalent discourse on the topic of pain and culture asserts that pain indeed has language (Asad, 2000; Fabrega & Tyma, 1976; Glucklich, 2001; Jackson, 1994), albeit sometimes muted, silenced, and redirected such as through somatization. The function of language to label and communicate bodily sensations and meaning (Villaruel, 1995), besides delivering messages of empathy and hope, points to the need to give language its scientific and clinical due.

While researchers are called to test communication approaches designed to effectively engage linguistically distinct persons affected with pain, clinicians are called to understand culturally and linguistically distinct consumers who use different gestures and terms, even in English, to convey aspects of their pain experience. Both verbal and nonverbal messages need to be accurately interpreted in order to best respond to the pain experience. In turn, the terminology and communication approaches that are used with consumers and their families must be chosen carefully (Salimbene, 2000), even if they are English speaking. Moreover, the clinician is expected to communicate to the consumer what she or he has understood.

Attention to language is particularly warranted given the expanding linguistic diversity across the world and the disparate health care outcomes that are attributed to linguistic difference. Today, as documented by the U.S. Census Bureau (2000), more than 4.6 million people in the United States report not speaking English as their primary language, and more than 21 million report speaking English less than "very well." More astounding is the U.S. Census report that more than 300 languages are spoken in the United States. Persons who report having limited English proficiency are less likely to have a regular source of primary care (Kirkman-Liff & Mondragon, 1991; Weinick & Krauss, 2001); to undergo surgery, such as cholecystectomy (Diehl, Westwick, Badgett, Sugarek, &

Todd, 1993); and to receive preventive care (Woloshin, Schwartz, Katz, & Welch, 1997) and more likely to experience medical errors (Ghandi, Burstin, Cook et al., 1998). Moreover, persons who report having limited English proficiency report less satisfaction with the care they receive (Carrasquillo, Orav, Brennan, & Burstin, 1999; Morales, Cunningham, Brown, Honghu, & Hays, 1999). Ample evidence suggests that failure to address language and cultural issues can result in inferior quality of care, adverse outcomes, and increased health care costs (Baker, Parker, Williams, Coates, & Pitkin, 1996; Flores, Abreu, Olivar, & Kastner, 1998; Flores, Abreu, Schwartz, & Hill, 2000; Harsham, 1984).

Both federal and state laws mandate that health care organizations provide appropriate linguistic access for consumers with limited English language skills. (*Note:* While current reference to consumers who have limited English language skills is *limited English proficient [LEP] patients*, this author prefers to "place consumers first," followed by the descriptive phrase to avoid risk of labeling. The ideal would be to let consumers communicate their preference for how they would like to be categorized.) Accreditation agencies such as the Joint Commission on the Accreditation of Health Care Organizations (JCAHO) and the National Committee on Quality Assurance (NCQA) set standards and monitor compliance in language services, in addition to other health care services. The Office of Civil Rights' (OCR) "Policy Guidance on the Prohibition Against National Origin Discrimination as It Affects Persons With Limited English Proficiency," which applies to part of Title VI of the 1964 Civil Rights Act, aims to ensure equity in critical health and social services to persons with limited English language skills (Ross, 2001). Signed in August 2000, the OCR policy guidance outlines the legal responsibilities of providers who receive federal financial assistance from Health and Human Services (HHS) including:

- Develop a plan for providing written materials in languages other than English
- Establish policies and procedures for identifying and assessing language needs of the individual provider and its client population
- Provide a range of oral language assistance options, appropriate to each facilities circumstances
- Provide notice to persons with limited English language skills of the right to free language assistance
- Provide staff training and program monitoring (Ross, 2001, p. 2)

There are a number of resources available for clinicians and sponsoring institutions that need support in providing linguistic and cultural competent treatment of care:

the Department of Health and Human Services (DHHS) Office of Minority Health (OMH; http:www.omhr.gov); American Translators Association (http://www.ata-net.org); National Center for Cultural Competence (http://gucdc.georgetown.edu); Office for Civil Rights (http://www.hhs.gov/ocr); the American Medical Association's Cultural Competence Compendium (http://www.ama-assn.org/ama/pub/category/3066.html); and Cross Cultural Health Care Program (http://www.xculture.org) to list a few. The National Council on Interpreting in Health Care (NCIHC; http://www.ncihc.org), a multidisciplinary organization dedicated to promoting cultural and linguistic competent care in the interest of health care equity, provides a number of valuable Web site resources including working papers that are relevant to linguistic competence, an evaluation tool to assist organizations in assessing their linguistic needs, and links to related Web sites.

The challenge of arriving at approaches that can most appropriately assess and treat pain across cultures and linguistic traditions demands an array of multilevel competencies in various domains including knowledge, skills, and values. While the notion of achieving a *set of competencies* that permits effective work across cultures is commonly regarded as *cultural competency*, the terms are variously defined and designated (Boyle & Springer, 2001). The assortment of definitions of cultural competency and standards for cultural competency that have been drafted, while begging for uniformity, attest to the importance placed on improving outcomes and eliminating inequity in health care. (The terms *competence* and *cultural and linguistic competence* are defined earlier in this chapter.)

STANDARDS AND APPROACHES FOR MULTILEVEL CULTURAL AND LINGUISTIC COMPETENCIES

Most literature on cultural and linguistic competence primarily focuses on conceptual exploration and neglects the assessment of the theorized structure and outcome of cultural and linguistic competency. There is little evidence available on what cultural and linguistic competencies, applied when and in what fashion, work best. There is less information available on what training or background best conditions specific cultural and linguistic competencies.

Despite the limited direction that scholarship provides in the training, measurement, and clinical application of cultural and linguistic competencies, many human service and health care settings seem to be ambitiously working toward cultural and linguistic competency. Approaches and guidelines for cultural and linguistic competency, largely based on practice, observation and wisdom, have emerged in rapid fashion and are too many to reference here. This section briefly discusses national

standards for cultural and linguistic competency and outlines select multilevel competencies.

STANDARDS FOR CULTURAL AND LINGUISTIC COMPETENCY

The first set of national *Standards for Cultural and Linguistic Competence* in health care delivery, released recently by the OMH (Ross, 2001) of the U.S. DHHS, as a result of the its Cultural and Linguistic Competence Standards and Research Agenda Project, represents an important step toward a more uniform and comprehensive approach to culturally and linguistically appropriate services (CLAS). The 14 standards are based on an analytical review of key laws, regulations, contracts, and competence standards and measures used by federal and state agencies and national organizations. The standards' aims are not only to ensure that services are more responsive to the individual needs of all consumers; the standards aim for health care providers, policy makers, and others in the health care community to create accountability within their organizations for providing equitable, quality services (Ross, 2001).

Evolution of instrumentation to measure and assess the status of cultural-linguistic competency has been slow but is gaining momentum (see Boyle & Springer, 2001, for discussion of well-known measures). As mentioned previously, the NCIHC offers a multilevel process by which health care organizations can evaluate their existing structure and capacity for providing linguistically and culturally appropriate care and accessibility. In a report entitled, *Cultural Competency Methodological and Data Strategies to Assess the Quality of Services in Mental Health Systems of Care: A Project to Select and Benchmark Performance Measures of Cultural Competency,* produced by the New York Office of Mental Health, the Nathan Kline Institute for Psychiatric Research, and Center for the Study of Issues in Public Mental Health (2002), a conceptual framework that explains multilevel pathways toward cultural competency, operationalization of all concepts, and data sources for each measure proposed is offered.

MULTILEVEL CULTURAL AND LINGUISTIC COMPETENCIES

A number of approaches or guidelines to help advance cultural and linguistic competencies in health care have been offered (Bakker, 1995; Flores et al., 2000; Galanti, 1997; Hizar, Shearer, & Giger, 1997; Koenig & Gates-Williams, 1995; Purnell & Paulanka, 1998; Salimbene, 2000; Spector, 2000) and are too many to fully enumerate here. While these guidelines are designated for specific health care settings, consumers, or health statuses, most are similar in that they propose multilevel competencies in the domains of knowledge, skills, and values. Most guidelines are relevant across cultures, settings, and health

or illness focus. This section focuses on summarizing eight competencies that are considered basic for cultural and linguistic competent care. Among the many competencies that have been proposed as important, Table 5.1 provides added information on the competencies that are considered basic by this author:

- Understand self in relationship to others
- Understand culture
- Value cultural beliefs and diversity
- Establish and sustain working relationships
- Recognize linguistic complexity
- Facilitate learning between providers and consumer communities
- Involve community in defining and assessing needs
- Professionalize staff hiring and training
- Institutionalize cultural and linguistic competency

Kleinman's often-quoted set of eight questions (Kleinman, 1988; Kleinman, Eisenberg, & Good, 1978), which is designed to elicit a person's explanatory model for his or her illness, is regarded as a useful guide by many person-centered clinicians who view consumers as experts of their lived-with-pain experience. The questions when addressed and adapted skillfully can be considered a classic approach to cultural competency that holds currency in modernity: (1) What do you call your problem [pain]? (2) What do you think caused your problem [pain]? (3) Why do you think it started when it did? (4) What do you think the sickness [pain] does? How does it work? (5) How severe is the sickness [pain]? Will it have a long or short course? (6) What kind of treatment do you think you should receive? What are the most important results you hope to receive with this treatment? (7) What are the chief problems [and benefits] the illness [pain] has caused? (8) What do you fear most about the [pain]?

CONCLUSION

The moral imperative to treat or palliate pain effectively and appropriately faces the challenge of adjusting to an increasingly diverse consumer base that is not only culturally and linguistically distinct, but subject to a disproportionate burden of disparate outcomes, including inadequate pain treatment. Our commitment to optimally respond to pain and to achieve equity in doing so requires a combination of sustained efforts. Further research on what culture and pain mean as well as on the routes and patterns of cultural influence on pain can provide needed information to improve not only the treatment and care of pain but also its prevention, when appropriate. While efforts to advance cultural and linguistic competency in the treatment and care of pain need continued philosoph-

TABLE 5.1
Approaches to Culturally and Linguistically Competent Care

Understand self in relationship to others
  Become aware of our own cultural background
  Know how our cultural heritage affects our definitions of normality and abnormality
  Recognize the stereotypes and preconceived notions that we hold of others
  Understand how we socially impact others
  Recognize the limits of our competencies and expertise
Understand culture
  Acquire broad knowledge of cultural and subcultural groups
  Regard potential culture-specific information as tentative insight and not an "end point" to understanding
  Understand how subcultural categories based on shared attributes and shared life experiences contribute to a person's "personal culture"
  Recognize the challenges present in understanding culture
  Acquire practical, experience-based knowledge about the community being served (e.g., Chinese teaspoons are generally larger than American ones)
Value cultural beliefs and diversity
  Respect cultural orientation, including beliefs of moral goodness
  Acknowledge decision-making preferences
  Avoid assuming anything
  Avoid making judgments
  Avoid the "golden rule"
  Trust that pain is whatever the consumer says it is
  Communicate acceptance
  Incorporate consumers' models of care with treatment plan
Establish and sustain working relationships
  Develop and use communication and facilitative skills (e.g., empathy, genuineness, warmth) to build trust, accurately assess, corroborate clinical observations, and negotiate conflicts
  Appropriately and accurately assess background, decision-making preferences, and culturally mediated beliefs, theories, and practices related to health, illness, pain, suffering, healing, caring, treatment types, health care providers, families
  Operate from strengths' perspective
  Regard consumer as expert and having the best understanding of the pain, what has helped, what has not helped, and what is likely to help
  Evaluate what beliefs would interfere with your treatment plan
  Effectively explain culture and orientations from which you are operating
  Be conservative in relating news or in providing details of potential complications
  Encourage procedures that affirm consumers' values (e.g., have larger conference rooms and waiting areas for consumers who value family)
  Avoid a treatment plan that conflicts with person's beliefs and lifestyle
  Selectively align treatment strategy with consumer's beliefs
Recognize linguistic complexity
  Recognize the linguistic variation within a cultural group
  Recognize the cultural variation within a language group

TABLE 5.1 (Continued)
Approaches to Culturally and Linguistically Competent Care

  Recognize the variation in literacy levels in all language groups
  Distinguish between translation, interpretation, and medical interpretation
  Receive training to enhance linguistic capacities and increase knowledge of cultural practices
  Contract with telephone interpreter services
  Screen all materials for cultural and linguistic appropriateness
Facilitate learning between providers and consumer communities
  Regard individuals and communities as experts
  Create and sustain "learning loops" between health care providers and consumer communities
  Partner professionals and consumers when providing professional training
Involve community in defining and assessing needs
  Enlist community members in governing boards
  Involve community members in community advisory boards, patient panels, task forces, or neighborhood meetings
  Sponsor community-based research and integrate results into program design
  Affirm that understanding gained from community-based research belongs to communities
Professionalize staff hiring and training
  Establish specific hiring qualifications and mandated training requirements in cultural and linguistic competence
  Develop and provide comprehensive and replicable training curricula
  Allocate funding and time for staff training
Institutionalize cultural and linguistic competency
  Integrate cultural/linguistic competence into all aspects of planning
  Make funding for staffing and training for cultural/linguistic competence sustainable
  Design cultural/linguistic competence activities that can be replicated and developed
  Create procedures that help disclose cultural preferences
  Apply knowledge of cultural beliefs to program areas

ical and administrative support, they will benefit the most by evidence-based direction. Scholarship must be encouraged to develop the methods and analytical tools necessary to best assess the structure and outcomes of cultural and linguistic competency, and must examine these in relationship to consumer, provider, treatment, and organizational characteristics. The development of curricula that emphasize the cultural influence on the pain experience and the examination of what training approaches work best will need continued support if quality and equity in our clinical responses to pain are to be achieved. Workers in relevant disciplines, particularly those who are underutilized in the treatment and palliation of pain, such as social workers, spiritual care providers, and music therapists, need to creatively and, at times, aggressively carve out their niche in research, clinical, and training contexts that aim for appropriate and effective pain care and equity

in clinical outcomes. Finally and perhaps most impor-
tantly, just and effective clinical responses to pain across
cultures are more likely to occur if consumer communities
exercise their strengths and power to advise and govern
the institutions that serve them.

Pain and the Family

Suzanne Young Bushfield, PhD, MSW

INTRODUCTION AND OVERVIEW OF CONCEPTUAL FRAMEWORK

Individuals construct their world of meaning in many ways and within many contexts. Pain is a powerful organizing force; living with pain becomes a central element in shaping the lives and stories of families. To be successful in mediating the experience of pain, practitioners must pay attention to the context in which the pain occurs. As Jerome Bruner (1990) argued, "interpretive meanings are very sensitive to context" (p. 24). Pain is essentially experienced subjectively, and despite attempts to address one's experience of pain objectively, the subjective reality expands beyond the individual's physical condition to include the psychological, sociocultural, and spiritual self. Helping, for the person experiencing pain, may also need to extend beyond the physical and most certainly to family and community. Pain, more than other symptoms, has a powerful potential for negatively affecting one's quality of life. The complexity of the pain experience may require a complex set of interventions and approaches that considers the knowledge, attitudes, beliefs, and practices present in the family, as well as in the larger sociopolitical context in which pain resides.

"Person, environment, and time interact dynamically" (Hutchison, 2003, p. 17). This multidimensional model for understanding human behavior recognizes that effective practice requires attention that is balanced between the uniqueness of the individual in his or her situation and the general knowledge of patterns, derived from theory and empirical research (Meyer, 1993). This tension between the objective reality and the subjective experience seems to characterize the "place" in which the person experiencing pain resides. Incorporating a multidimensional approach to understanding the person in pain demands that we acknowledge the paradox of the person as both free and constrained, and of family and social life as both cohesive and conflicted. This perspective accepts both consistencies and contradictions and will be used to examine the influence of theories of human behavior on direct interventions targeted at the management of pain. A critical review of the evidence of the effectiveness of diverse approaches is expected to yield a greater variety of options, some of which might "fit" the diverse and unique experiences of the person experiencing the common impacts of pain, within a family context.

THE FAMILY DEFINES PAIN

WHAT IS THE FAMILY

The family, two or more people who love and care for each other, is essentially a system with attitudinal, behavioral, and communicational rules; reciprocal roles; and boundaries. "Every event within a family is multiply-determined by all the various forces operating within that system" (Andrae, 1996, p. 606). Families, whether intact or not, retain their primary influence in people's lives. Families revolve around themes and patterns that may be multigenerational, and horizontal as well as vertical (Bowen, 1978; Brown, 1991; Carter & McGoldrick, 1989). Family members must maintain both separateness from and connectedness to families. Major disruptions in the family life cycle always have an impact on its members. These basic principles related to families are important in understanding the role of the family when one of its members is experiencing pain. Early experiences, family traditions and beliefs, ascribed roles, and reciprocal encounters are all essential features of the pain experience within families.

While medicine may categorize pain according to biological, psychological, or idiopathic sources, most pain sufferers become focused on a quest for relief from the pain. Organizing one's life around pain restructures families so pervasively that often, by the time patients present for comprehensive pain management, new patterns of communication, roles, and structures have replaced the family environment that existed before pain became the central organizing feature. The relationships and transactions within the family are shaped by the pain, which becomes the proximal, contingent, and immediate environment (Saleeby, 2004). Acknowledging the importance of family, as well as the reciprocity within family systems, Northen (1994) indicated that "an illness or disability seriously influences the functioning of the family and the functioning of the family seriously influences the course of the patient's rehabilitation" (p. 168). The pervasiveness of family influences on pain is demonstrated in a variety of ways. There is evidence that family support is an important factor in the rehabilitation of chronic pain (Jamison & Virts, 1990), while family enmeshment and rigidity (Liebman, Honig, & Berger, 1976) have been associated with intractable pain. Pain has been called a "metaphor for family dysfunction" (Wynn, Shields, & Sirkin, 1992, p. 3), and chronic pain results in significant structural, communication, role and rule changes within the family system (Marcus, 1986).

What Is Pain

Webster defines pain as "**a**: usually localized physical suffering associated with bodily disorder (as a disease or injury); *also*: a basic bodily sensation induced by a noxious stimulus, received by naked nerve endings, characterized by physical discomfort (as pricking, throbbing, or aching), and typically leading to evasive action; and **b**: acute mental or emotional distress or suffering" (Merriam-Webster, 1991, p. 846). Pain becomes "chronic" when it has been in existence for 6 months and is recognized for its debilitating psychological and social effects (Snelling, 1990). Pain sufferers have very concrete needs, but their lives have been characterized by "a sense of loss of self" (Kelley & Clifford, 1997, p. 276). Just as pain becomes primary in its sufferer's world, it also becomes central in the family's world. There are significant personal and social costs associated with pain: loneliness, isolation, withdrawal and avoidance, anxiety, depression, fear, lack of trust, impaired sexual relationships, loss of productivity, strained marital and family relationships, overuse or misuse of medical care, addiction, and the development of a pain identity (Kelley & Clifford, 1997).

What Is Suffering

The distinction between pain and its companion, suffering, has been explored (Van Hooft, 1998). Mirriam-Webster

(1991) describes *suffering* as: "Deep and poignant distress; a profound and disturbing crisis and threat to one's sense of being that exceeds the bodily sensation is characteristic of suffering" (p. 1179). Recognizing the reality of suffering as larger, more systemic, and more profound than pain allows the practitioner to understand the need for a comprehensive approach to the larger family system, in order to relieve suffering. The practitioner would be well advised to approach the patient and family with competency regarding the diverse cultural and linguistic constructs of pain and suffering. Cultural competence carries requirements of both organizations and personnel to value diversity and manage and adapt to the cultural contexts of the individuals and communities served (Goode, Jones, & Mason, 2002).

INFLUENCE OF THEORETICAL MODELS AND IMPLIED TREATMENT STRATEGIES

There is a rich range of theories found to have significant utility in contemporary practice (Andrae, 1996). This "theoretical plurality" can be both an asset and a hindrance to the practitioner. In the absence of practice-based evidence, theories may prevent us from recognizing alternative explanations. This overview of theoretical models and the treatment strategies for pain that they imply assumes that individuals, families, dyads, groups, and communities turn to professionals for treatment that is ethical, accountable, value sensitive, and effective (Andrae, 1996). Therefore, interventions for which there is a strong theoretical basis, and for which there is sufficient evidence of efficacy, are the primary focus.

Ego Psychology

Ego psychology is built around concepts of ego functions, defenses, ego mastery and adaptation, and object relations (Goldstein, 1996). Pain research based on principles from ego psychology has identified a number of significant contributing factors to the perception and experience of chronic pain, including a history of childhood abuse and family dysfunction (Mersky & Boyd, 1978), physical and emotional abuse (Engel, 1959; Violon, 1980), and increased dependency and the resulting attitudes of caregivers (Berry & Ward, 1995). Effective interventions focus on helping the patient to understand the pain experience and providing short term, ego supportive counseling (Roy, 1981).

While this perspective may imply a focus on the family in terms of reworking family-of-origin issues and addressing current family functioning, its focus is primarily the inner life. There are limitations of the strategies derived from ego psychology due to the reliance on insight for change, and the impact from pathologizing of the person in pain. In addition, negative attitudes toward the patient may further contribute systemically to the patient's

existing damaged sense of self and ability of the patient to feel empowered to control or manage his or her pain. There is further evidence that these negative attitudes are disproportionately experienced by women, minorities, and those for whom power and access to medical care are further limited by societal power structures (Lee, 1994).

BEHAVIORAL APPROACHES

Pain is normally viewed as a warning signal that something is not right; when it persists as chronic pain, it may be influenced by operant mechanisms (Skinner, 1988). The behavioral approach assumes that when pain responses, such as grimacing, complaining, sighing, and moaning, are systematically followed by favorable consequences, such as sympathy, attention, and avoidance of unpleasant tasks, the pain behavior is reinforced and maintained (Hudgens, 1977; Marcus, 1986). The negative role of the spouse in maintaining and perpetuating chronic pain receives considerable focus in this model.

The contingency management approach (Bonica, 1990; Fordyce, 1990) to pain management is widely accepted, and many distinguished pain management programs are derived from this model. Approaches address the patient's self-talk, reframing the situation to promote cognitive restructuring, changing contingencies (reinforcers) within the family, and enlisting family as part of the treatment strategy. The goal of treatment is to help the patient return to normal functioning without pain medications, or with reduced reliance on medication. Pain behaviors are ignored; appropriate activity and interactions are reinforced with attention and praise. The approach may result in the patient learning to live a normal life by ignoring the pain. Changing family interactions and responses to pain is reframed as constructive caring, and the role of the worker in this model is to teach patients with pain and their families to eliminate the subject of chronic pain from their family system interactions (Hudgens, 1977).

Success in this model is highly dependent on several factors: (1) a supportive family amenable to retraining, (2) a patient able to learn new skills, and (3) available community supports to maintain changes (Hudgens, 1977; Marcus, 1986). The behavioral model acknowledges the impact of knowledge and attitudes on pain (Brockopp, Warden, Colclough, & Brockopp, 1996) and may include effective nonpharmacological strategies such as relaxation, imagery, and distraction (Korcz, 2003).

"Family oriented" treatment in this model places a significant focus on modifying the family response behaviors to pain, as an aspect of contingency management. However, manipulation of the environment sometimes requires collusion on the part of the family and may certainly interrupt or change the delicate balance of reciprocity within families. Acknowledging the interconnectedness of systems, it is important to recognize that the unintended consequences of behavioral manipulation may precipitate other, equally intractable problems within the family. The behavioral approach may further fail to recognize the significant attitudinal barriers from health care professionals and others regarding pain, addiction, and the harmful effects of pain medication (Korcz, 2003).

STRENGTHS AND EMPOWERMENT PERSPECTIVES

The empowerment approach makes connections between social and economic justice and individual pain and suffering (Lee, 1996). Drawing from theories on strengths (Saleeby, 1997), empowerment (Gutierrez, Parsons, & Cox, 1998), resilience (Fraser, 1997), hardiness (Kobasa, 1979), and solution-focused philosophies (De Jong & Miller, 1995), these models suggest how people overcome and resist the effects of adversity (McMillen, 1999). While there may be benefits from adversity (McMillen, 1999; Tedeschi & Calhoun, 1995), people with few coping skills, children, and those with low socioeconomic status may be less able to benefit from adversity. Pain management, in this paradigm, will address the strengths of the patient and family through a comprehensive assessment and holistic approach that acknowledges the interdependence and transactional nature of the person in his or her environment (Germain, 1991).

A strengths and empowerment perspective acknowledges the powerlessness that comes from the pathologizing of pain (either physical or psychological), versus the empowerment that derives from a validation of the experience of suffering and its impact on the individual and family. The empowerment process resides in the person, not the helper (Lee, 1996). This model assumes a biopsychosociocultural-spiritual approach to understanding the pain experience and may incorporate a variety of both active and passive techniques for pain management, including relaxation, imagery, distraction, reframing, cognitive reappraisal, patient education, patient involvement, psychotherapy, peer support, and pastoral counseling. Incorporating a humanistic perspective, this model recognizes that living with pain is a life course that calls into question meaning and suffering. People often cope with suffering and pain by seeking and finding meaning (Frankl, 1962). For many people, spirituality is a source of hope in the midst of despair (Puchalski, 2002).

The strengths and empowerment paradigm suggests a holistic approach to pain management and the family, and may include providing additional support and attention to the suffering, in order to assist the sufferer in making sense of his or her world. In contrast to behavioral approaches, exploring the person's historical experiences of pain, the sick role, and care giving and care receiving within the context of the family is both welcomed and advised. There is evidence that the patient experiencing chronic pain needs validation and understanding, both from the health care team and from family and friends (Kelley & Clifford,

1997). This need exists concurrently with concrete needs and the need for very specific coping skills. The REEP model proposed by McMillen (1999) recommends a process of reflecting, encouraging, exploring, and planning benefit, which may assist pain sufferers in constructing changes needed to facilitate recovery and growth.

Professionals addressing pain using the strengths perspective may need to focus on the experience of vulnerable populations and the need for empowerment and advocacy in the processes of accessing resources for pain management (Mendenhall, 2003), recognizing the losses experienced with chronic pain, validating the patient's struggles for survival, and formulating a plan of action to enhance a sense of control over pain, relationships, and lives (Macdonald, 2000). The practice focus in this model may include individual and family empowerment counseling, advocacy, and organization of sufferers into viable advocacy groups to influence research, policy and program construction (Glajchen & Blum, 1995).

INTERLOCKING, INTERCONNECTING, INTERINFLUENCING ASPECTS OF PAIN

A multidisciplinary team approach is necessary to maximize the potential for effectively addressing the biological components of pain both pharmaceutically and with other medical aspects; the psychological components of pain, taking multidimensional perspectives into account; the sociocultural context of pain for the person in his or her family and environment; and the spiritual components of pain, especially the meaning of pain and suffering to the individual and family. Evidence of health system inflexibility, lack of role definitions in health care, cultural and attitudinal barriers, and knowledge deficits in pain management among health care professionals all suggest that approaches must be interlocking and interconnecting with respect to direct service, education, advocacy, and research (Glajchen & Blum, 1995).

FUTURE DIRECTIONS FOR PAIN AND THE FAMILY

As the field of pain management undergoes rapid changes and development of new techniques, drugs, and intervention strategies, it is necessary for practitioners who focus on pain relief to stay current. In addition, understanding the rapid social changes affecting the family and roles within families may suggest successful approaches to pain management in the context of family. Research trials in recent years have included attention to the efficacy of alternative medicine and complementary approaches. As evidence is established for new resources, practitioners will need to disseminate this information and knowledge so that patients and families are better able to make use of new discoveries. The study of alternative approaches, including acupuncture, massage, touch, meditation, and prayer, combined with new developments in genetics, scanning, and understanding of the neurobiology of pain and addiction, may yield entirely new approaches to pain management. In addition, greater recognition of the role of the larger community and social supports for the family may offer additional resources in managing chronic pain (Subramanian, 1991).

Policies that recognize the unique needs of women, children, minorities, and disadvantaged groups may address some of the contextual issues in which pain resides. How society responds to pain and those seeking relief is closely tied with ethical and policy issues. Continued research will need to incorporate an understanding of how social justice influences care for those experiencing pain.

The power of expectation, meaning, possibility, and intentionality may be one of the "next frontiers" in pain management. Support and acceptance of alternative resources, "what works," and the sharing and validating of these personal experiences and stories often provides pain sufferers and their families with necessary relief.

Recognizing the true anatomy of pain and suffering may need to include hope. "Cross cultural practitioners consistently report that hope is an important curative factor in all cultures and societies. The more one has hope about the power or potential for help in the healing relationship or healing process, the greater the chance that the healing process will be effective" (Harper & Lantz, 1996, p. 10).

Sex, Gender, and Pain: Clinical and Experimental Findings

Roger B. Fillingim, PhD, and Barbara A. Hastie, PhD

INTRODUCTION

DEFINITION OF SEX AND GENDER

In recent years, burgeoning evidence indicates sex and gender differences in pain in both clinical and experimental settings. In order to discuss these findings, it is helpful to understand the distinction between "sex" and "gender." Specifically, *sex* refers to biological substrates that clearly distinguish an organism as "male" or "female" in terms of their genetic composition including chromosomes (XX for females and XY for males), hormones, anatomy, and the subsequent development of secondary physical characteristics, which place the organisms in the category "female" or "male" (Frable, 1997; Hughes, 2003; Pollad & Hyatt, 1999; Wizemann & Pardue, 2001). Gender refers to the way in which an individual is defined based on socioculturally shaped behaviors and traits (such as femininity and masculinity) that are an amalgam of the psychological, social, and cultural factors that influence it (Pollard & Hyatt, 1999; Robinson et al., 2000; Wizemann & Pardue, 2001). Other theorists define gender as "the structured set of gendered personal identities that results when the individual takes the social construction of gender and the biological 'facts' of sex and incorporates them into an overall self-concept." (Ashmore, 1990; Pollard & Hyatt, 1999; Robinson et al., 2000; Wizemann & Pardue, 2001). It is important to recognize that gender roles are sculpted by both biological and social factors. Indeed, the relevance of social learning and its effect on sex differences in pain modulation have been presented from a neurobiological perspective (Choleris & Kavaliers, 1999).

Historically, before the 1970s, the term *gender* was glaringly absent from biomedical research literature (Ashmore, 1990; Choleris & Kavaliers, 1999; Greenberger, 2001; Pollard & Hyatt, 1999; Robinson et al., 2000; Wizemann & Pardue, 2001). In the 1970s, the movement toward equality of genders downplayed any differences either inadvertently or, in some cases, by conducting research in strictly uni-gender samples. Noting the grave inequalities in treatment as well as overrepresentation of one gender with certain pain conditions, there has been a movement in the past decade not only to study sex and gender differences but also to create models of testing and understanding the nature and origins of such differences.

Thus, in contrast to gender, it is important to highlight that the term "sex" is used exclusively for nonhuman animal investigation, as it is practically impossible to operationalize gender roles in nonhumans. Conversely, in human pain research, it is entirely possible for both sex and gender to contribute to the individual's experience of pain. Fillingim and Maixner (1995) previously proposed an interactive model of pain that encapsulated neurobiological, physiologic, hormonal, and genetic factors that dynamically and interchangeably influenced and were affected by psychological (affective), cognitive, and sociocultural factors (e.g., social learning, gender role, etc).

Thus, whereas the study of sex differences in pain may be more straightforward in nonhumans, it is extraordinarily complex in humans because it seems to be a dynamic and fluid interplay of both sex and gender. Thus, it is critical to make the distinction between sex and gender and to study their mutual, yet varying, influences

on a person experiencing pain. The influence of sex versus gender is not a philosophical principle, but an empirical question, particularly with regard to health outcomes. Moreover, it is important to note the distinctions since not only can gender aspects affect expression of pain as well as the interpretation of biological traits, and the experience of pain, but also sex-related biological characteristics can contribute to, diminish, or amplify gender differences in pain.

INTEREST IN SEX, GENDER, AND PAIN

Interest in sex, gender, and pain has proliferated in the past decade. This amplified interest has been accompanied (and perhaps driven) by increased federal funding for research on this topic. This proliferation of research likely reflects the growing attention to the issue of gender in the laypublic (e.g., Mars and Venus), but also is fueled by novel findings documenting important sex differences in the neurobiology of pain in preclinical investigations. This has sparked concerted efforts to conduct translational research to the human dimension (e.g., Mogil et al. (175)). These efforts have been coupled with resurgence in clinical attention to sex and gender differences, such that clinical scientists have applied the preclinical and experimental findings to gender and sex differences in clinical treatment and outcome. Yet, despite this remarkable growth in the spectrum of research on sex and gender differences in pain, it is still a relatively nascent field of exploration.

The purpose of this chapter is to review the literature regarding sex, gender, and pain. This includes results of community surveys, epidemiological investigations, and clinical research in specific pain conditions that have addressed the issue of gender-related differences in pain. In addition, findings from human laboratory research and nonhuman animal studies are also presented. Potential mechanisms underlying sex and gender differences in pain are discussed, and important future directions for research on sex, gender, and pain are proposed.

SEX, GENDER, AND CLINICAL PAIN

COMMUNITY SURVEYS

As early as 1985, one of the first community surveys on pain in the United States was conducted. The Nuprin Pain Report was a national survey conducted on a random sample of 1254 adults. It was the first nationwide survey to provide quantitative data on pain prevalence and severity, demographic characteristics of pain sufferers; how people cope with pain; the relationship between pain and stress; the relationship between pain and health locus of control scales; use of medical and other professionals in the treatment of pain; the relationship between pain and different lifestyles and behavior patterns; and the impact of pain on work and other activities (Sternbach, 1986; Taylor & Curran, 1985). Gender was essentially a demographic variable (50.2% male; 49.8% female) and women were divided into "homemakers" and "working mothers" and men had the designation of executives, floor trader, professional/managerial/proprietor, sales/service, skilled and unskilled labor (Taylor & Curran, 1985).

Results from the survey showed that compared with men, women reported more headaches and were more affected than men in their daily activities by headache-related pain. The Nuprin Report also found that women experienced backaches, joint pains, and stomach pains slightly more than men (Taylor & Curran, 1985). Subsequently, the American Pain Foundation conducted surveys in various states to determine the extent to which pain affects the average citizen. Their findings revealed that more than 55% of the general population in different states experienced pain in the moderate to severe range and more than 40% face some kind of chronic pain condition and women seemed to outnumber men in each of the types of pain (American Pain Foundation, 2002). Other community surveys have revealed similar findings such that in general U.S. populations, women tended to report higher prevalence of several types of pain (Riley et al., 1998; Scudds & Robertson, 1998; Verhaak et al., 1998; Von Korff et al. 1988), and additional data suggest that these sex differences are most robust in middle age (LeResche, 1997; Riley & Gilbert, 2001; Verhaak et al., 1998; Von Korff et al. 1988). Specifically, women are more likely than men to experience recurrent headache disorders in each type except cluster headache (Holroyd & Lipchik, 2000; Lipton et al., 2001; Schwarts et al., 1998; Stewart et al., 1992). Women are also reported to have greater frequency than men in experiencing joint pain, abdominal pain, including irritable bowel syndrome, fibromyalgia, oral pain, specifically temporomandibular disorder (TMD), and low back pain (Barsky et al., 2001; Buckwalter & Lappin, 2000; Chang & Heitkemper, 2002; Drangsholt & LeResche, 1999; Wolfe et al.,. 1995; Wolfe et al., 1995).

In other population-based surveys, compared to men, women reported greater frequency of pain-related symptoms across multiple age groups (Buckwalter & Lappin, 2000; Croft et al., 2001; LeResche, 1999; Unruh, 1996). Furthermore, compared to men in the general population, women experienced more disruption, distress, and disability from pain (Affleck et al., 1999; Keefe et al., 2000; Leveille et al., 2000; Sandanger et al., 2000; Soares & Jablonska, 2004). In addition, other investigators found women to report more frequent use of analgesics (Eggen, 1993; Isacson & Bingefors, 2002). However, some researchers have reported increased disability among men compared to women with conditions such as low back pain in middle adulthood (Kostova & Koleva, 2001; Walsh et al., 1992).

Cultural influences on sex differences in pain are only beginning to be addressed. Thus, community surveys in cultures other than those represented in American and Western European countries are few in number. Consequently, it is acknowledged that pain experiences and expression may vary by cultures and gender-related issues such as social roles may play a part in differences displayed (Costa et al., 2001). The notion of cultural factors influencing responses to accident-related pain and subsequent development of chronic pain conditions has been briefly explored. Accident victims from Eastern European countries do not appear to report the chronic pain-related symptoms to the extent that are reported in many Western societies, including the United States (Ferrari et al., 1999; Obelieniene et al., 1999). There is evidence that coping styles, environment and other psychosocial factors across and within countries may influence recovery and pain conditions (Buitenhuis et al., 2003; Ferrari et al., 2003; Maraste et al., 2003; Miettinen et al., 2002); whether gender contributes to these sociocultural differences in pain expression has not been determined. Thus, in epidemiological studies, sex differences in pain report emerge across multiple countries and in various pain conditions; however, the extent to which these differences are due to sex differences in pain reporting versus sex differences in the experience of pain is not known (Vallerand, 1995).

EPIDEMIOLOGICAL FINDINGS

Considerable data on sex differences in pain prevalence and incidence arose inadvertently from population studies that were focused on specific diseases and pain as a secondary aspect of such health conditions (Gordis, 1988; LeResche, 1999; Unruh, 1996). When discussing gender-related differences, it is important to consider the three salient theoretical perspectives from an epidemiological perspective that include population, developmental, and ecological views (LeResche, 1999). Briefly, the population view espouses that to understand pain conditions fully, they must be examined from general populations and not just from those in treatment centers (e.g., with preexisting pain conditions). The second view, the developmental approach, asserts that it is critical to investigate pain across the lifespan since factors that influence risk may change with age and the prevalence may vary between genders at different points in the life cycle. The ecological perspective of epidemiological research promotes that any disease is a product of a combination of disease agents (e.g., genetics/biological), characteristics of the host (e.g., psychological), and the environment (e.g., social), which is highly consistent with the biopsychosocial model of pain (LeResche, 2000).

Epidemiological findings related to pain have identified several common recurrent pain conditions that differ in frequency among women and men. These include head-

ache, migraine, facial/oral pain, musculoskeletal pain, back pain, and abdominal pain (Crombie et al., 1999; LeResche, 2000; Unruh, 1996). It should be noted that the findings discussed below come predominantly from investigations conducted in North America or Western Europe. These results must be interpreted in light of the possibility that the sex differences in the prevalence of pain may vary depending on geographic region as well as sociocultural and ethnic factors.

One of the advantages of epidemiological studies in pain is that the findings can lend explanation to magnitude of differences observed as well as risk factors in gender-specific prevalence. This is especially useful because several recent reviews of gender-related differences in pain have revealed that women have higher prevalence of pain in many different conditions and across several settings (Barsky et al., 2001; Berkley, 1997; Fillingim & Maixner, 1995; Unruh, 1996). Epidemiological research adds specificity in that women are more likely than men to report temporary or chronic pain, and it tends to be more severe, more frequent, and of longer duration than men (Andersson et al., 1993; Blyth et al., 2001; Crombie et al., 1999; Taylor & Curran, 1985; Unruh, 1996). A brief description of the most prevalent pain conditions will ensue. For a more in-depth analysis of these issues, the reader is referred to the publication by the International Association for the Study of Pain, *Epidemiology of Pain* (Crombie et al., 1999).

Back Pain. Some evidence suggests that back pain is more common among females than males (Balague et al., 1999; Hartvigsen et al., 2003); however, other data suggest minimal sex differences in the prevalence of back pain (Croft et al., 1999; Leboeuf-Yde & Kyvik, 1998; LeResche, 2000; Wedderkopp et al., 2001). Nevertheless, what is conclusive is that back pain is variable across the lifespan with changing levels of debilitation depending on the etiology and other factors often not addressed in epidemiological studies. Moreover, factors other than gender, such as genetics, occupation, socioeconomic issues, and cultural influences, may represent more important predictors of back pain (Croft et al., 1999; Leboeuf-Yde, 2004; LeResche, 2000).

Headache and Migraine. Investigations predominantly in the United States and Western Europe have reported higher rates of headaches in women than men with the exception of cluster headache (Holroyd & Lipchik, 2000; Lipton et al., 2002; Schwartz et al., 1998; Stewart et al., 1992). However, studies from myriad worldwide populations have provided some conflicting evidence, depending on the population in question (Scher, Stewart, & Lipton, 1999). A comprehensive overview of national and international studies is addressed in-depth in the International Association for the Study of Pain's (IASP) Publication entitled *Epidemiology of Pain* (Scher et al., 1999). Despite some discrepancies between studies in prevalence, based on 29 epidemiological studies, inves-

tigators report that the prevalence of headache in men appears as a flat slope across the lifespan, while in women, it appears flat until reproductive age, where there is an increase, and then a significant drop after age 60 (Scher et al., 1999). LeResche (2000) reports that in a lifetime, 60% of males and 75 to 80% of females will report experiencing headache at some point, although in women it tends to decrease with age. Thus, what is typically not contested is that even when the prevalence curves take similar shape, women tend to experience headaches in much greater number, frequency, duration, they tend to be more debilitated by them, and the female:male ratio seems to be most marked in migraines (Celentano et al., 1992; LeResche, 2000).

Abdominal Pain. Population-based studies of gastrointestinal functional-related abdominal pain have revealed a higher frequency and severity in women than men across all ages (Adelman et al., 1995; Agreus et al., 1994; Chang & Heitkemper, 2002; LeResche, 2000; Mayer et al., 1999). Moreover, the prevalence in both genders seems to be steady until the age of 40, at which time, there is a trend to decline (Unruh, 1996). However, no gender differences in onset of abdominal pain were reported in one large prospective epidemiologic investigation (Halder et al., 2002).

Joint Pain/Fibromyalgia. Women are at greater risk for joint pain and fibromyalgia/chronic widespread pain compared to men. In accordance with diagnostic criteria from the American College of Rheumatology, population studies report that women are at greater risk and have higher prevalence for both joint pain and fibromyalgia (Buckwalter & Lappin, 2000; Gran, 2003; Wolfe et al., 1995). Women and girls also report more painful sites, more intense pain, and more frequent pain (Anderson et al., 1993; Hasvold & Johnsen, 1993; White, Speechley, Harth, & Ostbye, 1999). Interestingly, the prevalence curves for men and women are similar, with an increase until approximately age 65, then a slight decrease between 65 and 74 years of age, and a gradual increase after that (LeResche, 2000; Macfarlane, 1999).

Orofacial Pain/TMD. Most epidemiological studies on orofacial pain/TMD report that women have higher prevalence as well as more pain and tenderness in jaw muscles and temporomandibular joint, and other researchers have found increased sensitivity and decreased pain tolerance and threshold in women with such disorders (Sallfors et al., 2003; Wahlund, 2003). Notably, the prevalence seems to increase sharply for females during adolescence (Pilley et al., 1992; Sallfors et al., 2003). Peak prevalence for both sexes is typically between the ages of 40 and 50 years old, (Goulet et al., 1995; Macfarlane et al., 2001; Von Korff et al., 1988) and these findings seemed to be consistent in other Western countries (Sipila et al., 2001; Wahlund, 2003). There are limited studies addressing gender-related differences in adolescents although the

same trend seems to emerge with girls reporting increased prevalence, and more pain and symptoms compared to boys (List et al., 1999; Wahlund, 2003).

These epidemiological findings offer strong evidence that in contrast to men, women are more likely to report pain at multiple body sites and they tend to be more at risk for developing certain chronic pain disorders such as TMD, fibromyalgia, irritable bowel syndrome, migraine headache, and other forms of musculoskeletal pain (LeResche, 1999; Unruh, 1996). It is important to highlight that most of these epidemiological data address adults, although a number of studies have found similar trends in children and adolescents with a higher prevalence and severity in girls compared to boys (Haugland et al., 2001; McGrath, 1999). Despite the absence of information regarding potential cultural influences, these data offer compelling evidence that women are at greater risk for developing several chronic pain conditions compared to men. Whether the *severity* of pain in clinical settings differs in women and men is now discussed.

SEX DIFFERENCES IN CLINICAL PAIN SEVERITY

Sex differences have been investigated in the acute clinical pain setting. For example, women reported greater pain than men following oral surgery as well as orthopedic and other surgical procedures (Averbuch & Katzper, 2000; Taenzer et al., 2000). Women have also reported higher pain ratings in acute cancer-related pain (Cepeda et al., 2003), procedural pain such as colonoscopy (Froehlich et al., 1997); and conditions presented in emergency rooms (Boccardi & Verde, 2003). A recent review article addressed the issue of gender-related risk in developing post-whiplash-related chronic pain condition(s) following acute injury and females were at increased risk given their initial presentation of more severe pain in the acute stage (Scholten-Peeters et al., 2003). These data highlight the importance of possible gender-correlated complications in the acute pain stage particularly that high initial pain intensity is often an important predictor for delayed functional recovery, which is consistent with the involvement of central centralization in the development of — or transition to — a chronic pain condition.

Additionally, research into gender-related differences in children's pain is a growing area of investigation. Despite the need for more empirical evidence, some studies have found that girls tended to report more pain than boys from venipuncture (Goodenough et al., 1997, 1999); although other investigators have found no sex differences among children undergoing certain medical procedures (Lander et al., 1989, 1990). To date, few investigators have examined any gender-related influences on pediatric procedural pain and more research is needed to identify such differences.

As reviewed above, there are clear gender differences in the prevalence of several chronic pain disorders; however, the evidence supporting differences in the severity of pain-related symptoms within chronic pain populations is less compelling. For example, among individuals with pain that limited their activity, women reported more frequent pain, greater pain-related affective symptoms, and higher pain-related disability compared to men (Mullersdorf & Soderback, 2000). Women reported higher levels of arthritis pain and disability than men (Affleck et al., 1999; Keefe et al., 2000), and at the time of total hip arthroplasty women reported higher levels of pain and disability than men (Holtzman et al., 2002). Similarly, pain among patients with multiple sclerosis was more frequent and severe among women (Warnell, 1991). Also, in a heterogeneous chronic pain population recruited from a multidisciplinary pain clinic, women had higher pain severity than men (Fillingim et al., 2003). However, other investigators have reported minimal sex differences in pain severity in heterogeneous chronic pain populations (Edwards et al., 2003; Robinson et al., 1998; Turk & Okifuji, 1999). Also, no sex differences in measures of clinical pain, experimental pain sensitivity, psychological/personality factors or illness behaviors were reported among patients with pain due to TMD (Bush et al., 1993). A recent study found that men had higher levels of pain and poorer pain-related adjustment in a sample of patients seeking treatment primarily for myofascial pain in a multidisciplinary clinic (Marcus, 2003). Taken together, these findings suggest that sex differences in the severity of pain-related symptoms are inconsistent among patients with chronic pain in clinical settings. This lack of differences could reflect the selection bias introduced by the decision to seek treatment.

SEX DIFFERENCES IN RESPONSES TO NOXIOUS EXPERIMENTAL STIMULI

Overall, the literature reviewed above indicates that women experience greater clinical pain than men. While multiple factors inevitably determine these sex differences in clinical pain, we have previously proposed that enhanced pain sensitivity among women may be an important contributor (Fillingim & Maixner, 1995). Before reviewing the experimental literature on sex differences in pain perception, a brief discussion of experimental pain methods will be provided. Multiple noxious stimuli are used in examining laboratory pain responses, and they differ along important dimensions, including temporal and spatial qualities, anatomical site stimulated, specificity of afferent fibers stimulated, and whether the evoked pain mimics clinical pain. Thermal and mechanical stimuli are the most commonly used methods, due to their ease of administration and convenience. It is important to recognize that when multiple pain assays are conducted in the same subjects, correlations across pain stimuli are generally low (Janal et al., 1994; Lautenbacher & Rollman, 1993). Thus, different stimulation method(s) can yield discrepant results; therefore, using multiple stimulation methods that differ along important dimensions often will be most informative.

In addition to the varieties of noxious stimuli available, the methods for assessing pain-related responses must also be considered. Pain threshold (i.e., the minimum amount of stimulation required to produce a pain) and pain tolerance (the maximum amount of stimulation an individual is willing to endure) are common measures. While these responses are intuitively appealing and quantitative, they are unidimensional in nature, which makes it difficult to disentangle the behavioral, affective/motivational, and sensory components of the responses. Numerous scaling methods are available for determining perceptual responses to noxious stimuli, such as numerical rating scales, visual analog scales, and multiple item scale (e.g., the McGill Pain Questionnaire). These methods offer the advantages of permitting assessment of multiple pain dimensions and determining responses to stimuli dispersed throughout the noxious range (e.g., stimulus–response functions). A complete discussion of pain assessment methods is beyond the scope of this chapter, but the interested reader can find more detailed information elsewhere (Arendt-Nielsen & Lautenbacher, 2004; Jensen Karoly, 2001).

Numerous studies have investigated sex differences in responses to experimentally-induced pain, and both qualitative (Berkley, 1997; Berkley & Holdcroft, 1999; Fillingim, 2000; Fillingim & Maixner, 1995) and quantitative (Riley et al., 1998) reviews of this literature are available. To summarize the findings of these reviews, women display lower pain threshold and tolerance and generally report higher ratings of experimental pain compared to men. A meta-analysis revealed that the effects sizes for sex differences in pain threshold and tolerance were moderate, and the magnitude of the sex difference varies across pain stimuli (Riley et al., 1998). The least consistent results emerged from measures of thermal pain sensitivity.

Since the publication of these reviews, additional data addressing sex differences in experimental pain responses have been reported. For example, we (Fillingim et al., 1998) previously reported that, relative to men, women displayed greater temporal summation of thermal pain, and these findings have since been replicated and extended. Specifically, Robinson et al. (2004) reported greater temporal summation of thermal pain among women and that psychological factors, including anxiety and willingness to report pain, partially mediated this sex difference. Also, Sarlani and Greenspan (2002) reported greater temporal summation of mechanical pain among women than men. Cairns and colleagues (Cairns et al.,

2001; Svensson et al., 2003) reported that injection of glutamate into the masseter muscle produced higher peak pain, longer lasting pain, and a greater area of pain among women compared to men, consistent with their finding that glutamate injection evoked significantly greater muscle afferent activity among female compared to male rats.

These findings from humans are supported to some degree by findings from nonhuman animals. Several investigators have reported greater behavioral responses to laboratory pain stimuli among female compared to male rodents (e.g., (Barrett et al., 2002, 2003; Terner et al., 2003); also for reviews see (Berkley, 1997; Bodnar et al., 1998)), while others report no such differences (Kayser et al., 1996; Mogil et al., 1993). In a particularly large study, which included 8000 observations of thermal nociceptive responses in mice, females exhibited enhanced sensitivity relative to males (Chesler et al., 2002). In contrast, studies of nonhuman primates suggest greater nociceptive responses in males than females. As a whole, nonhuman animal findings seem to show less-consistent and smaller-magnitude sex differences in basal nociceptive sensitivity compared to the human literature. This is likely related to multiple factors, such as genetics, differences between nociceptive assays used in nonhumans and humans, and greater involvement of psychological factors in humans, which are discussed in more detail below.

SEX DIFFERENCES IN RESPONSES TO ANALGESIC MEDICATIONS

In addition to basal pain sensitivity, sex-related influences on responses to analgesic drugs have been reported. The antinociceptive effects of several pharmacologic agents in animals have been found to be sex dependent. Specifically, male rats exhibit greater analgesic responses to both μ and opioid agonists (Bodnar et al., 1988; Cicero et al., 1996; Cicero et al., 1996, 1997; Craft, 2003a, 2003b; Islam et al., 1993; Kepler et al., 1989; Kepler et al., 1991; Kest et al., 2000; Kiefel et al., 1992). Sex differences in morphine-induced analgesia occur following either systemic or central intracerebroventricular administration (Berglund & Simpkins, 1988; Bodnar et al., 1988).

In contrast to these findings from rodents, Miaskowski and Levine (1999) reviewed studies of patient-controlled analgesia after surgery and found that in more than half of the studies women consumed significantly less opioid medication than men; however, analgesic responses were not directly assessed in most of these studies. Additional clinical investigations that assessed both pain and opioid consumption provide contradictory findings. For example, a large study recently demonstrated that women consumed substantially less opioid medication postoperatively and females had similar or lower postsurgical pain ratings than males (Chia et al., 2002). In contrast, Gordon and col-

leagues (1995) reported no sex differences in the analgesic effects of morphine administered after oral surgery. Likewise, Kaiko et al. (1983) reported no sex differences in morphine analgesia in a large sample of patients with chronic cancer pain. More recently, Cepeda and Carr (2003) found that women required 30% more morphine than men to achieve comparable levels of postoperative analgesia. In another series of studies examining analgesic responses to -agonist-antagonists using an oral surgery model, women showed greater analgesic responses to pentazocine and more prolonged analgesia to nalbuphine and butorphanol (Gear et al., 1996) compared to men. Also, low-dose nalbuphine (5 mg) increased pain ratings in men but not women, while higher doses (10 and 20 mg) produced analgesia of longer duration in women than men (Gear et al., 1999). More recently, among 94 patients (45 F, 49 M) presenting to the emergency department with trauma-related pain, butorphanol produced greater pain relief than morphine for women, and there was a trend toward greater morphine analgesia in men than in women (Miller & Ernst, 2004). Taken together, these clinical findings suggest more robust analgesic responses to -agonist-antagonist medications among women, but sex differences in μ-opioid analgesia are less consistent.

Sex differences in responses to opioids have also been investigated with experimental pain models. Sarton and colleagues (Sarton et al., 2000) examined morphine analgesia among 10 healthy women and 10 healthy men using an electrical pain model. Women showed greater analgesic potency but slower onset and offset of analgesia. These authors had previously reported greater morphine-induced respiratory depression among women than men (Dahan et al., 1998; Sarton et al., 1999). More recently, they reported no sex differences in analgesic responses to morphine-6-glucuronide, an active metabolite of morphine (Romberg et al., 2004). Zacny (2002) reported that the μ-opioid agonists morphine, meperidine, and hydromorphone produced greater analgesic responses among women than men using cold pressor pain, but no sex differences in analgesia emerged for pressure pain. Using a substantially larger sample size than previous investigators (41 F, 38 M), we recently reported that there were no sex differences in pentazocine analgesia for pressure, thermal, and ischemic pain (Fillingim et al., 2004). Thus, evidence from laboratory studies suggests that women may experience greater μ-opioid analgesia for some pain assays than men, and the only experimental study of a -agonist-antagonist found no sex difference in analgesic responses.

The evidence reviewed above presents an inconsistent picture of sex differences in pain and analgesic responses, since the presence, direction, and magnitude of the differences reported seem to vary across pain assays and patient populations. It is also important to note that these findings refer to quantitative sex differences; i.e., do women and men differ in the amount of pain or analgesia

that they display? Of potentially greater importance are qualitative sex differences in pain and analgesia; i.e., do certain factors (e.g., genetics) moderate pain and analgesic responses differently in women versus men? Such differences are particularly compelling as they may indicate sex-specific mechanisms underlying individual differences in pain and analgesia.

MECHANISMS UNDERLYING SEX DIFFERENCES IN PAIN

Before discussing the mechanisms underlying sex differences in pain responses, some general interpretive issues should be noted. First, an individual's sex (i.e., male vs. female) is not the cause of the observed group differences; rather, sex represents a convenient grouping variable that is a surrogate for potentially clinically and scientifically important biological and psychosocial factors. Second, there are two types of sex differences that should be considered, quantitative and qualitative differences. Quantitative sex differences refer to whether women and men differ in the amount of pain or analgesia that they display, and these are the most common conceptualization of sex differences. Of potentially greater importance are qualitative sex differences in pain and analgesia, which relates to whether certain factors (e.g., genetics, anxiety) influence pain-related responses differently in women versus men. Such differences are particularly compelling as they may indicate sex-specific mechanisms underlying individual differences in pain. Thus, the following discussion of mechanisms underlying sex differences in pain is relevant to both quantitative and qualitative differences.

It is important to recognize that sex differences in pain are inevitably mediated by multiple biopsychosocial factors, including basic biological mechanisms such as genetic and hormonal influences as well as sex differences in the functioning of pain modulatory systems. In addition, psychosocial factors represent important mediators of sex differences in pain responses. Examples include cognitive/affective variables (e.g., pain coping, mood, expectancies), gender role influences, and family history. While these mechanisms are frequently described as either psychosocial or biological, this conceptualization is artificial and is based more on the level of analysis than on the actual mechanism of action. For instance, sex differences in expression of pain are often attributed to the effects of stereotypic sex roles, which is typically viewed as a psychosocial issue. However, we must remember that there are neurophysiological correlates of masculine versus feminine sex roles, which may be related to differences in nociceptive processing. Thus, the "psychosocial" and "biological" mechanisms mediating sex differences in pain responses could refer to the same fundamental processes described at different levels of analysis.

Several "biological" processes have been proposed to explain sex differences in both clinical and experimental pain responses. Considerable evidence suggests that gonadal hormones are important. The clinical symptoms of several pain disorders vary across the menstrual cycle (Anderberg et al., 1999; Heitkemper & Jarrett, 1992; Keenan & Lindamer, 1992; LeResche et al., 2003), and exogenous hormone use has been associated with increased risk for or severity of clinical pain (Brynhildsen et al., 1998; LeResche et al., 1997; Musgrave et al., 2001; Wise et al., 2000). Similarly, responses to experimentally induced pain vary across the menstrual cycle in healthy women (Fillingim & Ness, 2000; Riley et al., 1999), and postmenopausal women taking hormone replacement show enhanced sensitivity to thermal pain compared to age-matched women not on hormone replacement (Fillingim & Edwards, 2001). Sex differences in analgesia may also be influenced by both organizational (i.e., long-term developmental influences) and activational (acute, receptor-mediated) effects of sex hormones (Cicero et al., 2002). A review by Fillingim and Ness (2000) concluded that, among female animals, high estrogen levels were associated with diminished opioid analgesia, which suggests activational effects of estrogen on antinociceptive responses. Cicero and colleagues (2002) found that neonatal but not adult castration significantly decreased morphine analgesia in male rats, and neonatal testosterone treatment enhanced morphine analgesia in females. Likewise, neonatal castration in males reduced the analgesia produced by morphine injected into the ventrolateral periaqueductal gray (vlPAG), while neonatal testosterone in females increased vlPAG morphine analgesia (Krzanowska et al., 2002). Thus, opioid antinociception is influenced by both activational and organizational effects of gonadal steroids. However, hormonal effects may depend on which opioid receptor subtype is activated, as it has been reported that estrogen-attenuated analgesia for μ- but not κ-opioid agonists (Sandner-Kiesling & Eisenanh, 2002). To date, limited information is available regarding hormonal effects on analgesic responses in humans.

In addition to the influence of sex hormones, endogenous pain inhibitory systems may function differently in females and males. Male rodents exhibit more robust stress-induced analgesia (SIA) than females (see Berkley, 1997; Sternberg & Liebeskind, 1995 for reviews), and SIA appears to be mediated by different neurochemical mechanisms in females and males (Kavaliers & Choleris, 1997; Mogil et al., 1993). Recent findings from humans demonstrated that tonic experimental muscle pain produced a greater decrease in μ-opioid receptor availability in several brain regions among men compared to women, apparently due to increased pain-induced binding of endogenous ligand to the receptor (Zubieta et al., 2002). This suggests that the μ-opioid system may differentially modulate pain in women and men.

Genetic factors may contribute to sex differences in pain. Indeed, substantial evidence from nonhuman animals suggests that both basal nociceptive sensitivity and antinociceptive responses to drugs show significant heritability (Lariviere et al., 2002; Mogil et al., 1999a, 1999b; Mogil, 1999). Of particular relevance to the current topic are findings that sex differences in basal nociceptive sensitivity and opioid analgesia are dependent on the strain of rodent tested (Barrett et al., 2002; Cook et al., 2000; Mogil et al., 2000; Mogil et al., 2003; Terner et al., 2003). However, there is limited evidence of genetic influences on pain sensitivity and analgesic responses in humans. Pressure pain threshold was assessed in monozygotic and dizygotic twins and showed a heritability of only 10% (Macgregor et al., 1997). In contrast, recent studies suggest significant associations between single nucleotide polymorphisms (SNPs) of specific genes and experimental pain responses. One group of investigators reported heritability estimates of 22 to 46% across three pain modalities and a SNP of the δ-opioid receptor gene (*OPRD1*) was associated with thermal pain responses among men but not women (Kim et al., 2003), consistent with the results of a previous linkage mapping study in mice (Mogil et al., 1997). Zubieta and colleagues (2003) reported that an SNP of the catechol-*O*-methyltransferase gene (COMT) was marginally associated with pain report and significantly associated with pain-induced brain μ-opioid receptor binding. It was recently demonstrated that genotype at the melacocortin-1-receptor gene was associated with analgesic responses to pentazocine among women but not men (Mogil et al., 2003). These findings from both rodents and humans indicate that genetic factors are associated with pain responses, and some of these associations are sex-dependent.

In addition to these multiple "biological" factors, numerous "psychosocial" variables also contribute to sex differences in pain responses. For example, the greater levels of depression and anxiety reported by women may be associated with increased clinical pain (Kroenke & Spitzer, 1998; Moldin et al., 1993; Rajala et al., 1995), as well as enhanced experimental pain sensitivity (Cornwall & Donderi, 1988; Graffenried et al., 1978). The association of negative affect to pain may be sex related, as several investigators have reported a stronger relationship between emotional distress and pain-related symptomatology among men than women (Edwards et al., 2003; Edwards et al., 2000; McCracken & Houle, 2000; Riley et al., 2001). Relatedly, we previously reported that anxiety was more strongly associated with experimental pain sensitivity among men than women (Fillingim et al., 1996). Taken together, this evidence indicates a stronger association between psychological distress and enhanced pain responses among men.

Cognitive variables may also contribute to sex differences in pain. For instance, numerous studies have reported sex differences in cognitive and behavioral coping strategies, with women reporting higher levels of many forms of pain coping (Affleck et al., 1999; Keefe et al., 2000; Mercado et al., 2000; Osman et al., 2000; Unruh et al., 1999). Keefe et al. (2000) reported that catastrophizing mediated the higher levels of pain and disability reported by women compared to men with osteoarthritis. Another potentially important cognitive factor is self-efficacy, which predicts improved adjustment to chronic pain (Jensen et al., 1999; Jensen & Karoly, 1991), decreased procedural pain (Kashikar-Zuck et al., 1997), and lower sensitivity to experimental pain (Keefe et al., 1997). Both women and men report that men are better able than women to tolerate pain (Robinson et al., 2001), and a greater perceived ability to tolerate and control pain has been related to lower pain sensitivity among women but not men (Fillingim et al., 1996).

Stereotypic gender roles may also contribute to sex differences in pain. Among men, masculinity has been associated with higher pain thresholds (Otto & Dougher, 1985), and one study found that men but not women reported less pain to an attractive opposite-sex experimenter than to a same-sex experimenter (Levine & De Simone, 1991). Importantly, while two studies have demonstrated that sex roles are associated with experimental pain responses, in neither study did sex role measures account for the gender difference in pain (Myers et al., 2001; Otto & Dougher, 1985). In an experiment that manipulated gender role expectations, Robinson, Gagnon, Riley, & Price (2003) found that sex differences in pain responses disappeared when subjects were given gender-specific expectations regarding pain tolerance. Thus, in the laboratory setting, gender role expectancies may contribute to sex differences in pain responses; however, little information is available regarding the association of gender roles to clinical pain.

Familial factors may contribute to sex differences in pain. Several chronic pain conditions are characterized by familial aggregation, including fibromyalgia (Buskila et al., 1996; Buskila & Neumann, 1997; Pellegrino et al., 1989), headache (Aromaa et al., 2000; Ehde et al., 1991; Messinger et al., 1991; Ottman et al., 1993; Schrader et al., 1996; Turkat et al., 1984), irritable bowel syndrome (Kalantar, Locke, Zinsmeister, Beighley, & Talley, 2003; Kalantar et al., 2003), and low back pain (Balague, Troussier, & Salminen, 1999). Moreover, in community studies, individuals reporting a family history of pain have increased pain complaints (Edwards et al., 1985; Koutantji et al., 1998; Lester et al., 1994; Sternbach, 1986). The association between family history and pain may differ across sexes, as reported that familial pain history predicted pain complaints more strongly among women than men (Edwards et al., 1985). Also, an association between family pain history and enhanced experimental pain sensitivity has been reported among women but not men

(Fillingim et al., 2000; Neumann & Buskila, 1997). Whether this stronger association between familial factors and pain responses among women is due to social learning or genetic factors has yet to be determined.

Thus, multiple biopsychosocial factors contribute to sex differences in clinical and experimental pain responses. The biospychosocial model of pain suggests that biological, psychological, and sociocultural factors interact to influence pain responses. Additional research is needed to elucidate these interactions in the context of sex differences in pain.

CONCLUSIONS AND FUTURE DIRECTIONS

The literature reviewed above clearly demonstrates that pain is characterized by both quantitative and qualitative sex differences. Multiple factors contribute to sex differences in pain responses, including those traditionally referred to as "biological" (e.g., genetics, hormones, pain modulatory systems) and "psychological" (e.g., cognitive/affective variables, social roles, family history). A major challenge for the future will be translating these findings into clinical practice. An example of this might be sex-related treatment tailoring. It seems plausible that sex differences in analgesic responses may ultimately lead to the development of sex-specific medications and/or dosing regimens. Similarly, some evidence indicates sex differences in the outcomes of nonpharmacologic treatment for pain. For example, women but not men showed significant benefit following multidisciplinary treatment for back pain (Jensen et al., 2001) and pain due to TMD (Krogstad et al., 1996). Moreover, the predictors of treatment outcomes have differed for women and men in some studies (Burns et al., 1998; Edwards et al., 2003). Therefore, in the future it may be possible to tailor interdisciplinary pain treatment by sex to optimize treatment outcomes.

Another important issue is that clinicians and scientists should be educated regarding the existence and nature of sex differences in pain. Increasing our awareness of these differences should help reduce gender-related biases, which can adversely influence treatment decisions. Indeed, some findings indicate that women presenting with chest pain were less likely than men to receive both invasive and non-invasive cardiac procedures (Roger et al., 2000). Although multiple reasons could produce these differences in medical decisions, we must avoid minimizing women's pain reports based on the assumption that women are overreporting or exaggerating symptoms, since it could just as well be true that men are underreporting (Barsky et al., 2001).

In summary, based on considerable basic and clinical pain research, we can now state the obvious with confidence, women and men are different. Women report more frequent and/or more severe clinical pain and display enhanced perceptual responses to experimentally-induced pain. In addition, responses to analgesic medications have shown sex differences, although the results are somewhat inconsistent across studies. Multiple biopsychosocial factors contribute to sex differences in pain, and continued research to further characterize the nature of sex differences in pain will inform pain treatment for patients of both sexes.

Racial and Ethnic Issues in Chronic Pain Management: Challenges and Perspectives

Michael E. Schatman, PhD

INTRODUCTION

One of the greatest obstacles to the effective treatment of chronic pain is the temptation of clinicians to explain it solely in terms of physiological mechanisms. Without recognizing the complex interaction between pathophysiology and psychosocial factors, chronic pain cannot be adequately understood and, accordingly, cannot be adequately treated. Since the pioneering work of Chapman and Jones, (1944) and Zborowski (1952), numerous researchers have examined racial and ethnic influences on patients' perceptions and responses to acute and chronic pain experience. The findings of a myriad of studies on group differences in pain experience and response are mixed, which may be due, to a certain extent, to methodological issues. While additional research on racial and ethnic differences in the experience and meaning of pain may be useful, the possibility exists that findings will only marginally affect the quality of treatment minorities with chronic pain receive. Of greater importance, perhaps, is how diverse racial and ethnic groups' views of pain, health care providers, medications, and the medical system as a whole along with physician and medical system variables affect their access to the treatment that is likely to meet their specific needs.

A review of the literature suggests that some of the disparity in findings on racial and ethnic issues in chronic pain management relates to inconsistencies in operational definitions of race and ethnicity. *Race* refers to differences in major groups of people based on ancestry and physical characteristics, while *ethnicity* refers to distinctions based on behavior and culture as well as on biological and physical differences (Edwards et al., 2001).

It is also important to specify an operational definition of "chronic pain," as this is another issue regarding which considerable disagreement exists. While certain clinicians and investigators view chronicity as based on the duration of symptoms, others consider chronic pain to be defined by the amount of dysfunction it causes across a wide range of dimensions of one's life. For purposes of consistency, the International Association for the Study of Pain (IASP) definition of chronic pain as that persisting "beyond normal tissue healing time, which is assumed to be 3 months" (IASP, 1986) is used in this chapter. Both malignant and nonmalignant chronic pain are discussed.

PAIN PERCEPTION

Most of the research on racial and ethnic differences in pain experience has focused on acute pain, with much of this research involving experimental rather than clinical pain. However, a number of investigators have examined intergroup variance in the perception of chronic pain severity (Ang et al., 2003; Bates & Edwards, 1992; Bates et al., 1993; Bates et al., 1995; Garron & Leavitt, 1979; Gaston-Johansson et al., 1990; Green et al., 2003a; Greenwald, 1991; Jordon et al., 1998; Kramer et al., 2002a, b; Kramer et al., 2002; Lawlis et al., 1984; Lipton & Marbach, 1984; McCracken et al., 2001; Plesh et al., 2002; Riley et al., 2002) with mixed results. For example, while Edwards et al. (2001), Green et al. (2003a), and McCracken et al. (2001) each found that African American patients seeking treatment for chronic pain reported higher pain severity than did their Caucasian counterparts,

Ang et al. (2003), Jordan et al. (1998), and Riley et al. (2002) found no interracial differences in pain intensity in their studies, and Plesh et al. (2002) found interracial differences in pain intensity only at certain body locations. While several studies (Bates & Edwards, 1992; Bates et al., 1995; Lawlis et al., 1984) have indicated that Hispanics suffering from chronic pain report higher levels of pain severity than non-Hispanic Caucasians, it has been suggested that problems with relatively simple conceptual models and the use of univariate statistical approaches limit the meaning of these findings (Edwards & Keefe, 2000; Lipton & Marbach, 1984).

Medical research often considers Hispanics a homogeneous group, with insufficient attention paid to the considerable differences between various Hispanic cultures. Keefe (1982) noted, for example, large differences between foreign-born versus American-born Mexican Americans in terms of help-seeking behavior. Similar differences are likely to exist between Puerto Rican patients with chronic pain who were born in Puerto Rico versus those born in the mainland United States, based on levels of acculturation. Comparing Puerto Ricans with Mexican Americans in their experiences of chronic pain, to take the issue yet further, should be done only with extreme caution. These same issues are likely to exist in considering the literature examining chronic pain experience among African Americans. In an excellent editorial, Edwards and Keefe (2000) noted that the meaning of pain for an individual who has recently emigrated from the Caribbean may differ greatly from that of an African American whose fourth-generation status has resulted in a different experience of acculturation. Bates and Edwards (1992) noted that "ethnic stereotyping is as dangerous as inattention to cultural variables." As the tendency for researchers of differences between races in chronic pain experience has clearly been toward ethnic stereotyping, the meaning and value of the body of existing literature in this area are questionable. More sophisticated and thoughtful research on racial and ethnic differences in the chronic pain experience would potentially be beneficial.

RESPONSE TO CHRONIC PAIN

A related area of investigation that has received considerable attention has been differences between racial and ethnic groups in terms of emotional and behavioral responses to chronic pain. Again, studies examining emotional and behavioral adaptation to chronic pain have yielded mixed results (Ang et al., 2002; Bates & Edwards, 1992; Bates et al., 1995; Brena et al., 1990; Gatchel et al., 1995; Green et al., 2003a; Greenwald, 1991; Ibrahim et al., 2003; Jordon et al., 1998; Li & Moore, 1998; McCracken et al., 2001; Riley et al., 2002; Sanders et al., 1992). However, a review of the literature suggests that the findings on racial and ethnic differences in response to pain are more consistent than are those on intergroup differences in pain perception. For example, African American patients with chronic pain were found to display less adaptive coping strategies (Ang et al., 2002; Jordon et al., 1998), to demonstrate higher levels of physical and psychological disability (Green et al., 2003a, b; McCracken et al., 2001), and to be more avoidant of physical activity (McCracken et al., 2001) than were Caucasian patients with chronic pain. Non-Caucasians were found to be more likely to be classified as "disabled" 6 months following acute back injuries than were Caucasians (Gatchel et al., 1995). Two studies (Bates & Edwards, 1992; Bates & Rankin-Hill, 1994) have suggested that Puerto Rican patients with chronic pain reported more psychological distress and higher degrees of interference with physical activities than non-Hispanic Caucasians, with these findings attributed to differences in locus of control. While the studies implicating locus of control as responsible for differences in behavioral and emotional responses to chronic pain have compared Puerto Ricans with Anglo-Americans, external locus of control has been related to maladaptive responses to illness among African Americans as well (Bell et al., 1995; Wilson et al., 1994). Issues of locus of control are addressed later in this chapter. It should be noted, however, that the studies that suggest that Caucasians' emotional and behavioral adjustment to chronic pain is superior to those of racial and ethnic minority patients with pain may have been reliant on independent variables that were not necessarily culturally sensitive.

Two studies on cross-cultural differences in response to chronic pain should be mentioned by virtue of their blatant problems with ethnic stereotyping. Brena et al. (1990) determined that Japanese patients with chronic low back pain were less impaired psychologically, socially, vocationally, and avocationally than were American patients with low back pain. In a study of "Chronic Low Back Pain Patients Around the World," Sanders et al. (1992) compared levels of chronic low back pain–related self-perceived dysfunction in samples of American, Japanese, Mexican, Colombian, Italian, and New Zealander sufferers of chronic low back pain. The authors concluded that "there were important cross-cultural differences in chronic low back pain patients' self-perceived level of dysfunction, with the American patients clearly the most dysfunctional." They attributed the differences that they found to potential explanations including a number of sociocultural factors and differences in emotional and cognitive functioning. Unfortunately, the authors of both of these studies failed to state what constitutes being an American. Given that the American population is likely the most heterogeneous in the world, the findings of these studies tell us little of meaning regarding differences between groups in pain-related self-perception of chronic low back pain disability. Brena et al. (1990) noted that

their findings may have been due to the stoicism and ethnic homogeneity of Japanese culture, making pain-related impairment less acceptable than it is in the "liberal, permissive, and pluralistic American society." However, the validity of this statement is limited due to a lack of information regarding the specific composition of the American sample.

DIFFERENCES IN THE TREATMENT OF MINORITIES VERSUS NONMINORITIES WITH CHRONIC PAIN

In general, racial and ethnic minorities have been determined not to have the same access to medical treatment and other health services as do the non-Hispanic Caucasian population, with African Americans at particular risk for underservice (Mayberry et al., 2000). As discussed above, the mixed results of research on racial and ethnic differences in pain perception do not support drawing particularly meaningful conclusions, and investigations of intergroup differences in emotional and behavioral response to pain suggest that African American and Hispanic patients may respond less favorably to chronic pain than do non-Hispanic Caucasians. However, these bodies of literature provide little insight into the disparity in treatment of chronic pain that is received by minorities as opposed to nonminority groups in the United States. The existence of this disparity is well documented in the literature, in which numerous studies on racial and ethnic differences in both acute and chronic pain treatment can be found. It appears likely that the results of many of the investigations that suggest that minorities are at higher risk for the ineffective treatment of acute pain may generalize to the treatment of chronic pain as well.

While results of several studies (Ducharme & Barber, 1995; Selbst & Clark, 1990; Wilson & Pendleton, 1989) have indicated that the inadequate prescribing of analgesics for patients in pain in emergency rooms is common, it appears that racial and ethnic minorities who present at emergency departments are at even greater risk for oligoanalgesia, despite similar levels of pain complaints (Todd et al., 1993; Todd et al., 2000). Todd and his colleagues (1993) found that 55% of Hispanics received no analgesic for long bone fractures, while no analgesic was provided for only 26% of non-Hispanic Caucasians with identical diagnoses. Of note are the results of a 1994 companion study (Todd, Lee, & Hoffman, 1994) to Todd et al.'s original work, in which no difference between physicians' assessments of pain between Caucasian and Hispanic patients was identified. Accordingly, physician error in assessment of pain levels could not account for the identified disparity in the administration of analgesics between Hispanics and non-Hispanic Caucasians. Similarly, African American patients with extremity fractures were at

66% greater risk for receiving no analgesic from an emergency medicine department than were Caucasians (Todd et al., 2000).

Ng and colleagues (1996a, b) published results of two studies that examined differences in the treatment of postoperative pain between Caucasians and racial/ethnic minorities. These investigations were conducted to assess whether the findings of Todd and colleagues (1993, 1994) would generalize from the emergency room to the postoperative setting. In both studies, Caucasian patients were provided with higher doses of analgesics than were racial or ethnic minority patients. Ng et al. (Ng et al., 1996a) acknowledged that their results could not determine whether this disparity was due to the attitudes and behaviors of the patients, of the medical staff, or some combination of the two. As is the case with the aforementioned studies on racial and ethnic differences in emergency room treatment of fractures, the results of the studies by Ng and colleagues (1996a, b) become more striking in light of a study that indicated that white patients reported *less* postoperative pain than did African Americans or Hispanics (Faucett et al., 1994).

Although the body of literature on racial and ethnic differences in the treatment of acute pain is limited, studies on such differences in the treatment of cancer pain are somewhat more abundant. Overall, the literature suggests that minority patients with cancer are more likely to be faced with oligoanalgesia than are Caucasian cancer patients. In an early study of racial and ethnic disparities in the treatment of cancer pain, Cleeland et al. (1997) compared medication practices of oncology clinics that treated primarily African Americans and Hispanics with those treating more heterogeneous patient populations. The authors determined that while 42% of all recurrent or metastatic cancer patients were undermedicated, those seen in centers that treated predominantly minorities were three times more likely than were patients treated elsewhere to report inadequate pain management. In a follow-up study, Cleeland and his colleagues (1997) determined that 65% of minority patients suffering from recurrent or metatstatic cancer did not receive Pain Management Index–recommended analgesic prescriptions, as compared with only 50% of nonminority patients. Hispanic cancer patients in this study were found to be more inadequately medicated for their pain than were African American patients, which is particularly intriguing given the results of an investigation that determined that Hispanic cancer patients reported higher levels of pain and lower quality of life than did non-Hispanic Caucasian or African American cancer patients (Juarez et al., 1999). Consistent with these results are findings that elderly minority cancer patients were statistically more likely to receive no analgesia than were elderly nonminority patients, with African Americans being 63% more likely to be untreated for their

cancer pain than were non-Hispanic Caucasians (Bernabei et al., 1998).

Although a number of studies of racial and ethic disparities in the treatment of acute pain and cancer pain have been published, there are relatively few studies examining disparities in treatment between racial/ethnic minorities and nonminorities who suffer from benign chronic pain conditions. In an extensive review of racial and ethnic disparities in access to medical care, Mayberry et al. (2000) concluded, "the literature shows that racial and ethnic minorities frequently do not have the same access to medical treatment and other health services as the majority white population," and that this difference is particularly true for African Americans. While Mayberry and his colleagues reviewed the literature on racial disparities in the treatment of cancer, they did not include benign pain conditions in their review.

Among the published studies of racial and ethnic disparities in the treatment of chronic pain, the majority appear to relate to issues of *access* to services. Access to services appears to be related to a combination of patient variables, communication issues, physician issues, and social system variables, all of which contribute to suboptimal outcomes for too many minority patients with chronic pain. These variables and their impact on access to appropriate medical care for chronic pain conditions are the focus of the remainder of this chapter.

PATIENT VARIABLES

As mentioned earlier in this chapter, the findings of studies of differences between racial and ethnic groups in their perceptions of chronic pain have been mixed and therefore nonconclusive. Accordingly, these differences, if they do exist, are unlikely to adequately explain racial and ethnic disparities in access to chronic pain management services. However, as the research appears to suggest the existence of racial and ethnic group differences in emotional and behavioral responses to chronic pain, these differences merit investigation as a possible explanation for disparities in access to appropriate services.

The literature suggests that differences between racial and ethnic minorities' patterns of seeking medical assistance in dealing with chronic pain are rooted deeply within their cultures. This appears to be particularly true of Hispanic sufferers of chronic pain, although intraethnic differences may exist. Perhaps the most prolific investigators of Hispanic/Caucasian differences in chronic pain experience and response have been Bates and her colleagues (Bates & Edwards, 1992; Bates, Edwards, & Anderson, 1993; Bates & Rankin-Hill, 1994; Bates et al., 1995; Bates, Rank-Hill, & Sanchez-Ayendez, 1997). Bates and Edwards (1992), Bates, Edwards, & Anderson (1993), and Bates and Rankin-Hill (1994) determined that locus of control style is an important predictor of chronic pain

experience, affecting not only the subjective experience of pain severity, but also behavioral, psychological, and attitudinal responses. The Latino cultural tradition is one that emphasizes external locus of control, viewing reality as something that cannot be manipulated or transformed by the individual. This worldview, suggest Bates and Edwards (1992), is one that is accepted as realistic by Hispanic researchers, despite the tendency of Caucasian researchers to see external locus of control as reflective of a passive and pessimistic attitude. Bates and Rankin-Hill (1994) determined that patients with external locus of control were more likely to have sought immediate medical care upon the onset of their pain symptoms. However, their study did not indicate that locus of control style affected patients' likelihood of seeking and/or continuing to pursue medical care once a pain condition had become chronic. A review of the literature suggests that the relationship between a patient's locus of control style and willingness to seek treatment for *chronic* pain has yet to be investigated. This topic certainly merits exploration, particularly given the identified tendency of Hispanics to manifest external health locus of control (Sugarek et al., 1988; Aruffo et al., 1993; Spaulding, 1995).

Bates and Rankin-Hill (1994) suggest that among patients with chronic pain, an internal locus of control is beneficial in that it helps patients regain the perception of control over their lives and their pain. However, if an external locus of control is actually associated with seeking medical attention upon the onset of pain symptoms, is an external locus of control style necessarily maladaptive? A study by Gatchel and colleagues (2003) identified patients with acute low back pain determined to be at risk for developing chronic low back pain. Those who received early medical intervention fared better on a wide range of work, heath care utilization, medication use, and self-report of pain variables at 1-year follow-up than did those patients who did *not* receive early medical treatment. Their results were consistent with those of earlier studies (Epker et al., 1999; Gatchel et al., 1995; Jordon et al., 1998; Linton et al., 1993; Schultz et al., 2002). While Hispanics' tendencies toward external locus of control may indeed result in suboptimal emotional and behavioral responses to chronic pain, in terms of access to medical services, this culturally ingrained tendency may actually serve the function of helping avoid the development of chronicity. Further investigation is required to determine whether Hispanics' external locus of control styles actually do result in passivity and pessimism, as such attitudes could theoretically result in hopelessness and thereby serve to prevent Hispanic chronic pain sufferers from seeking access to potentially beneficial medical treatment.

It should be noted that intracultural variation in help-seeking behavior may relate to differences in access to treatment for chronic pain among Hispanics, although no such specific study appears in the literature. Keefe (1982),

however, noted that foreign-born Mexican Americans are less likely to seek help from doctors than are native-born Mexican Americans. The author suggested that this distinction is likely to relate to socioeconomic status, level of acculturation, intensity of religious affiliation, the presence of a strong social support network, and familiarity with available services. While Keefe's study pertained specifically to mental health issues, it seems plausible that her results may be generalized to the seeking of treatment of other conditions, including chronic pain.

Without regard to locus of control style, Hispanics may choose to seek medical treatment for their chronic pain less frequently than do non-Hispanic Caucasians because of their tendency to rely on family and friends for assistance prior to or rather than seeking outside help. Bates and Edwards (1992) found that Hispanic sufferers of chronic pain were significantly more likely to consult friends and family for advice regarding their pain than were other ethnic groups in their study. Additionally, there exists a tradition in Hispanic culture to rely on *espiritismo* (faith healing), which may serve as a substitute for seeking mainstream medical care for chronic pain. While this possibility has not been formally investigated, Ruiz and Langrod (1976) identified a culturally accepted belief system in faith healing in a Hispanic urban ghetto. However, Lipton and Marbach (1984) noted that the levels to which pain sufferers rely on home remedies and spiritist healers are likely to be subject to intra-ethnic variation based on degree of assimilation into American society and acculturation of medical norms.

Hispanics in the United States are not the only racial or ethnic group likely to demonstrate lower levels of formal help-seeking for their chronic pain, choosing to rely on spiritual approaches instead. Jordan et al. (1998) determined that African American women were more likely to engage in "praying and hoping" as a primary strategy for dealing with chronic pain than were Caucasian women in their study. The authors noted that African Americans' greater use of praying/hoping was consistent with their emphases on church, prayer, and religion within their community, which has been supported elsewhere in the literature (Arcury, 1996; Bill-Harvey et al., 1989; Coulton et al., 1990; Cronan et al., 1993; Jacobson, 1987; Mutran, 1985). Ang et al. (2002) determined that African Americans were less than half as likely as Caucasians to consider arthroplasty as a treatment option for their severe arthritis, identifying African Americans' belief in the "helpfulness of prayer" as an important explanatory variable for this disparity.

Another patient variable that may explain, to some degree, undertreatment of chronic pain among African Americans is the relationship between their pain experience and perceived quality of life. In two studies by Ibrahim and colleagues (Ibrahim et al., 2002, 2003), negative correlations between pain quality variables and global

quality of life ratings were identified among Caucasians suffering from osteoarthritis, but not among their African American counterparts. While neither of these studies directly examined the relationship between race and the perceived overall impact of chronic pain on seeking medical intervention, the possibility exists that African Americans are more likely to consider their pain as less meaningful than are Caucasians within the frequently unfortunate socioeconomic context of their lives. A number of studies (Fiscella & Franks, 1997; Fuhrer et al., 1993; Myers et al., 2002; Vermom et al., 1982) have suggested that African Americans are more likely than Caucasians to experience hopelessness in general, and it is plausible that this phenomenon can explain their decision to be reticent to seek aggressive treatment for their chronic pain. Studies have suggested that Hispanics in the United States are also more likely to evidence hopelessness than are Caucasians, and may actually manifest greater hopelessness than do African Americans (Fuhrer et al., 1993; Garcia & Marks, 1989; Kemp et al., 1999; Myers et al., 2002; Vermom et al., 1982). Accordingly, generalized hopelessness may serve as an explanation for Hispanics' reticence to seek chronic pain treatment as well. Research in this area could be useful in terms of designing psychosocial interventions for racial and ethnic minority chronic pain sufferers manifesting high levels of hopelessness.

The involvement of psychologists in interdisciplinary (and some multidisciplinary) treatment programs for chronic pain may provide yet another explanation for racial and ethnic minorities' reduced likelihood of seeking chronic pain management services. The literature suggests that African Americans are less likely to seek mental health services than are Caucasians (Alvidrez, 1999; Bristow & Patten, 2002; Diala et al., 2000; Padgett et al., 1994; Snowden, 1999; Wells et al., 2001), that African Americans view mental health services as not being particularly useful (Snell & Thomas, 1998), and that African Americans have more negative expectations of mental health services than Caucasians (Richardson, 2001). Hispanics have been found to be less likely to seek mental health services than non-Hispanic Caucasians (Alegria et al., 2002; Alvidrez, 1999; Greenberg & Rosenheck, 2003; Padgett et al., 1994; Pumariega et al., 1998; Starrett et al., 1992; Wells et al., 2001) and to be more likely to drop out of counseling prematurely (Cheung & Snowden, 1990). Some of the Hispanics' discomfort with mental health services is certainly likely to relate to issues of communication secondary to language barriers, which will be addressed later in this chapter. The possibility that racial and ethnic minorities suffering from chronic pain avoid appropriate treatment due to an aversion toward mental health services is particularly distressing given the findings that suggest that African Americans with chronic pain demonstrate less adaptive coping strategies, evidence higher levels of psychological disability, and are more

avoidant of physical activity than Caucasian patients with chronic pain (Ang et al., 2002; Edwards et al., 2001; Green et al., 2003a; Jordon et al., 1998; McCracken et al., 2001;). Similarly, the strong need for psychological services in the treatment of Hispanic patients with chronic pain is supported by research that suggests that they reported higher levels of psychological distress and interference with physical activities than did non-Hispanic Caucasians with chronic pain (Bates & Edwards, 1992; Bates & Rankin-Hill, 1994). If the proponents of the aforementioned theory that Hispanics' external locus of control is detrimental to coping with chronic pain are accurate, psychologists may be particularly important in their treatment in terms of providing them with cognitive behavioral intervention, including biofeedback training. Such treatment has been found to be effective in increasing internal health locus of control among patients suffering from chronic pain and illness (Gruber et al., 1988; Mizner et al., 1988; Rybarczyk et al., 2001).

Another patient-related factor that may have an impact on access to appropriate treatment for chronic pain among racial and ethnic minorities is trust of medical professionals and the medical system in general. This factor, however, is likely to be influenced by communication issues as well as medical and social system variables, which are addressed in greater detail later in this chapter. Despite the existence of a body of literature indicating that racial and ethnic minorities trust physicians and the medical system less than do Caucasians (Doescher et al., 2000; Corbie-Smith et al., 2002; Boulware et al., 2003), there is a paucity of research on issues of trust of the medical establishment among minorities suffering from chronic pain. Lipton and Marbach (1984) determined that African American patients presenting for treatment at a facial pain clinic were significantly more skeptical regarding what they believed their physicians could do to help them as compared with Caucasian patients. Otherwise, no investigations of this type appear in the literature, and additional research is merited.

COMMUNICATION ISSUES

Related to trust issues is communication between minority patients with chronic pain and the providers of pain management services. This is obviously a physician/medical staff issue as well as a patient variable. Language barriers can certainly exist in the treatment of chronic pain, as is the case with all medical treatment. Hispanic patients who are not conversant in English are at risk of simply not understanding physicians who are non-Spanish speaking, and they are similarly likely to have problems conveying the physical, emotional, and behavioral aspects of their pain conditions to their physicians. The hope is that the rapidly growing Hispanic population and the increasing number of Spanish-speaking health care pro-

viders in the United States will progressively reduce the magnitude of this issue. The importance of physician–patient communication in cases of chronic pain can be evidenced through the results of a study by Lacroix et al. (1990), who determined that patients with chronic low back pain who had a strong understanding of their condition were statistically more likely to return to work during the course of the study than were patients with a poor understanding of their condition.

Bates et al. (1997) suggest that due to a lack of understanding of the views and values of ethnic minority patients with chronic pain by clinicians, these patients are likely to experience higher levels of treatment-related distress. Accordingly, minority patients with chronic pain are more likely to avoid medical services and are at greater risk for dropping out of treatment. Goldberg and Remy-St. Louis (1998) emphasize the importance of nonminority clinicians making a conceptual shift to understand the meaning of pain to the minority patient, as failing to do so adversely affects the credibility of the health care professional, thereby rendering treatment ineffective.

Davidhizar et al. (1997) postulate that ethnically and culturally diverse patients with pain demonstrate their pain either stoically or emotively. These two divergent response styles are determined, to a great extent, by the cultural traditions which specify the rules of conduct and conformity regarding the expression of pain. When dealing with nonminority health care professionals, both of these response styles can be problematic, as nonminority providers have the expectation that pain will be expressed neither in an overly stoic nor in an overly emotive fashion, but rather in a manner consistent with their own styles of communication. Bates et al. (1995) state that Puerto Ricans and Anglo-Americans appear to perceive and experience chronic pain differently, and that the difference is neither positive nor negative in itself. While the emotive expression of chronic pain among Puerto Ricans is considered normal and acceptable to Puerto Rican patients and medical professionals, non-Hispanic clinicians are likely to interpret the Puerto Ricans' emotive style as indicative of their inability to cope appropriately with chronic pain. The authors noted that Puerto Rican health care providers considered the patients' open display of what Anglo providers would consider excessive pain behavior to be normal and appropriate. Despite significant differences in style of expression of pain, Bates et al. (1995) did not find any differences between their Puerto Rican and non-Hispanic Caucasian groups in terms of interference with work, social, or family activities. In a study of 372 patients with chronic pain from six different ethnic groups that was conducted in New England, Bates and Edwards (1992) found that the Hispanic group's self-reported expression of pain was higher than that of the non-Hispanic Caucasian groups. While the authors did not mention the response to the Hispanics' emotive

expression of pain by the clinicians who were involved in this study, it is unlikely that they considered the Hispanics' pain behavior "normal and acceptable" as had the Puerto Rican medical professionals in the Bates et al. study (1995). As Anglo health care providers are likely either directly or indirectly to express their expectations regarding "appropriate" expression of pain to Hispanic patients (and may do so in a perceivably judgmental manner), Hispanics suffering from chronic pain may feel misunderstood and alienated and, accordingly, may choose not to seek or to withdraw from treatment that could potentially benefit them.

Although a number of investigators have addressed the impact of the emotive style of Hispanic patients with chronic pain, less has been written regarding the impact of the stoic style. Kramer et al. (2002a, b) studied pain-related beliefs and the manner in which symptoms are communicated among Native Americans suffering from chronic arthritis joint pain. In both studies, the authors determined that Native Americans suffering from chronic pain tended to voice subtle pain complaints, used vague verbal descriptions for their pain, and accordingly, may have understated serious symptoms. The investigators reported that while most of these Native American pain sufferers eventually sought medical attention, the under-recognition of the severity of their symptoms resulted in suboptimal treatment as opposed to appropriate multidisciplinary care (Kramer et al., 2002b). A strength of both of these studies was the drawing of their samples from an urban area in which more than 200 different Native American tribes were represented, thereby enhancing the generalizability of their results.

A surprising paucity of research on chronic pain among Asians is evident, particularly given the rapid growth rate of the population within the United States. Salimbene (2000) emphasizes the importance of taking Asians' traditions of stoicism into consideration when providing medical services to these minority groups. The author notes the strong Buddhist and Taoist emphases in their teachings regarding stoicism, behavioral reserve, and suppression of negative thoughts and complaints. Lee et al. (1997) notes that Asians are more passive in their relationships with health care providers than are Caucasians and that they will rarely admit ignorance or ask questions regarding their care. While no literature on Asian-Americans' access to chronic pain management services has been published up to this point, Brown (1987) determined that higher levels of stoicism among Vietnamese Americans limited their utilization of the mental health care system. Stoicism among Asian Americans appears to be supported in the acute pain literature, as the results of a number of studies (Carnie & Perks, 1984; Carragee et al., 1999; Houghton et al., 1992; Houghton et al., 1993; Streltzer & Wade, 1981) have indicated that Asians require

and/or request substantially lower dosages of opioids than Caucasians post-operatively.

In a review, Lee et al. (1997) noted that although ethnic differences in the pharmacokinetics of opioids may exist, results of such studies have been mixed and have not demonstrated clinical significance. Accordingly, it appears likely that differences in requests for narcotic analgesics between Caucasians and Asians relate to the Asians' stoicism. Based on these studies, the possibility that Asian Americans are at risk for not seeking appropriate treatment for chronic pain conditions certainly should be considered. However, once again it is important to avoid stereotyping. As the pain experiences and emotional and behavioral responses to chronic pain may differ drastically between Mexican Americans and Puerto Ricans, it cannot be assumed that all Asian Americans will evidence the same levels of stoicism in regard to their chronic pain. Despite certain cultural similarities, the meaning of pain to a third-generation Japanese American is likely to be very different from that of a Vietnamese refugee whose level of acculturation is still minimal and whose history of privation due to living in the midst of a war for many years has dramatically altered his or her view of life in general.

Peripherally related to stoicism as a variable that may be related to the undertreatment of chronic pain is fear of dependence on or addiction to narcotic analgesics. Anderson et al. (2002) found that more than 90% of African Americans and 76% of Hispanics in their sample of cancer patients expressed belief that they should not be reliant on pain medications. The majority of patients in both of these groups expressed concerns regarding addiction and developing tolerance to opioids. Of the Hispanic patients, 65% reported that they were concerned regarding their families' reactions to their use of pain medications. Hispanics have been found to be particularly concerned regarding their utilization of narcotic analgesics due to a fear of becoming addicted or developing tolerance (Cleeland et al., 1997; Juarez et al., 1999). Nemoto and colleagues (1999) identified an Asian cultural construct of fear of addiction. While Caucasians suffering from chronic pain also often fear that they will become addicted to or dependent on opioids, the limited literature available suggests that this fear may be more pronounced among certain racial and cultural groups, potentially resulting in their undertreatment. Several studies (Lin & Ward, 1995; Ward & Hernandez, 1994; Ward et al., 1993) that examined fear of addiction and tolerance to opioids among cancer patients of different ethnic backgrounds have suggested that these concerns are strongest among lower socioeconomic status patients. Given the strong negative correlation between racial/ethnic minority status and socioeconomic status (U.S. Bureau of the Census, 2001), however, minority chronic pain sufferers are at greater risk

for undermedication due to fears of addiction and toler-ance to narcotic analgesics.

HEALTH CARE AND SOCIAL SYSTEM VARIABLES

Mayberry et al. (2000) provided a comprehensive review of racial and ethnic differences in access to medical care. Their conclusion that racial and ethnic minorities, particularly African Americans, do not have the same access to health services is consistent with their thesis of pervasive racism in the American health care system. In *any* society, *individual* health care providers are not immune to the risk of discriminatory behavior. Mayberry and colleagues (2000) wrote, "The history of medical care in the United States is replete with discriminatory practices that denied ethnic minorities access to services based on skin color. Thus, the medical system of the past is correctly described as a racist institution, and the legacy of racism should not be minimized. Clearly, the patient's race, but specifically skin color, influence decision making, whether it is overt prejudice or subconscious perceptions" (pp. 134–135). However, Mayberry and colleagues also wrote, "The lack of SES (socioeconomic status) indicators in the study of racial and ethnic differences in health care is a common refrain among researchers" (p. 117). The importance of taking socioeconomic status into account in studies of racial and ethnic differences in health care can be fully appreciated through Mayberry et al.'s finding, "In some cases, when important variables [among which they include SES, describing it as the "most important" explan-atory variable] are controlled, racial and ethnic disparities are reduced and may even disappear under certain circum-stances" (2000, p. 112). The authors reviewed evidence of racial and ethnic inequities in the treatment of a number of health conditions, including heart disease and stroke, cancer, diabetes, HIV/AIDS, mental disease, and chil-dren's health issues. Little was mentioned in the article regarding chronic pain. Mayberry and colleagues (2000) did not specify whether they believed that the racism in health care in the United States is consciously or uncon-sciously motivated.

Mayberry et al.'s (2000) findings suggest that despite the existence of a number of studies that indicate that racial and ethnic minority chronic pain sufferers are at greater risk than Caucasians for being undertreated, it is difficult to specifically attribute this disparity in treatment to health care providers themselves. Given the numerous variables that can contribute to unequal treatment, meth-odological problems are likely to result in confounded findings. Investigators have tended to rely on the use of medical vignettes as a research approach for determining whether medical professionals treat chronic pain differ-ently based on race and ethnicity. Chibnall and Tait (1999)

present vignettes to nonphysician medical center employ-ees in which ethnicity, the presence of litigation, and the strength of medical evidence were varied. Each participant was asked to evaluate the "patient's" pain, disability, and emotional distress; to attribute causality for the patient's pain and disability; and to rate the patient's veracity and the extent to which the patient evoked sympathy from the participant. While interaction effects were identified, the study did not yield any main effects associated with eth-nicity. The authors express surprise regarding the lack of a unique effect of patient ethnicity on either attributions or symptom evaluation, and suggest that their ethnicity manipulation may have been too obvious to the partici-pants. Therein lies a significant weakness of this type of vignette study. In another vignette study, Weisse et al. (2001) found interaction effects but no main effects of race on primary care physicians' willingness to prescribe narcotic analgesics for pain associated with kidney stones or acute back pain. Weisse et al. (2003) also used vignette methodology in a study of internists' pain management practices in cases of renal colic and persistent back pain. Again, no main effects for patient race were found, despite the identification of interaction effects.

Given the aforementioned weaknesses of vignette studies, the results of the investigations by Chibnall and Tait (1999) and Weisse et al. (2001, 2003) should not be taken to suggest that health care provider bias against racial and ethnic minorities in their chronic pain manage-ment practices does not exist. As mentioned above, a lack of an appropriate methodology for assessing provider bias in treating patients with chronic pain limits the confidence with which one can attribute racial and ethnic differences in chronic pain management services to racism. Perhaps the strongest suggestion of health care providers discrim-inating in their chronic pain management practices relies on extrapolation from the companion studies by Todd et al. (1993, 2000) mentioned earlier in this chapter in which Hispanics received less analgesia than non-Hispanic Cau-casians for acute long bone fracture pain, despite a lack of difference in assessments of pain severity between the two groups by physicians. Todd and colleagues (1994) suggest that this finding of discrepant treatment could be explained by a "straightforward bias by physicians who are equally aware of pain in both ethnic groups, but less interested in treating it when patients are Hispanic" (p. 928). However, the body of literature as a whole suggests that if health care providers are actually providing inferior levels of chronic pain management services to racially and ethnically diverse minorities due to actual prejudice, the empirical evidence for such a disparity is weak.

What, then, can potentially explain the findings of inferior access to chronic pain management services to which racial and ethnic minorities appear to be subjected? As mentioned earlier in this chapter, the negative relation-ship between racial/ethnic minority status and socioeco-

nomic status has been well established (U.S. Bureau of the Census, 2001). In addition to the numerous patient variables that were mentioned earlier in this chapter, it appears that the lower socioeconomic status of racial and ethnic minorities rather than minority status itself is responsible for much of the limited access to chronic pain management that underserved minorities experience.

There exists a substantial body of literature that suggests that low socioeconomic status, independent of race and ethnicity, is positively related to underservice in medicine in general (Becker & Newsom, 2003; Franks & Fiscella, 2002; Krzyzanowska et al., 2003; Merzel & Moon-Howard, 2002; Newacheck et al., 2003a, b; Omalley et al., 2001; Ozminkowski et al., 1998; Scarinci et al., 2001). A Norwegian study (Brekke et al., 2002) in which race was not considered determined that socioeconomic status related negatively to severity of musculoskeletal pain, higher levels of pain-related physical disability, mental distress, and low life satisfaction. Most recently, Portenoy and his colleagues (2004) utilized survey methodology to assess racial and ethnic differences in pain experience between Caucasians, African Americans, and Hispanics in the United States. They found that a composite variable identified as "disabling pain" was negatively associated with socioeconomic status, although not with racial and ethnic minority status once they had controlled for socioeconomic factors. While a review of the literature indicates a lack of investigations of the specific relationship between socioeconomic status and access to appropriate treatment for chronic pain, some of the studies that have examined the relationship between racial and ethnic minority status and access to services suggest that socioeconomic factors are heavily implicated in the identified disparities.

Escalante et al. (2000) determined that recipients of hip replacements for severe arthritis were less likely to be Hispanic than of other races and ethnicities. The authors cited low socioeconomic status as one of the reasons for this underrepresentation. Similarly, Ang et al. (2003) determined that despite similar self-reported degrees of pain and dysfunction secondary to joint involvement in cases of osteoarthritis, Caucasians were significantly more likely than African Americans to undergo hip and knee replacement surgery. The authors noted that the underlying reasons for this ethnic variation are likely to be "multifactorial" and may include issues of insurance coverage. Hootman et al. (2002) determined that African Americans and Caucasians had the same number of ambulatory medical care visits for arthritis and other rheumatic conditions, but that African Americans were more likely to be seen in emergency rooms and hospital outpatient centers as opposed to private physicians' offices. The authors included insurance coverage and level of socioeconomic resources among the reasons for this disparity. In a study of cancer pain in Puerto Rico, Ward and Hernandez (1994)

attribute the use of inadequate analgesia to misconceptions regarding their utilization. The authors suggest, however, that these misconceptions were likely to relate to their subjects' low socioeconomic status rather than to their Hispanic ethnicity itself. Cleeland et al. (1994, 1997) determined that cancer patients treated in community clinical oncology programs that treated primarily minority patients were more likely to receive inadequate analgesia than were patients treated in centers that did not treat primarily minorities. The authors fail to mention the possibility that socioeconomic differences rather than racial and ethnic issues may have caused the identified disparity. Finally, a study by Payne et al. (2003) determined that African Americans suffering from breast cancer underuse hospices and palliative care relative to the general population. The authors note, however, that African Americans may find hospice care inaccessible for economic reasons.

One of the most intriguing studies of racial and ethnic minority difficulties with access to appropriate pain management services examined their relative lack of access to strong prescription narcotic analgesics. Morrison and colleagues (2000) determined that only 25% of pharmacies in minority neighborhoods in New York City carried supplies of narcotic analgesics sufficient to treat severe pain, as opposed to 72% of pharmacies in predominantly non-Hispanic Caucasian neighborhoods. Reasons for inadequate opioid supplies reported by surveyed pharmacists included a lack of demand for certain drugs, concern regarding disposal, fear of fraud and illicit narcotic use that could result in Drug Enforcement Administration investigations, fear of robbery, and problems with reimbursement by health plans and Medicaid. Surprisingly, Morrison and colleagues (2000) make no reference whatsoever to the socioeconomic status of the inhabitants of the "minority areas" in which pharmacies were surveyed. New York City's segregation is certainly as socioeconomically based as racially and ethnically based. Areas such as the South Bronx and Harlem, whose populations are composed almost entirely of racial and ethnic minorities, are among the most poverty-stricken urban areas in the nation. Studies of availability of narcotic analgesics in impoverished areas of the country which are inhabited by non-Hispanic Caucasians would help determine whether the issue of access to opioids is related to racial/ethnic or to socioeconomic factors.

While there have not been any studies published on the relationship among racial/ethnic minority status, access to chronic pain management services, and ability to pay for these services, a review of related literature may, in part, explain disparities in access. Minorities have been found to be significantly less likely to purchase health insurance, even after adjustments for income and wealth have been made (Saver & Doescher, 2000). Lillie-Blanton et al. (2000) determined that minority Americans were more concerned about health care's cost than about

other issues of access to medical services. Income has been determined to be a more significant predictor of lack of health insurance coverage than is race, although racial and ethnic minorities were found to be overrepresented in the low income group (Shi, 2001). Recently, Callahan and Cooper (2004) determined that the socioeconomic variable of lack of formal education was a substantially greater predictor of a lack of health care insurance than was racial/ethnic minority status. As a group, these studies suggest that racial and ethnic minorities are more likely than non-Hispanic Caucasians to be without health care insurance, but that this lack of coverage is related to socioeconomic status and the perceived value of health insurance rather than to racial and ethnic minority status per se.

Chronic pain management services can be costly, particularly when provided in a multidisciplinary or interdisciplinary fashion. A study by Marketdata Enterprises (1995) determined the average cost of pain rehabilitation programs to be $8,100.00. This type of treatment, however, has been found to be considerably more cost-effective than any other options (Turk, 1996). The average cost of multidisciplinary chronic pain management services at present has not been assessed in the literature, but is likely to be greater than the average cost of such services at the time of the Marketdata Enterprises study due to dramatic increases in the cost of health care services in general. Regardless, it is unlikely that many patients are able and willing to pay for multidisciplinary chronic pain management services out of pocket. Accordingly, the frequent lack of adequate health care insurance among racial and ethnic minorities is likely to result in limited access to appropriate treatment of their chronic pain. Racial and ethnic minorities are overrepresented on the Medicaid rolls (Mills & Bhandari 2003). As many practitioners and for-profit chronic pain treatment centers are unwilling to accept Medicaid for their services, racial and ethnic minorities are again at greater risk for lack of access to appropriate treatment. It should be noted, however, that the insurance-related lack of access to the best possible chronic pain management services is a *socioeconomic* rather than a racial/ethnic variable.

CONCLUSIONS

The question of why racially and ethnically diverse minorities suffering from chronic pain are underserved in the United States is certainly a complex one. However, in reviewing the literature on patient variables, communication issues, health care provider issues, and social system variables, it appears that deeply ingrained cultural patterns of seeking access to chronic pain management services and the dual health care system based primarily upon socioeconomic status are most strongly implicated in this disparity. While some of the identified racial and ethnic inequity in access to chronic pain management services

may relate to issues within the medical and social systems independent of socioeconomic status, there exists no empirical evidence that would suggest that minorities are underserved due to overt prejudice. Nevertheless, specific instances in which racial and ethnic minorities suffering from chronic pain are undertreated based on prejudice certainly occur, as they do in other service areas within American society.

Because completely eradicating overt prejudice in medicine is unlikely, it is important that health care providers make an effort to do everything possible to overcome the impact of the patient variables that cause racial and ethnic disparities in access to chronic pain management services, as well as consciously monitoring themselves against inadvertent minority stereotyping. The key to providing more equitable access to chronic pain management services is appropriate education of both minority chronic pain sufferers and the pain management specialists who have the potential to ease their suffering. While revamping the American health care system to assure that socioeconomic factors do not affect access to quality care would be a noble undertaking, the complexities of doing so within a larger system characterized by such pervasive inequalities between social classes would be overwhelming.

Educating members of racial and ethnic minorities who suffer from chronic pain may represent a difficult undertaking, as issues of trust of the Caucasian majority-dominated medical establishment are likely to impede such efforts. Some of the patient variables (e.g., racial and ethnic minority reliance upon the family and prayer) discussed earlier in this chapter that may potentially limit access to chronic pain management services are so deeply and pervasively culturally ingrained that extreme caution would need to be taken not to risk further alienation of racial and ethnic minority members. Rather than making what are likely to be futile efforts to educate racial and ethnic minority patients with chronic pain regarding the "superiority" of the standard biomedical approaches, it would perhaps behoove health care providers to accept minorities' emphases on family and prayer. In addition to building trust, acceptance of complementary and alternative medicine *in conjunction with traditional biomedical approaches* appears to be clinically reasonable based on empirical support. Hunt et al. (2000) found that Mexican American patients with diabetes who very actively used alternative treatments such as prayer also tended to be very active using traditional biomedical methods. Ni et al. (2002) studied a sample of more than 30,000 U.S. adults, finding that people who used methods such as prayer, spiritual healing, and herbal medicine were more likely to have customary health care providers and to have visited a physician during the previous year than were those who did not use complementary and alternative medicine.

To deal with the sense of hopelessness that likely makes members of racial and ethnic minorities reluctant

to seek treatment for their chronic pain, psychoeducational counseling may be beneficial. As mentioned earlier in this study, racial and ethnic minorities are less likely to seek psychological counseling than are non-Hispanic Caucasians, likely due to issues of communication and perceived benefit as well as finances. As proportionally more racial and ethnic minorities are being trained in mental health service provision (National Science Foundation, 2003), the hope exists that communication issues will become less problematic, thereby enticing minority patients to accept counseling within the context of their chronic pain treatment. Additionally, studies suggest that nurses can be effective providers of counseling services in the comprehensive treatment of chronic pain (Wells-Federman et al., 2002; Olason, 2004).

In terms of educating health care providers regarding the treatment of racial and ethnic minorities suffering from chronic pain, an article by Bates and colleagues (1997) on the effects of the cultural context of health care on the treatment of chronic pain offers clinicians some excellent ideas for maximizing patient response. The authors noted that medical professionals in Puerto Rico maintained different norms for patients' pain behaviors than did health care providers in the mainland United States, who expected more stoicism by patients. Pain behavior, when observed by Anglo health care providers, was viewed not as indicative of severe pain but rather as a sign that the patient was "overly emotional." Accordingly, Hispanic patients who demonstrated pain behavior in the presence of Anglo health care providers were not given any consideration for prompt treatment. Thus, the Hispanic chronic pain patients being treated in the mainland United States were at risk for feeling alienated by health care practitioners likely to have been seen as uninvolved and incapable of empathy, with little chance of a working alliance developing.

Bates et al. (1997) noted that cultural differences in the doctor–patient relationship exist. The authors suggested that the relationships between patients with chronic pain and their physicians in Puerto Rico were less formal and more personal than in the mainland United States. In Puerto Rico, a greater emphasis is placed on spending significant amounts of time with patients and listening to them express their concerns, fears, anger, and frustrations. Visits to patients' homes by their physicians are not uncommon. Patient-centered medical practice emphasizing empathy has been linked to improved compliance and more positive medical outcomes (Comstock et al., 1982; Scopp, 2000; Sullivan et al., 2000; van Dulmen & Bensing, 2002). Based on the research of Bates and colleagues (1997), the importance of placing more emphasis on the practitioner–patient relationship when treating Puerto Ricans with chronic pain should not be understated. Research on the importance of empathetic, patient-centered approaches in the treatment

of other racial and ethnic minorities suffering from chronic pain would also be useful.

A final difference between health care providers in Puerto Rico and those on the mainland who work with patients with chronic pain that should be mentioned is that providers in Puerto Rico function as patient advocates and counselors as well as biomedical pain practitioners (Bates et al., 1997). The authors reported that Puerto Rican physicians counseled patients with chronic pain on social and economic problems associated with their disabilities, served as patient advocates in medicolegal matters, and even served the role of vocational counselors. While no mention was made of treatment of chronic pain in Puerto Rico through a truly interdisciplinary team, the numerous roles that physicians played in patients' recoveries provided chronic pain sufferers with the benefits of interdisciplinary treatment. While multidisciplinary and interdisciplinary chronic pain management programs may include physicians, psychologists, social workers, and vocational counselors, Bates et al. (1997) described the pain physician in Puerto Rico as encompassing all of these roles. The practice of the pain physician in Puerto Rico is the antithesis of that of the pain physician in the mainland United States in terms of accessibility and scope of practice. It is accordingly not surprising that Puerto Rican patients in the mainland United States, along with other racial and ethnic minorities, do not possess the level of trust that Bates et al. (1997) described of patients with chronic pain in their article. The authors stated: "As long as the cultural backgrounds of both patients and providers are ignored in assessment and treatment programs, expensive treatments will remain primarily ineffective. Long-term investment in educating health care providers in personal cultural self-awareness, awareness of the culture of biomedicine, and in cultural relativity may lead to more effective care and treatment, and ultimately save money and reduce human suffering" (p. 1445).

THE FUTURE

Cultural awareness training is finally becoming a part of the training curricula for health care providers in the United States (Donini-Lenhoff & Hedrick, 2000). Nevertheless, racial and ethnic minorities are likely to continue to be underserved for many years to come, as changes in training, attitudes of practitioners and minority patients, and socioeconomically based issues of access to appropriate pain management are likely to occur only very gradually. A study by Anderson et al. in 2000 provided a modicum of optimism, as the authors found that only 30% of African American and Hispanic cancer patients in the study were receiving inadequate analgesics, as compared to 65% of minority patients with cancer in a study that the group had conducted only 3 years earlier (Cleeland et al., 1997). Anderson and colleagues (2000) identified a

change they hope will be perpetuated. However, if this is to occur, racial and ethnic minority patients, health care providers, and the medical and social systems will all need to contribute by demonstrating initiative and flexibility.

Assuring the Quality of Pain Services: Assessing Outcomes

Michael E. Clark, PhD, Ronald J. Gironda, PhD, and Stacey Carter, PhD

INTRODUCTION

Quality assurance (QA) refers to the program of steps necessary to maximize customers' confidence in the reliability and utility of a product. Within health care systems, maintaining and improving quality typically involves a multitude of procedures, mechanisms, and interventions designed to evaluate health care services, identify and remove barriers to care, and enhance outcomes. QA is an *active* process that focuses on implementing change within organizations or systems within organizations. It is this focus on change that differentiates QA from other health care system structures that use more passive approaches in an attempt to change *responses* to the system, rather than changing the system itself.

Among the many components required for effective QA, whether applied to health care programs in general or specifically to pain services, assessing and monitoring outcomes is perhaps the most important. Outcomes assessment drives the QA process. It provides the means for identifying areas that need improvement, and directs efforts to change. It must be global enough to be sensitive to a range of potential service delivery problems, yet specific enough to suggest possible causes and solutions. Like QA, outcomes assessment is an ongoing process rather than a static event and requires constant maintenance, revision, and "fine tuning."

Within health care settings, outcomes assessment is a multipart process that involves "the systematic collection and analysis of information that is used to evaluate the efficacy of an intervention" (Clark & Gironda, 2002, p. 995). To be *systematic* data must be collected in a con-

sistent and repetitive manner using identical or very similar outcomes measures or instruments. The resulting data then undergo *analysis,* which refers to the process of summarizing and interpreting the data to identify any meaningful trends. Although many settings excel in collecting data, the process of analysis often is neglected or underutilized. Data that are collected but not analyzed do not fulfill the spirit of outcomes measurement nor do they contribute to QA.

In the following sections we discuss the rationale underlying the use of outcomes measures in health care settings focusing on pain-related issues. Next we offer a brief review of instruments used to assess pain outcomes focusing first on the consumer of services and second on the service delivery system. We then talk about the processes of selecting appropriate outcomes domains and applying them in clinical practice. Last, we close with some impressions and general recommendations as applied to efforts to enhance the quality of pain services provided in health care settings.

IMPORTANCE OF OUTCOMES MEASUREMENT IN CLINICAL CARE SETTINGS

The emphasis on measuring the quality of pain treatment services has intensified in the past 15 years and is exemplified by the fact that Congress declared the first decade of the 21st century as the Decade of Pain Control and Research (Joint Commission on Accreditation of Healthcare Organizations [JCAHO], 2003). Improving pain management practices is a primary component of health

care's humanitarian mission, and interest in the application of QA processes to pain began following recognition that pain often is undertreated and managed inappropriately (American Pain Society Quality of Care Committee, 1995; JCAHO, 2003). This recognition spawned several movements to enhance the availability and quality of pain treatment, initially in medical settings and eventually in all patient populations. Subsequently, guidelines for pain treatment have been developed (Agency for Health Care Policy and Research, 1992, 1994; Clinical Practice Working Group [CPWG], 2003), which provide a consensus-based model of care against which health care settings can compare their own services.

Recent regulatory initiatives and legal precedents have increased the demand for quality pain care. Both health care organizations and physicians have been held financially liable for inadequate pain management (Lande & Loeser, 2001). Many states have codified statutes and regulations addressing multiple aspects of pain management (for a complete review of state pain policies see the Pain and Policies Study Group website, University of Wisconsin Comprehensive Cancer Center; http://www.medsch.wisc.edu/painpolicy/). Additionally, recommendations specific to certain treatment methods have been developed, such as the joint Department of Veterans Affairs/Department of Defense guidelines for the use of opioids for pain treatment (http://www.oqp.med.va.gov/cpg/cot/ot_base.htm; CPWG, 2003).

Changes in health care accreditation standards also are responsible for increased attention to assuring quality pain management services. For example, the Rehabilitation Accreditation Commission (CARF) has been a leader of these efforts by developing elaborate outcomes standards for pain treatment programs (1999). The American Academy of Pain Management (AAPM) began its voluntary pain program accreditation service in 1992, initially requiring participating programs to submit data to the National Pain Data Bank for benchmarking and quality assurance (AAPM, 2001). In 2001, the Joint Commission of Accreditation of Healthcare Organizations (JCAHO) incorporated pain management and assessment into its survey and accreditation process for all organizations providing direct care (Gordon et al., 2002; JCAHO, 2001). These standards build on earlier guidelines developed by the Agency for Healthcare Research and Quality (AHRQ) and the American Pain Society (APS) outlining responsibilities for improving outcomes in pain management. However, unlike these voluntary guidelines, JCAHO standards are required — health care institutions must demonstrate compliance by their pain management programs, including evidence of ongoing quality monitoring.

In addition to complying with regulatory issues and accreditation requirements, establishing routine assessment practices for the provision of pain services allows for the collection of research data to validate treatment efficacy and to establish evidence-based standards of care (Gordon & Dahl, 2004). Pain management guidelines have been developed for different patient populations (pediatric, adult, geriatric), types of pain (acute or chronic), and conditions or procedures (low back pain, postoperative pain, cancer pain; see JCAHO, 2003, for a list of pain management guidelines).

Not only is the measurement of pain services warranted to promote clinical effectiveness, it is also advantageous from a cost-effectiveness standpoint (Turk, Loeser, & Monarch, 2002). In the age of managed care, resources for health care are limited. The use of outcome data provides a managed care organization (MCO) an evaluative tool to assist in determining which products to make available to their patients. Indeed, MCO medical directors have indicated that the likelihood of a disease program's being funded is increased by providing evidence of clinical data supporting its effectiveness (Lande & Loeser, 2001).

Finally, and perhaps most importantly, outcomes data should be integrated into the clinical decision-making process in order to improve the quality of pain treatment services provided. This is true not only for day to day patient contact, but at a systemic level as well. While this may sound daunting, this is a routine component of practitioner care. At the most basic level, all revisions in patient care stem from evaluations of treatment outcome. As an example, consider an individual presenting to a provider with chronic noncancer pain. Initially, a trial of nonsteroidal anti-inflammatories (NSAIDs) may be initiated. At the next visit, effectiveness of the NSAIDs in relieving pain and improving function will be assessed. Depending on the results of that assessment of treatment outcome, the NSAIDs may be continued unchanged, revised, or discontinued. If they are discontinued, other pharmaceuticals (e.g., opioids) or interventions (e.g., physical therapy, nerve blocks) may be considered instead. In this example, the practitioner assessed the patient's pretreatment symptom report, administered an appropriate treatment, and then assessed post-treatment symptoms. These assessments guided the provider's decision-making process and allowed for treatment modifications as clinically necessary.

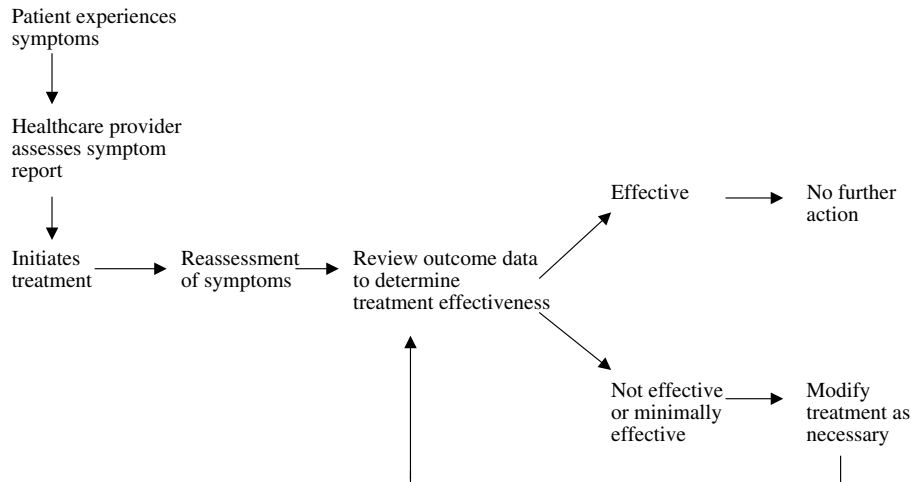
The same process can be incorporated into a larger pain treatment delivery system. For instance, in a multidisciplinary pain treatment program, pretreatment measures can be collected at the time of admission into the program. Review of the results of these same measures administered at the time of discharge provides information regarding the effectiveness of the program in changing targeted domains and suggests avenues for modifying the treatment regimen to enhance outcome. In other words, there exists a continuous feedback loop providing the health care provider with quantitative information to guide subsequent treatment decisions. Figure 9.1 depicts this


FIGURE 9.1 Clinical decision-making process.

decision-making process. With this said, however, it is important to note that assumptions regarding causation most often are based only on correlational data (i.e., changes in quality are correlated with the interventions for change employed) and, therefore, provide neither confirmation nor rejection of any hypothesized causative link. Other known or unknown factors also could account for the observed changes, particularly in settings where multiple interventions or events may have transpired between the initial assessment and the post-intervention assessment. Therefore, multiple episodes of data collection are preferred as they facilitate the identification of trends in the data that may be more reliable indicators of intervention-related change.

SELECTING RELEVANT OUTCOMES DOMAINS

Selecting appropriate outcomes measures is the key to developing a meaningful outcomes monitoring system. Two factors should be considered as part of the outcomes selection process (Clark & Gironda, 2002):

1. Pain outcomes focus (patient focused or process focused)
2. Practice setting

PAIN OUTCOMES FOCUS

Patient-focused outcomes measures concentrate on changes in individuals' pain experience following interventions. To quantify change, measures must be administered at least twice (before and after treatment). For treatments spanning lengthy time intervals, repeated administrations (e.g., every month) may provide a more detailed picture of change.

Patient-focused measures often are used to evaluate a single patient's response to treatment. When they are used collectively to evaluate a specific treatment intervention or program of interventions, they serve as aggregate outcomes measures. The most common patient-focused outcome measure is pain intensity. Other measures might include pain-related interference, emotional distress, or physical capacities.

Process-focused measures concentrate on the pain service delivery system and usually are components of performance improvement activities. In some cases measures may be collected only once, but more often they will be collected repeatedly over time to evaluate trends in the measures or to assess the impact of a system intervention.

Results may be used to evaluate how well the pain service delivery system is meeting facility goals, regulatory statutes, or accreditation body (e.g., JCAHO) standards. Common measures include pain clinic waiting times, adequacy of pain assessment and treatment documentation, or compliance with patient pain education standards.

PRACTICE SETTING

Practice setting refers to attributes of the pain service delivery environment. Pain treatments may range from minimally complex (e.g., medication management) to highly technical (e.g., dorsal column stimulator implants).

In general, pain service settings that require minimal resources and use uncomplicated treatments may not warrant elaborate, expensive, and time-consuming outcomes measurement practices when less complex approaches would suffice. In contrast, more complex treatment settings requiring greater resource investment or patient risk may want to use broader, multidomain outcomes measures to assess change in a variety of pain experience areas.

The rationale underlying this variation in outcomes approach is twofold. First, from a cost–benefit perspective, when resource investment is greater, such as in complex

pain treatment settings, it is reasonable to expect that outcomes should be improved. Utilization of more comprehensive outcomes measures that assess function in a greater range of domains may provide evidence of a greater range of treatment-related improvements. Second, complex pain treatment settings are likely to treat individuals with more complicated and severe pain conditions and increased pain-related dysfunction that extends across multiple domains of function. Therefore, more elaborate measures of outcomes may be needed to accurately reflect both the extent of pain-related disability and the degree of improvement attained.

ASSESSING DOMAINS OF PAIN OUTCOMES

The assessment of pain treatment outcomes is multifaceted, and the selection of appropriate measures is dependent on the objectives of outcomes measurement. Patient-focused outcomes approaches are concerned primarily with treatment-related changes in patients' pain experience. Service delivery outcomes approaches focus on monitoring and enhancing pain service delivery systems. These two approaches should not be considered mutually exclusive; more elaborate outcomes systems may include aspects of each.

Patient Domains

Current standards for chronic pain treatment are based on biopsychosocial conceptualizations of chronic pain as a complex, multidimensional phenomenon with diverse etiologic and sustaining factors (Turk & Flor, 1999). Consistent across biopsychosocial perspectives is the underlying assumption that the chronic pain experience is a result of a dynamic interaction among biological, psychological, behavioral, and social factors that shape the individual's response to physical perturbations (Turk & Flor, 1999). Accordingly, recommendations for comprehensive treatment target multiple domains of patient functioning including the physical, perceptual, behavioral, and psychosocial status of the individual. Reflecting this multidimensional approach to conceptualization and treatment, current guidelines for pain outcomes assessment mandate the measurement of treatment-related change within each major domain of an individual's chronic pain experience (Rehabilitation Accreditation Commission, 2002).

The discussion that follows considers each of the domains of patient functioning that we believe to be an important aspect of the pain experience. While not all of these patient-centered domains are likely to be directly targeted by any single treatment approach, changes may be observed in any of these areas following even the most focused interventions due to the interrelationships among these domains. Where appropriate we have suggestions for measures that may be used to assess outcomes in each

of these domains. However, it should be noted that only those measures that have been validated with pain patient samples and were judged by the authors to have some utility for outcomes assessment were included in this discussion. Criteria for inclusion in this review were (1) evidence of acceptable reliability, (2) data supporting instrument validity, (3) prior use as a pain outcomes instrument, and (4) high utility for pain outcomes assessment, as judged by the authors. If such measures are not available, suggestions for alternative assessment strategies are provided. The domains assessed by the instruments that are reviewed are presented in Table 9.1. Absent from this review are several well-validated measures, such as the Coping Strategies Questionnaire (CSQ; Rosensteil & Keefe, 1983), which tap important aspects of the pain experience and have been widely used in pain research, but lack significant evidence of utility for general pain outcomes assessment. For the reader who is interested in a wider range of pain measures, more comprehensive reviews may be found elsewhere (Bradely, Haile, & Jaworski, 1992; Jensen & Karoly, 2001; Tait, Pollard, Margolis, Duckro, & Krause, 1987).

Pain Intensity

While practitioners may not agree on the relative importance of pain reduction as a treatment objective, pain intensity is clearly an essential outcomes assessment domain from most perspectives. Fundamentally, the sensory experience of pain is a subjective aversive phenomenon that is unique to each individual, and as such, it is difficult to describe and quantify objectively. Fortunately, several easy-to-administer, psychometrically sound scales have been developed to assess this domain of the pain experience. There are three broad categories of commonly used pain intensity measures: the Visual Analog Scale (VAS), Numeric Rating Scale (NRS), and Verbal Rating Scale (VRS). The VAS and NRS typically consist of a single item requiring patients to quantify the intensity of their "current," "usual," "least," or "worst" pain. Empirical evidence suggests that the combination of "least" and "usual" pain ratings provides the best estimate of actual pain intensity, while "least" may be the single most accurate predictor (Jensen, Turner, Turner, & Romano, 1996). However, for practical purposes clinicians can have confidence in the choice of a single VAS or NRS rating of "usual" pain, which appears to provide a reasonably valid estimate of actual pain. Interestingly, "current" and "worst" pain ratings were found to have a weaker relationship with actual pain intensity (Jensen et al., 1996).

A reliable and well-validated form of the VAS is a 10-cm line anchored with the phrases "no pain" and "worst possible pain" or "excruciating pain." Patients are instructed to bisect the line at the point that best represents their level of pain, and the score is simply the length of

the segment to that point. The VAS has been found to be valid and sensitive to changes in acute, cancer, and chronic pain (Breivik, Bjornsson, & Skovlund, 2000; De Conno et al., 1994; Hutten, Hermens, & Zilvold, 2001; Jensen & Linton, 1993; Ogon, Krismer, Soellner, Kantner-Rumplmair, & Lampe, 1996), and it yields ratio level data (Jensen, Turner, & Romano, 1992). Although comparisons of horizontal and vertical line orientations yield mixed results, using the VAS horizontally may provide slightly higher sensitivity (Jensen, Turner, Romano, & Fisher, 1999; Ogon et al., 1996; Stratford, Binkley, Riddle, & Guyatt, 1998).

The NRS consists of a numeric range from 0 to 10 or 100 with anchors similar to those of the VAS, which can be administered in oral or written form. Individuals are asked to quantify their pain levels by choosing a single number from the 11- or 101-point scale. The NRS has been found to have good psychometric characteristics (Jensen et al., 1999) and to be sensitive to changes in acute, cancer, and chronic pain (De Conno et al., 1994; Paice & Cohen, 1997). The data provided by the NRS can be treated as ratio level (Jensen & Karoly, 1992).

Verbal rating scales typically consist of a list or lists of pain descriptors that are rank-ordered along a continuum of severity. Patients are asked to select the most appropriate descriptor or set of descriptors, and a score is assigned based on the rank(s) of the chosen word(s) (Jensen & Karoly, 1992). The McGill Pain Questionnaire (MPQ; Melzack, 1975a) is a well-validated, widely used VRS that consists of 20 lists of descriptors of the sensory,

affective, and evaluative dimensions of pain (Melzack, 1975b). The standard scoring procedure yields a Pain Rating Index (PRI) for each of the three subscales listed above, although in practice these subscales are often summed to create a single PRI. The PRI has been shown to be sensitive to change and valid for use among acute, cancer, and chronic populations (Davis, 1989; Lowe, Walker, & MacCallum, 1991; Sist, Florio, Miner, Lema, & Zevon, 1998). However, as is true of other verbal scales, it only yields ordinal level data as questions have been raised about the assumption of equidistance between ranked descriptors (Choiniere & Amsel, 1996). Additionally, support for the tripartite structure of the MPQ is mixed, and factor analyses generally reveal significant overlap between factors (Donaldson, 1995; Holroyd et al., 1992; Turk, Rudy, & Salovey, 1985).

Another verbal pain scale, often used in analgesic research, is a 0 to 3 categorical scale with 0 corresponding to "no pain," 1 to "mild pain," 2 to "moderate pain," and 3 to "severe pain." While there is evidence for the validity of this approach when used to differentiate between categories of pain intensity (Jensen & Karoly, 2001), this ranked-score approach often is treated as if it represented an interval scale where differences between any successive rankings are assumed to be equal. This may result in misleading estimates of changes in pain intensity and is therefore best reserved for use only as a descriptive scale.

Practical considerations suggest that the VAS or the NRS may be preferred to the MPQ or other verbal scales

for the clinical assessment of pain intensity as they provide psychometrically superior data that are relatively easy to collect and score. When ease of administration and scoring are of greatest concern, the 11-point NRS may be the best choice. In contrast, when greater measurement precision is desirable, the advantage goes to the VAS or to the 101-point NRS.

Pain Interference

A central goal of pain intervention is to reduce the extent to which pain impairs physical activity, emotional functioning, and psychosocial role fulfillment. The term *pain interference* has been used to define this broad construct, which taps patients' perceptions of the degree to which pain disrupts physical and emotional functioning. Measures of pain interference should not be confused with instruments that simply quantify functional status without attempting to account for the role of pain in the reported impairment. This difference is illustrated by the contrast between the Sickness Impart Profile (SIP) psychosocial scale, which measures the extent of emotional and social difficulties that are attributed to the pain condition, and the Beck Depression Inventory (BDI; Beck, 1987), which assesses depressive symptomatology without concern for etiology.

The Pain Disability Index (PDI; Pollard, 1984) is a seven-item measure of pain interference in physical and psychosocial role performance. The PDI has good internal consistency ($\alpha = 0.87$; Tait et al., 1987) and 1-week test–retest reliability (intraclass $r = 0.91$; Gronblad et al., 1993), and it has been shown to effectively discriminate groups of pain patients with varying levels of disability (Tait, Chibnall, & Krause, 1990). The measure appears to be sensitive to change (Strong, Ashton, & Large, 1994), and it is valid for use with patients with chronic and post-operative pain (Pollard, 1984). Factor analysis supports the classification of the PDI as a unidimensional measure of pain interference (Tait et al., 1990). The PDI has practical appeal as a brief, easy-to-use, and psychometrically sound measure of general pain interference when less comprehensive assessment of pain-related disability is adequate.

The SIP is a widely used, 136-item measure of perceived impairment (Brown, 1995; Williams, 1988) with high test–retest reliability (0.92) and internal consistency (0.94; Bergner, Bobbitt, Carter, et al., 1981). The SIP administration instructions were altered by Turner and Clancy (1988) to reflect pain-related impairment rather than general physical impairment. The 14 SIP subscales assess pain interference across a wide range of functioning, and they are combined to form the physical, psychosocial, and total scales. The SIP scales have been found to possess good concurrent validity in patients with chronic pain and cancer pain (Beckham, Burker, Lytle, Feldman, & Costakis, 1997; Watson & Graydon, 1989), and they are sen-

sitive to change resulting from multidisciplinary inpatient treatment for chronic pain (Jensen, Strom, Turner, & Romano, 1992). From a practical standpoint, the main weaknesses of the SIP are its length and the relative difficulty of scoring the inventory. In addition, individuals with pain may find many SIP items to be less face valid and relevant to their condition than those of measures developed specifically to tap pain-related disability. Nevertheless, the SIP remains the "gold standard" for detailed assessment of self-reported pain interference.

The Oswestry Disability Questionnaire (ODQ) is a 10-item questionnaire assessing pain and pain-related limitations in daily activities (Fairbank, Couper, Davies, & O'Brien, 1980). Testees choose one of six response options for each item, and scores are summed across items. The ODQ has evidenced adequate stability (Davidson & Keating, 2002) and internal consistency (Hsieh, Phillips, Adams, & Pope, 1992), as well as discriminative validity (Leclaire, Blier, Fortin, & Proulx, 1997) and sensitivity to change (Davidson & Keating, 2002). ODQ item content suggests that it may be most useful for patients with more severe limitations or disability (Baker, Pynsent, & Fairbank, 1989).

Emotional Distress

Emotional distress is highly prevalent among individuals with pain, and it is a core feature of most chronic pain syndromes. Not only does emotional distress often exacerbate a pain condition, but it may also have a significant impact on treatment outcomes regardless of whether it is addressed clinically or not. Accordingly, treatment standards recognize the importance of incorporating the treatment of concurrent anxiety and depression into the intervention approach. Presented here are measures of emotional distress that, although not pain specific, are widely used in pain intervention outcomes assessment. These measures were selected based on their brevity, convenience, and general acceptance among pain researchers for outcomes assessment.

The BDI is a 21-item measure of depressive symptomatology (Beck, 1987). This widely used instrument has been shown to have adequate psychometric properties (Beck, Steer, & Garbin, 1988), and it is sensitive to change resulting from multidisciplinary pain clinic treatment (Kleinke, 1991). The BDI discriminates well between patients with chronic pain with and without depression (Geisser, Roth, & Robinson, 1997). However, researchers have raised questions about the appropriateness of using the BDI to detect depression among patients with pain (Williams & Richardson, 1993). Several BDI items contain somatic content (e.g., sleep disturbance, fatigability, and somatic preoccupation) that is confounded with commonly observed symptoms of chronic pain syndromes, and several studies have suggested that patients with pain

may produce higher scores on these items as a function of their pain-related physical symptomatology (Plumb & Holland, 1977; Wesley, Gatchel, Gorofalo, & Polatin, 1999). While this may limit total score comparisons with nonpain populations, removal of the somatic items has not been found to improve the accuracy of the measure for discriminating depressed from nondepressed patients with chronic pain (Geisser et al., 1997). Consequently, clinicians may choose to use the BDI for treatment outcomes, although accurate classification of depressive symptomatology may require higher cutoffs.

An alternative measure of depression favored by some researchers for pain outcomes is the 20-item Center for Epidemiologic Studies Depression Scale (CES-D; Radloff, 1977). The CES-D has high internal reliability (α = 0.85) in normal populations and good concurrent validity in chronic and cancer pain populations (Beckham et al., 1997; Radloff, 1977). The CES-D may be more sensitive to change than the BDI (Turk & Okifuji, 1994). Normed on a normal population, the CES-D suffers from many of the same limitations as the BDI, potentially producing a high number of false positives among patients with chronic pain and cancer pain. However, like the BDI, the CES-D has been shown to discriminate between patients with chronic pain with and without depression, and removal of somatic items did not appreciably improve accuracy (Geisser et al., 1997; Turk & Okifuji, 1994). Nonetheless, higher cutoffs should be used in pain populations.

The impact of anxiety on pain treatment outcome has not been studied as extensively as that of depression. However, the existing evidence suggests a high concordance between pain and anxiety (Polatin, Kinney, Gatchel, Lillo, & Mayer, 1993), and the need to address these symptoms in comprehensive pain intervention is well recognized. The State-Trait Anxiety Inventory (STAI) is a 40-item self-report inventory of state and trait anxiety that possesses adequate psychometric properties (Spielberger, 1983) and is widely used for pain outcomes measurement. The STAI is sensitive to change (Mongini, Defilippi, & Negro, 1997) and is an adequate choice for the clinician wishing to quantify levels of both acute anxiety and the more stable tendency to perceive one's environment as threatening.

Pain-Related Fear

Recently, researchers have begun to focus on the role of pain-specific emotional distress in the experience of pain. Emerging data indicate that pain-specific emotional distress, particularly pain-related fear, may play a more important role than general levels of affective disturbance in the development and maintenance of pain-related physical disability (McCracken, Faber, & Janeck, 1998). The construct of pain-related fear may be defined broadly as the fear of pain and the avoidance of behaviors that are anticipated to produce painful sensation or injury.

Although no evidence currently exists linking levels of pain-related fear to treatment outcome, the available data suggest that pain-related fear may seriously compromise an individual's willingness to initiate and persist in the degree of physical reactivation and restoration that is essential to reversing the progression of pain-related disability. Accordingly, clinicians and researchers are beginning to pay more attention to the role of pain-related fear in pain treatment outcome.

Of the few available measures of pain-related fear, the Pain Anxiety Symptoms Scale (PASS; McCracken, Zayfert, & Gross, 1992) and the Tampa Scale (TS; Kori, Miller, & Todd, 1990) are the most promising. The PASS is the longer of the two measures, with 40 items assessing cognitive and pain-related physiological anxiety symptoms, escape and avoidance responses, and fearful appraisal of pain (McCracken et al., 1992). The four PASS subscales have good internal consistency (McCracken, Zayfert, & Gross, 1993), and the total score has good predictive validity and appears to be adequate for outcomes assessment (McCracken et al., 1998). Scores on the PASS have been found to predict self-reported pain severity, disability, pain behavior, and range of motion on straight leg raise (McCracken, Gross, Aikens, & Carnrike, 1996; McCracken, Gross, Sorg, & Edmands, 1993). In addition, pain patients classified as "dysfunctional" by the Multidimensional Pain Inventory (MPI; Kerns, Turk, & Rudy, 1985) were more likely to produce high scores on the PASS than those classified as "interpersonally distressed" or as "adaptive copers" (Asmundson, Norton, & Allerdings, 1997).

Perhaps a better measure of the pain-related anxiety is the TS, a 17-item instrument developed to assess kinesiophobia, or the fear of movement and activity due to concerns about injury or reinjury (Kori et al., 1990). Although limited, recent evidence suggests that the TS may possess greater predictive validity than the PASS and other measures of pain-related fear. The TS has been found to be a superior predictor of a range of pain symptoms and behaviors, even after controlling for known confounding factors such as pain intensity and duration, gender, and negative emotionality. For example, the TS was an incrementally valid predictor of self-reported disability and behavioral performance during a lifting task after controlling for pain onset, lower extremity radicular pain, and pain intensity, while the PASS was not (Crombez, Vlaeyen, Heuts, & Lysens, 1999). In addition, the TS has been found to be a superior predictor of disability as compared with pain intensity, biomedical signs and symptoms, and negative emotionality (Crombez et al., 1999; Vlaeyen et al., 1999). Although there are no data on the ability of either the TS or the PASS to capture treatment-related change, either measure may be appropriate. However, given its superior predictive validity and shorter length, the TS appears to be the instrument of choice for assessing treatment-induced changes in pain-related fear.

Activity Level

Individuals with pain conditions often exhibit a pattern of gradually declining physical activity. In many cases, activity is associated with the experience of discomfort or the potential for reinjury and, therefore, is generally avoided. The resulting deconditioning increases the probability that activity will be experienced as aversive or harmful. In this manner, inactivity is reinforced and becomes an entrenched behavioral pattern. Accordingly, physical reactivation is a central component of most multidisciplinary treatment approaches, and most outcomes batteries include a measure of activity level. Unfortunately, most measures of activity rely on patient self-report, which may be subject to considerable biases stemming from such factors as differences in self-perceived effort expenditure, secondary gain factors, or inaccuracy in retrospective reporting. In response to this measurement issue, some pain experts have begun to consider the potential utility of actigraphy as a means to capture treatment-related changes in physical activity. Currently, there are at least two commercially available actigraphs that promise to provide an objective measure of this important outcomes domain. Both devices are wrist-worn and provide an unobtrusive method of recording ongoing activity counts over a period of up to 30 days. While very little literature documenting the use of these devices for pain treatment outcomes currently exists, interest in the pain research community is growing and likely to produce support for this approach within the next few years.

Physical Capacities

In contrast to functional capacities, little empirical or theoretical attention has been devoted to consideration of the role of physical capacities in pain-related disability. However, the importance of this construct, which refers to an individual's theoretical peak physical capabilities, is evident in the focus of many treatment programs on improving physical status variables such as strength, endurance, and range of motion. Unfortunately, the lack of agreement between self-report and actual physical capacities (Clark, 1996; Deyo, 1988) has complicated outcomes measurement leading many pain practitioners and researchers to suggest that objective physical capacity measures may serve as better indicators of treatment-related changes in this domain. At present there are no "gold standard" objective outcomes measures of pain-related physical capacity, although a variety of methods have been employed in attempts to quantify changes in the physical abilities of individuals with pain. Standardization of assessment methods is lacking, and practitioner ratings of function remain very popular despite numerous studies demonstrating their poor reliability. Although there are a few commercial systems that may eventually provide adequate validation data, they are very expensive and time intensive, limiting their utility for clinical settings. The best-supported performance measures, which tend to be less resource intensive, are the dual inclinometer method of assessing changes in trunk range of motion (Engelberg, 1993; Keeley et al., 1986; Mayer, Kishino, Keeley, Mayer, & Mooney, 1985) and the use of hand dynameters to evaluate upper extremity strength (Mathiowetz, Rennells, & Donahoe, 1985; Mathiowetz, Weber, Volland, & Kashman, 1984). In settings where rapid assessment is necessary, current alternatives appear limited to goniometer measures or practitioner ratings until alternative approaches are developed and validated.

Employment Status

Employment status is a key functional outcomes variable that is commonly used to evaluate the global success of chronic noncancer pain treatment programs. In fact, many treatment outcomes guidelines, such as those promulgated by CARF (Rehabilitation Accreditation Commission, 2002), mandate the use of work status as an outcomes indicator. Similarly, changes in disability status may be an important measure of the overall clinical impact of the intervention approach. Unlike most other outcomes domains discussed here, standardized measures are not required to assess changes in employment status. Current employment and disability status can be collected as part of pre- and post-treatment interviews, most commonly as a categorical variable in which the participant is characterized as being employed full-time, part-time, or not at all. An alternative approach may be to quantify the extent to which a person was gainfully employed and at work during a given period of time. Also important are changes in disability status that affect an individual's eligibility for employment, coded categorically as having a claim pending or not. Finally, for retirees or persons already established as being disabled, an increase in avocational activities may be an appropriate measure of pain treatment success as measured by volunteer work, increases in household chores or activities around the home, initiation of hobbies, or other changes consistent with general productiveness.

Relationship Outcomes

Central to current biopsychosocial conceptualizations of pain is the role of interpersonal relationships, particularly those with immediate family members. Interpersonal relationships may promote the development and maintenance of chronic pain conditions, and family involvement in the treatment process has long been recognized as an important predictor of outcome. Current treatment standards call for active significant other participation in treatment through activities such as family education, shared goal setting, and compliance support. Measurement of the effectiveness of these intervention components will

depend in part on the specific aspects of the social context that are addressed clinically. Although providers may want to include general measures of family functioning such as the Dyadic Adjustment Scale (Spanier, 1976), pain-specific and behaviorally focused measures may be most useful. One option is the Significant Others Response scale of the West Haven-Yale Multidimensional Pain Inventory (Kerns et al., 1985). Also important to assess may be satisfaction with sexual intimacy in the dyadic relationship. Unfortunately, there are few standardized measures of many aspects of relationship functioning (such as sexual intimacy) that are posited to have an impact on chronic pain disability, and therefore, providers must rely on nonspecific measures validated in other populations. Interested readers are referred to Jacob and Kerns (2001) for a comprehensive review of the available measures in this area.

Health Care Utilization

Individuals with chronic pain utilize health care resources at higher rates than those without pain (Gironda, Clark, Neugaard, & Nelson, 2004). From a patient-focused outcomes perspective, excessive use of health care resources may be conceptualized as reflecting sick role behavior, and therefore, utilization variables may serve as useful indices of functional status. Reduced reliance on provider intervention may indicate a reduction of symptomatology or a shift on the part of the patient to a more self-reliant proactive role in pain management. Patient-focused health care outcomes variables may range from simple counts of medical contacts for pain over a given period of time to quantification of the socioeconomic costs to the patient for the identified visits.

Patient Satisfaction

Satisfaction with treatment is a key outcome domain that may have significant implications for patient behavior and treatment success. Treatments that meet patients' expectations are more likely to facilitate a working therapeutic relationship and engender compliance (Aharony & Strasser, 1993; Carr-Hill, 1992). However, measurement of treatment satisfaction is hindered by widely varying conceptualization and by patients' difficulty in separating their satisfaction with pain management from their satisfaction with other aspects of care (e.g., relationships with the health care providers). One of the only treatment satisfaction measures to be developed specifically for use with patients with chronic pain is the Pain Treatment Satisfaction scale (PTS). This five-item scale, which consists of items from the National Pain Data Bank comprehensive outcomes measurement system (AAPM, 2000), is included in the post-treatment version of the Pain Outcomes Questionnaire (POQ) and can also be used as a

stand-alone measure. The PTS scale has been demonstrated to have good internal consistency ($\alpha = 0.83$ to 0.90) and good concurrent and predictive validity (Clark, Gironda, & Young, 2003). As such, the PTS offers an easy-to-administer, pain-specific, and effective alternative to the generic satisfaction measures commonly relied upon by pain providers.

Drug-Related Problems

A drug related problem (DRP) is any undesirable event that involves some aspect of the patient's drug therapy and has the potential to negatively affect outcome. DRPs may include not taking or receiving the needed drug, taking or receiving the wrong drug, taking or receiving too little or too much of the correct drug, or experiencing an adverse drug reaction including drug–drug or drug–food interactions. Unfortunately, there are no widely available tools or standards for monitoring of DRPs. Providers who are interested in tracking DRPs should develop a coding and recording system that captures the types of problems described above and can be incorporated into standard assessment and documentation practices. Aggregate counts of DRPs may be tracked over time to provide a measure of the safety of prescribing practices. A root cause analysis or similar technique should be employed to refine, correct, or discontinue provider practices if the number of DRPs exceeds a predetermined threshold for a given period of time. DRP thresholds should vary according to the severity of the associated consequences (e.g., a brief medication-induced hypertensive episode vs. a medication-related death).

Multidimensional Measures

The preceding discussion has focused on unidimensional instruments, each of which measures a single pain outcomes domain. Unidimensional pain outcomes instruments generally are readily available, inexpensive, and necessitate minimal administration training time. Additionally, they are an efficient means of collecting data when only a limited number of outcomes domains are to be assessed. However, to assess multidomain pain treatment outcomes using unidimensional measures, it is necessary to assemble a battery of individual instruments. Because instrument selection is likely to vary across settings, the idiosyncratic nature of these batteries often restricts or prevents comparisons between local outcomes data and community benchmarked data. In addition, some of these instruments are quite lengthy and may include items that are not directly relevant to pain. Thus, while unidimensional measures may be the most efficient means of collecting pain data for one or two selected pain outcomes domains, the use of many unidimensional measures to cover all key chronic pain outcomes domains may

decrease the utility of the obtained data while increasing staff and patient burden. In response to the limitations associated with batteries of unidimensional instruments, a few *multidimensional* pain outcomes tools have been developed. Three of these are discussed below.

Brief Pain Inventory

The Brief Pain Inventory (BPI; Cleeland & Ryan, 1994) is a 32-item instrument developed to assess pain history, pain intensity, perceived recent response to medication/treatment, and pain interference. The BPI is well validated among patients with cancer and chronic disease (e.g., osteoarthritis) pain (Clark & Gironda, 2002), and it has been translated into several languages. Factor analytic studies consistently have revealed the two-factors of pain severity and pain interference in physical functioning across samples and language versions (Caraceni et al., 1996; Radbruch et al., 1999; Saxena, Mendoza, & Cleeland, 1999; Wang, Mendoza, Gao, & Cleeland, 1996). However, empirical data are limited mostly to cancer and chronic disease samples, and little is known about the sensitivity to change or psychometric properties of the instrument when used with chronic pain populations.

Multidimensional Pain Inventory

The MPI, formerly the West Haven-Yale Multidimensional Pain Inventory, is a popular pain measure that was developed to facilitate the comprehensive assessment of patients with chronic pain (Kerns et al., 1985). Designed to be used in conjunction with behavioral and psychophysiological measures, the 52 items comprise 12 subscales that are dispersed across three sections: (1) pain intensity, pain interference, dissatisfaction with current functioning, appraisal of support form others, perceived life control, and affective distress; (2) punishing, solicitous, and distracting responses from significant others to displays of pain behaviors; and (3) frequency of the performance of household chores, outdoor work, activities away from home, and social activities (Kerns et al., 1985). Kerns and colleagues (1985) showed that the 12 subscales possess good internal consistency (α = 0.70 to 0.90) and acceptable 2-week test–retest reliability (r = 0.62 to 0.91). Adequate levels of unique variance and concurrent validity have been demonstrated for most scales (Kerns et al., 1985). The MPI appears to be sensitive to change, but the utility of specific subscales may vary across levels of adaptation and functioning (Strategier, Chwalisz, Altmaier, Russell, & Lehmann, 1997).

In addition to the measurement of treatment outcomes, the MPI has been used to classify patients with chronic pain to identify major treatment needs. Cluster analyses have yielded a three-group typology of patients with chronic pain consisting of dysfunctional, interpersonally distressed, and adaptive copers or minimizers categories (Turk & Rudy, 1990). Clinicians may find this typology useful for purposes such as planning pain treatment or testing the effectiveness of different interventions or intervention components across MPI groups of patients.

Pain Outcomes Questionnaire

The POQ is a pain outcomes package consisting of intake, post-treatment, and follow-up questionnaires. The POQ, which was originally based on the National Pain Data Bank questionnaires (AAPM, 2000), was developed specifically to assess treatment outcomes and therefore encompasses the key domains of functioning for comprehensive outcomes measurement. The outcomes package allows the clinician to track changes in pain intensity, pain interference, emotional distress, activity impairment, pain-related fear, vocational functioning, treatment satisfaction, perceived improvement, and medical resource utilization from intake through follow-up, obviating the need to use more than one measure (Clark et al., 2003). The POQ contains six core subscales which assess pain intensity, pain-interference in activities of daily living (ADLs) and mobility, negative affect, vitality impairment, and pain-related fear. The subscales possess excellent generalizability (r = 0.78 to 0.93) and acceptable 7- to 14-day test–retest reliability (r = 0.63 to 0.89). In addition, the subscales have good convergent and discriminant validity, and they are sensitive to change. Finally, confirmatory factor analyses have verified the multidimensional structure of the subscales (Clark et al., 2003). A similar but less comprehensive outcomes tool is the Pain Outcomes Profile (AAPM, 2003), which is published by the American Academy of Pain Management. It contains all of the POQ core scale items but does not assess employment status, medical utilization, or treatment satisfaction.

Advantages and Disadvantages of Multidimensional Measures

Multidimensional pain outcomes measures have several advantages relative to unidimensional measures. Because these instruments were specifically designed for pain populations, they often contain fewer total items than combinations of corresponding unidimensional measures and tend to be better integrated. Additionally, as the instruments are uniform, results can be compared across treatment settings or geographic regions, which may assist in the eventual development of universal pain outcomes benchmarks. Disadvantages of the multidimensional measures are that they may be more difficult to obtain, may require additional administration or scoring training as well as more data entry and management time, are more costly in some cases, and may not cover all of the key chronic pain outcomes domains. Nevertheless, when assessing multiple domains of outcomes in clinical settings, multidimensional measures generally are more practical.

HEALTH CARE SYSTEM DOMAINS

The preceding discussion provides an overview of the key domains of *patient* functioning that may be incorporated into an outcomes assessment system. While patient-focused assessment is critical to selecting, delivering, and refining intervention practices that produce improved patient functioning, measurement of health care system outcomes domains also provides important indices of the utility and effectiveness of pain treatment. Also called process outcomes dimensions or "service delivery outcomes" (Clark & Gironda, 2002, p. 998), these domains are the focus of efforts to monitor and improve pain service delivery systems. Typically, health care system outcomes procedures are part of facility performance improvement and accreditation activities. Unlike most patient-focused domains, health care system outcomes are not tracked using standardized measures, but rather involve monitoring aspects of service delivery or patient documentation by reviewing medical and facility records. The following discussion outlines important domains of health care system outcomes, including pain care delivery, pain care costs, and staff competency.

Pain Care Delivery

Pain care delivery outcomes encompass a range of service provision variables including pain screening and assessment procedures, clinic waiting times, patient education, the occurrence of pain-related events, and treatment effectiveness.

Pain Screening and Assessment

The foundation of effective pain treatment is thorough and reliable assessment of pain. Unfortunately, despite JCAHO standards mandating that pain be assessed in all patients, routine pain assessment is not consistently practiced across general health care settings, an omission that often results in the undertreatment of pain (American Pain Society, 1999). Evaluation of pain assessment practices is only possible when the medical records fully document the completed assessment process. It is important to note that pain intensity scores alone do not constitute a comprehensive assessment. Pain assessment should include documentation of the effects of pain on a broad range of life functions (Clark et al., 2003). Measures of pain assessment compliance may simply be the percentage of cases that evidence appropriate pain assessment documentation.

Waiting Times

Prompt access to pain treatment is an implicit corollary of current pain treatment standards. Assessment of waiting time may assess the period between the following sets of events: clinic referral and first available appointment, scheduled clinic appointment time and the time the patient actually is seen, initiation of a pain medica-

tion order and the administration of the pain medication (inpatient setting), and the patient's pain medication request and the time the medication is dispensed (inpatient setting). In some settings at least a portion of these data will be available in computerized medical record systems. However, it is likely that most facilities will need to develop specific monitors to record the relevant waiting periods.

Patient Education

Active patient and family participation in the treatment process is perhaps most successfully promoted through education regarding the experience of pain and the importance of effective pain management. Accordingly, patient and family education is considered an essential component of successful pain management programs. As with other health care systems outcomes domains, documentation of patient education should be available in the medical record. Another strategy may be to survey patients and their families regarding the nature and extent of pain education that they received.

Pain-Related Adverse Events

A pain-related adverse event may be defined as any event associated with the pain experience that negatively affects or has the potential to negatively affect the patient's well-being or probability of benefiting from treatment. Examples of common pain-related adverse events include (1) falls that result in injury, reinjury, or the reinforcement of pain-related fear of activity and (2) misuse of an opioid analgesic. Once again, careful documentation of all occurrences of pain-related adverse events is essential to evaluate clinical practices. Systematic tracking of these adverse event episodes over time may facilitate the identification of risk factors that exist within the pain service delivery system.

Treatment Effectiveness

From a health care systems outcomes perspective, treatment effectiveness evaluation differs from the patient-focused approach presented above in that the unit of measurement is not the individual patient but rather the system of clinical service provision. Appropriate units of measurement may include a provider, a group of providers, a group of clinics, etc., while the common goal is to assess the general effectiveness of the defined clinical delivery system for a group of patients treated during a given period of time. This type of evaluation is at the heart of PI efforts and may be as simple as reporting aggregate data collected as a component of the patient-focused outcomes process. An example of this approach is the evaluation of treatment-related pain intensity changes for all patients treated in a multiprovider clinic during a three-month period.

Pain Care Costs

It is estimated that direct and indirect costs associated with chronic noncancer pain exceed $125 billion yearly (Okifuji, Turk, & Kalauokalani, 1999). As mentioned previously, in this environment of soaring health care expenditures, treatment practices that do not demonstrate cost-effectiveness will no longer be economically viable as third-party payers and policy makers shift limited resources to proven intervention strategies. In a general sense, cost-effectiveness is based on a comparison of the benefits derived from receiving pain management services in relation to costs associated with those services. Important but often neglected in this discussion is the issue of cost-offset, which refers to the delayed benefits of an intervention that can be operationalized as reductions in health care costs that are reasonably believed to be attributable to the pain treatment. To conduct a cost-effectiveness evaluation, a system for capturing health care utilization and patient benefits must be developed. Monetary values must be assigned to the various types of services and patient outcomes within each category to allow estimation of the relative economic impact of patient benefits and health care expenses. If a common criterion of success is defined (e.g., return to work), costs associated with a variety of interventions can be compared (see Straus, 2002, and Turk et al., 2002, for specific examples).

Staff Competency

Staff competency in pain treatments maximizes the probability of the appropriate selection and delivery of effective interventions and minimizes the likelihood of the occurrence of pain-related adverse events. Ongoing training and education in both general and discipline-specific pain management are essential to cultivating staff competency. Routine testing of staff following completion of education or training experiences may be used to demonstrate that team members possess a criterion level of pain knowledge relevant the patient population being served. An example of this approach can be found in the work of McCaffery and Pasero (1999) who have developed and validated a test of nurses' pain knowledge and attitudes. Alternatively, changes in pain treatment approaches following focused educational experiences may be used as measures of increased pain competency.

IMPLEMENTING AN OUTCOMES-DRIVEN MODEL OF PAIN CARE

The process of designing a pain outcomes methodology consists of a series of discrete steps and requires that factors relevant to the outcomes system development process, such as those described above, be considered carefully. In the following we provide an outline of our suggested approach to this endeavor in the hope that it will assist the reader through this process.

IDENTIFY OUTCOMES OBJECTIVES

The first step in developing a pain outcomes measurement system consists of identifying the goals, objectives, and scope of the outcomes program.

- Identify the basis for establishing the pain outcomes strategy. It may be a new hospital policy, legal opinion, or accreditation standard. Familiarity with the underlying rationale may make it easier to enlist administrative and staff support.
- Determine whether the outcomes objectives primarily focus on pain treatment issues or on the efficiency of pain service delivery. This distinction will have important implications for the eventual selection of outcomes measures.
- Define the scope of the outcomes plan. Are all available pain treatments to be included, or will only selected treatments be monitored? Does the plan cover every type of pain (acute, cancer, and chronic), or is it limited to only one or two?
- Choose which types of service settings will be included. Is it limited to outpatient areas, inpatient units, or specialty pain clinics? Are all providers working in the defined areas participating, or only some?
- Decide whether the outcomes data collection will be ongoing or limited to a preselected time interval.

IDENTIFY ADMINISTRATIVE SUPPORTS AND LIMITATIONS

Without sufficient administrative support, efforts to develop a pain outcomes system will fail. Staff will resent the added responsibilities in the absence of increased staff or concrete rewards. Presumably the basis for developing the pain outcomes system (JCAHO standards, insurer recommendations) will enhance administrative interest in the effort.

- Meet with the appropriate administrative representative to discuss anticipated costs and needed resources, citing any relevant local policies, local or national regulations, professional practice guidelines, or local competitors' outcomes practices and marketing data.
- Define the administrative limits (funds, positions) that are operative.

- Negotiate an agreement regarding support for the necessary resources.

SELECT THE RELEVANT OUTCOMES DOMAINS

Decisions regarding which pain outcomes domains to include often involve compromises between available resources and outcomes objectives. Resources may be limited, and outcomes efforts may be too ambitious. Collecting data for outcomes domains that are not central to the outcomes program objectives is a waste of staff resources and patient time.

- Select the relevant outcomes domains according to the focus of the outcomes program (treatment effects or service delivery), type of pain population involved (acute, cancer, or chronic), and setting.
- Avoid adding outcomes domains that are not directly relevant to the outcomes objectives. Additional domains may be added later if objectives change.
- Review any applicable guidelines, standards, or policies to ensure that all needed domains are included.

SELECT OR DESIGN THE NEEDED OUTCOMES MEASURES

Selecting Patient Outcomes Measures

If the objectives of the outcomes program involve evaluating the effects of pain treatment, it is likely that suitable pain outcomes instruments will be available for use. This will avoid the difficulties associated with designing and validating a new instrument and will minimize delays in implementing the outcomes programs.

- Identify potential instruments that assess the outcomes domains of interest (Table 9.1 may be helpful when matching outcomes instruments to outcomes domains).
- Investigate the reported reliabilities and review the validation data available for the identified instruments.
- Review any available data concerning reading level requirements, and determine whether those requirements are consistent with the target population's reading abilities.
- Attend to instrument length, administration and scoring requirements, and costs so as to maximize value and minimize resource demands.
- Determine whether the instruments are available in other languages if this is desirable given the characteristics of the target population.
- Choose the instrument or battery of instruments to use based on the above information.

Designing Service Delivery Outcomes Measures

As indicated previously, service delivery outcomes measures generally are not available in the form of validated outcomes instruments. In fact, with the exception of generic customer satisfaction measures, pain service delivery measures typically need to be designed locally. Fortunately, these measures are relatively simplistic. Usually they involve tracking whether required pain documentation is present or whether designated pain services were provided in an efficient and timely fashion. Thus, designing appropriate service measures may involve no more than developing pain-specific chart review forms or simple customer feedback tools.

- Identify the specific service delivery outcomes questions of interest.
- Design the necessary outcomes tools (e.g., chart review forms, customer satisfaction surveys).
- If patient surveys or questionnaires are involved, evaluate item wording, specificity, and reading level to meet the target population's abilities.

DEVELOP PROCEDURES NEEDED FOR IMPLEMENTATION

Once the scope of the outcomes project has been defined and the outcomes measures have been selected, specific procedures for implementing the outcomes system must be developed.

- Determine how the pain patients targeted for the study will be identified.
- Identify the roles, responsibilities, and training needs of all involved staff.
- Develop a timeframe for implementing all aspects of the outcomes system.
- Decide on a sampling strategy (i.e., randomly sample from among all possible data sources or attempt to collect data from every source during the data collection phase) depending on the sample size desired and the projected timeframe.

DESIGN AND PREPARE THE OUTCOMES DATABASE

Preparation of the outcomes database prior to implementation of data collection requires the review of every outcomes item or measure as well as all data entry and organization issues. Often this process yields valuable information that may streamline data collection and data management procedures.

- Decide what database and data analysis tools will be used.
- Design the necessary records storage and retrieval tools and conduct a "dry run" of data entry to identify any data collection problems.

- Make certain that the confidentiality of any patient information is maintained by discarding identifying information or by using elaborate coding or encryption strategies.
- Develop a data analysis plan in advance of data collection efforts.

COLLECT THE OUTCOMES

- Provide training in outcomes measure administration and data collection routines to relevant staff.
- Test the data collection procedures using only a few patients (treatment outcomes project) or records (service delivery project) prior to full-scale implementation.
- Arrange for backup coverage for the individuals collecting the data in the event of unexpected absences.
- Periodically review the workflow and data collection procedures to identify and troubleshoot any problem areas.

ANALYZE, TREND, AND REPORT THE DATA

Unfortunately, it is common to find that elaborate outcomes data have been collected at significant expense but then have been virtually ignored! Outcomes data analysis and trending is the cornerstone of an effective outcomes program. Analysis involves more than "eyeballing" the data. Although the level of statistical analysis will vary depending on the objectives of the outcomes plan and the psychometric sophistication of the staff involved, at the very least, it will be necessary to statistically summarize the data in a way that directly addresses the outcomes questions of interest. Ongoing review of the results by key personnel is critical and is mandated by some regulatory or accrediting bodies.

- For an ongoing outcomes program, establish a timeframe for systematically reviewing and reporting on the obtained data (monthly, quarterly, semiannually, or annually).
- Develop a report "template" that provides summary data regarding the outcomes questions and use that same template for each reporting period in order to allow comparisons over time.
- If performance improvement actions are instituted prior to or during a data collection period, note the nature of the changes implemented, along with the date, in the database so that the effects of the changes can be evaluated.
- After each reporting period, review data from all prior periods in concert with the current

results in order to identify trends of change in the data.
- Provide each staff person involved in the project with copies of the analysis report and schedule a meeting after each data collection period for review and discussion of the data and any identified trends.
- Design and complete a brief version of the analysis report for distribution to key administrators to help maintain their support for the project.
- Use the obtained data to explore any additional outcomes questions or to investigate observed trends in the data.
- Implement treatment protocol changes based on the identified trends. Changes should be introduced sequentially in order to allow the effects of each change to be evaluated separately.
- Review the outcomes data following each change in treatment protocol and decide whether to accept or reject the change.

CONCLUSIONS

The assessment of treatment outcomes is a necessary component of health care delivery and a key indicator of the quality of care delivered. In past years, evaluations of the effectiveness of pain interventions typically were based on providers' queries regarding treatment-related changes collected at patients' follow-up visits. Today, as a result of the demands of regulatory, accreditation, and advisory bodies, this informal outcomes assessment process no longer suffices. Instead, the focus is turning to the systematic collection and analysis of reliable data using validated measures. Indeed, the recent development of JCAHO pain standards and the growing national interest in pain issues have already had a profound effect on outcomes assessment within the pain management field. Outcomes measures now have become a standard component of pain treatment practices both for an individual practitioner and for health care systems. Given today's trends, it appears as if the importance of consistently monitoring, analyzing, and documenting the effects of pain treatment will continue to increase.

In this chapter we have attempted to summarize and briefly explore some of the key issues related to pain outcomes measurement endeavors. We also discussed the rationale underlying the use of outcomes measures in health care settings, focusing on pain-related issues, and provided a brief review of instruments and methods used to assess pain outcomes focusing first on the consumer of services and second on the health care delivery system. Last, we offered a method for designing and implementing appropriate outcomes measures in clinical practice settings. In recognition of the wide variety of pain practitioner settings and outcomes objectives, we tried to maintain a generalist's approach to the topic. In this

regard, we may have sacrificed precision to enhance utility. Nevertheless, it is our hope that the information we have provided will be of value to clinicians seeking to implement procedures to evaluate the effectiveness of their pain treatment interventions.

Chronic Pain and Addiction

David A. Fishbain, MD, FAPA

INTRODUCTION

There are a number of reasons pain clinicians have been historically interested in the area of addiction. At first, chronic pain clinicians had the clinical impression that pain treatment outcome was influenced by addiction issues (Fishbain et al., 1992b). As such, the mantra in the 1980s and the early 1990s was that chronic pain patients (CPPs) should be detoxified from opioids and that placement on opioids leads to addiction. This position radically changed in the late 1980s when publications began to appear claiming success in treating intractable CPPs with chronic opioid analgesic treatment (COAT) without the development of significant addiction (Portenoy, 1989; Portenoy & Foley, 1986). The COAT literature has increased and now contains a significant number of randomized controlled trials. They have recently been the subjects of a meta-analysis (Graven et al., 2000). Findings of this meta-analysis were that patients with nociceptive and neuropathic chronic pain may benefit from COAT, while this positive effect was less clear for patients with chronic idiopathic pain. Thus, because of the clinical interest in COAT as a way of helping intractable CPPs, addiction has become a hot topic within the pain literature.

This interest in COAT and the associated addiction issue has also been influenced by a number of other developments, which have occurred at the same time. First, a significant literature developed that spoke to the chronic undertreatment of pain by health care professionals (Bendtsen et al., 1999). Second, research studies reported that some physicians were prejudiced against the use of opioids (opiophobia) because of fears of iatrogenic addiction (Bendtsen et al., 1999; Weinstein et al, 2000). Third, in the late 1990s, because of the chronic undertreatment

of pain, state licensing boards began to develop policies that supported appropriate opioid prescribing rather than policies that hindered opioid prescribing. Fourth, in the early 2000s, Joint Commission on Accreditation of Health Organizations (JCAHO) incorporated the adequate treatment of pain as a patient right. Fifth, in the early 1990s, drug technology developed a number of controlled-release opioids, which were touted as controlling pain in a more effective manner than the immediate-acting opioids.

At the present time, COAT is mired in controversy. Clinicians who do not accept the current evidence for COAT efficacy still use the addiction issue as an argument against COAT. At the same time, clinicians who use COAT note that there appear to be addiction difficulties with some patients. Thus, at the present time, the issue of addiction is of intense interest to the pain clinician.

As the reader is aware, there are numerous books on the subject of addiction and its treatment. As such, the purpose of this chapter is not to review this literature, but to familiarize the pain clinician with addiction problems and issues that would be relevant to his or her pain practice. Thus, this chapter reviews the most recent research in reference to the following: substance abuse terminology definitions, identification of psychoactive substance use–related disorders or addiction, prevalence of addiction within CPPs, methods for diagnosing addiction in CPPs, risk of addiction in CPPs on opioid exposure, risk of re-addiction in addicts with chronic pain on opioid exposure, diversion, aberrant drug-taking behaviors as indicators of addiction, pseudo-addiction, psychiatric comorbidities in CPPs with addiction, use of short-acting opioids versus long-acting opioids for COAT, opioid treatment agreements, opioids and driving, legal issues in addiction and chronic pain, and opioid detoxification methods in addicts

and non-addicts. As can be seen, this chapter deals mainly with opioids and addresses other drugs of abuse, such as cocaine and cannabinoids, only peripherally. The reader is referred to addiction textbooks for in-depth discussion of the addiction issues relating to these drugs.

SUBSTANCE ABUSE TERMINOLOGY DEFINITIONS

Unfortunately, before we proceed to the addiction research relevant to chronic pain treatment, we need to address a major problem that has served as a confounder to much of this work. This is the confusion over substance abuse terminology (Fishbain et al., 1992b). Historically, there was little agreement between researchers on terms such as drug abuse, psychological dependence, drug dependence, and drug addiction (Rinaldi et al., 1988). Addiction initially meant a habit; however, in 1957 the World Health Organization (WHO) defined addiction as follows: a state or period of chronic intoxication characterized by (1) an overpowering desire or need or compulsion to continue taking the drug and to obtain it by any means; (2) tendency to increase dose; (3) a psychic (psychological) and generally physical dependence on the effects of the drug; and (4) detrimental effect on the individual and/or society (Fishbain et al., 1992b).

Because it was noted that some individuals could be physically dependent on a drug without compulsive use, and vice versa, the WHO then decided to use "dependence" as its crucial variable. Therefore, in 1964 the WHO defined drug dependence as "a state of psychic or physical dependence, or both, on a drug arising in a person following administration of that drug on a periodic or continuous basis." Around that time Rinaldi et al. (1988) performed a four-state Delphi survey of substance abuse experts to "achieve greater clarity and uniformity" for substance abuse definitions. These experts reached the consensus on 50 substance abuse terms. Seven definitions important to this article are taken from this list and presented in Table 10.3: Drug abuse, tolerance, physical dependence, psychological dependence, drug addiction, drug dependence, and drug withdrawal syndrome. It is to be noted that in the definition of drug addiction (Table 10.3), compulsive drug use is a central concept agreed upon by the experts. In addition, the following important concepts are to be noted in reference to the seven definitions in Table 10.3: they are distinct concepts in themselves and they should not be used interchangeably, physical and psychological dependence are encompassed within drug dependence, psychological dependence is distinct from tolerance and physical dependence, and tolerance and physical dependence develop on parallel time courses, but the rate of development of tolerance varies greatly between individuals (Rinaldi et al., 1988).

Psychological dependence is a behavior pattern characterized by continued craving for the substance and does not occur in every patient exposed to the substance. Compulsive drug-seeking behavior leading to overwhelming involvement in drug use and obtaining drugs is a manifestation of this craving. It is interesting to note that in some individuals compulsive drug-seeking behavior can occur before true physical dependence develops (Portenoy, 1989). These other points also apply to the interrelationship between these various concepts: one can be physically dependent without being drug addicted; one can be drug addicted without being physically dependent or drug tolerant; those who are drug addicted are likely to be physically dependent; not all drugs produce physical dependence, psychological dependence, and tolerance, with some drugs producing one manifestation only; and drug-addicted patients who are physically dependent are usually drug tolerant (Ludwig, 1980). Newman (1983) has therefore proposed that addiction needs to be redefined. He has concluded that narcotic addiction can be viewed as an "atypical response to exposure to opioids characterized by a tendency toward progressively greater consumption of the drug and a persistent disposition to relapse to drug use when abstinence has been achieved and physical dependence reversed." He then defined addiction as an "atypical behavioral pattern of drug use characterized by overwhelming involvement with the use of the drug (compulsive use), the securing of its supply, tendency toward progressive drug intake (loss of control) and the high tendency to relapse after drug withdrawal, and reversal of physical dependence."

The American Psychiatric Association (2000) incorporates some of these concepts into its diagnosis of substance dependence (Table 10.1). Unfortunately, there is difficulty in applying these criteria to CPPs for a diagnosis of addiction. For example, of seven criteria (of which three are required to fulfill this diagnosis), one relates to tolerance (criterion 1) and one to withdrawal (criterion 2). If patients with chronic pain are on significant opioids, they are invariably tolerant to opioids and manifest withdrawal when removed from opioids. Thus, these two criteria could lead to over-inclusiveness for this diagnosis in CPPs. In addition, criteria 3 and 4 (Table 10.1) can simply relate to the need to control pain. Thus, four of seven criteria may lead to over-inclusiveness in the application of this diagnosis to the patient with chronic pain.

Because of this confusion over the addiction concept and difficulties with its diagnostic application in CPPs, the American Academy of Pain Medicine, the American Pain Society, and the American Society for Addiction Medicine approved the following definition for addiction (American Academy of Pain Medicine, 2001). "Addiction is a primary, chronic, neurobiologic disease with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behaviors that include

TABLE 10.1
Criteria for a Diagnosis of Substance Dependence (DSM-IV)

Substance Dependence

A maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by the occurrence of three (or more) of the following during the same 12-month period:

1. Tolerance, as defined by either of the following:
   a. A need for markedly increased amounts of a substance to achieve intoxication or a desired effect
   b. Markedly diminished effect with continued use of the same amount of a substance
2. Withdrawal, as manifested by either of the following:
   a. Symptoms characteristic of withdrawal from a substance
   b. The ability to take a substance or one closely related to it, to relieve or avoid withdrawal symptoms
3. A need to take a substance in larger amounts or over a longer period than intended
4. A persistent desire to take a substance in larger amounts or over a longer period than intended
5. A great deal of time spent in activities necessary to obtain a substance (e.g., visits to multiple doctors or driving long distances), to use a substance (e.g., chain-smoking), or to recover from its effects
6. Abandonment of or absence from important social, occupational, or recreational activities because of substance use
7. Continued substance use despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance (e.g., continued cocaine use despite recognition of cocaine-induced depression or continued drinking despite recognition that an ulcer is made worse by alcohol consumption)

Source: Adapted from American Psychiatric Association (2000).

one or more of the following: impaired control over drug use, compulsive use, continued use despite harm, and craving." No diagnostic criteria, however, were proposed. As such, the pain clinician has the option of diagnosing addiction, using the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) criteria (Table 10.1), keeping in mind the criteria confounders described above, or using the above American Pain Society definition. This definition is defined by five Cs: *chronicity*, impaired *control*, *compulsive* use, *continued* use despite harm, and *craving*. Of these, chronicity, impaired control, and continued use despite harm could also be a manifestation of seeking pain relief. As such, this definition does not shed light on the issue of the difficulty of making an addiction diagnosis in the context of chronic pain. Support for the above comes from a recent study (Elander et al., 2003) with patients with sickle cell disease. Here researchers assessed DSM-IV symptoms of substance dependence and abuse and applied the DSM-IV criteria to differentiate between pain-related symptoms and nonpain-related symptoms. Pain-related symptoms were more fre-

quent, accounting for 88% of all symptoms reported. When pain-related symptoms were included in arriving at a diagnosis, 31% of the sample met DSM-IV criteria for substance dependence versus only 2% when only the nonpain-related symptoms were used to meet criteria.

IDENTIFICATION OF PSYCHOACTIVE SUBSTANCE USE–RELATED DISORDERS OR ADDICTION IN CPPs

Because of the above discussion, the identification of addiction is a complex problem. Complicating this problem is the fact that some patients inaccurately report the use of prescribed medications or fail to report the use of nonprescribed medications or medication prescribed by other physicians, or fail to report the use of illicit drugs (Berndt et al., 1993; Fishbain et al., 1998a; Katz & Fanciullo, 2002). Thus, the use of external sources of information can be helpful. This can include an interview with the spouse, a review of medical records, and the input of prescription monitoring programs. In addition, testing of biological materials (urine) can be extremely helpful. This will be dealt with in its own section below. Because of the problem of inaccurate patient reports, the detection of addiction begins with a high index of suspicion, first trying to identify addiction risk factors (Table 10.2) and then

TABLE 10.2
Addiction Risk Factors

- Biological parent who abuses drugs
- Biological parent who has an antisocial personality
- Lower socioeconomic status
- Child of a divorce home and/or single-parent home
- Behavioral problems as a child
- Comorbid depression, alcohol abuse, antisocial personality disorder, anxiety disorder
- Current dysfunctional or enabling family system (drug abuse in a family)
- Regular contact with high risk people (drug-using friends) or involvement with high-risk activities (regular time spent in a bar)
- Smoking
- Gambling
- Impulsivity
- Multiple physical traumas
- Behaviors with compulsive, addictive quality
- High neuroticism, high extraversion
- Antisocial behaviors (arrests, fighting, early drunkenness, truancy, difficulty with school)
- Use of illicit drugs
- Belief of needing some substance to feel "normal"
- Positive response if asked if use of drugs/alcohol contributed to a problem for them

TABLE 10.3
Substance Abuse Terminology Definitions

Term	Definition
(Drug) addiction	A chronic disorder characterized by the compulsive use of a substance resulting in physical, psychological, or social harm to the user and continued use despite that harm
(Drug) dependence	A generic term that relates to physical or psychological dependence, or both; it is characteristic for each pharmacological class of psychoactive drugs; impaired control over drug-taking behavior is implied
Drug abuse	Any use of drugs that causes physical, psychological, economic, legal, or social harm to the individual user or to others affected by the drug user's behavior
Physical dependence	A physiological state of adaptation to a drug or alcohol, usually characterized by the development of tolerance to drug effects and the emergence of a withdrawal syndrome during prolonged abstinence
Psychological dependence	The emotional state of craving a drug either for its positive effect or to avoid negative effects associated with its absence
Tolerance	Physiological adaptation to the effect of drugs, so as to diminish effects with constant dosages or to maintain the intensity and duration of effects through increased dosage
Drug withdrawal syndrome	The onset of a predictable constellation of signs and symptoms involving altered activity of the central nervous system after the abrupt discontinuation of or rapid decrease in dosage of a drug

Source: Adapted from Rinaldi, R. C. et al., 1988

looking for suggestive behavioral patterns (Table 10.4). This is then followed by a search for suggestive physical findings (Table 10.5). In addition, certain laboratory tests (Table 10.6) can provide clues. There are also a number of pencil and paper tests designed to identify drug/alcohol abuse/dependence: the Michigan Alcoholism Screening Test (MAST; Katz & Fanciullo, 2002; Pokornyet al., 1972), CAGE (Steinweg & Worth, 1993), Alcohol Use Disorders Identification Consumption Test (AUDIT-C; Bush et al., 1998), Benzodiazepine Dependence questionnaire (Baillie & Mattick, 1996), the Drug Abuse Screening Test (DAST; Skinner, 1982), the Self-Administered Alcohol Screen Test (Bailey et al., 2002), and the Addiction Severity Index (Savage, 2002). However, to the author's knowledge, none of these tests taps the concept of addiction described above and will not arrive at such a diagnosis. These tests will define the patient at risk for addiction if that patient answers the questions honestly. In addition, these tools have been developed for use with alcoholics

TABLE 10.4
Suggestive Behavioral Patterns for Suspicion for Drug Abuse

- Cigarette smoking
- Absenteeism
- Marital discord
- Driving problems
- Financial difficulties
- Suicide attempt history
- Child abuse history
- Use of stimulants
- Frequent accidents and falls
- Blackouts
- Memory loss

TABLE 10.5
Suggestive Physical Findings for Suspicion for Drug Abuse

- Evidence of current intoxication (sleepiness, nodding)
- Spider angiomata
- Hepatomegaly
- Red facies
- Liver palms
- Salivary gland enlargement
- Cigarette burns
- Unexplained bruises/frequent falls
- Diabetes/blood pressure/ulcers not responsive to treatment
- Inflamed/eroded nasal septum
- Dilated pupils
- Track marks/injection sites
- Gunshot/knife wounds
- Poor hygiene
- Nutritional deficits
- Frequent hospitalizations
- Alcohol withdrawal signs (flushing/hyperreflexia, elevated blood pressure and pulse, tremors)
- Opioid withdrawal signs (mydriasis, sweating/irritability/rhinorrhea)

TABLE 10.6
Suggestive Laboratory Findings for Suspicion for Drug Abuse

- Abnormal liver function tests
- Elevated MCV over 95
- Hypophosphatemia
- Hyperlipidemia.
- High carbohydrate-deficient transferrin
- MCH high
- Anemia
- Positive urinalysis for illicit drugs
- Positive for HIV
- Positive for hepatitis B or C

MCV = mean corpuscular volume; MCH = mean corpuscular hemoglobin.

and/or street addicts. There have been no large clinical trials confirming the validity of these tests with patients given opioids for pain (Nedejkovic et al., 2002). For details and descriptions of these tests, the reader is referred to addiction textbooks.

There are a number of addiction tools that are in the process of development specifically designed for use in medical patients. The first of these is the Screening Instrument for Substance Abuse Potential (SISAP). This five-item screen helps the clinician categorize patients for lower or higher risk of abusing prescribed opioids. The five SISAP questions are as follows:

1. If you drink alcohol, how many drinks do you have on a typical day?
2. How many drinks do you have in a typical week?
3. Have you used marijuana or hashish in the past year?
4. Have you ever smoked cigarettes?
5. What is your age?

The SISAP has been shown to have a low clinical false-negative rate when tested against the database of a large ($N = 11,634$) Canadian epidemiological survey of alcohol and drug abuse (Coambs & Jarry, 1996). It has not been prospectively tested in a chronic pain population. The SISAP is designed to pick up a high percentage of alcohol or polydrug abusers. As such, it has a high false-positive rate (18%). According to the SISAP, caution should be used in prescribing opioids for the following patients:

1. Men who exceed four drinks per day or 16 drinks per week
2. Women who exceed three drinks per day or 12 drinks per week
3. A patient who admits to marijuana or hashish use in the past year. (It is recreational use of cannabis for euphoric effect that is of concern. The use of tetrahydrocannabinol, THC, derivatives to treat pain is still very controversial. Clinicians should exercise caution in recommending opioid therapy to a patient who is using cannabinoids regularly.)
4. A patient under 40 who smokes.

The second tool in development that may be relevant to CPPs is called the Screening Tool for Addiction Risk (STAR; Li et al., 2001). This is a 14-item tool that has been shown to differentiate CPPs from CPPs with a history of drug addiction on three items: prior treatment in a drug rehabilitation facility, nicotine use, and feelings of excessive nicotine use. Prior treatment in a drug facility had a 93% positive prediction value for addiction. However, it is to be noted that predictive validity was not tested here.

What is interesting here is that both the SISAP and STAR associate nicotine use with addiction risk.

If the above tools have not been developed specifically for CPPs, should the pain clinician utilize these tools in evaluating CPPs? It is the author's opinion for medicolegal reasons that the use of such tests is indicated if a clinician wishes to enlist a CPP into COAT treatment. The reasons for this are discussed below. Two other issues are important to COAT: addiction fear and detoxification fear. Recently, a number of authors have tapped the concept of addiction fear as a reason for noncompliance with COAT. Greer et al. (2001) noted addiction fear in 10.8% of patients undergoing orthopedic procedures. Patients with neuropathic pain have also been noted to voice this fear; 31.8% (Bailey et al., 2002) have expressed such a fear. Outside of potential noncompliance issues to COAT emanating from such a fear, it is likely that this group of patients would not be at risk for addiction unless it contained patients who had previous addiction and were now abstinent. To date, there has not been a questionnaire developed to tap this fear. There has, however, been a tool developed to tap the fear of detoxification. The Detoxification Fear Survey Schedule (DFSS; Ling et al., 1987) is a tool designed to quantify fear of detoxification. As pain patients are often detoxified from narcotics, such a tool could be a useful instrument to target a problem seen in some pain patients.

THE PREVALENCE OF ADDICTION WITHIN CHRONIC PAIN PATIENTS

In an early structured review, Fishbain et al. (1992b), reviewed studies relating to the prevalence of addiction within CPPs. They reported that different authors used different addiction definitions and criteria, making the data suspect. However, overall the prevalence percentages for drug abuse/drug dependence/drug addiction for patients with chronic pain were in the range of 3.2 to 18.9%. They caution that the results did not tap the concept of addiction and that the prevalence of addiction was likely to be at the middle of this range (Fishbain et al., 1992b). Since this review there have been a significant number of other studies that have directly or indirectly explored this issue. Hoffman et al. (1995a) found an addiction rate of 23.4%. Chabal et al. (1997) found an addiction rate of 34%, and Kouyanau et al., (1997) found a rate of 12%. There has also been one report of a chronic pain population at a Veterans Administration (VA) facility and a primary care setting. Here Reid et al., (2002) reported that prescription opioid abuse behavior was recorded for 24% of the VA patients and 31% of the primary care patients. As "opioid abusive behavior" does not necessarily translate into addiction (discussed below), one does not know how to interpret these results.

TABLE 10.7
Prevalence of Various Psychoactive Substance-Related Disorders within CPPs

Psychoactive Substance-Related Disorders	Prevalence within CPPs, %	More Common than General Population	Discrepancies between Authors
Current alcohol abuse/dependence	2–10.6 (Fishbain, Goldberg, Meager, & Rosomoff, 1986; Hoffmann, Olofsson, Salen et al., 1995; Katon, Egan, & Millder, 1985; Rafil, Haller, & Poklis, 1990)	No	Yes
Current drug dependence (opioids, barbiturates, sedative, cannabinoids)	5.2–34 (Skinner, 1982; Evans, 1981; Fishbain, Goldberg, Meager, & Rosomoff, 1986; Hoffmann, Olofsson, Salen et al., 1995; Katon, Egan, & Millder, 1985; Medina & Diamond, 1997; Rafil, Haller, & Poklis, 1990; Portenoy & Foley, 1986)	Probably	Yes
Current illicit drug abuse (cocaine cannabinoids, speed)	6.41–12.5 (Fishbain et al., 1998a; Evans, 1981; Rafil, Haller, & Poklis, 1990)	Probably	Yes
Total current alcohol and other drug dependence	14.9–23.4 (Fishbain, Goldberg, Meager, & Rosomoff, 1986; Hoffman, Olofsson, Salen et al., 1995; Magni, Caldieron, & Regatti-Luchini, 1990)	Probably	Yes

In addition, there have been two studies using urine toxicologies for prevalence of illicit drug use in patients with chronic pain. In the first study Fishbain et al. (1998a) reported that 8.4% of the patients had illicit drugs in their urine, while Raffi et al. (1990) reported a rate of 12.5%. Because illicit drug use has a high correlation with a predisposition to addiction in patients with chronic pain (Sees & Clark, 1993), these figures probably represent the lower end in the range for prevalence of addiction. Table 10.7 summarizes these studies in reference to various subcategories of drug abuse/dependence.

Although the above studies attempted to develop prevalence percentages for substance use disorders, none of them used control groups. A study by Brown et al.(1996) compared rates for substance use among patients with chronic pain attending a family medicine clinic with patients attending for other reasons. There was no statistical difference in prevalence between the two groups. Thus, it is possible that prevalence for drug addiction in patients with chronic pain is no greater than in other settings. This statement is even more relevant if one considers that the above drug addiction data were reported from tertiary facilities where patients with chronic pain have more significant problems. Overall, these data indicate that the prevalence of addiction may not be too much different from the general population. However, these data are limited by the problems with the definition and diagnosis of addiction.

These figures should also be viewed in the context of the prevalence rate for addiction in the United States. This has been estimated to be from 3 to 16% for alcoholism (Savage, 1993) and from 5 to 6% for other forms of substance abuse (Portenoy, 1993). Prevalence rates for alcoholism are much greater in hospitals. Here the rates

have been reported to be 25% for medical services, 19% for neurology, and 23% for general surgery (Savage, 1993). Comparison of these prevalence rates to CPP reported prevalence rates indicates that CPP addiction prevalence rates are not necessarily greater than would be expected from general population data.

Another indirect line of evidence for/against addiction in CPPs is that of opioid use related to the presence of pain. Theoretically, opioid users with chronic pain should have higher levels of pain versus non-opioid users with chronic pain. If they do not, then they are using these drugs for addiction reasons. There have been two studies that have addressed this issue. In the first study, Ciccone et al. (2000) compared chronic pain opioid users and non-opioid users about to enter a pain management clinic for predictor variables. Opioid users were more likely to be physically disabled, be depressed, and report higher levels of pain and in more locations (Ciccone et al., 2000). Conversely, comparison of CPPs utilizing opioids long term versus only anti-inflammatories found that age, depression, personality disorder, and a history of substance abuse predicted opioid use with 79% being correctly classified (Breckenridge & Clark, 2003). Pain intensity did not predict opioid use (Breckenridge & Clark, 2003). It is to be noted that these two studies are not exactly comparable, as the second study used CPPs already selected for COAT. However, the latter study indicates that within this population, there were patients who had a history of substance abuse and that this predicted being on opioids.

The above section can then be summarized as follows: (1) addiction is found within CPPs; (2) at the present time prevalence percentages can be presented only as ranges due to disagreements between researchers; (3) at the present time it is unclear if these ranges are greater than

TABLE 10.8
Development of Craving on Exposure to Opioids in Volunteers (Non-drug Abusing)

Author, Year	Type of Population	No. of Patients Exposed	Percent with Craving
Zacny, 2003	Non-drug-abusing volunteer	18, acutely exposed to 6 sessions (oxycodone, morphine, lorazepam [placebo active])	Liking and wanting ratings no different from placebo after 24 h

that of the general population; and (4) some of the evidence indicates that these ranges may not be greater than for the general population.

ADDICTION GENETICS, RISK OF ADDICTION ON OPIOID EXPOSURE AND RISK OF RE-ADDICTION ON OPIOID EXPOSURE IN PATIENTS WITH A HISTORY OF ADDICTIVE DISEASE

Researchers working in the area of addiction have for years noted that many individuals are self-exposed to alcohol and drugs of abuse and many continue to use alcohol or illicit drugs on occasional or even on a regular basis yet only some individuals go on to develop specific addictions. This indicates that there may be a genetic predisposition in some individuals to developing addiction. Further evidence comes from family, twin, and adoption studies, which establishes the heritability of alcoholism with heterogeneity of inheritance patterns in alcohol abuse disorders and in part for other substance abuse disorders (Anthenelli et al., 1997; Kreek, 2002; Nurnberger et al., 2001). Recently, it has been postulated that an inherited neurotransmitter deficiency in the D_2 receptor makes people vulnerable to addictions and compulsions, such as alcoholism, smoking, cocaine addiction, and attention deficit hyperactivity disorder (Goldman, 1996). This has been called "the reward deficiency syndrome"(Goldman, 1996). Thus, it is likely that, on a biogenetic basis, some individuals have a greater risk than others of developing addiction on exposure to intoxicating substances (Anthenelli & Schuckett, 1997). As such, exposure of individuals with this predisposition to opioids could precipitate addiction. Similar exposure to opioids of those recovering from addictive disease could also precipitate the reemergence of addictive disease. In addition, cross-vulnerability to developing addiction to a variety of substances has been documented (Regier et al., 1984). This suggests that individuals with one addiction, for example, nicotine or alcoholism, may be at higher risk than the general public for developing addiction to other substances, for example, therapeutically prescribed opioids. Because of the above genetic vulnerability to addiction in some patients, there has been significant concern in the medical and pain literature on the development of addiction on exposure to opioids. Studies addressing this issue have been summarized in Table 10.8, Table 10.9, and Table 10.10. Table 10.8 presents a unique study performed with non-drug-abusing volunteers acutely exposed to opioids. Here, liking/wanting ratings, a measure of craving, were no different from placebo. The results of this study would then be in accord with the genetics of addiction discussed above.

The second table (Table 10.9) is divided into three sections: studies addressing general medical patients; studies addressing patients with chronic noncancer pain; and one study addressing epidemiological opioid exposure evidence. The following observations can be made from the data in Table 10.9: (1) In medical populations, the frequency of addiction on opioid exposure is almost nil. (2) In patients with chronic noncancer pain exposed to opioids, researchers report a range of addiction development from 0 to 17.3%. The studies reporting higher percentages (17.3%, Tennant et al., 1988; 9.2%, Lu et al., 1988) used aberrant drug-related behaviors (discussed below) as a means of diagnosing addiction. This may create many false positive cases. (3) A major epidemiological study (Joranson et al., 2000) demonstrated that although nationally opioid use increased, abuse cases decreased.

Overall, these data indicate that some clinicians do see addiction development with opioid exposure in patients with chronic noncancer pain, but most clinicians report low percentages for this problem.

The benzodiazepine drugs are also routinely used with CPPs. As such, there has also been concern over addiction development on exposure to these drugs. Table 10.10 highlights the one available study that has addressed this issue in a medical population. The frequency of addiction was low at 1.6%.

Use of illicit drugs is a good measure of potential addiction. Table 10.11 addresses this issue. Here CPPs exposed to opioids in a COAT treatment were subjected to urine toxicology screens. The range of urine positive for illicit drugs was from a low of 7.5% to a high of 23.1%. These data indicate that a significant percentage of CPPs *with* substance abuse problems are being placed on COAT. These substance abuse problems are likely preexistent to the COAT treatment.

TABLE 10.9
Development of Alleged Addiction on Exposure to Opioids in Medical Populations

Author, Year	Type of Population	No. of Patients Exposed	Percent with Abuse/Addiction Exposure
Studies Addressing General Medical Patients			
Porter & Jick, 1980	Hospital General	11,882	0.03%
Perry & Heidrich, 1982	Burns	?	0%
Medina & Diamond, 1977	Headaches	2,369	0.13%
Chapman & Hill, 1989	Cancer	?	Insignificant
Cicero et al., 1999	Medical population exposed to Tramadol, a very weak opioid	757,558	0.001 to 0.002% (975 of the abuse cases had previous history of substance abuse)
Studies of Patients with Chronic Noncancer Pain			
Moulin et al., 1996	Chronic noncancer pain	46	8.7%
Milligan et al., 2001	Chronic noncancer pain	301	1%
Dellemijn et al., 1998	Neuropathic pain	30	0%
Broaughton et al., 1999	Cancer and chronic noncancer pain	101	2%
Cowan et al., 2001	Chronic noncancer pain	36	0%
Burchman & Pagel, 1995	Chronic noncancer pain patients maintained on opioids	81	2.5% developed aberrant drug-related behavior (tried to fill prescriptions at other pharmacies)
Schaffer-Vargas et al., 1999	Chronic noncancer pain	30	0%
Doguong-Cantagrel et al., 1991	Chronic noncancer pain	91	1.1%
Cowan, 2003	Chronic noncancer pain	104	2.8%
Taub, 1982	Chronic noncancer pain	313	4.1% (presented management problems of which 61.5% had previous substance abuse)
Tennant & Uelman, 1983	Chronic noncancer pain	22	0%
France et al., 1984	Chronic noncancer pain	16	0%
Urban et al., 1986	Neuropathic pain	5	0%
Tennant et al., 1988	Chronic noncancer pain	52	17% (abuse behaviors)
Portenoy & Foley, 1986	Chronic noncancer pain	38	5.3%
Portenoy, 1989	Chronic noncancer pain	20	0%
Zenz, 1992	Chronic noncancer pain including neuropathic	100	9%
Lu et al., 1988	Chronic noncancer pain	76	9.2% (escalated their dosages)
Jamison, 1998	Chronic noncancer pain	36	2.7%
Kell, 1992	Chronic noncancer pain	16	0%
Study of Epidemiological Opioid Exposure Evidence			
Joranson et al., 2000	Nationally representative sample of hospital emergency department admissions resulting from drug abuse	Medical use in grams per 1,000,000 population and mentions of drug abuse as percent of population	From 1990 to 1996 there was a 59% increase in use of morphine and a 6.6% increase in mentions per year of opioid abuse, but the proportion of mentions of opioid abuse relative to total drug abuse mentions decreased from 5.1 to 3.8%

A number of researchers (Collins & Streltzer, 2003; Nedejkovic et al., 2002; Sees & Clark, 1993; Weaver & Schnoll, 2002) have indicated that a previous history of addiction should not be an exclusion criteria for opioid treatment for pain. These patients with a history of addiction should be treated the same for their pain as other pain patients. At issue, however, is whether these patients develop re-addiction when exposed to opioids. Only two studies have addressed this issue and they are presented in Table 10.12. These studies report 0 to 45% and speak to a completely different experience. Both studies have low patient numbers. As such, it can only be concluded that re-addiction can occur on opioid exposure, but this issue requires much research.

TABLE 10.10
Development of Alleged Addiction on Exposure to Benzodiazepines in Medicaid Populations

Author, Year	Type of Population	No. of Patients Exposed	Percent with Escalation (as a measure of abuse/addiction exposure)
Soumerai, 2003	New Jersey Medicaid beneficiaries who received benzodiazepines for at least 2 years (low-income women with children, elderly, those receiving aid for permanently and totally disabled)	2,440	1.6% (occurred in those receiving lorazepam, on antidepressants, pharmacy hoppers [filling a prescription for the same benzodiazepine at two different pharmacies within 7 days])

TABLE 10.11
Development of Alleged Addiction on Exposure to Opioid as Identified by Drug Toxicology

Author, Year	Type of Population	No. of Patients Exposed	Percent with Abuse/Addiction Exposure
Vaglienti, 2003	Chronic noncancer pain maintained on opioids	186	23.1% had (+) urine for illicit drugs (4.8% cocaine, 18.2% THC)
Katz et al., 2003	Chronic noncancer pain maintained on opioids	122	21.3% had (+) urine for illicit drugs 13.9% had (+) urine for nonprescribed controlled drugs 13.9% had an aberrant drug-related behavior
Passik, Schreiber, Kirsch et al., 2000	Combined cancer, HIV, and chronic noncancer patients maintained on opioids	111	50% had evidence of illicit drug, a prescription medication not ordered or alcohol; note that this was a patient sample
Belgrade, 2001	Chronic noncancer patients	93	30% had some pain on noncompliant urine screen 6.5% refused urine toxicology 7.5% had illicit drugs 12.9% had unauthorized opioids 7.5% did not have expected opioid (no opioids)
Fishbain et al., 0000	Chronic non-cancer pain patients	226	11.8% did not have expected opioid
Fancullo et al., 0000	Chronic non-cancer pain patients maintained on opioids	78 of which 15 had a history of substance abuse.	3.9% positive for cocaine 20% positive for cannabinoids 7.7% positive for alcohol Approximately 33% negative for prescribed drug.

TABLE 10.12
Development of Alleged Re-Addiction on Exposure to Opioids in Addicts

Author, Year	Type of Population	No. of Patients Exposed	Percent with Abuse/Addiction Exposure
Dunbar & Katz, 1996	Substance abusers with chronic noncancer pain	20	45%
Collins & Stretzler, 2003	Substance abusers with chronic noncancer pain	4	0%

Collins & Streltzer (2003) have presented possible protective factors for re-addiction on opioid exposure, and a number of authors (Collins & Streltzer, 2003; Nedejkovic et al., 2002; Weaver & Schnoll, 2002) have attempted to develop measures to be taken to reduce re-addiction in addicts on opioid exposure. These concepts are outlined in Table 10.13 and Table 10.14. Close attention should be paid to Table 10.14, as it is the opinion of these authors that CPPs with a history of addiction can be offered COAT, but that the informed consent of these patients and monitoring should be extra stringent versus COAT patients.

TABLE 10.13

Protective Factors for Re-Addiction for Substance Abusers Exposed to Opioids for Chronic Noncancer Pain

- Prior history of alcohol dependence *alone*
- Active participation in alcoholics anonymous
- Presence of family support
- Absence of opioid treatment at entry

Source: Adapted from Dunbar, S. A. & Katz, N. P. (1996).

TABLE 10.14

Measures to Be Taken to Reduce the Risk of Relapse to Addiction in Addicts with Chronic Noncancer Pain Exposed to Opioids

- Obtain and document informed consent for risk of addiction with opioid exposure
- Consult with addiction specialist before beginning opioid exposure
- Document appropriateness/need for opioid treatment
- Encourage patient to participate in 12-step program
- Involve social support for patient (e.g., significant other) in the treatment
- Avoid rapidly peaking medications (Gardner, 1997; Kreek & Koob, 1998)
- Require frequent visits with weekly prescription
- Require one physician
- Require one pharmacy
- Ask patients to bring medications left over each visit
- Require random urines for toxicology
- Require treatment agreement
- Include measures/ways of medication compliance, e.g., written medication schedules

Source: Adapted from Collins & Stretzler, 2003; Nedejkovic, Wasan, & Jamison, 2002; Weaver & Schnoll, 2002.

The above discussion indicates that some pain researchers believe that at this time addiction or a history of addictive disease should not be considered an absolute contraindication to COAT. However, some authors have indicated that some patient characteristics may be predictive of poor response to COAT (Table 10.15). In addition, some authors have tried to develop exclusion/inclusion criteria for COAT (Table 10.16). Note that in Table 10.16, to be a candidate for COAT, a CPP should have intractable chronic pain and be a failure in other treatment. A history of addiction is a relatively exclusionary criterion.

ABERRANT DRUG-RELATED BEHAVIORS

In 1992, Jaffee described a group of drug-related behaviors, which he thought could be operationally used to diagnose/define addiction. These behaviors are presented

TABLE 10.15

Red Flags or Potential Contraindications to Chronic Opioid Analgesic Therapy

- Excessive pain intensity (10/10)
- Extreme ratings of emotional distress
- Poor coping
- Use of multiple pain descriptions
- Poor perceived social support
- Multiple pain sites
- Poor employment history
- Long-term reliance on health professionals

Source: Adapted from Nedejkovic, Wasan, & Jamison, 2002.

TABLE 10.16

Guidelines for Chronic Opioid Analgesic Therapy in Patients with Chronic Noncancer Pain

A. Inclusion Criteria (both required)
- Chronic pain (intractable)
- Failure of all other reasonable attempts at analgesia

B. Potential Exclusion Criteria (relative)
- History of substance abuse
- Chaotic home environment
- Severe character pathology

Source: Adapted from Portenoy, 1990.

in Table 10.17 and appear to represent behaviors that are sociopathic/antisocial in reference to drug use. The short list of eight behaviors developed by Jaffee (1992) was expanded to 18 behaviors by Portenoy (1994) from his own clinical experience with CPPs maintained on opioids (Table 10.17). Since then, these behaviors have been ranked by pain clinicians in order of severity (Passik, Kirsh et al., 2002). In addition, the frequency of some of these behaviors within CPPs on COAT has also been recorded (Table 10.17). A number of observations can be made from Table 10.17: (1) Clinicians consider sociopathic behavior, such as selling prescription drugs, stealing/borrowing drugs from others, injecting oral formulations, as very serious. (2) In general the more sociopathic behaviors are not frequently found in COAT patients. (3) The most frequent behaviors are aggressive complaining about need for more drug (18.2%) and requesting specific drugs (10.2%). These frequencies fall in range of those reported by Katz et al. (2003). It is to be noted that these figures may not represent or be indicative of addiction, as indicated below. (4) However, it is to be noted that 1.9% of the COAT patients admitted to concurrent use of alcohol or illicit drugs. This again indicates that within this population there may be a CPP subpopulation with significant addiction problems. Based on another study

TABLE 10.17
Representative Aberrant Drug-Related Behaviors

Probably More Predictive

- Selling prescription drugs (**1**)*
- Prescription forgery (**2**)*
- Stealing or "borrowing" drugs from others (**5**)*
- Injecting oral formulations (**3**) (1.5%)*
- Obtaining prescription drugs from nonmedical sources (**6**)*
- Concurrent abuse of alcohol or illicit drugs (**4**) (1.9%)*
- Multiple dose escalations or other noncompliance with therapy despite warnings (**8**) (13.3%)*
- Multiple episodes of prescription "loss"*
- Repeatedly seeking prescriptions from other clinicians or from emergency rooms without informing prescriber, or after warnings to desist (**7**) (5.6%)
- Evidence of deterioration in the ability to function at work, in the family, or socially that appears to be related to drug use (1.8%)
- Repeated resistance to changes in therapy despite clear evidence of adverse physical or psychological effects from the drug

Probably Less Predictive

- Aggressive complaining about the need for more drug (**9**) (18.2%)
- Drug hoarding during periods of reduced symptoms (**11**) (1.1%)
- Requesting specific drugs (10.2%)
- Openly acquiring similar drugs from other medical sources
- Unsanctioned dose escalation or other noncompliance with therapy on one or two occasions (**12**)
- Unapproved use of the drug to treat another symptom (**10**)
- Reporting psychic effects not intended by the clinician
- Resistance to a change in therapy associated with "tolerable" adverse effects with expressions of anxiety related to the return of severe symptoms

Notes: Percentages represent the frequencies of these aberrant behaviors found in 388 CPPs treated with chronic opioid analgesic therapy (Passik et al., 2002b). Numbers 1–12 represent the relative ranking of these 52 aberrant behaviors by clinicians.

* Aberrant drug related behaviors identified by Jaffe (1992) as predictive of addiction.

TABLE 10.18
Differential Diagnosis of Aberrant Drug-Taking Behaviors

Addiction
Pseudo-addiction
Other psychiatric diagnoses as a reason for inability to comply with treatment
- Encephalopathy
- Borderline personality disorder
- Depression
- Anxiety
Criminal intent (diversion)
Self-medication of mood, sleep, trauma (flashbacks), and other distress

Source: Adapted from Kirsh et al., 2002; Savage, 2002.

TABLE 10.19
Hints for the Possibility That an Established CPP on COAT Is Addicted[97]

- Unwillingness to taper opioids when other treatments are offered
- No relief from any other modality except opioids
- Preference for short-acting versus long-acting opioids

Source: Adapted from Goldman, 1993.

the more sociopathic behaviors may be more closely aligned with addiction. Finally, aberrant drug-related behaviors can best be used as a red flag during COAT treatment. Once noted by the clinician, they should trigger a search for a reason for the behavior noted according to the differential diagnosis described in Table 10.18.

If the clinician eliminates all other possibilities besides that of addiction as the reason for the aberrant drug-related behaviors, then he or she may wish to search for other hints for addiction in the patient in question (Table 10.19). There is one item in Table 10.19 that requires comment: preference for short-acting opioids versus long-acting opioids. There is some research on this issue that could potentially be clinically useful. Because short-acting opioids are thought to be associated with euphoria, transition to long-acting opioids could be a test for addiction. Some authors have therefore suggested that patients resistant to moving to long-acting opioids from short-acting opioids could have addiction issues. Raggi (2001) reported on 100 CPPs whom they attempted to switch to long-acting opioids from short-acting opioids. They reported that 28% resisted leaving the short-acting opioids and suggested that these patients could have been seeking the euphoria associated with this drug group. However, it is to be noted that there are a number of potential differential diagnoses besides that of addiction that could be the reason(s) for the resistance/refusal to move to long-acting opioids. This differential list is presented in Table 10.20.

(Kirsh et al., 2002) these results would need to be put into appropriate context. Kirsh et al. (2002) found that current aberrant drug-related behaviors were seldom reported by CPPs, but attitude items revealed that patients would consider engaging in aberrant drug-related behaviors or would possibly excuse them in others if pain or symptom management were inadequate (Passik et al., 2000). Thus, in interpreting the presence of aberrant drug-related behaviors, the clinician needs to keep in mind that these behaviors are indicative of the differential diagnosis presented in Table 10.18.

What, then, do aberrant drug-related behaviors represent and what is their clinical utility? At the present time it is unclear whether these behaviors are indicative of or represent addiction. It is also unclear which of these behaviors are more closely related to addiction, although

TABLE 10.20

Differential Diagnosis for Those Chronic Pain Patients Who Resist/Refuse Transfer to Long-Acting Opioids

- Fear of increased pain
- Actual poor pain relief (i.e., breakthrough pain)
- Fear of loss of control over pain
- Fear of a loss of a coping strategy for pain
- Addiction

TABLE 10.21

Procedures to Follow if and when the Pain Clinician Suspects Addiction in a COAT CPP

- Obtain collateral information
- Reduce prescription interval
- Use pill counts
- Review patient agreement (discussed below) with patient and invoke relevant sanctions
- Do blood/urine toxicology
- Consider referring patient to addiction medicine and/or facility
- Document actions taken

Source: Adapted from Goldman, 1993.

A final issue here relates to what the pain clinician should do if he or she continues to harbor a significant suspicion that the patient is becoming addicted. Table 10.21 outlines the necessary options.

PSEUDO-ADDICTION

As noted above, pseudo-addiction is within the differential diagnosis of aberrant drug-related behaviors. As such, this concept can be understood only within the context of aberrant drug-related behaviors. Pseudo-addiction is operationally defined as aberrant drug-related behaviors that make the patient with chronic pain look like an addict. However, these behaviors stop if opioid doses are increased and pain improves (Weissman & Haddox, 1989). This indicates that the aberrant drug-related behaviors were actually a search for relief, i.e., pseudo-addiction. However, it is to be noted that there is little specific evidence for the concept of pseudo-addiction. This concept originated from one case report (Weissman & Haddox, 1989). Outside of one large-scale study reported as an abstract (McCarberg & Laskin, 2001), no studies of pseudo-addiction exist. In this last study of 500,000 patients, 316 were identified as problem opioid patients. Most of these patients, however, appeared to be pseudo-addicts. There is also some collateral evidence for the pseudo-addiction concept. Arthritic rats appeared to self-administer opioids at rates required to control their pain,

TABLE 10.22

Alleged Distinctions between Pseudo-Addiction and Addiction in Patients with Chronic Pain

Variable	Pseudo-Addicted	Addicted
Escalation of dose	Will stop escalating dose when pain controlled and may even decrease dose	Will continue escalating
Euphoria	Will not try to achieve euphoria	Will try to reach euphoria
Signs of intoxication (e.g., sedation, confusion)	No	Yes
Focus on side effects	Yes	No
Focus on consequences of side effects	Yes	No
Follow recommendations for other forms of treatment	Yes	No

rather than for the rewarding effects of the drug (Colpaert et al., 2001). This indicates that the two behaviors may also be separated in humans.

It is almost impossible to differentiate a patient with chronic pain with addiction who escalates the dose of mediation to obtain euphoria from a non-addicted patient with undertreated pain because both will exhibit aberrant drug-related behaviors (Weaver & Schnoll, 2002). The best approach for the physician is to provide more pain medications and to observe the patient for aberrant drug-related behaviors (Weaver & Schnoll, 2002) and some of the characteristics listed in Table 10.22. Although the pseudo-addiction concept lacks significant scientific support and it is unclear how clinically relevant in is, it has nevertheless become widely accepted within the pain physician community. As such, this concept has now become a focus in some medicolegal cases. Thus, pain clinicians who do COAT treatment, or who are planning to, should be aware of this concept and address it in their patient notes.

Finally, it is to be noted that there is also a differential diagnosis for pseudo-addiction that relates to inadequate pain management. This differential diagnosis is presented in Table 10.23.

COAT TREATMENT AGREEMENTS

The concept of a Treatment Agreement for COAT was first developed by Burchman and Pagel (1995). The alleged benefits of such an agreement have now been outlined in the literature (Biller & Caudill, 1999; Bolen,

TABLE 10.23
Differential Diagnosis of Pseudo-Addiction

Inadequate pain management secondary to

- Progressive pathology
- Tolerance development
- Stable conditions, but suboptimal analgesia
- Development of opioid-induced hyperalgesia (discussed below)

2003; Burchman and Pagel, 1995; Doleys & Rickman, 2003; Fishman & Kreis, 2002) and are now thought to be the following: a constructive element for a physician–patient partnership; a motivational tool for both sides to reflect on their expectations and responsibilities; a demonstration that the decision to use opioids was seriously considered by all parties involved; an informed consent tool; a tool that allows the physician to break confidentiality to call a pharmacy, etc.; indirect protection of the physician from the fear of inappropriate investigation by regulatory authorities by establishing strict guidelines under which opioids will be administered; protection of the physician against subsequent medicolegal problems because of the informed consent aspects. Because most of the state licensing boards require written treatment plans for patients on COAT, the COAT treatment agreement can substitute for the treatment plan. It is to be noted that the COAT treatment agreements have been recommended for use by legal experts in the field (Bolen, 2003). Bolen pointed out that the Federation of State Medical Boards Model Guidelines in the use of controlled substances to treat pain contemplate the use of written treatment agreements with patients with pain who have a history of or present a problem with substance abuse. These experts suggest that the COAT treatment agreement should contain the elements outlined in Table 10.24. Finally, it is to be noted that the ability of COAT treatment agreements to prevent prescription abuse has not been established in the literature (Biller & Caudill, 1999). As such, the physician using these agreements should not expect to be free of patients who may abuse opioids.

DIVERSION AND THE DRUG ENFORCEMENT AGENCY

Diversion is the use of a controlled substance for other than its intended medical use. Commonly, industry drugs are diverted to street use because their quality control makes them desirable and safe. Sources of diversion (and the legal agency responsible for that diversion) are presented in Table 10.25. A number of observations are to be noted in reference to this table. At the present time, the largest sources are patient-modified prescriptions and sale of drugs to addicts by patients. This table also confronts

TABLE 10.24
Elements to Be Included in a COAT Treatment Agreement

- Details of what the service physician will provide
- The condition or diagnosis necessitating the use of controlled substances (COAT)
- Goal of COAT, e.g., pain relief, increased function
- Risks of COAT (informed consent)
- Risks of off-label drugs, if those are to be prescribed
- Alternatives to COAT or that there are no alternatives (what reason) or that patient refused alternatives
- A list of compliance measures to be used (one pharmacy, one doctor for prescribing, pill counts, urine/serum random toxicologies, calling other pharmacists, etc.)
- Circumstances under which the agreement would be terminated and patient tapered off COAT (e.g., no decrease in pain, tolerance, no increase in function, escalation)
- An explanation of what would be considered noncompliance leading to agreement termination and referral to an addiction specialist and/or addiction program

TABLE 10.25
Sources of Diversion

- Health care professional, self-use (State Licensing Board)
- Illegitimate prescriptions:
  - Nonpatient prescription forgeries (police)
  - Patient-modified prescriptions (police)
  - Prescription obtained by illegitimate patients via doctor shopping (police)
- Drug burglary/robbery (FBI)
- Employee theft of drugs or scripts (police)
- Sale of drugs to addicts by legitimate patients (police)
- Illegal sales of prescriptions or drugs by health care professionals or pharmacies (DEA)

a general misconception of physicians who believe that the Drug Enforcement Agency (DEA) monitors any and all types of diversions. As noted in this table, the DEA is interested only in illegal sales of prescriptions of drugs by health care professionals. Thus, unless the physician is participating in such an activity, he or she is unlikely to come in contact with the DEA.

The DEA is governed by the Controlled Substance Act. As such, "it is the position of the DEA that controlled substances should be prescribed, dispensed or administered when there is a legitimate medical use" (*Physician Manual,* 1990). Therefore, the DEA cannot hold a physician criminally responsible for prescribing in the "usual course of medical practice." The DEA will send its agents into the offices of physicians whom it suspects are working outside of the "usual course of medical practice" in order to obtain controlled substances (buys). Here, the agent will look for physician–patient contact, an examination, a diag-

TABLE 10.26
Red Flags for Identifying Illegitimate Patients

Be suspicious of anyone who presents with characteristics below

- Without a family member
- Wanting appointment at end of office hours/arriving end of office hours (presents when regular physicians cannot be reached)
- As a cash-paying patient
- Insisting on being seen immediately (in a hurry)
- Not interested in having a physical examination or tests
- Unwilling to give permission for old medical records
- No physician referral
- Claims old medical records are lost
- Unwilling/unable to give names of past health care professionals
- Claims out of town and lost prescription, forgotten to pack medication, or claims it was stolen
- Has no interest in referral, wants prescription now
- Shows unusual knowledge of controlled substances
- Requests specific drug or unwilling to try any other
- Claims allergies to non-opioid analgesics
- No visible means of support except welfare/disability
- Frequent address change

---

nosis, and a prescription to meet the needs of that diagnosis. Physicians not fulfilling these criteria in the "buy" may be charged.

There are ways for physicians to protect themselves against diversion that relates to illegitimate prescriptions: always designate number of refills, even if none; use serialized, duplicate copy–resistant prescriptions; and write alpha and numeric quantity, dosage, and strength. There are also a number of signs (red flags) that may signal an illegitimate patient. These are designated in Table 10.26.

The final type of diversion that relates to physicians is that of the sale of drugs to addicts by legitimate patients. Little is known about this type of diversion except that it is claimed to be common. This type of diversion is extremely difficult to identify. To the author's knowledge, there are currently only two red flags for the possibility of this type of diversion: (1) the urine/blood toxicology screen does not contain the expected opioid or (2) the serum value of the opioids is much below what would be expected according to the patient's current dosage. As discussed under blood/urine toxicology procedures (below), a negative urine/blood toxicology does represent a differential diagnosis. As such, the patient with this type of result cannot be automatically considered to be diverting. In reference to serum values being below expected, patients do differ genetically in their opioid metabolism (Heiskanen et al., 2000). Thus, this result is also not an absolute proof of diversion.

URINE TOXICOLOGY MONITORING IN COAT AS A MEANS FOR MONITORING FOR ADDICTION

Previous research (Belgrade et al., 2001; Fishbain et al., 1998a; Joranson et al., 2000; Katz et al., 2003; Passik et al., 2000; Rafil et al., 1990; Vaglienti et al., 2003) has shown that urine toxicology studies can provide valuable information in CPPs as to their opioid and illicit drug use status. Thus, urine toxicology studies can play an important role in determining suitability for COAT and COAT adherence monitoring. However, before trying to interpret urine toxicology results, the pain clinician should understand the limits (Fishman et al., 2000) of the information provided by urine toxicology. These are outlined below.

Urine assays yield qualitative results only (positive or negative). Testing of opioid in urine is generally of two types: a screening method and a confirmatory test. Confirmatory testing may provide specific identification of individual opioid agents. Morphine, codeine, oxycodone, oxymorphone, hydrocodone, hydromorphone, heroin, methadone, and meperidine are routinely tested for in these screens. Limitations of the urine toxicology screen are the following: (1) A negative screen can rule out only opioids that are detectable. For example, it will not rule out fentanyl, buprenorphine, butorphanol, nalbuphine, and pentazocine, which are not routinely tested for in opioid screens. (2) An opioid may be present in the urine, but the detection limit of that screen may be set above the concentration of the drug in urine, thus resulting in a false-negative result. (3) Poppy seed ingestion may lead to a false-positive opioid screen. (4) Some opioids, such as oxycodone, may be less detectable than others (morphine, codeine) at therapeutic dosages, resulting in a false-negative screen. (5) Because confirmatory tests are usually limited to a certain number of opioids, not all positive determinations on a screening method will go on to be recorded as a positive test, thus leading to a false-negative result. (6) The period of detection for opioids in urine is 1 to 3 days after ingestion; however, this time period is dependent on the physiology of the individual and his or her current physiological status, e.g., hydration. Thus, there is significant individual variation in opioid clearance, which can lead to either a false-positive or false-negative result.

In general, the pain clinician can expect two types of urine toxicology results. The first of these is the unexpected substance (Table 10.27). In this situation, one would see either an illicit drug or unexpected opioid. The differential diagnosis for each of these situations is then presented in Table 10.27. The second type of urine toxicology result is that of the expected substance not being present in urine (Table 10.28). This situation was first noted by Fishbain et al. (1998a) who reported that 11.8% of the patients claiming to be taking a drug did not have evidence of that drug by urine toxicology. Since then, two

TABLE 10.27
Differential Diagnosis of Unexpected Substance in Urine

A. Illicit Drug
  • Drug abuse
  • Addiction
  • Non-adherence to treatment agreement
B. Unexpected Opioid
  • Addiction
  • Non-adherence to treatment agreement
  • Pseudo-addiction
  • Forgetfulness/carelessness
  • Use of medications for other symptoms (sleep, anxiety, depression)
  • False-positive test

TABLE 10.28
Differential Diagnosis of Expected Substance (Opioid) Not Present

A. Opioid Left Over
  • False-negative test
  • Fear of side effects
  • Forgetfulness/carelessness
  • Lack of education regarding medication regimen
  • Fear of social stigma
  • Fear of pain episodes (hoarding drug)
  • Nonbelief in drug therapy
  • Medication costs
  • Religious/moral beliefs
B. Opioid Not Left Over
  • False-negative test
  • Addiction
  • Diversion
  • Medication costs
  • Pseudo-addiction
  • Use of opioids for other symptoms (sleep, anxiety, depression)
  • Non-adherence to treatment agreement

other researchers have reported on this problem in COAT patients. Belgrade et al. (2001) reported that 7.5% of his patients did not have the expected opioid in urine, while Fancullo (Joranson et al., 2000) reported that 33% of his patients did not have the expected opioid or drug in their urine. The differential diagnosis for this situation is presented in Table 10.28. It is suggested in this table that if this situation occurs, the pain clinician should ask the patient to bring in any left-over pills. The differential diagnosis in Table 10.28 is then subdivided into patients who do and do not have opioids left over. It is to be noted that if no opioids are left over, diversion is within the differential diagnosis.

The differential diagnoses lists presented in Table 10.27 and Table 10.28 are important because they point out one major problem with urine toxicology testing. The results of the urine toxicology will not make a diagnosis of addiction or diversion, but only potentially lead to the suspicion of these problems. However, patients on COAT with urine toxicologies positive for illicit drugs are likely to have substance abuse problems and are therefore at high risk for addiction.

DO LONG-ACTING OPIOIDS HAVE LESS ADDICTION POTENTIAL?

As discussed in the introduction, the development of the technology of long-acting opioids such as controlled-release morphine, oxycodone, and fentanyl has had a significant impact on the growth and popularity of COAT. Recently, these drugs have been recommended by the European Federation of Chapters of the International Association for the Study of Pain as the drugs of choice for COAT in the treatment of chronic noncancer pain (Kalso et al., 2003). This recommendation was not based on the fact that the long-acting opioids have equal efficacy for effective pain control versus short-acting opioids (Chou et al., 2003), but on the theory that there may be less addiction risk and less tolerance development on exposure to long-acting opioids versus short-acting ones. The addiction part of this theory is based on the observation that as a general rule, opiate abusers cue in on the rate "rush" (Savage, 1999) onset in the central nervous system. This "rush" explains the popularity of lipid-soluble substances such as heroin, Dilaudid (Palladone), or fentanyl, and the lower abusability of substances such as morphine or methadone, which have slower onset. It appears that duration of action is less important than the intensity of the euphoria and the rapidity of the "rush." If the duration of the agent is too short, however, substance abusers will re-dose frequently, because the physiological components of pain continue to sustain nociceptive input. This, coupled with the fact that the patients prefer to evaluate their substances by the "rush," results in the frequent re-dosing seen when substance opiate abusers are given ready access to their medications. This is seen in situations in which patients are given patient-controlled analgesia (PCA) devices in a perioperative situation. If, however, the prescribed dosing scheduling is too long, allowing for the central nervous system levels to fall below the pain threshold, "roller coasting" can result. This is seen when brief periods of analgesia are coupled with periods of breakthrough pain. If given the opportunity, these patients may not only increase the number of doses they use (to cover painful periods), but increase the doses at each interval to increase the intensity of the euphoria.

The controlled-release opioids, because of the controlled-release aspect, have less of a tendency to create the "rush." At the same time, because of their extended

activity, these agents prevent "roller coasting." In reference to tolerance development, it has been noted that as a general rule, the shorter the duration of activity of the drug, the more frequent the dosing interval necessary, the more rapid the development of tolerance.

Is there any evidence for this theory? There is one study performed with 130 drug abusers (Brookoff, 1993). In this survey study, 85% of these patients reported having tried controlled-release opioids and of these 60% reported that they were of little or no use to them (Brookoff, 1993). The reported street price of the drugs at that time seemed also to reflect this preference. The street price of controlled-release morphine was 1/16 that of hydromorphone, 1/6 that of meperidine, and 1/9 that of immediate-release morphine (Brookoff, 1993).

Since that time, drug abusers have developed methods of circumventing the controlled-release opioid delivery systems. As such, the street value of controlled-release morphine, oxycodone, and fentanyl has increased. The increase in the street price when the delivery system was compromised is indirect evidence that long-acting agents have less attraction to drug abusers. The fact the controlled release delivery system can be compromised does not decrease the theoretical potential value of these drugs. If used correctly, these drugs may lead to less addiction and slower tolerance development. However, this area requires further study.

OPIOIDS AND DRIVING

Most drugs that affect the central nervous system have the potential to impair driving (Fishbain et al., 1999). Because opioids are psychotropic central nervous system depressing drugs, there has been disagreement on the part of medical practitioners regarding whether patients taking opioids chronically and on a consistent dose schedule can drive safely and should be allowed to drive (Fishbain et al., 1999). In the United Kingdom, a medical commission on Accident Prevention, Medical Aspects of Fitness to Drive has stated, "the more powerful narcotic analgesics, such as morphine, produce marked sedation and patients requiring them should not drive." This opinion has, however been challenged by a number of researchers who cite evidence that patients taking stable doses of opioids may drive and work safely (Fishbain et al., 1999). This controversy grew in importance with the wide acceptance of COAT utilizing controlled-release opioids for cancer pain and chronic nonmalignant benign pain. Because potential instructions to stop driving to a patient using opioids essentially dooms the patient to a life of disability, the answer to this controversy has widespread implications for the patient and the medical practitioner. There is concern for what is best for the patient but also medicolegal concerns if a CPP on COAT is advised to drive and has a

motor vehicle accident (MVA). Fishbain et al. (1999, 2003) in two evidence-based structured reviews attempted to summarize the literature on driving and opioids in order to make some recommendations to COAT pain practitioners. In the first review Fishbain et al. (1999) reviewed the scientific evidence for the involvement of opioids in intoxicated driving, MVA fatalities, and MVAs. The results of this structured evidence-based review indicated that there was consistent epidemiological type B evidence that opioids probably were not associated with intoxicated driving, MVA fatalities, and certainly not associated with MVAs. In the second review, Fishbain et al. (2003) reviewed the scientific evidence for the following issues: opioids affecting psychomotor abilities of COAT patients; effect of *new/additional doses* of opioids in psychomotor abilities of COAT patients; if COAT patients are more likely to have more convictions for motor vehicle violations and MVA; and if coat patients demonstrate driving impairments as measured in driving simulators and off/on road driving? The results of this review (Fishbain et al., 2003) were as follows: (1) There was moderate, generally consistent evidence for no impairment of psychomotor abilities of opioid-maintained patients. (2) There was inconclusive evidence on multiple studies for no impairment on cognitive function of opioid-maintained patients. (3) There was strong consistent evidence on multiple studies for no impairment of psychomotor abilities immediately after being given doses of opioids. (4) There was strong consistent evidence for no greater incidence in motor vehicle violations/motor vehicle accidents versus comparable controls of opioid-maintained patients. (5) There was consistent evidence for no impairment as measured in driving simulators off/on road driving of opioid-maintained patients. Based on the above results, it was concluded that the majority of reviewed studies appeared to indicate that opioids do not impair driving-related skills in opioid-dependent/tolerant patients. This evidence was consistent in four of five research areas investigated, but inconclusive in one.

Based on the above results of these two reviews, Fishbain et al. (2003) recommended an approach to the driving problem that utilizes the above data, but also puts the responsibility for the driving decision onto the patient. The specifics of this recommended approach are outlined below.

First, the patients placed on COAT should be advised of the current status of this research. Second, they should be advised that whether they do/do not drive should be based on this information, but that it is their own personal decision. Third, they should be advised that if they choose to drive, they should follow the following rules:

1. After beginning opioid treatment or after a dose increase, they should not drive for 4 to 5 days.
2. They should not drive if they ever feel sedated.

3. They should report sedation/unsteadiness/cognitive decline immediately to the pain clinician so that reduction in dosage can be initiated.

4. Under no circumstances should they use alcohol or illicit drugs such as cannabinoids and drive.

5. They should avoid taking any over-the-counter antihistamines.

6. They should not make any changes in their medication regimens without consulting with the pain clinician.

For the situation where the pain clinician is requested to complete paperwork in which questions are asked about the patient's driving ability, the same type of approach is recommended. The pain clinician should report the current status of this research in the paperwork. In addition, the physician should report whether he or she has noted any opioid side effects, which may interfere with driving, or the absence of these. However, if a specific question relating to whether the patient can/cannot drive is encountered, that question should be marked unknown. As an explanation, the physician should state that he or she does not have knowledge of the patient's ability to drive, as that can only be determined in a driving simulator and/or on-road/off-road driving tests.

It is to be noted that the above recommendations apply to COAT patients who do not use illicit drugs. As most MVAs involving opioids usually involve the concomitant use of alcohol and other drugs, pain clinicians may not wish to make these recommendations to COAT patients whom they know have addictive disease.

ADDICTION IN CPPs AND ASSOCIATED PSYCHIATRIC COMORBIDITIES

Feinstein (1970) developed the concept of *comorbidity*. He defined this term as "any distinct clinical entity that has existed or that may occur during the clinical course of a patient who has the index disease under study." Comorbidity is important for two reasons. First, the presence of an additional disease can complicate, interfere with, or make the treatment of the index disease more difficult, making the prognosis worse (Merikangas & Gelernter, 1990). Second, in medical research and especially outcome research, failure to classify and analyze comorbid diseases may create misleading medical statistics and may cause spurious comparisons during the planning and evaluation of patient treatment (Merikangas & Gelernter, 1990). For these reasons, in the past few years there has been an explosion in the number of psychiatric studies exploring comorbidity.

Five large categories of comorbidities have been studied in psychiatric patients (Fishbain, 1999; Fishbain et al., 1998b): comorbidities between psychiatric disorders on

Axis I of the DSM-IV (4th ed.); comorbidities between psychiatric disorders on Axis I and Axis II (personality disorders) of the DSM-IV; comorbidities between psychoactive substance use disorders of Axis I and other psychiatric disorders on Axis I of the DSM-IV; comorbidities between all psychiatric disorders and other medical nonpsychiatric disorders; and comorbidities within psychoactive use disorders only. Of relevance to this chapter are comorbidities relating to addiction. It has been found in psychiatric patients that patients with psychoactive use disorders usually have significant other psychiatric comorbidities on Axis I, with the most common disorders depression and anxiety. For the addictions, there is also significant comorbidity with Axis II. Generally patients with addictions will demonstrate a personality disorder. Finally, patients with one addiction will generally manifest comorbid additional addictions. For example, opioid dependence can be associated with nicotine dependence, cannabinoid abuse, alcohol dependence; i.e., there is comorbidity between substance use disorders.

It is interesting, but sad, that little work has been done on delineating whether the same types of comorbidities as described above are found in CPPs. In an early DSM psychiatric diagnosis study, Fishbain et al. (1986) found that the majority of their CPPs had more than one diagnosis on Axis I: 58.4% of the men and 61.4% of the women. Thus, comorbidities between Axis I diagnoses should be frequently encountered in CPPs. In a follow-up study, Fishbain et al. (1998c), looking at this problem, found that some affective and personality disorder diagnoses were more commonly found in CPPs who had a psychoactive substance abuse disorder diagnosis versus those who did not. This study then demonstrated that CPPs with psychoactive substance abuse diagnoses have the same pattern of comorbidity as psychiatric patients.

There have also been some interesting recent additional studies that may be clinically useful on the subject of addiction comorbidity. In a case control study (Haddox et al., 2003), it was reported that CPPs with unexplained symptoms were as likely as CPPs without those symptoms to have problems in regard to medication abuse/dependence. The question of whether CPPs with unexplained symptoms are seeking drugs is often raised. As such, this is often used as a rationale for not placing these CPPs on COAT. This study then should partially alleviate this concern. Haddox et al. (2003) recently reported on a forensic review study of overdose deaths allegedly related to oxycodone or controlled-release oxycodone. They found that of 919 deaths, 96.7% involved more than one drug, i.e., multiple addictions. Thus, individuals with multiple addictions may be at greater risk for overdose deaths. The above information on addiction and psychiatric comorbidity can be used clinically and this is the reason it is presented. First, the identification of any kind of addictive disease, e.g., opioid dependence, should trigger a search for asso-

ciated psychiatric comorbidity, associated psychoactive use disorders, or associated Axis II disorders. And, second, the presence of any significant psychiatric disorder, e.g., severe depression, should trigger a search for possible associated addiction.

ADDICTION IN CPPS AND DRUG/ALCOHOL DETOXIFICATION

As pointed out above, there may be some evidence that some CPPs on COAT will display aberrant drug-related behaviors and as such may require opioid detoxification and addiction treatment. Fishbain et al. have written a number of papers and chapters on opioid (Fishbain et al., 1993) and other drug (Fishbain, 1993; Fishbain, 2002b; Fishbain et al., 1992) detoxification protocols in CPPs. However, at issue is whether CPPs with physician-perceived drug problems are best treated at multidisciplinary pain treatment facilities or drug and alcohol treatment facilities. There is no evidence in the literature that CPPs would do better if they underwent detoxification and treatment at drug and alcohol treatment facilities versus pain treatment facilities (Fishbain et al., 1986). In fact, one study (Tennant & Rawson, 1982) indicated that CPPs would do better if they undergo detoxification in pain treatment facilities. In this study from a drug treatment facility, no patient initially perceived that chronic pain due to a medical condition would be an impediment to withdrawal from opioids. However, pain masked by opioids emerged during detoxification and proved to be an insurmountable barrier to total opioid withdrawal in the majority of CPPs (Tennant & Rawson, 1982). This study speaks to the potential advantage of CPPs undergoing detoxification at multidisciplinary pain treatment facilities, where simultaneous pain treatment is also available. There are also two studies (Currie et al., 2003; Khatami et al., 1979) that looked at multidisciplinary pain facility outcome for CPPs with addiction. Both studies reported favorable treatment outcomes in terms of opioid use, with one study (Currie et al., 2003) reporting that one half of patients were opioid free at 12 months. It is also to be noted that Fishbain et al. (1995, 1997) have recommended that drug abuse/dependence/addiction is one of a set of criteria that can be used to select CPPs for multidisciplinary pain facility referral (Fishbain et al., 1995, 1997). As such, physician perception of drug problems in CPPs can then be an indication for a multidisciplinary pain treatment facility referral.

There may also be one other reason for opioid detoxification in CPPs if COAT appears to be failing. This is the development of hyperalgesia, which is thought to be secondary to tolerance and desensitization of opioid receptors (Broder & Taub, 1978). Here, pain sensitivity actually increases (Collins & Streltzer, 2003). There are actually some clinical data (Broder & Taub, 1978; Savage, 1993) that indicate that in some CPPs, pain improved with detoxification from opioids. Thus, failure of COAT in CPPs secondary to hyperalgesia could be another indication for multidisciplinary pain facility detoxification.

LEGAL ISSUES IN ADDICTION AND CHRONIC PAIN TREATMENT

Recently, because of the medical malpractice crisis, there has been significant interest in pain medicine forensics (Bolen, 2003; Fishbain, 2002a). Substance abuse/addiction in CPPs has been recognized as an area with medicolegal risk. Thus, the purpose of this section is to alert the pain clinician to issues that have already generated malpractice claims and issues that are at high risk for generating malpractice claims if not correctly documented. It is to be noted that malpractice claims are generated when there is an adverse outcome, which the medical expert in that area claims is related to a physician action, which is deemed "below the standard of medical care in the community." Thus, if a treatment agreement might have prevented an adverse action and the treatment agreement is the standard, but was not done, the physician may be held liable. Hence, it is important for the pain clinician working with patients who are at risk for addiction to be aware of these potential standards. Table 10.29 has been developed to reflect this concept. It lists both issues that have already been raised as potential standards and those that have generated malpractice claims and or potential standards that one day may generate a malpractice claim. A large part of this table shows actual standards that have been recommended by state regulatory agencies.

CONCLUSIONS

At the present time, the research area of chronic pain/addiction is in a state of flux and is developing. It is evolving into a coherent body of knowledge that at this time has some clinical utility. However, much work remains to be done.

TABLE 10.29
Potential "Standards" in COAT Treatment That Have Already Generated Malpractice Claims or May Do So in the Future

Failure of Potential Standard	Preventive Response
Failure to document COAT according to elements recommended by State Practice Guidelines for COAT	
A. Appropriate indicators	A diagnosis of intractable chronic pain
B. Document history physical examination, physical impact on pain, psychological impact of pain, and potential for substance abuse	
C. Treatment plan	Can be satisfied via treatment agreement
D. Risk/benefit discussion (informed consent)	Can be satisfied via treatment agreement
E. At each visit should document (1) pain status, (2) function status, (3) side effects, and (4) lack or presence of aberrant drug-related behaviors	
Nonrecognition of possible pseudo-addiction (Fishbain, 2002)	Document if you think the patient is demonstrating pseudo-addiction if he or she demonstrates aberrant drug-related behaviors
Lack of knowledge of methods of rotation to methadone (Fishbain, 2002)	Follow only recommended rotation schedules
Failure to ask and document part of present substance abuse/addiction history	Reason why some addiction schedules should be used
Failure to act on substance abuse/addiction information when doing COAT (Bolen, 2003)	Document actions taken or reasons for not taking actions (Table 10.21)
Failure to act on diversion suspicion	If you document diversion suspicion, call police
Failure to document that you have informed consent for reemergence of addiction in patients with a history of opioid dependence/abuse before placing on COAT (Bolen, 2003)	Should include discussion of potential for physical dependence, tolerance, side effects, cognitive effects, risk of addiction, testosterone problems, driving issues, etc.
If placing patients with previous addiction on opioids, failure to document protective factors and measures taken to prevent re-addiction	Document
Failure to document aberrant drug-related behaviors and why what action is taken	If no action taken, document why
Placing a patient on COAT without a treatment agreement	Document why you did not think treatment agreement was necessary
Failure to use urine toxicology when indicated	Document why urine toxicology was not necessary
Failure to provide informed consent on driving issue	Document
Failure to refer a COAT patient for detoxification when indicated	Document reason why not referred

Opioid Therapy for Chronic Noncancer Pain: Cautions, Concerns, Misconceptions, and Potential Myths

Michael E. Clark, PhD, Robert W. Young, Jr., PhD, and B. Eliot Cole, MD, MPA

INTRODUCTION

In the last decade there has been a substantial increase in the use of opioids for the treatment of chronic noncancer pain. In 1999, approximately 11% of individuals experiencing back or neck pain consumed opioid analgesics (Luo et al., 2004). Clark (2002) found that among U.S. military veterans, 44% of the individuals with chronic noncancer pain (CNCP) were receiving opioid analgesics. Sales of opioids in the United States have increased dramatically, with opioid analgesic revenues increasing 18% between 2001 and 2002, and 136% from 1998 (Savage, 2002). This increase in opioid usage parallels the success of national efforts to make opioid analgesics more available to individuals with cancer pain and terminal illnesses, coupled with changes in the accreditation standards for health care organizations (Joint Commission on Accreditation of Healthcare Organizations [JCAHO], 2000), recommendations by the Federation of State Medical Boards of the United States (FSMBUS, 1998), public statements by leading pain organizations and regulatory agencies (American Pain Society and American Academy of Pain Medicine, 1996; American Pain Society, American Academy of Pain Medicine, and American Society of Addiction Medicine, 2001, 2004), medical board actions (*OR Medical Board v Paul Bilder*, 1999, 2003), and civil suits (*Bergman v Chin,* 2001 and *Tomlinson v Whitney*, 2003) for the undertreatment of cancer-related pain. By the end of the 1990s and the beginning of the new millennium

the "perfect storm" conditions existed to make long-term administration of opioid analgesics an acceptable part of the overall management of pain for hundreds of thousands of Americans. Yet, the routine use of opioid therapy (OT) in the treatment of chronic noncancer pain remains a controversial and contentious issue. The increasing abuse of opioids by people with and without long-term pain has resulted in growing national concern and even prosecution of practitioners deemed to have been lax in their prescribing practices. Proponents and opponents for OT now abound, often substituting their unique fervor for scientific evidence.

Empirical data clearly indicate that there are numerous disadvantages and even dangers associated with opioid use. In this chapter we review some of these less-publicized data in order to heighten practitioners' awareness of these issues and to promote informed and balanced clinical decision making. Those now prescribing OT for their patients should note, however, that we do not offer an exhaustive review of all documented untoward effects of OT. For example, we do not address the multitude of common, less serious, and potentially controllable adverse effects associated with opioid use that are listed in standard pharmaceutical textbooks and product information sheets. Instead, we focus on considerations and effects with which practitioners may be less familiar and on opioid-related issues where misinformation likely abounds. Our primary purpose in writing this chapter is to address clinical issues associated with chronic daily consumption

of opioid analgesics rather than their occasional short-term use as might be used in acute pain interventions.

In the following pages we present eight major concerns relating to the use of OT for the treatment of CNCP, and within each area we cite empirical data supporting our concerns. Following each concern we present recommendations for practitioners based on the available data and a conservative practice model. While these recommendations are not codified into laws, regulations, or rules in all cases, they are nevertheless our best attempt to present a framework for the therapeutic management of CNCP. We acknowledge that our beliefs, cautions, and recommendations may be just as controversial as the current drive to use OT.

CONCERNS ASSOCIATED WITH OT FOR CHRONIC, NONCANCER PAIN

No Published Data from Randomized Controlled Trials Indicating that OT Results in Long-Term Pain Relief for Individuals with CNCP

Consistent with clinical guidelines evidentiary rules, randomized, double-blinded, controlled studies (RCTs) are the standard for evaluating the effectiveness of treatment interventions (Nedeljkovic, Wasan, & Jamison, 2002). RCTs minimize error and maximize estimates of specific pharmaceutical effects by requiring, at a minimum, random subject assignment, no subject or experimenter knowledge as to which group they are in (i.e., "double blinded"), and comparisons between the experimental group and one or more control groups. Control groups may represent other pharmaceutical agents, current "standard of care" practices, alternative dosing approaches, or active or inactive placebo treatments.

In identifying studies for consideration in this section, we limited our literature searches to randomized, double-blinded, controlled studies of OT with individuals with CNCP. Furthermore, because our interest was in long-term OT, we limited our search to studies using oral opioids. Searches were conducted using Medline, PubMed, PsychInfo, and Google (a popular Internet search engine), and we also consulted the reference sections of published CNCP clinical guidelines. We operationalized "long-term" as trials of at least 6 months in length. Although one could argue that because OT for CNCP may last years or even decades, long-term opioid RCTs should span periods of at least several years, given the impracticality of such lengthy trials we elected to use a more practical definition.

OT and the RCT Literature

Consistent with other reports (Ballantyne & Mao, 2003; Harden, 2002), we were unable to locate any studies meeting our RCT and long-term criteria despite decades of OT research. To date, randomized, double-blinded, RCT stud-

ies have all been relatively brief (generally only weeks). The lack of long-term opioid RCT data is particularly surprising given that a number of well-known pain professionals and researchers have called for such research for well over a decade (Turk & Brody, 1991).

Given the lack of long-term studies, we next searched the literature for RCT studies of any length that met our selection criteria. A total of 18 studies were identified and form the foundation of evidence supporting short-term opioid effectiveness. Each study then was examined in detail. In evaluating these studies it is important to note that many break study blinds after relatively short time periods, although data collection may continue. In such investigations only the blinded portion of the study was considered as part of the actual RCT.

A summary of these 18 studies is presented in Table 11.1. As is evident in the table, RCT periods have been uniformly brief, with none exceeding 9 weeks. The average RCT period over all tabled studies was only 3.74 weeks. Thus, estimates of long-term OT effectiveness rely solely on the effectiveness data reported in these relatively brief RCT studies. Additionally, our detailed examination of these studies yielded evidence of a host of methodological limitations and procedural problems, some of which are serious enough to jeopardize conclusions that OT is effective even in the short term. The most significant of these methodological problems are listed below.

High RCT Termination Rates

RCT studies of OT with CNCP have identified subject termination rates of up to 53% (Roth et al., 2000). Dropout rates for the RCT studies included in this review are presented in Table 11.1. To provide a better estimate of "real-world" effectiveness, when a placebo-controlled parallel groups design (i.e., two experimental groups, one of which is administered placebo and the other an opioid analgesic) was employed, rates were computed only for the opioid conditions of the tabled studies. Termination rates for crossover studies (i.e., all subjects experience all experimental conditions), in contrast, were based on both the opioid and the placebo periods. Although there is considerable variation in these rates, as indicated in Table 11.1, on the average approximately one third of participants dropped out of these short-term studies. These high subject termination rates probably reflect, at least in part, the frequent adverse effects associated with OT. Adverse effects occur on the average in about 50% of subjects, although rates in excess of 90% have been observed (Hale et al., 1999). Even though most adverse effects can be successfully managed, they complicate treatment and may lead to reduced compliance or potential opioid termination. Individuals who terminate OT represent real-world treatment failures, and it is reasonable to expect that the number of individuals dropping out of OT in clinical settings over longer time periods is even higher than dropout

TABLE 11.1
RCT Duration, Sample Size, and Dropout Rates in OT Studies

Study	RCT duration	No. enrolled in opioid arm(s)	No. completing opioid trial	Type of placebo	Opioid drop-out rate(s)
Arkinstall et al., 1995	1 week	46	30	Inactive	35%
Caldwell et al., 1999*	4 weeks	112	35	Inactive	69%
Caldwell et al., 2002	4 weeks	222	134	Inactive	40%
Hale et al., 1999*	2 weeks	57	44	None	37%
Huse et al., 2001	4 weeks	12	12	Inactive	0%
Kjaersgaard-Anderson et al., 1990	4 weeks	83	40	None	52%
Maier et al., 2002	2 weeks	49	37	Inactive	25%
Morley-Forster et al., 2003	20 days	19	11	Inactive	42%
Moulin et al., 1996*	9 weeks	61	43	Active	30%
Muller et al., 1998	2 weeks	55	54	None	2%
Mullican & Lacey, 2001	4 weeks	462	369	None	20%
Peloso et al., 2000	4 weeks	51	31	Inactive	39%
Roth et al., 2000	2 weeks	88	45	Inactive	51%
Rowbotham et al., 2003	8 weeks	81	59	None	27%
Sindrup et al., 1999	4 weeks	48	34	Inactive	29%
Thurel et al., 1991	2 weeks	50	41	None	18%
Watson & Babul, 1998	4 weeks	50	38	Inactive	24%
Watson et al., 2003	8 weeks	45	24	Active	47%
Means	3.74 weeks	85	58		33%

* Dropout rate includes dropouts during the titration period in these studies.

rates reported for short-term RCTs. In fact, Cowan and colleagues (2003) found that among 104 patients with CNCP treated at a pain clinic in England over an average of 14 months, 86.5% reported at least temporary cessation of their treatment, while 65% ceased OT permanently. Thus, while on the average about one third of participants drop out of short-term opioid RCTs, long-term clinical treatment probably results in higher rates of termination and, subsequently, higher failure rates.

One way to correct for high rates of treatment termination is to conduct *intent to treat* analyses. These corrective procedures include treatment dropouts in overall clinical trial efficacy calculations (Dworkin et al., 2001). Although the criteria and strategies for conducting these analyses vary (Dworkin et al., 2001), in general they provide a more realistic estimate of the overall effectiveness of the treatment. When studies fail to conduct such analyses, but experience significant subject dropout over the course of the trial, effectiveness likely will be exaggerated. Of the 18 RCT studies listed in Table 11.1, only 5 included intent to treat analyses in their methodologies, and the intent is even less common in non-RCT clinical studies. As a result, overall impressions of the efficacy of OT for the treatment of CNCP likely are overestimated.

Small Sample Sizes

Sample sizes employed in RCT studies of OT, with a few exceptions, have been small. As illustrated in Table 11.1,

50% of the tabled studies had fewer than 40 subjects complete the opioid trials, and 2 of the 18 studies reported fewer than 15 completers. As a result, associated findings may be less reliable and may be influenced greatly by characteristics of the participants (e.g., sex, race, age). The impact of small sample sizes is magnified by the practice of consolidating multiple pain types within studies. When sample size is small and one or more types of pain are over- or underrepresented, OT effects may be underestimated or overestimated if those pain conditions are differentially responsive to opioids. These sources of variation limit the generalizability of the results of smaller studies to CNCP populations beyond the research study subject pool.

Limited Reproducibility of Results

One of the foundations of the scientific method is reproducibility of results. Related to this requirement, studies must provide sufficient information concerning the procedures and measures employed to allow others to undertake replication of the investigation. A corollary of this principle implies that measures used in the study should be validated and generally available to other researchers. Furthermore, to compare results across studies of a similar nature (e.g., CNCP OT studies), core dependent variables should be similar to measures used in other investigations, and comparisons of effects (e.g., placebo vs. an active agent) should be comparable. Unfortunately, among the

18 tabled RCT studies, the majority failed to meet one or more of these standards. Four studies provided an incomplete or unclear methodology, five did not report changes in pain from baseline values, and eight relied on nonstandard pain intensity measures or used derivative measures that preclude direct comparisons with other studies.

Use of Opioid Rescue Medications

Controlled trials, whether contrasting the effects of opioids versus placebos, other active pharmaceuticals, or alternative methods of care, are conducted to evaluate the utility of specific analgesics. However, 4 of the 18 core RCT studies allowed the use of opioid rescue medications during treatment. This introduces another treatment variable into the study and prevents attributions of changes in pain intensity or pain-related functioning solely to the opioid agent(s) used in the treatment group(s).

Ineffective Blinding Procedures

In any controlled study, but particularly in placebo-controlled studies, effective blinding of the subjects and investigators is of critical importance. If subjects or experimenters are able to guess which group is the active treatment group, systematic biases may be introduced into the results particularly when subjective measures such as pain intensity, mood, or perceived impairment are used. As indicated in Table 11.1, the vast majority of RCT placebo studies examining the effectiveness of OT for treating CNCP have used *inactive placebos* as a comparison treatment. Inactive placebos may not be an appropriate control group as their inert nature may aid participants in identifying which group they are in and thereby jeopardize the study's blind assignment (Dworkin et al., 2001). They are particularly problematic in crossover studies where subjects have been exposed to both the active and inactive treatments and therefore may be better able to identify active agents based on adverse effects as well as any pain relief actions. The use of opioid rescue medications also may contribute to blinding problems in inactive placebo studies as subjects' use of the opioids may be accompanied by internal sensations that are not experienced after taking the inactive placebo.

The potential impact of this issue is evident when considering the results of the minority of studies that have assessed the integrity of their blinding procedures. To accomplish this, investigators typically ask subjects to indicate which treatment arm they were involved in (in parallel studies) or which condition included the active agent (in crossover studies). This method provides a means of estimating the success of the blinding. The results of these assessments raise questions concerning the reliability of the blinding procedures used in these core OT studies. For example, Huse and colleagues (2001) reported that the majority of study patients and all of the study physicians in their investigation comparing morphine sulfate with inactive placebo were able to correctly identify the opioid treatment. Maier and colleagues (2002), in a comparison of the effectiveness of sustained-release morphine and inactive placebo, reported that *93% of the subjects* identified correctly their involvement in the morphine arm of the study, along with 87% of the physicians and 89% of the psychologists. Attal (2000), in an opioid infusion RCT not presented in Table 11.1, reported somewhat better blind maintenance in that only 7 of 15 subjects accurately identified the opioid treatment group, while 6 were unsure and 2 believed the inactive placebo represented the active agent. Nevertheless, in this same study the examiner correctly identified the opioid treatment group in 10 of 15 cases and inaccurately identified the placebo treatment as the active condition in only 1 case. Overall, these results call into question the success of blinding procedures used in inactive placebo RCTs. Subjects or experimenters who are aware of their actual treatment condition may introduce bias in dependent measures consistent with their underlying beliefs concerning opioid effects.

One potential solution to this problem of ineffective blinding involves the use of an *active placebo* as the opioid comparison group. An active placebo is a pharmaceutical selected based on similarities between its adverse effects profile and that of the opioid under study. If ineffective blinding due to the use of inactive placebos occurs, one would expect to find increased pain reduction when appropriate active placebos are employed. In the CNCP OT literature we could identify only two studies that used an active placebo (benztropine). In the first study (Moulin et al., 1996), the authors found that following the opioid to placebo crossover, the pain intensity scores of active placebo subjects actually were *lower* than those of opioid subjects (see Figure 11.1, weeks 15 through 20), suggesting that either their crossover procedures failed or that morphine was no more effective than the active placebo in reducing pain. The fact that Moulin and colleagues also systematically assessed the integrity of their blinding procedures and reported that 47.8% of subjects and 67.4% of investigators correctly identified treatment with morphine suggested that the blind was only partially successful. In the second study (Watson et al., 2003), which examined opioid efficacy with neuropathic pain, the active placebo subjects experienced substantially less pain reduction than the opioid group. However, when they assessed the integrity of their blinding procedure, they found that 88% of their subjects and investigators correctly identified the opioid condition. Thus, in this case the blind clearly was not maintained despite the use of a placebo with an adverse effects profile similar to the opioid analgesic, and the advantage of opioid over placebo that they reported may have reflected subject and experimenter bias. They also commented on the special difficulties maintaining study blinds in crossover trials, even

when active placebos are used, due to subject and experimenter exposure to both conditions.

The failure of opioid RCT double-blinding procedures may account for the relatively low levels of pain reduction associated with inactive placebos. We examined this possibility by averaging mean pain reductions from baseline for inactive placebo subjects in the nine studies where such data either were reported or could be computed from values presented in tables or figures. The average pain reduction associated with placebos over these studies was 10.4%, which is substantially smaller than the more typical 25 to 30% placebo effect observed in subjective measures used in other pharmaceutical agent studies (de Craen et al., 2000; Rickels & Schweizer, 1998). We then calculated the mean inactive placebo pain reduction for the two studies where the blinds were severely compromised (Huse et al., 2001; Maier et al., 2002) and compared it with the mean reduction found in the third inactive placebo study that was only partially compromised (Attal, 2000). As expected, the placebo effect for the seriously compromised studies (10.2%) was substantially smaller than the size found in the partially compromised study (24%). Although the latter study was evaluating the efficacy of opioid infusion rather than oral agents, the results are at least suggestive that blinding success may affect placebo success.

It is clear that RCT OT studies that fail to maintain subject and experimenter blinds are subject to biases that potentially invalidate their results. In the opioid RCT literature, all five of the studies that have examined the integrity of their blinds reported evidence suggestive of at least partial blind failure. This occurred even when active placebos were used. Blinding difficulties likely are maximized in crossover studies where participants have the opportunity to experience both experimental conditions (usually a placebo and an opioid treatment). *Ideally, all RCT studies should systematically assess the integrity of their blinding procedures and use data only from subjects and experimenters who are unable to differentiate (i.e., either they are incorrect or they are unable to decide) between the placebo and the opioid condition.* Although this would necessitate an increased sample size, it would provide some degree of assurance that subject and experimenter bias is minimized and that differences observed between an opioids and a placebo, or between an opioid and an alternative pain medication, reflect a real difference in efficacy. Use of appropriate active placebos either alone or in combination with a nonsteroidal anti-inflammatory drug (NSAID) in these experiments might enhance the reliability of experimental blinds and more accurately identify the pain reduction advantages specific to opioids. Until such studies are conducted, current data suggest that the findings from all opioid RCT studies conducted thus far are subject to question and that more attention needs to be devoted to this potential confound.

Longer-Term Opioid Studies

Generally, studies that do not meet the double-blinded, placebo-controlled, RCT standards have reported more favorable, longer-term OT outcomes. For example, Jamison, Raymond, Slawsby, Nedeljkovic, and Katz (1998), in a randomized but nondouble-blinded study of individuals with back pain, reported that OT was associated with decreased pain and improved mood (but not activity) when compared with naproxen during 16 weeks of treatment. Schofferman (1999), in a noncontrolled study, reported reduced pain and enhanced self-reported functioning in a sample in 21 of 33 individuals with chronic pain treated with a 6- to 12-week opioid trial. After 1-year of opioid maintenance therapy, the 21 responders continued to report reduced pain and improved function.

Several of the opioid RCT studies reported results for open-label extensions of their original investigation. Caldwell and associates (2002) treated 131 subjects with osteoarthritis pain completing the RCT component of their study with an opioid over 36 weeks and reported sustained pain reduction on the order of 10 to 15%. Huse and colleagues (2001) followed 9 of their original 12 patients with phantom limb pain who remained on morphine following conclusion of the RCT over a period of 12 months. They reported significant and sustained pain reduction (relative to baseline) for subjects. Roth et al. (2000) enrolled 106 patients with osteoarthritis in an open-label, 6-month extension of their original study of oxycodone and reported good long-term pain relief.

Although the results of all of these longer-term studies reported support for the efficacy of OT, their value is limited by their susceptibility to a variety of confounding effects. Indeed, placebo effects alone can exceed 32% in opioid studies (Clegg et al., 1996), indicating that data from nonplacebo-controlled studies must be interpreted accordingly. When coupled with biases that may exist in nonblinded studies (Dworkin et al., 2001), additional caution is indicated when interpreting the results from these less rigorously controlled investigations.

In summary, there remains no well-controlled, empirically sound evidence supporting the long-term effectiveness of OT for CNCP. Studies meeting clinical guidelines' evidentiary standards for strong support (i.e., double-blinded RCT studies) have not to date extended beyond 9 weeks, and all suffer from a variety of methodological weaknesses, chief of which is questionable integrity of their double-blind conditions. There continues to be a strong need for longer duration, randomized, double-blinded, placebo-controlled studies of OT that extend at least 6 to 12 months and include systematic assessment of the integrity of the study blinds. Although such a lengthy blinded trial poses substantial challenges, without such data we cannot be certain that OT works for the long term, nor can we discriminate between good and poor OT

candidates. In the interim we suggest that practitioners approach decisions regarding the use of OT for CNCP cautiously, in a manner similar to other unproven but potentially helpful interventions.

Associated Practitioner Recommendations

- Evaluate every patient's response to prior treatments and reserve OT for those individuals with moderate to severe pain who have failed alternative treatments. This is consistent with the World Health Organization's (WHO, 1990) analgesic ladder, which has received almost universal acceptance. Individuals with less severe pain, those with promising responses to other treatments, or those unable to tolerate past OT interventions might be better managed using alternative (non-opioid) means.

- Refer individuals who have not participated in rehabilitation-oriented treatments to appropriate rehabilitation providers if they are available prior to initiation of OT. Strong evidence exists that alternative interventions such as physical therapy (Cheng et al., 2002; Dias, Dias, & Ramos, 2003; Fransen, Crosbie, & Edmonds, 2001; Jull et al., 2002), cognitive-behavioral therapy (Guzman et al., 2002; van Tulder et al., 2000), and comprehensive multidisciplinary pain treatment approaches incorporating psychosocial, physical, and pharmacological interventions (Turk & Okifuji, 1998; Weir et al., 1992) are effective in managing a variety of pain conditions.

- When pain is not effectively managed by non-OT approaches, or when alternatives are not available due to patient circumstances, consider initiation of OT. When possible, use it in combination with other treatments that have demonstrated effectiveness in the treatment of chronic pain, such as exercise (Frost et al., 1998; Moffett et al., 1999) or relaxation training (Stetter & Kupper, 2002). Before initiating OT, establish with patients what outcomes (decreased pain intensity, enhanced performance of activities of daily living, or improved quality of life) will be used to determine OT success (Cole, 2002).

When Tolerated, Successful OT for CNCP Results in Only Modest Reductions in Pain Intensity

A second concern regarding opioid therapy relates to the degree of pain relief attained, in that even successful opioid therapy for chronic noncancer pain results in only modest reductions in pain intensity. Table 11.2 presents

the mean pain reduction (i.e., change from baseline values) reported in opioid RCTs. Note that 4 of the 18 opioid RCT studies did not provide sufficient information to compute or estimate changes in pain from baseline values. For the remaining studies, pain relief percentages presented in Table 11.2 were those reported in the text or, when not reported, were computed from study tables or estimated from study figures.

As illustrated in Table 11.2, there is wide variation in the amount of pain reduction achieved in the tabled OT studies. Individual responses to OT may range from no improvement, or even intensification of pain, to total relief. In fact, in published studies up to 38% of patients undergoing an OT trial fail to report any benefit (Harden, 2002). Examination of Table 11.2 reveals that for the 14 randomized opioid trials where relief rates were reported or could be computed, the weighted average pain relief attained was 30%, which is similar to the 32% weighted average relief reported by Turk, Loeser, and Monarch (2002) in their review of eight partially overlapping OT studies. In evaluating changes in pain attributable solely to opioid analgesics, this 30% average pain relief must be compared with the 10% average pain relief we found in response to inactive placebos. The resulting 20% average benefit of opioids relative to placebos, when considered in light of recent data regarding the clinical significance of the magnitude of pain relief (Cepeda et al., 2003) among postsurgical patients, equates with patient reports of "minimal improvement." Moreover, if the 28% pain reduction experienced by active placebo subjects reported by Watson and colleagues (2003) represents the "true" placebo effect, there would be little difference between the pain relief associated with opioids and that linked to active placebos. Furthermore, consider that these pain relief estimates for OT are only for those who complete treatment. Individuals who drop out of treatment may well experience less relief, but this lower level of efficacy will not be reflected in data derived from only those who complete an OT trial.

Reported rates of opioid-related pain relief also must be considered with respect the reduced efficacy of opioids over time. In general, we know that the magnitude of pain reduction associated with stable-dose OT decreases with increasing duration of use due to the development of tolerance (Ballantyne & Mao, 2003). Tolerance refers to the need to escalate opioid doses over time to obtain constant analgesic effects. Tolerance frequently occurs in response to OT, and studies that allow dose titration over longer trial periods typically report dose escalation (Maier et al., 2002; Peloso et al., 2000). The 22-week-long study by Moulin and associates (1996) is a good example of this effect, as tolerance clearly is evident by week 5 of the study (see their figure 1, p. 143). Therefore, short-duration opioid efficacy studies may overestimate the amount of pain relief associated with fixed opioid doses continued

TABLE 11.2
Mean Pain Relief Attained in the OT Arm of RCT Studies

Study	Sample	Pain Relief
Arkinstall et al., 1995	30 PHN patients	26%
Caldwell et al., 1999	35 OA patients[1]	43%
Caldwell et al., 2002	184 OA patients	18%
Hale et al., 1999	47 CBP patients	50%[1]
Huse et al., 2001	12 CNP patients	30%
Kjaersgaard-Anderson et al., 1990	40 OA patients	17%[2]
Maier et al., 2002	49 M-NP & NOC	33%
Morley-Forster et al., 2003	11 M-NP	10%
Peloso et al., 2000	31 OA patients	55%[3]
Roth et al., 2000	20 OA patients	21%[4]
	25 OA patients	38%[5]
Rowbotham et al., 2003	29 M-P&CNP patients	43%[6]
	30 M-P&CNP patients	22%[7]
Sindrup et al., 1999	34 PNP patients	31%[8]
Thurel et al., 1991	20 LBP patients	33%[9]
	21 LBP patients	35%[10]
Watson et al., 2003	24 DN patients	67%[11]
Weighted mean pain relief		30%

Note: PHN = Postherpetic neuralgia; OA = osteoarthritis; M-NP = mixed neuropathic pain; M-P & CNP = mixed peripheral and central neuropathic pain; NOC = nociceptive pain; PNP = polyneuropathic pain; LSP = lumbar spine pain; CBP = cervicobrachial pain; DN = diabetic neuropathy; LBP = low back pain.

[1] Reduction in daily pain intensity averaged across controlled release and immediate release oxycodone groups.

[2] Reduction in "all week pain" from baseline obtained over the 4-week treatment period and computed from Kjaersgaard-Anderson et al., 1990, Table 111.

[3] Reduction in average weekly pain intensity.

[4] Reduction in pain intensity from baseline for the low-dosage group (10 mg OxyContin capsule) from Roth et al., 2000, Figure 2.

[5] Reduction in pain intensity from baseline for the high-dosage group (20 mg OxyContin capsule) from Roth et al., 2000, Figure 2.

[6] Reduction in pain intensity from baseline for the high-dosage levorphanol group (.75 mg) from Rowbotham et al., 2003, Figure 2.

[7] Reduction in pain intensity from baseline for the low-dosage levorphanol group (.15 mg) from Rowbotham et al., 2003, Figure 2.

[8] Reduction in daily pain rating from baseline for the Tramadol group from Sindrup et al., 1999, Table 2.

[9] Reduction in pain intensity occurring between day 8 and day 15 of the treatment period for patients in the paracetamol-dextropropoxyphene group from Thurel et al., 1991, Table 2.

[10] Reduction in pain intensity occurring between day 8 and day 15 of the treatment period for patients in the paracetamol-codeine group from Thurel et al., 1991, Table 2.

[11] Reduction in pain intensity corresponding to the evaluable patients presented in Watson et al., 2003, Table 2 rather than the patients who actually completed the study.

over longer time intervals. Although the obvious clinical solution to this is to escalate the dose, there are no long-term studies that have tracked the amount of opioid increase needed to maintain stable pain reductions over long time intervals. Whether opioid tolerance plateaus, continues indefinitely, accelerates, or decelerates during long-term OT is unknown, nor can we predict which indi-viduals may be more likely to experience it. Future research examining the mechanisms associated with the development of tolerance also needs to attend to its tem-poral patterns and long-term treatment implications.

Thus, opioid therapy alone rarely is a solution for CNCP complaints. Individuals who tolerate opioid therapy likely do experience short-term pain reduction on the order

of 20% greater than that associated with inactive placebos, but the clinical meaningfulness of this degree of relief appears to be questionable. Additionally, it is likely that similar degrees of pain reduction will not be sustained over longer time intervals due to the effects of tolerance or other mediators of opioid response, and that actual placebo effects likely are larger than generally observed due to biases introduced by double blinding failures.

Associated Practitioner Recommendations

- Assess for changes in average pain intensity following initiation of opioid therapy and routinely reassess pain intensity throughout treatment.
- Monitor and address all adverse effects.
- Titrate therapy to provide maximum pain relief with a minimum of adverse effects.
- Discontinue the opioids if pain is unchanged or increases following dose escalations, if necessary dose escalations exceed prudent practice, or if adverse effects cannot be managed adequately.

OPIOID THERAPY HAS NOT BEEN SHOWN TO IMPROVE DAILY FUNCTIONING CONSISTENTLY EVEN WHEN PAIN INTENSITY IS REDUCED

Unlike cancer pain where the focus tends to be more on palliation, in cases of noncancer pain our primary goal most often is rehabilitation (Harden, 2002). Rehabilitation, in this context, includes not only physical capabilities and performance, but also emotional, social, and work-related functioning, and necessitates multidimensional outcomes assessment (Clark & Gironda, 2002).

Opioids and Functional Improvement

Although there are a few exceptions, initial claims that OT enhances daily functioning have not been substantiated. For example, Caldwell and colleagues (2002) evaluated changes in pain intensity, sleep, and physical function on the part of 295 individuals with osteoarthritis treated with controlled-release morphine (Avinza® or MS Contin®) or inactive placebo during a 4-week randomized trial. Improvements in sleep and reductions in pain from baseline were greater for participants receiving the controlled-release morphine products relative to the placebo group. However, no significant differences between groups emerged for the physical function measure. Huse and colleagues (2001) compared the effects of morphine sulfate to an inactive placebo in a study of 12 patients with phantom limb pain. They reported that individuals treated with morphine sulfate experienced reduced pain when compared with the placebo group. However, the attained pain reduction was unrelated to scores on measures of mood, coping, catastrophizing, or social support

and interaction. Kjaersgaard-Andersen and colleagues (1990) noted improved pain control in patients with osteoarthritis of the hip in response to codeine coupled with acetaminophen, compared with acetaminophen alone, during the first week of an OT trial that was subsequently closed due to high rates of adverse effects. However, no differences in disability or psychological measures were observed. Moulin and colleagues (1996) used an active placebo (benztropine) in their crossover study of 61 individuals with CNCP of mixed etiology treated with morphine. Despite reporting that that morphine elicited reduced pain intensity prior to crossover and led to greater pain intensity reductions from baseline following crossover, they found no significant differences between the treatment conditions in measures of mood, pain disability, or self-perceived pain-related impairment and no changes from baseline values. Sator-Katzenschlager and colleagues (2003), in a large-scale study of 477 consenting consecutive mixed pain referrals (including cancer pain) to a university pain center, used a range of interventions to reduce pain while assessing a wide range of additional outcomes. The majority of patients (63%) were treated with opioids either alone or in combination with adjuvant medications. The authors found significantly reduced pain from baseline levels through a 1-year treatment and follow-up period, along with improvement in self-reported pain avoidance and "cognitive control." However, no changes in emotional status, as measured by the Profile of Mood States (POMS), or activity from pretreatment levels were found, except for an *increase* in the POMS anger measure from pretreatment to post-treatment for men. Watson and Babul (1998) used the POMS and the Beck Depression Inventory (BDI) to assess mood changes in 50 patients with postherpetic neuralgia treated with either OxyContin or inactive placebo. Although they reported significant differences in pain intensity and in an investigator rating of disability between the OxyContin and placebo subjects, no differences in any of the POMS six mood scores or the BDI were obtained.

Not all opioid studies have failed to find evidence of functional improvement, however. For example, Arkinstall and colleagues (1995) reported improved Pain Disability Index (i.e., impairment) scores on the part of 30 patients with CNCP of varied etiology treated with 7 days of controlled-release codeine compared with 7 days of inactive placebo. Maier and associates (2002) treated 49 individuals with morphine and an inactive placebo in a randomized, double-blinded study. They reported that OT was associated with significant reductions in pain, along with improved "mood" and sleep. However, depression (which apparently was not considered to be a mood variable) and exercise endurance did not change. Peloso and colleagues (2000), in a double-blind RCT, reported improved self-ratings of physical function on the part of patients with osteoarthritis treated with controlled-release

codeine compared with inactive placebo. Finally, Roth et al. (2000) reported improved pain, mood, and sleep in subjects receiving 14 days of treatment with 20-mg controlled-release oxycodone compared with inactive placebo, although significant changes were not found in measures of work, activity, walking ability, or relations with others. Haythornthwaite and associates (1998) examined emotional and cognitive changes in 19 individuals receiving long-term OT for CNCP. They found that individuals treated with long-acting opioids, when compared with "usual care" subjects, reported reduced pain, hostility, and anxiety but not depression. Although the authors interpreted the results as support for a link between long-acting OT and improved "mood," the "usual care" comparison group also was undergoing OT (albeit with short-term agents) for chronic pain during the study. Therefore, the author's findings regarding reduced hostility and anxiety may reflect the impact of factors other than OT and do not lend support to relationships between OT and functional improvement.

Opioids and Functional Decline

Overall, the results do not consistently support presumptions that reduced pain intensity secondary to successful OT leads to general functional improvement. Depression in particular appears to be least responsive to OT. And most studies reporting positive effects on at least one functional measure failed to find significant associations for other similar variables. In fact, there is evidence that functioning may *decline* among some patients treated with opioids. This has been called the *Downward Spiral Hypothesis* (Schofferman, 1999; Turner et al., 1982). Although the concept has been disputed (Ciccone et al., 2000), there is clear evidence that at least in some cases, functional decline is associated with the initiation of opioid therapy. This decline includes increased pain (Brodner & Taub, 1978; Taylor et al., 1980), reduced activity levels (Fillingim et al., 2003; Turner et al., 1982), increased depression (Fillingim et al., 2003; Finlayson et al., 1986; Jarvik et al., 1981; Sproule et al., 1999), and cognitive or motor impairment or decline (Allen et al., 2003; Bruera et al., 1989; Sjogren et al., 2000).

In recent years, the potential for OT-related cognitive decline has received increasing attention due, in part, to concerns about liability stemming from motor vehicle or machinery accidents on the part of individuals consuming opioid analgesics for pain. Overall, the literature has been markedly inconsistent, with some studies reporting potential decrements in function, particularly psychomotor speed, that were related to opioid ingestion (Allen et al., 2003; Bruera et al., 1989; Jarvik et al., 1981), while others failed to find such associations (Lorenz, Beck, & Bromm, 1997; Sabatowski et al., 2003). In the best review and integration of this topic, Chapman, Byas-Smith, and Reed

(2002) concluded that OT-related cognitive impairment, to the extent that it occurs, likely is maximized during the first days of opioid intake and declines thereafter. Unfortunately, attempts to specify direct opioid effects in these studies are complicated by a variety of confounding factors, the most prominent of which is that pain itself appears to negatively affect cognitive functioning (Vainio et al., 1995). Furthermore, it is not clear that poor performance in neuropsychological tests predicts accident proneness. Simulation studies provide a more direct method to compare effects in this area. One preliminary report of comparisons of 17 patients with chronic pain treated with OT, 13 non-opioid patients, and 49 matched pain-free controls failed to detect consistent differences in performance on simulated driving tasks (Chapman, 2001). Clearly more research is needed in this area to clarify potential relationships between OT and accident risks or other hazards. The current, limited data suggest that if there are such risks, they may be most problematic at the outset of OT and may decline thereafter.

Thus, although there are inconsistencies with respect to the specific components of the downward spiral and no data as to its prevalence among CNCP patients treated with long-term OT, substantial evidence is available to support the presence of such effects among at least some individuals. Among all CPS symptoms, depression appears to be the least likely to improve in response to OT.

In conclusion, to date the preponderance of empirical data have failed to link OT-related declines in pain intensity to enhanced function. Although there is variability in some of the results, particularly with respect to cognitive function, there is little question that physical function and pain-related coping do not necessarily improve. Data also indicate that affective changes, particularly in depression, are the least responsive to successful OT and that some individuals may exhibit a decline in function following opioid initiation. Furthermore, one must consider that almost all of the blinded, placebo-controlled OT studies assessing functional changes utilized inactive placebos with little or no assessment of the integrity of their subject blinds. This approach enhances the probability of obtaining results supporting OT-related functional improvement due to subject and experimenter biases.

Associated Practitioner Recommendations

- When initiating OT, caution patients to avoid operating vehicles or engaging in activities that might endanger themselves or others due to slowed reaction times or reduced psychomotor speed for a *minimum* of 1 week and for several days after dose escalations. Note that data are mixed regarding more persistent cognitive effects and that a conservative approach would suggest extending the period of danger.

- Routinely assess for changes in physical, cognitive, and emotional functioning following initiation of opioid therapy.
- If depression is present, be aware that even successful OT is unlikely to enhance mood and, if appropriate, consider referral to a mental health professional for treatment.
- Consider cessation of opioid therapy if pain increases or function declines.

Some Individuals with CNCP and Substantial Psychosocial Impairment (i.e., Patients with Chronic Pain Syndromes), Treated with OT Achieve Greater Pain Reduction and Functional Improvement Following Cessation of Opioids during Multidisciplinary Treatment

Chronic pain syndromes (CPS) involve significant dysfunction across a broad spectrum of areas that typically include pain, pain-related impairment, and depression (Klapow et al., 1993) among others. Often these patients have undergone years of opioid and other treatment for their pain problems with no lasting benefit. Very little information is available concerning the rates of CPS. Although Klapow et al. found that approximately 25% of their sample of patients with chronic low back pain exhibited signs of a CPS, this issue has not been addressed directly in the literature since then. Some indirect information about these rates can be considered based on the frequency of depression, which is a hallmark symptom of a CPS, among individuals with chronic pain. For some individuals, depression is intricately linked with the experience of pain (Elliott, Renier, & Palcher, 2003), increases proportionally with increases in pain intensity (Currie & Wang, 2004), appears to potentiate the degree of pain-related disability (Currie & Wang, 2004; Ericsson et al., 2002b), and independently predicts the onset of significant back or neck pain (Carroll, Cassidy, & Cote, 2004) as well as disability status (Ericsson et al., 2002). Reid, Guo, Towle, Kerns, and Concato (2002) found that between 44 and 54% of their two independent samples of individuals with mixed chronic pain had a diagnosis of depression entered in their medical records, while Elliott et al. (2003) reported a 52% prevalence rate for depression among 242 participants in a multidisciplinary chronic pain treatment program. Thus, the high rates of depression found among individuals with chronic pain suggest that Klapow and colleagues' (1993) estimate of a 25% CPS prevalence rate likely is an underestimate. In fact, the best available evidence suggests that CPS prevalence rates fall in the 40% range (Gironda, 2004). In any event, it is clear that a significant proportion of individuals with chronic pain exhibit the broader range of dysfunction associated with CPS.

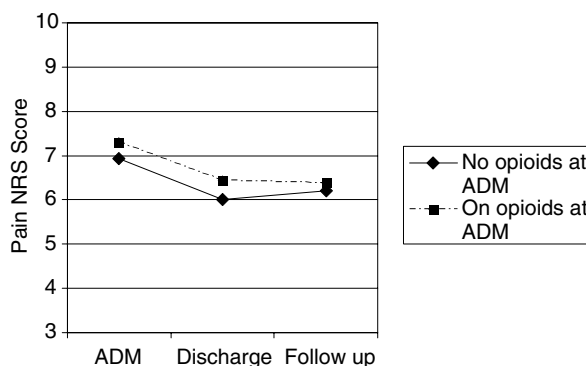
To date there have been no studies examining the short-term or long-term effectiveness of OT specifically for indi-


FIGURE 11.1 Mean numeric pain scores by opioid status at program admission.

viduals with a CPS. However, there now is some recent evidence that individuals with a CPS treated with OT improve after *cessation* of opioids (Clark & Gironda, 2001). In this study, 108 patients with mixed chronic pain diagnoses underwent multidisciplinary pain treatment in an 18-day, inpatient, Rehabilitation Accreditation Commission (CARF)-accredited pain program in the southeastern United States. All individuals receiving OT at admission underwent a gradual cessation of opioids during the first 7 to 10 days of treatment. Treatment emphasized physical restoration and improved pain management skills, and included a strong cognitive-behavioral focus. Multiple outcomes domain measures were administered at admission, at discharge, and at a 90-day follow up assessment.

Figure 11.1 presents the mean pain intensity scores obtained from program participants based on an 11-point numeric pain scale assessing average pain in the last week. The dotted line in the graph represents 36 patients who were taking daily opioids at admission, while the solid line reflects means for 72 patients who were not taking opioids at admission. All participants were opioid free at discharge and the 3-month follow up.

As illustrated in Figure 11.1, individuals receiving daily opioids at admission exhibited significant and equivalent reductions in pain intensity during treatment that were maintained at follow-up despite the cessation of opioids. Although pain intensity declined significantly from admission to discharge and follow up, there were no significant differences in mean pain scores between the two groups at any of the time points. Although one could hypothesize that the lack of significant differences in pain intensity at admission might have reflected the pain amelioration effects of OT, in such a case opioid cessation during treatment should have resulted in higher pain scores for these individuals at discharge and at follow up. The lack of pain intensity differences across all time points instead suggests that opioids were not contributing to pain reduction in these individuals. Thus, opioid cessation had no effect on participants' pain levels.

The ineffectiveness of opioids in this study was not confined to changes in pain intensity. Almost identical patterns were observed for measures of pain interference in activities of daily living and mobility, activity and strength, and negative affect. In each case, both groups of participants demonstrated significant and equivalent improvements in function, and there were no significant differences between the opioid and non-opioid groups at any of the three time points.

The data described above are tentative, and at present we are replicating the results in a larger sample incorporating additional measures. However, these initial results are consistent with clinician observations concerning the lack of OT-related improvement among individuals with symptoms of a CPS (Harden, 2002; Schofferman, 1993).

In summary, it is our contention that individuals with CNCP and a concurrent CPS are less likely to benefit from OT. For these individuals, the current pain treatment literature suggests that approaches incorporating a range of interventions delivered in a multidisciplinary treatment setting may provide the best outcomes at the least expense (Turk et al., 2002).

Associated Practitioner Recommendations

- Complete a comprehensive pain assessment prior to initiation of OT. A comprehensive assessment should include, at a minimum, measures of mood, pain-related impairment, physical status, social functioning, and pain intensity.
- When significant psychosocial impairment (e.g., depression, anxiety, family problems, work difficulties) is suspected or observed, consider referral to an appropriate pain specialist to determine if a CPS is present.
- If a moderate to severe CPS is confirmed, a multidisciplinary pain clinic referral should be considered, particularly when there is evidence of a poor prior response to OT.
- When either a multidisciplinary pain clinic is not available or referral is not indicated, inclusion of an active, restorative treatment component, such as physical therapy and/or a monitored and paced exercise program, may enhance outcomes (Harris & Susman 2002; Iversen, Fossel, & Katz, 2003; Liddle, Baxter, & Gracey, 2004).

RATES OF OPIOID MISUSE (I.E., OPIOID ABUSE, OPIOID NON-ADHERENCE, OR OPIOID ADDICTION) AMONG INDIVIDUALS TREATED WITH OT ARE SIGNIFICANT

Concerns about opiate use permeate our society today. Individuals with chronic pain fear becoming "addicted" or "drugged" and may refuse opioid analgesics as a result

(Gilron & Bailey, 2003). Practitioners may be reluctant to prescribe opioids (Morley-Forster et al., 2003; Potter et al., 2001), in part due to concerns about addiction (Bendtsen et al., 1999). Yet many pain specialists minimize these risks of opioid analgesic use (Aronoff, 2000; Passik & Weinreb, 2000), even among individuals with a history of substance abuse or dependence (Compton, Athanasos, & Elashoff, 2003; Currie et al., 2003), while others voice concerns related to its use (Ballantyne & Mao, 2003; Harden, 2002; Zuniga, 1998).

OPIOIDS, ADDICTION, AND MISUSE

Some of the disparity in practitioner opinions regarding the abuse potential of opioid analgesics may stem from differences in defining opioid abuse. Many pain professionals equate abuse with true addiction, or the compulsive need for and use of a habit-forming substance that is characterized by tolerance and by physiological withdrawal symptoms. True addiction to opioid analgesics appears to be relatively infrequent among individuals with CNCP. For example, Cowan and colleagues (2003) found a 2.8% addiction rate in their survey of 104 patients with chronic pain treated with OT. Kouyanou, Pither, and Wessely (1997) reported that 6.4% of 125 individuals with CNCP treated at pain clinics in London met the criteria for active substance dependence. However, practitioners' concerns may be broader and encompass not just opioid addiction, but also other patterns of opioid misuse. These include patterns such as opioid overuse, diversion, sharing, use with illicit drugs or alcohol, or use for nonpain-related purposes (e.g., sleep; anxiety reduction), all of which constitute risks to the patient or to society but do not necessarily meet the criteria for true addiction.

When patterns of inappropriate opioid use are considered together, data from chronic pain studies suggest that the rates of opioid misuse in this population are far from trivial. For example, when cases of opioid misuse, nonadherence, or addiction were considered together, Turk et al. (2002) reported a mean rate of opioid misuse of 18.4% across 13 opioid studies. Others have found even higher rates of misuse. Reid and colleagues (2002a) retrospectively examined the medical records of 98 randomly selected individuals with long-standing chronic pain treated with at least 6 months of OT in two primary care (VA and urban, hospital-based) settings. They reported that 24% of VA and 31% of non-VA primary care sample patients had documented evidence of prescription opioid abuse in their medical records. When they examined predictors of this recorded opioid abuse, the best predictor was a past history of a substance abuse disorder, followed by younger age. Chabal and associates (1997) developed an opioid abuse checklist based on accepted diagnostic criteria and administered the instrument to 76 pain clinic participants undergoing OT. They reported that 34% of

the patients in OT met one of the abuse criteria, and 27.6% met three or more of the criteria. Kouyanou and colleagues (1997) reported that 83% of their subjects taking medications were potentially misusing them. Ackerman and associates (2003) compared self-reported opioid medication use with manufacturer recommendations of use among 690 individuals with chronic pain and found that patient's utilization varied significantly from what was recommended. Katz and colleagues (2003) tested urine samples of 122 CNCP clinic patients and compared the results with medical record documentation of five behaviors associated with misuse. They found that 21% of the patients had positive toxicology screen results alone (illicit substances, nonprescribed controlled medications, or alcohol), 14% had documented behaviors consistent with misuse in the absence of positive urine screens, and 8% presented with both signs. Thus, almost one half of substance-misusing patients demonstrated toxicological evidence of substance abuse or misuse in the absence of recorded abuse behaviors. Saper and colleagues (2004) reported on the 3- to 8-year outcome of 160 patients receiving daily scheduled opioids for intractable head pain (an open-label adjunct to an overall management program including many behavioral approaches). They noted that 70 patients used OT for at least 3 years, but only 26% of the 160 patients had pain relief greater than 50%. Furthermore, problem drug behaviors (dose variations, lost prescriptions, obtaining medication from more than one prescriber) were seen in 50% of the patients leading the authors to appropriately conclude, "the relative low percentage of patients with demonstrated efficacy and unexpectedly high prevalence of misuse have clinical relevance" (p. 1692).

Misuse also includes episodes of opioid intoxication resulting in death. Opioid-induced deaths may occur due to an unintentional overdose of opioid-addicted individuals or from intentional suicide. Unlike some other countries, the overall rates of opioid analgesic–related deaths are unknown in the United States due to the absence of national tracking methods. However, some data have been reported linking specific opioid agents with an increased number of deaths. Foremost among these are the much-publicized reports of increasing OxyContin overdoses (Schulte & McVicar, 2002). However, frequent overdoses of other selected opioid analgesics also have been reported. For example, the Drug Enforcement Agency (DEA) reported that emergency room visits due to hydrocodone overdose increased 48% between 1998 and 2001 (Mathews & Fields, 2003) leading to a recent proposal to reclassify the drug from a Schedule III to a Schedule II controlled substance. Another Schedule III opioid (propoxyphene) was found to be the most common method of drug-related death from presumed suicide and was second only to gunshot wounds as the cause of death by suspected intentional causes among outpatients at a southeastern medical facility over a 2-year period (Maudlin, 2004).

Overall, although the actual risk of death associated with opioid analgesic abuse undoubtedly is small, there are indications that heightened risks may be associated with certain opioid agents, suggesting that practitioners may need to exercise increased caution when these analgesics are prescribed.

Thus, available data suggest that opioid abuse, opioid nonadherence, or opioid addiction among individuals with CNCP treated with opioid analgesics occurs with a relatively high frequency. Of course, not every instance of misuse necessarily should lead to the cessation of OT. Nevertheless, the reported frequencies suggest that practitioners need to remain sensitive to the potential for misuse of opioids or the use of other substances that may negatively affect OT.

Associated Practitioner Recommendations

- Monitor every patient undergoing OT for signs of misuse, non-adherence, and addiction. The addition of periodic toxicology screens may enhance detection of abuse or misuse.
- Signs of potential misuse or non-adherence may include unusual or noncompliant usage patterns, self-reported loss or accidental destruction of prescriptions or analgesics, elaborate explanations of why adherence was not possible, and strong preferences for specific substances that are frequently abused, among others. Assume that when explanations are not clear or do not make sense either some critical information is missing or there is some type of misrepresentation occurring (Cole, 2003).
- When behavioral signs alone suggest misuse, non-adherence, or addiction, or if opioid diversion is suspected, consider observed sample collection and repeat toxicology testing.
- If misuse is identified, address safety issues (e.g., diversion, intentional or unintentional overdose) immediately; consider cessation and notifying authorities.
- If OT is terminated, monitor and treat potential withdrawal.

INITIATION AND CESSATION OF OT HAS BEEN LINKED TO THE DEVELOPMENT OF HYPERALGESIA IN HUMANS

Hyperalgesia refers to the subjective experience of increased pain that is defined by a reduced pain threshold or reduced pain tolerance. Hyperalgesia differs from opioid-related tolerance in that the latter focuses on the need for increasing opioid dosages to maintain the same degree of pain reduction.

Hyperalgesia has been found to occur following opioid administration and initially was linked to relatively

rapid escalation of opioids as might occur postsurgically. However, more recently it has been documented following stable and long-term opioid use (Arner, Rawal, & Gustafsson, 1988; Ossipov et al., 2003) and during methadone maintenance therapy (Doverty et al., 2001a, 2001b). In the last several years evidence of the development of hyperalgesia in response to the *withdrawal* of opioids has also been reported (Angst et al., 2003; Compton et al., 2003; Hood, Curry, & Eisenach, 2003), even following short-term opioid infusion (Angst et al., 2003). In fact, in one study a single administration of an opioid led to rapid and large (on the order of 70%) decrease in pain threshold and pain tolerance, when compared with pre-opioid administration levels, among non-opioid-dependent males (Compton et al., 2003). This was one of the first studies using human subjects that provided experimental support for the existence of a pain *sensitization* system that can be triggered by either opioid administration or withdrawal. Interestingly, in one study the hyperalgesic effects were much stronger for hydromorphone than for morphine sulfate (Compton et al., 2003), suggesting that substance-specific differences may exist.

The development of hyperalgesia has been hypothesized to be a form of neurotoxicity associated with the accumulation of opioid metabolites (Pereira, 1997), variations in opioid receptor concentrations (Wilson, 2001), or activation of descending rostral ventromedial medulla mechanisms that facilitate pain (Ossipov et al., 2003). While the exact mechanism responsible for this opioid effect remains unknown and is no doubt complex, its existence is problematic from a pain treatment perspective and poses a paradox to practitioners. That is, attempts to relieve pain via opioid administration may, for some individuals, actually provoke increased pain, as may opioid cessation following even very brief opioid exposure.

At present, we do not know how frequently opioid-induced hyperalgesia develops. In the past its incidence was presumed to be low. However, the recent reports of opioid withdrawal-induced hyperalgesia suggest that it may be more common than initially recognized. Certainly one could hypothesize that opioid-induced hyperalgesia may account for a portion of the numerous dropouts from RCT studies and clinic-based opioid trials. Additionally, it is quite possible that the opioid tolerance frequently observed in clinical trials and patient treatment may in actuality represent hyperalgesia. Indeed, it is widely viewed that they share the same or a similar mechanism (Ossipov et al., 2003), and in the absence of pain threshold or pain tolerance testing, it would be virtually impossible to distinguish between them during patient treatment as both would lead to decreased effectiveness and dose escalation. In any event, the potential for developing increased pain following brief or extended opioid administration or cessation clearly exists and needs to be considered by pain practitioners.

Associated Practitioner Recommendations

- Prior to initiating OT, evaluate the patient's history of opioid analgesic use and assess for past episodes of opioid-induced hyperalgesia. If evidence of potential hyperalgesic experiences exists, proceed cautiously. Consider the utility of administering a test dose and observing for subsequent increases in pain intensity.
- Until more information regarding the incidence of hyperalgesia under different OT protocols is known, assess each patient treated with OT for evidence of hyperalgesia during each clinical contact regardless of the duration of the individual's ongoing opioid use.
- Evidence of hyperalgesia (but not tolerance) may indicate that OT cessation is indicated. Attempts to "treat" hyperalgesia with escalating opioid doses, as is employed when responding to opioid tolerance issues, may be counterproductive. At present the value of rotating to an alternative opioid agent in the hope of avoiding hyperalgesic responses is unknown.
- When opioids are discontinued, following either short-term or long-term OT, assess for symptoms of hyperalgesia and treat accordingly.

Accumulating Evidence Indicates Strong Links between Oral or Intrathecal Opioid Administration and Rapid Onset Hypogonadism and Sexual Dysfunction among Both Men and Women with Chronic Pain

To date, five studies have examined the effects of opioid administration on hypogonadism among humans. The results of all five have been remarkably consistent among both men and women using both oral and intrathecal administration routes. A summary of the results of these studies is presented in Table 11.3.

Abs et al. (2000) compared hormonal levels in 29 men and 44 women with CNCP undergoing long-term intrathecal treatment with morphine with those of 20 non-opioid control subjects with similar pain conditions. Self-reported decreased libido or impotency was found in 96% (23/24) of the men and in 69% (22/32) of the women receiving intrathecal opioids. In addition, all 21 premenopausal women experienced either amenorrhea or an irregular menstrual cycle, with ovulation occurring in only one case. A similar pattern of findings was reported by Finch and colleagues (2000) in their comparison of 29 patients (10 men and 19 women) receiving intrathecal opioids as treatment for CNCP with 20 control subjects with pain but not receiving opioids. Testosterone levels in the males receiving opioid therapy were below normal and were significantly lower than levels in the male controls. Of the

TABLE 11.3
Incidence of OT-Associated Hypogonadism

Study	OT type	Rates	Comments
Abs et al. (2000)	Intrathecal	>86% (M)	Decreased Libido:
73 P (29 M, 44 F)	(*M* = 26.6 months)	100% (W)	96% Men
20 C (11 M, 9 F)			69% Women
Daniell (2002)	Oral	89%	Dose-related testosterone reduction: 87% reported sexual
54 P (males)	(range = <1 year–>10 years)		dysfunction
27 C (males)			
Finch et al. (2000)	Intrathecal	90% (M)	Decreased Libido:
30 P (11 M, 19 F)	(.02–8 years, median = 2.5 years)	75–90%(F)	60% Men
20 C (10 M, 10 F)			100% Women (premenopausal)
			Reduced testosterone (M)
			Reduced FSH and LH (F, postmenopausal)
Rajagopal et al. (2003)	Oral(minimum 12 months)	90%	Low Sexual Desire Inventory scores compared to healthy adults
20 P (males)			
Roberts et al. (2002)	Intrathecal	–74% 1 week	Testosterone levels measured
10 P (males)	(1–12 weeks)	–64% 4 weeks	Prospective study
		–48% 12 weeks	

P = patients; C = controls.

10 male subjects, 6 reported reduced libido with 4 of these subjects also reporting impotence. Reduced libido dating from the onset of opioid therapy was also reported by all 7 premenopausal women, although their median serum testosterone levels were within normal limits. In the postmenopausal women, testosterone levels were significantly lower than in the non-opioid controls although their sexual interest had fallen even prior to opioid treatment. In another study, Daniell (2002) assessed testosterone and hormones related to testosterone production in 54 male subjects receiving various forms of oral opioid therapy for CNCP. In contrast to control subjects, average hormone levels were significantly lower (in a dose-dependent manner) in the opioid group. Of the 45 men that reported normal erectile function prior to the beginning of the study, 39 reported severe erectile dysfunction or diminished libido after initiating opioid therapy.

Rajagopal and associates (2003) found reduced testosterone levels in 18 of 20 male patients with cancer-related chronic pain who had been receiving opioid therapy for at least 1 year. Compared with healthy controls, these subjects also reported significantly reduced sexual desire scores as measured by the Sexual Desire Inventory (Spector & Carey, 1990). In the only prospective study (Roberts et al., 2002) measuring the effects of opioid therapy on serum testosterone levels in 10 male subjects with CNCP, serum testosterone levels were measured prior to the onset of intrathecal opioid therapy and again after 1, 4, and 12 weeks of intrathecal infusion. Compared with baseline, serum testosterone was reduced by 74% after week 1, 64% after week 4, and 48% after week 12. Although the majority of the subjects reported poor libido and abnormal erec-

tile function at baseline, sexual dysfunction increased during the course of the study resulting in an absence of sexual activity in all 10 of the subjects after 12 weeks of OT.

Although none of the studies included comparisons between opioid and active or inactive placebo groups, the consistency of the results clearly implies causal links between initiation of OT and subsequent development of hypogonadism. Overall the studies suggest (1) there is a strong association between administration of opioids and subsequent signs of hypogonadism; (2) the gonadatrophic hormone changes occur rapidly following opioid administration; (3) there is some evidence that the association is dose related; (4) it affects the vast majority of individuals consuming opioids; and (5) gonadatrophic hormone changes correlate highly with reports of reduced libido or sexual dysfunction.

Additional research is needed to delineate both the degree and persistence of opioid-induced hypogonadism for individuals treated with long-term OT. For the present, symptoms of unexplained hypogonadism that appear to parallel OT initiation should be investigated fully.

Associated Practitioner Recommendations

- Evaluate patients for changes in sexual function following OT initiation and, if indicated, assess gonadatrophic hormone levels.
- If hypogonadism is confirmed, educate the patient and spouse or partner, if available, concerning its effects.
- Discuss the available options for treatment along with the potential adverse effects of the

treatments with the patient and partner, if available. Initiate treatment of the hypogonadism (e.g., hormonal therapy) or consider cessation of OT based on the results of this discussion.

EMOTIONAL DISTRESS AND OTHER PSYCHOSOCIAL VARIABLES ARE BETTER PREDICTORS OF WHETHER AN INDIVIDUAL WITH CHRONIC PAIN WILL BE PRESCRIBED OPIOIDS THAN IS PAIN INTENSITY OR OTHER PHYSICAL STATUS VARIABLES

Decisions regarding who should or should not receive OT for chronic pain are a complicated matter incorporating numerous patient, practitioner, and pain condition variables. Nevertheless, there is a consensus among practitioners, consistent with the WHO analgesic ladder, that opioid analgesics should be considered only for those with moderate to severe pain.

One implication of this position is that pain intensity should be positively associated with decisions to prescribe opioids for chronic pain. Yet the great preponderance of empirical data fails to find such a relationship between pain intensity and opioid use. For example, Turk and Okifuji (1997) compared 81 patients with chronic pain at a pain treatment center who were currently taking opioids for CNCP with 110 patients at the same center who were not taking opioids on a variety of measures. Turk and Okifuji found no differences between the groups on demographic, pain duration, pain onset, pain location, physical findings, or pain intensity variables. In fact, the only variables that differentiated between groups were those of number of pain behaviors, degree of functional limitation, and affective distress. For all of these variables, patients receiving opioids demonstrated significantly greater dysfunction. When the predictive value of all designated variables was investigated using logistic regression techniques, only pain behaviors emerged as a significant predictor of opioid use.

Breckenridge and Clark (2003) retrospectively examined patient and pharmacy records of 200 veterans with back pain receiving either NSAIDs ($n = 100$) or opioids ($n = 100$) for their pain. Again, they found no relationship between reported pain intensity and opioid use. Instead, logistic regression analyses revealed that individuals undergoing OT were approximately 5 times more likely to have a substance abuse disorder, 8 times more likely to experience depression, and more than 18 times more likely to have a diagnosed personality disorder than were veterans treated with NSAIDs. Clark (2002) found that 21% of his randomly selected medical clinic sample of U.S. military veterans with CNCP treated with opioid analgesics had documentation of a substance abuse history. Fillingim and colleagues (2003), in a study utilizing 240 individuals with back or neck pain evaluated at a multidisciplinary pain center, found significant positive associations between self-reported disability and dysfunction and opioid use for both men and women, and no relationship between pain intensity and opioid use. Interestingly, affective distress was positively associated with opioid use in men and negatively related in women. Similar findings noting the lack of relationships between pain intensity and/or physical findings and opioid use have been reported by Clark and Gironda (2001). Only one study has found the expected positive relationship between pain intensity and opioid use (Ciccone et al., 2000). However, consistent with the above findings, these authors also noted significant and positive associations between disability measures, activity impairment, and self-reported depression and opioid use.

Explanations proffered to account for these findings tend to cluster around the potential impact of patient behaviors on practitioner prescribing practices (Turk & Okifuji, 1997). In such a view, individuals exhibiting signs of increased physical or emotional distress, as well as those who persist in their efforts to obtain opioids, may be more successful than less dramatic or assertive individuals (i.e., the "squeaky wheel syndrome"). Indeed, the potential for patient pain behaviors to influence medical decisions is not unique to opioid prescribing alone, having been demonstrated with respect to back surgery decisions previously (Waddell et al., 1984). In this regard, pain behaviors may serve as one of a host of variables that influence practitioners' prescribing decisions (Turk & Okifuji, 1997).

An alternative explanation of these results might counter that pain intensity/opioid use relationships may be difficult to detect because in all of the above studies individuals were using opioids at the time measures were collected. Therefore, one might hypothesize that the pain-reduction effects of OT attenuated the size of the observed relationship between pain and opioid use, whereas if measures were administered *prior* to any practitioner decision whether to use opioids, significant associations might have emerged. Nevertheless, this would not explain reports noting the lack of relationship between physical examination variables or diagnostic test results and opioid use. An additional issue is that all subjects in the above studies were undergoing evaluation or treatment at specialty pain treatment sites. Given established differences between these patients and patients treated in other medical settings such as primary care (Crook, Weir, & Tunks, 1989), it may be that patients treated in other medical settings may demonstrate the expected pain intensity–opioid use relationship. Ultimately, clarification of the relationship between pain intensity or physical findings and opioid prescribing likely will await completion of one or more prospective studies that can manipulate or quantify intensity of pain behaviors and physical findings before therapeutic decisions are rendered. However, in the interim practitioners should be aware of the empirical findings thus far.

In summary, research to date has failed to find consistent relationships between pain intensity or physical findings and opioid use. Instead, the preponderance of the data has identified a range of psychosocial factors that predict opioid use. These include pain behaviors, affective distress, self-perceptions of functional limitations or pain-related impairment, active substance abuse, and presence of a personality disorder. The latter two associations are the most surprising in that substance abuse and personality disorders are potential *contraindications* for OT.

Associated Practitioner Recommendations

- Consistent with WHO recommendations, consider opioid therapy only for refractory chronic pain of moderate or severe intensity.

- Evaluate emotional distress as well as pain intensity. For individuals exhibiting significant depression, initiate a mental health referral for evaluation and treatment *prior* to deciding whether an opioid trial is indicated.

- When dramatic pain behaviors are present, proceed cautiously, and consider the possibility of other explanations for the patient's presentation including secondary gain, presence of a personality disorder, or substance abuse/misuse. If the above cannot be ruled out, refer to a mental health or substance abuse professional for assistance.

CONCLUSIONS

Empirical data indicate that the prescription of opioid analgesics is one of the most frequent interventions employed for the treatment of CNCP (Fillingim et al., 2003; Morley-Forster et al., 2003; Turk & Okifuji, 1997). Yet at present the effectiveness of long-term OT remains unsubstantiated. No long-term studies of OT efficacy have been reported despite widespread recognition of the need for such investigations. As a result, support for OT effectiveness stems from a series of short-term opioid studies. Primary among these are 18 RCTs that constitute the foundation for claims of the efficacy of OT in the treatment of CNCP. Yet, a close examination of this core of studies leads to a myriad of concerns regarding study design and the resulting findings. These concerns include the following:

1. brief (i.e., less than 6 weeks) RCT durations (15 of 18 studies);
2. high (greater than 20%) subject dropout rates (14 of 18 studies);
3. relatively small (fewer than 40 subjects completing the opioid trial) sample sizes (9 of 18 studies);
4. lack of intent-to-treat analyses (13 of 18 studies);
5. incomplete or unclear methodology (4 of 18 studies);
6. failure to report pain changes from baseline (5 of 18 studies);
7. reliance on nonstandard pain intensity measures or use of derivative measures that preclude comparisons with the results of other studies (8 of 18 studies);
8. use of opioid rescue medications during controlled trials (4 of 18 studies);
9. use of inactive rather than active placebos (10 of 12 studies); and
10. failure to assess the integrity of blinding procedures when placebos were used (9 of 13 studies).

This last methodological concern alone is sufficient to question the results of the RCT OT literature, in that the few investigators that have assessed the integrity of study blinds in both active and inactive placebo studies generally have found that the majority of subjects and providers are aware of which group or crossover period utilized opioids.

Future research evaluating OT effectiveness needs to address the many problems cited above. Although there are a variety of obstacles to conducting long-term (i.e., 6 months or more), reliable, RCT studies of opioid effectiveness, they remain the best way of determining the utility of OT in the treatment of CNCP. Additionally, there are a number of methodological improvements that could be made in shorter-term studies that would enhance the validity and value of the findings. Studies incorporating parallel treatment arms (rather than crossover designs); active placebo comparison groups; intent-to-treat analyses; validated measures of pain intensity, mood, pain interference, and disability; quantification of changes in pain from baseline as well as differences in pain intensity between experimental and control groups; and most importantly, routine and systematic assessment of the integrity of the blinding procedures are needed to redress the methodological shortcomings that plague the current OT research literature. In addition, long-term studies that may not meet the rigors of RCT methodologies, but that examine the longitudinal effects of OT on pain intensity and daily function while monitoring dropout rates and misuse, would provide needed information concerning the "real-world" utility of opioid analgesics in the treatment of CNCP.

Even if the methodological weaknesses characteristic of the opioid RCT research core are overlooked there remains much to question regarding OT effectiveness. The pain reduction associated with short-term OT, averaged over all studies we reviewed and irrespective of potential placebo effects, was only 30%, which, although signifi-

cant, clearly suggests that OT should be used in conjunction with other empirically supported treatment strategies. Nor has successful (defined by reduced pain intensity) OT been linked to improved function in studies incorporating such measures, particularly in the realms of depression and disability. In fact, the function of some individuals with CNCP appears to *decline* when treated with OT (Schofferman, 1999; Turner et al., 1982), and discontinuing OT for individuals with CPS has been linked with improved function and pain (Clark & Gironda, 2001). This argues strongly for increasing emphasis on multidisciplinary pain treatment approaches and for further research assessing relationships between CPS and OT effectiveness.

Another concern with respect to OT raised in this chapter pertains to provider decisions to prescribe opioid analgesics. We have seen that pain intensity and physical status variables are poor predictors of who will receive OT. In fact, rarely has pain intensity been associated with opioid analgesic use. Although relatively little research has focused on this issue, what information we do have indicates that *psychological* factors predominate. That is, individuals exhibiting more pronounced pain behaviors, affective distress, or perceived pain-related impairment are more likely to receive opioids (Turk & Okifuji, 1997). Indeed, those with substance abuse and personality disorder histories are overrepresented among individuals receiving OT (Breckenridge & Clark, 2003). If future research establishes the effectiveness of OT for the treatment of CNCP, concomitant efforts to target individuals experiencing higher levels of pain and lower levels of psychopathology as the recipients of OT would be beneficial.

Opioid analgesic use also has been linked with a variety of serious complications beyond the assortment of adverse effects with which practitioners are most familiar. Both opioid initiation and cessation have been demonstrated to elicit hyperalgesia even following very short-term exposure (Angst et al., 2003; Compton et al., 2003; Hood et al., 2003). The mechanisms underlying the pain sensitization effects associated with hyperalgesia also may mediate opioid tolerance (Ossipov et al., 2003). In fact, it is possible that tolerance may reflect undetected hyperalgesia. Integration or differentiation of these mechanisms depends in part on including pain threshold and pain tolerance tests in future RCT studies of opioid analgesic effectiveness. OT also has been causally linked to rapid onset hypogonadism in both men and women (Abs et al., 2000; Roberts et al., 2002). Although other factors undoubtedly contribute (e.g., depression), this link may explain in large part the strong association between chronic pain and reduced sexual interest or performance. Efforts to identify the long-term consequences of potential treatments for opioid-induced hypogonadism clearly are needed. In the interim, both OT candidates and their sexual partners need to be educated regarding these effects if they

are to participate in informed decision making. Finally, when rates of addiction, abuse, and non-adherence are considered together, approximately one quarter of individuals with CNCP treated with OT in primary care settings have exhibited signs of misuse (Reid et al., 2002a). Furthermore, selected opioid agents (hydromorphone, oxycodone, and propoxyphene) have been linked with more frequent overdoses and potential death. Improved methods for identifying links between specific opioid agents and risks of abuse are needed, as is research focusing on predictors of opioid analgesic misuse.

The opioid-related concerns discussed in this chapter are not exhaustive by any means. Other issues have been identified in the recent pain literature, but were not included based on their preliminary nature. These include possible racial barriers to opioid access (Tamayo-Sarver et al., 2003), opioid mediation of some aspects of anger expression (Bruehl et al., 2002; Bruehl, 2003), and the potential immunosuppressive effects of opioid analgesics (Alonzo & Bayer, 2002; Sacerdote et al., 2000) that actually may benefit individuals with selected immune system disorders such as rheumatoid arthritis. Only additional research will determine the salience of these concerns and the degree that providers will need to consider them in decisions to use OT.

We recognize that OT will continue to be used to treat CNCP and that there undoubtedly are individuals benefiting from this form of treatment. However, based on the current status of the OT literature, we believe that providers considering the use of opioid analgesics need to proceed cautiously. Data from a variety of empirical studies indicate that OT can be detrimental and that the overall effectiveness of OT for the treatment of CNCP has not been adequately demonstrated. Furthermore, while we can identify with some degree of confidence the characteristics of individuals who are poor candidates for OT, no reliable empirical data exist identifying the characteristics of individuals who are good candidates for OT. In the absence of this information, we have provided some recommendations for OT use based on the existing opioid literature to promote informed and balanced clinical decision making. These recommendations, however, do not supplant the urgent need for continued and expanded OT research, which must form the basis for the safe and effective utilization of opioids in the treatment of CNCP.

The Role of Nursing in Pain Management

Claudia E. Campbell, RN, BSN

INTRODUCTION

The role of the nurse, historically and currently, is solidly centered in the direct care of the patient. (Zerwekh & Claborn, 2003). When Pellino et al. (2002) completed a role delineation study for the American Society of Pain Management Nursing in 2001, it came as no surprise that survey respondents indicated assessment, monitoring, and evaluation of pain were nurses' most common activities while caring for patients in pain. In spite of the similarity in nursing activities, nurses practice in a variety of settings including clinics, offices, hospitals, surgical centers, extended-care facilities, hospices, businesses, schools, and patients' homes, to name a few (Pellino et al., 2002). Nurses may be engaged primarily in critical care, oncology, rehabilitation, home care, supportive or administrative roles, or any of the endless variety of specialized nursing practices. In most patient care settings, nurses are the members of the multidisciplinary team to spend the most time with the patient (McCaffery et al., 2000). Regardless of the practice setting or specialty, improvement in the provision of pain management services is dependent on the involvement of nurses with necessary clinical skills and a commitment toward relieving pain.

Nursing roles are numerous and complex, so it is difficult to reduce these to a single written description sufficiently detailed to describe the impact a skilled and caring nurse has on any patient's life. Instead, the goal for this chapter is to provide readers with insight into the practice of nursing as part of the multidisciplinary team. This chapter investigates the nursing role in patient education, pain assessment, analgesic interventions, assessment of the patient's response to pain management interventions, and documentation. In addition, it explores the nurse's role in collegial communication, patient safety, professional and community education, quality improvement, advocacy, and ethics. It also discusses nurses practicing in expanded roles.

ASSESSMENT OF PAIN

The importance of pain assessment was identified as a necessary first step in improving the effectiveness of pain management. In 1992 and again in 1994, the Agency for Health Care Policy and Research (AHCPR) published guidelines for the treatment of acute pain and cancer pain. In 1999, the Joint Commission on the Accreditation of Healthcare Organizations (JCAHO) released its standards on pain management. The JCAHO standards include a call for health care organizations to recognize the right of the patient to have his or her pain routinely assessed (JCAHO, 2001). A thorough assessment of pain is multidimensional and far more complex than simply obtaining the patient's self report of pain intensity. Patient communication about the nature and severity of pain and the impact this pain has on function and quality of life takes a skilled interviewer with sufficient time to develop the trust needed to facilitate eliciting detailed information. Although assessment of pain is the responsibility of all disciplines, nurses practicing in most settings have greater opportunities to establish this type of relationship with the patient than do the other members of the multidisciplinary team. The nurse's skill in obtaining a complete pain history will determine the quality of information made available to the other members of the team for use in decision making as the pain management regimen is determined.

0 – 10 Numeric Pain Intensity Scale

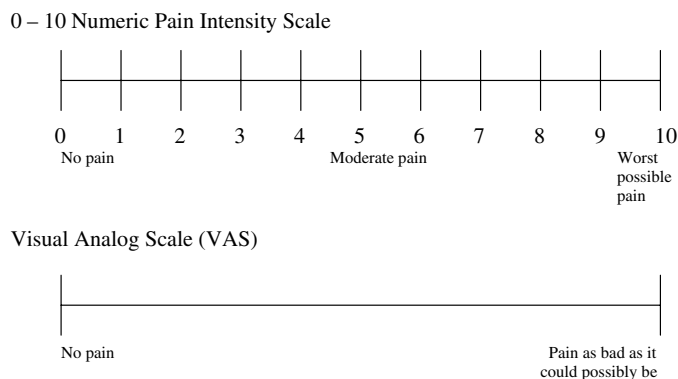
Visual Analog Scale (VAS)


FIGURE 12.1 Pain intensity scales. From *Acute Pain Management: Operative Medical Procedures and Trauma. Clinical Practice Guideline No. 1*, by Acute Pain Management Guideline Panel (1992, February). AHCPR Publication No. 92-0032. Rockville, MD: Agency for Health Care Policy and Research.

Nurses encourage patients to share details about the character, onset, location, duration, exacerbation, and radiation of the pain and how pain influences daily functionality and quality of life. During the interview process, it is imperative to know what worked previously, what never worked, medications that were used to alleviate pain, and if any nonmedication strategies were successful. As nurses conduct assessment interviews with patients, concerns and questions are noted, and communicative ability is determined. Barriers (e.g., language or culture), when identified, require special accommodations and considerations for comprehensive treatment planning.

The patient's self-report is the single most reliable indicator of the existence and intensity of pain (AHCPR, 1992). Determining the patient's perception of pain intensity, the nurse uses one of a variety of assessment tools such as the numeric rating scale or the visual analog scale (Figure 12.1).

Tools for pain intensity rating are only as useful as patients' ability to understand and use them. Nursing communication skills ensure that patients understand the use of chosen pain assessment instruments. Nurses use pain intensity rating scales appropriate to patients' cognitive ability and language skills. Patients are asked to report pain intensity ratings without undue influence from others. The McGill Pain Questionnaire (MPQ) measures affective pain experience components in addition to pain intensity, supplementing data obtained during the nursing interview (Melzack, 1995). Using assessment tools, nurses determine pain intensity scores for the least and most intense pain levels. Patients identify whether there is breakthrough pain and, if so, what pain intensity scores occur.

A final component for pain assessment is the determination of pain intensity goals. Goals are made with consideration for acceptable levels of pain relief and ability to function (referred to as comfort and function goals). Because patients may have difficulty determining precise comfort and function goals, nurses are often in the best position to spend the time necessary to assist them in setting realistic goals and expectations for pain relief and functionality (Vallerand, 2003). Noncommunicative patients present special challenges when assessing pain, and they are at greater risk for having their pain undermanaged than are communicative patients (American Pain Society [APS], 2003). Assessment tools specifically designed to measure pain behaviors (grimacing, crying, wincing, guarding with movement, or irritability) are particularly helpful, and with other nursing assessment skills, even noncommunicative patients can be evaluated. At the end of the assessment, nurses establish expectations regarding the frequency of pain reassessment and give patients permission to report changes in pain intensity occurring between assessments, reducing patients' concerns about bothering nurses with their pain complaints.

INTERVENTIONS TO TREAT PAIN

Nurses play a crucial role in the treatment of pain using pharmacological and nonmedication therapies. Whether they are assessing a patient for pain control or compliance with the treatment plan; reviewing a prescription; obtaining, delivering, or administering medications; or initiating a nonmedication therapy, nurses are vital to ensuring a safe and effective outcome for the patient.

PHARMACOLOGICAL TREATMENT

Nurses are the team members spending the most time with patients exploring side-effect experiences and the effectiveness of pain relief from analgesics. This specific information is passed to other team members to determine individual patient variations (Vallerand, 2003). Nurses routinely administer medications to patients for the first time, so are responsible for ensuring that medications ordered are appropriate. Range orders for analgesics, unless specifically addressed in policy, require nurses to select the dose to administer and the interval of adminis-

tration. Once administered, nurses' understanding of the onset of analgesia and expected duration of action, as well as potential side effects, guide nursing reassessment and subsequent administration of additional doses. These responsibilities underscore the need for collegial relationships with prescribers.

Increased numbers of opioid formulations along with a growing mainstream acceptance of pain management principles have increased the complexity of pain management decisions that nurses must make. Although more complex decision making is necessary, appropriate pain management orders reduce the need to advocate with reluctant team members. To function fully in the nursing role, a basic understanding of opioids is no longer sufficient. Nurses now must understand not only the mechanism of action of the various opioids, their rate of absorption, and the variety of routes of delivery, but also the impact of clinically significant metabolites in specific patient conditions. It is not enough to understand the timing of basic oral absorption. Opioids are now available in a variety of formulations allowing for administration of a specific formulation to relieve pain associated with a specific situation such as procedures or breakthrough pain or for around-the-clock coverage of persistent pain. This requires the nurse to understand the differences between formulations as the nurse times the administration of the opioid to achieve the best pain relief for each specific situation. Use of patient-controlled analgesia (PCA) to deliver opioids, which has become widely accepted, requires the nurse to have additional understanding of PCA and the ability to program and troubleshoot the PCA infusion devices accurately. The ability to assess side effects and determine the patient's pattern of PCA doses requested as opposed to the number of doses delivered will determine the success of PCA.

Nonopioid analgesics, such as acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs), should be included in any analgesic regimen unless contraindicated (APS, 2003). The recommended dosages and intervals for administration of acetaminophen (APAP) and NSAIDs are more concrete than are those for opioids, so it is easier to verify the appropriateness of these agents by consulting pharmaceutical reference books. However, side effects for these medications are significant, and nurses must understand potential risks involved with administration of these medications. Nurses often administer acetaminophen for its antipyretic and analgesia effects, leading to possible overdose and hepatotoxicity if more than 4000 mg is administered within 24 h. When nurses administer acetaminophen, previous doses, including those given in combination with an opioid, must be accounted for so that the total amount of acetaminophen does not exceed the recommended daily dosage. When administering NSAIDs and coxibs, it is a nursing responsibility to screen for conditions, such as renal sufficiency,

that make administration of NSAIDs or coxibs inappropriate. Even after therapy has started, nurses must continually monitor the medication's impact and potential organ system insult from the medication prescribed (e.g., the effect of an NSAID or coxib on renal function can be significant for patients who have hypotension or hypovolemia; APS, 2003). These conditions must be identified as soon as possible, and frequently it is nurses who are in the position to first identify these conditions and notify appropriate providers so the therapy may be discontinued.

Adjuvant medications, by definition, are medications whose primary indication is not the treatment of pain, but that do provide analgesia in certain conditions (Portenoy & McCaffery, 1999; Gordon, 2003). Nurses are faced with orders to administer "pain medications" that they recognize as common treatments for conditions such as seizures or depression. Nurses' understanding of these medications and their specific role in pain relief is essential. Patients require support and encouragement through a slow introduction and titration of these medications. Often it is necessary to try several different adjuvant medications before patients are able to report adequate pain relief.

INTERVENTIONAL PAIN MANAGEMENT TECHNIQUES

Nerve blocks, epidural steroid injections, electrical stimulation, and infusion of spinal opioids are interventional techniques used by pain management specialists to prevent chronic pain from occurring and to address complex pain when it occurs. The nurse assists with invasive pain procedures by completing the admission history and assessment, and by preparing patients physically and emotionally. Patient education addressing procedures reduces anxiety and encourages cooperation with postprocedural instructions. During procedures, nurses assist with patient positioning for comfort and safety, administration, and monitoring of sedation, and they provide conscious patients with information regarding progress. Nurses are knowledgeable about relevant anatomy and physiology associated with procedures and medications that are used. Nurses are able to anticipate problems and assist with emergency management. Nurses are able to monitor patient recovery and provide discharge instructions (Raj & Johnston, 2002).

NONMEDICATION TREATMENTS

Analgesic medications are the foundation for acute and cancer pain management regardless of patients' ages (APS, 2003). Regardless of the source or duration for pain, there are many nonmedication interventions that are additionally beneficial for pain management and are commonly used as adjuvants (Snyder & Wieland, 2003). Using these interventions for chronic pain allows patients to be active participants in controlling their pain rather than only

relying on medications or provider initiated pain therapies (Arnstein, 2003).

Because little evidence supports that using these interventions provide analgesia, nurses must avoid using these in a singular approach. Instead, nurses must utilize all tools at hand, including easily understood and implemented nonmedication interventions with carefully crafted analgesic plans designed to provide the most effective levels of multidimensional pain relief and functionality (McCaffery & Pasero, 1999). Nonmedication treatments are used as the sole method of pain management when patients feel pain relief from these nonmedication treatments is adequate (Dalton & Coyne, 2003).

Prior to initiating nonmedication interventions, nurses assess patients' physical and emotional readiness for participation and then select interventions that are most likely to be successfully implemented. Nurses caring for patients experiencing acute pain may find that interventions that require focused attention are less practical than simple, passive interventions that do not tax patients' limited energy. Patients with chronic pain rely on their nurses to introduce them to interventions that help them to improve coping and reduce their focus on pain. Nurses can influence patients' pain through skillful application of appropriate nonmedication interventions and should be watchful for opportunities to introduce these interventions to their patients. Additionally, nurses collaborate with other interdisciplinary team members to ensure that patients are given opportunities to participate in various nonmedication interventions.

Nurses should recognize that patients' responses to nonmedication treatments are greatly dependent on patients' interest in participating with this intervention. Nonmedication interventions can be as simple as using a reassuring voice, gentle touch, or applying ice to a painful area, or as complex as assisting patients in mastering biofeedback. Physical interventions may be used to reduce swelling, muscular tension, or spasms. Interventions involving focused attention help reduce anxiety or sleeplessness (Table 12.1).

REASSESSMENT OF PAIN AND PAIN TREATMENTS

Assessment of the effectiveness and safety of the analgesic regimen is an ongoing responsibility entrusted to nurses. Just as nurses are the team members most likely to administer analgesics to patients for the first time, nurses are present when medications peak in effect for the first time. Nursing assessment includes a reassessment of patients' pain intensity, level of sedation, respiratory status, and other analgesic side effects. Assessments occur routinely and frequently until analgesic routines stabilize and responses become predictable. Failure to appreciate

---

nurses' role in reassessing patients due to poor staffing patterns or lack of nursing education increases the potential that sedation and respiratory depression go unrecognized and lead to serious complications (e.g., respiratory arrest and death).

Nurses use the same assessment tools to reassess their patients' pain intensity and to encourage familiarity with the tools. The consistent use of pain intensity tools provides accurate trending of patients' response to analgesic regimens. Just as with initial pain assessments, nurses encourage patients to rate their pain at its least and most intense, and to identify episodes of breakthrough pain and associated intensity. Once assessments of patients' pain intensity are completed, nurses use this information to determine the timing of subsequent medication or nonmedication interventions. Patients may need increased or decreased dosage of their analgesics, rotation to other agents, or other routes of delivery. Nurses determine changes to analgesic regimens and implement changes within established range orders for analgesics or advocate with prescribers for new orders.

The nursing assessment for common analgesic side effects includes respiratory status, level of sedation, pruritus, nausea, vomiting, and urinary retention. Careful attention to recognition and management of side effects when initiating new medications often determines patients' willingness to permit sufficient time to establish these regimens. The extreme variability in patients' responses to the first few doses of opioid medications makes it impossible to determine an initial dosage that is safe for every patient (APS, 2003). For this reason, administration of opioid analgesics necessitates nursing assessments for patient's levels of sedation and respiratory sta-

tus. These assessments are essential for safe analgesia, and prescribers count on nurses' assessment skills when prescribing medications. Nurses prompt recognition of sedation as an indicator of impending respiratory depression, and monitoring for these changes may lead to reductions in dosage or frequency of opioids. When the respiratory status of patients becomes compromised, nurses respond with emergent administration of reversing agents to restore adequate respirations and then frequently reassess patients for continued stability.

PATIENT AND FAMILY EDUCATOR

Patients and their family members rely on the nurse to coach them through the often complex and confusing details of their pain management plan. Even the concept of "as-needed" analgesic regimens commonly prescribed for acute pain can be overwhelming for patients and families. The potential for treatment failure due to frustration and eventually noncompliance increases when patients do not understand their analgesic treatment plans and what they are suppose to do to take their medications properly.

The multidisciplinary team depends on nurses to evaluate the patient's and his or her family's ability to learn and their level of comprehension after teaching is given. Nursing assessments of patients and family members for learning barriers (e.g., anxiety, fear, and speaking languages different from those of the treatment team members) allow tailored education to meet individual patient's needs. With patients' level of understanding determined, nurses use ongoing communication with patients and their families to provide additional education.

Nurses are "interpreters" for patients and family members when they do not understand instructions given by other health care providers or team members. Introduction or reinforcement of new concepts such as the use of pain intensity rating scales, establishing a comfort and function goal, and the difference between persistent pain and breakthrough pain are often necessary before patients are able to actively participate in conversations regarding pain assessment and management. Terms describing different formulations of analgesics such as "long-acting" and "short-acting" should be presented simply and in the patient's own language whenever possible. Nurses provide patients and family members with clear instructions to report changes in the intensity of pain, when to request or use additional analgesics, how to report analgesic side effects, and whether the quality of the overall pain management regimen is facilitating recovery or improving quality of life. Nurses address misconceptions patients have about potential tolerance, dependence, or addiction to opioid analgesics with sensitivity and expertise. When needed, nurses utilize written instructions, pain diaries, and graphic representations to enhance patient understanding. Nurses commonly develop educational pamphlets, fact sheets, videos, and other materials to assist with patient and family teaching.

Use of multimodal balanced approaches to pain management are most effective in achieving adequate analgesia. However, the complexity of using multiple medications and nonmedication interventions for pain management may be difficult for patients and family members to grasp. Miaskowski et al. (2001) interviewed patients with cancer and found that the decisions patients must make regarding pain medications are more complex than those decisions required when taking an antihypertensive on a routine basis. Patients should be educated beyond the basic instructions of medication, dose, and timing to ensure development of adequate self-care skills (Schumacher et al., 2002). Lack of sufficient understanding may lead to medication errors, unnecessary medication side effects, and noncompliance with the pain management interventions. The nursing role in educating patients and their family regarding analgesic treatment plans is vital to the success and safety of pain management. Nurses are expert resources for patients and their families in vulnerable periods of care such as initiation of analgesic treatment plans or during transitions from one analgesic to another or from one route of administration to another. Principles of analgesic absorption, onset of analgesia, and expected duration of action are explained to patients and family members in simple and easily understood terms supported by written instructions. When patients are taking long-acting opioids for persistent pain relief and using short-acting opioids for breakthrough pain episodes, nurses provide coaching and encouragement so patients understand when each opioid should be taken and how to achieve the best pain relief.

Use of high-technology analgesic therapies such as intravenous, epidural, or intrathecal infusion requires additional education and support from nurses to ensure patients understand goals of treatment. When analgesics are delivered using the PCA button technology, the nursing role in education for patients is critical. Patients need to be instructed to use the PCA button properly and have a clear understanding that they should not allow anyone to push the PCA button for them due to potential ramifications should someone "assist" them.

Nurses teach about the concept of medication synergy when patients are taking adjuvant medications in combination with opioids. Often nurses initiate nonmedication interventions and provide support as patients learn and develop skills in the use of these treatments. Ongoing education and support, with answers to questions, are the hallmarks of the nursing role when patients face uncertain outcomes in their pharmacological treatment. As patients and their family members become more familiar with treatment regimens and timing of analgesics, consumption of these medications and the quality of analgesia are optimized. Patients become increasingly independent, more

likely to be compliant with the analgesic regimens, and less likely to make errors.

When patients are ready for discharge from one setting to another, discharge instructions regarding pain management are given in writing and then are reviewed verbally with patients and family members. Nurses are the members of multidisciplinary teams responsible for instructing patients prior to discharge. Nurses summarize written instructions of all team members and review them together with patients. Written and detailed instructions regarding the analgesic regimen including medications, dosages, intervals for administration, and when the next dosage should be taken are reviewed for accuracy and then provided to patients. Pain diaries may be helpful to assist patients and family members to continue an organized system of tracking and timing medication administration (Schumacher et al., 2002). Nurses are generally the last members of multidisciplinary teams to review all discharge instructions with patients and ensure that patients have adequate understanding. Additional information is provided where necessary prior to patients' discharges (AHCPR, 1992).

DOCUMENTATION

Nurses' documentation when reviewed by other team members becomes the core of the interdisciplinary team's communication process. This documentation is useful in quality improvement and risk management activities. Accrediting organizations, such as the JCAHO, review nursing documentation to determine organizational compliance with required standards and institutional policies.

Nurses are vital team members, functioning as coordinators of care and facilitators of multidisciplinary team communication (St. Marie, 2003). While other disciplines, out of necessity, spend only a limited amount of time with patients and write focused notes in medical records, in most care situations nurses interact with patients multiple times during the day, permitting more specific information regarding all aspects of patients' conditions and care to be elicited. Accurate and ongoing nursing documentation of patients' assessments of pain and its side effects provides a continuous treatment record that facilitates identification of trends and assists with decision making regarding future interventions. Nursing documentation is central to the multidisciplinary team's communication. Other team members use the nurses' 24-h record of the total amount of opioids administered when calculating equianalgesic doses in the process of transitioning patients from one delivery route to another or when rotating to alternative opioids. Decisions to increase opioid doses are based on documented trends of increasing episodes of breakthrough pain and reductions in function as pain influences patients' desire to engage in daily activities. In nurses' notes, other team members find the details of the hours and days of

patients' hospitalizations or identify trends over the final weeks and months in the lives of hospice patients.

There has been a significant change in the way nurses document as health care organizations move from pen and paper to electronic medical records (EMRs). Data collected by nurses in EMRs are easily and almost immediately available to all members of the health care team for use in decision making. Electronic data are more easily used in activities such as quality improvement measurement and research. Nurses are establishing themselves as leaders in medical informatics, using their unique perspective to design documentation and data collection programs suited to the flow of the work nurses perform. These programs are becoming increasingly dynamic and are able to prompt documentation of vital assessments including pain assessments and routine pain intensity scores. Infusion pumps used to deliver pain management therapies are undergoing a technology revolution, and soon infusion pumps will be designed to interface with the EMR allowing for frequent and routine downloading of data such as medication infusion rates, changes in dosage settings, and the total amount of medication delivered to the patient. The companies that manufacture these devices recognize the value of having nurses consult as they create safer and more efficient technology.

FACILITATOR OF COLLEGIAL RELATIONSHIPS AMONG MEMBERS OF THE MULTIDISCIPLINARY TEAM

Optimal pain management is best accomplished through interdisciplinary efforts (AHCPR, 1992; Loeser, 2001). The very nature of multidisciplinary care results in fragmentation as patients interact with team members regarding specific aspects of their pain management and plan of care. Nurses are vital multidisciplinary team members facilitating continuity and cohesiveness by coordinating communication between patients and team members. This collegial relationship between nurses and other team members is vital for pain management to be safe and effective. The relationship that exists between colleagues is built on trust and respect for each other's skills and expertise (Zerwekh & Claborn, 2003).

GUARDIAN OF PATIENT SAFETY

Nurses are guardians of patient safety, and their diligence in this role prevents negative outcomes related to pain management. Nurses safely administer medications at bedsides. When medications are administered, nurses check that the right drug is being given in the ordered dose, that they are using the correct route and time, and that the medication is being administered to the correct patient by checking two separate patient identifiers.

Reducing medical error and increasing reporting of errors has become a focus of the media, consumers of health care, health care organizations, and the organizations that provide hospital accreditation (AHA et al., 2002; JCAHO, 2001). Because nurses routinely administer many medications in their practice, they are the team members most likely to make a medication administration error. Nurses must be especially alert to avoid common errors such as those made when administering short-acting and long-acting formulations of the same opioid or when programming PCA infusion devices for intravenous, epidural, or intrathecal infusions. Nurses have sufficient knowledge to identify when prescriptions are erroneous or potentially dangerous. Because of their role in medication administration, nurses have a unique understanding of processes that are difficult or prone to error and are in positions to be valuable resources on the risk assessment team of health care systems working to improve the safety of pain management within their facilities.

QUALITY IMPROVEMENT

Quality improvement activities focused on institutional pain management processes have become prevalent since the 1999 release of the JCAHO standards on pain management. Because quality improvement efforts are best accomplished through an organized multidisciplinary approach, institutions are encouraged to form a standing multidisciplinary committee with the authority to make decisions regarding pain management processes. Nurses are recognized as valuable members and are often designated as leaders of these quality improvement teams. As is the case with other aspects of pain management, nurses are in unique positions to understand a broad range of problematic processes and readily identify barriers. These nurses should be well respected by their peers and members of the health care team and identified as change leaders in their areas of practice. Regardless of the composition of the committee's membership, there should always be representation from nursing (Pasero et al., 1999).

Outdated and tradition-based practices of managing pain are often deeply ingrained within organizations. In addition to institutional quality improvement activities, nurses are also involved in specific pain management improvement activities that are designed to reduce tradition and encourage appropriate pain management practices in their individual work areas. Nurses are often on teams that design treatment algorithms, protocols, and care pathways that improve the pain care that patients receive.

ETHICS AND ADVOCACY

The nurse's role in ethics and advocacy related to pain management is critical. Opportunities to recognize and manage ethical dilemmas and to actively advocate on

behalf of the patient present challenges for even the most passionate and experienced nurse. In spite of the challenges, nurses are speaking out in greater numbers and focusing their attention on the conflicts they face as a result of their unique relationship with patients and their role within the health care team (Zerwekh & Claborn, 2003). The American Society of Pain Management Nursing (ASPMN) is a national nursing organization that has taken an active and public advocacy role in pain management issues. ASPMN has issued position statements on a variety of issues (Table 12.2) with the goal of educating and guiding nurses as they face difficult ethical dilemmas in pain management and encouraging them to recognize these dilemmas as opportunities for advocacy.

The *International Council of Nurses Code for Nurses* and the American Nurses Association (ANA) *Code of Ethics*, developed by nurses, provide professional direction for nurses facing ethical decisions and outline desirable behaviors in the nurse–patient relationship. Nurses are responsible for the basic ethical principles of autonomy, beneficence, nonmaleficence, justice, veracity, and fidelity (ANA, 2001).

The patient's right to autonomy requires nurses and other members of health care teams to respect patients as unique individuals. They must respect patients' reports of pain and rights to accept or refuse analgesic medications, treatments, or procedures. Ensuring that patients provide informed consent prior to interventional pain treatments or procedures often requires the full efforts of health care teams. Nurses assist patients and families to review pertinent information they have received so that informed consent can be given based on whether the interventional pain treatment will enhance or detract from patients' quality of life (St. Marie, 2003).

Beneficence is the duty to actively do good for patients, while nonmaleficence calls upon nurses to accept the duty to prevent or avoid doing harm whether intentional or unintentional. There is a critical balance between these two principles when treating pain, and disagreements between health care team members regarding what constitutes adequate analgesia are often core ethical

dilemmas. In many of these instances, patients rely on nurses to be their advocates (Benner, 2003). Nurses advocate persistently and aggressively to ensure patients suffering with pain have the right to justice (pain relief): pain management services provided fairly and equally regardless of age, sex, ethnicity, socioeconomic status, and many other variables. Nurses have the responsibility as members of health care teams to assist patients in accessing expert pain care and ensuring that medications ordered to treat pain are accessible and affordable for patients. Nurses are reaching out to insurance providers and elected state officials advocating for reform and legislation with the goal of improving access to pain management specialists and appropriate pain medications for patients who are suffering. Legislative leaders increasingly recognize nurses as reliable advocates for improved pain management in local and national policy.

To develop trusting relationships between patients and health care teams there is a duty to tell the truth and avoid deception. It is the role of nurses to ensure that patients are presented with truthful information regarding their care, and this is the ethical rule of veracity. The use of placebos for pain management without patients' consent is in direct violation of this principle. In its position statement, *Use of Placebos for Pain Management*, ASPMN points out that the use of placebos requires deception and that as an organization it opposes the use of placebos to determine whether patients really are in pain or in place of legitimate analgesics for pain relief (ASPMN, 1996). When placebos are used, it should only occur with patients' informed consent, as in pharmaceutical trials. Unfortunately, nurses find themselves in the position of either participating in unethical administration of placebos or standing as an advocate for uninformed patients even if it means standing in opposition of the desires of prescribers. Nurses play a vital role in developing institutional policies regarding the use of placebos.

Patients depend on nurses to fairly and truthfully represent how pain management care will be provided and to follow through with the plans of care with fidelity. Nurses must master the challenge of weaving pain management interventions into the care they provide with careful attention to ensure that interventions are not delayed or missed. In turn, nurses and other members of the health care team have expectations regarding the actions of patients. Communication regarding these expectations is outlined in pain management agreements between patients and health care team members. Adherence to these pain management agreements facilitates the development of relationships built on fidelity.

NURSE EXPERT IN AN EXPANDED ROLE

Nurses who have developed an expertise in pain management are found in a variety of roles and settings, but share

a common goal and passion for improving of pain management practices and relieving the suffering of patients with pain. Whether primarily practicing at patients' bedsides as resources, case managers, clinical educators, specialists, independent practitioners, anesthesia providers, or managers of organized pain management services, nurses' expertise is valued by the multidisciplinary team.

THE PAIN RESOURCE NURSE

The science of pain management is relatively new, and nurses are now putting pain management beliefs of the past aside, to base their practices on evidence rather than tradition. Even so, many nurses today enter their profession without sufficient preparation in the science of pain management. Most patients they care for as novice nurses have pain. Fortunate patients and novice nurses have as a resource bedside nurses who are experts in pain management. The need to mentor nurses while they gain expertise is paramount in the efforts to change the culture of pain management. The City of Hope National Medical Center in Duarte, California, began the first Pain Resource Nurse (PRN) program designed to train the bedside nurse to function in the role of an expert resource and mentor for other nurses (Ferrell et al., 1993). Pain resource nurses are specially trained in the concepts of pain management. As experts, pain resource nurses assist other nurses to develop skills in all aspects of pain management including pain assessment, pharmacology and equianalgesia; treatment of analgesic side effects; and the use of high-technology pain management modalities. In addition to mentoring other nurses, pain resource nurses are active participants and change leaders for the improvement of pain management within the institutions and/or in the care setting where they work.

CASE MANAGER

Case management nurses have the primary function of assisting patients and multidisciplinary teams with a focus on cost containment through the provision of quality care. Whether this is accomplished using care pathways or through careful attention to the multidisciplinary plan of care, case management nurses with expertise in pain management act as valuable resources and coordinators of care (Jerin, 2002). Patients who have a complicated course of illness and recovery often require a level of care coordination that requires more time than is realistically available to the bedside nurse. Nurse case managers provide this expanded level of care with expert knowledge of insurance plans, referral information, and pain management specialists available in the geographical region. Case management nurses who have expert pain management skills recognize that the cost and availability of analgesics must be considered when initiating an anal-

gesic regimen because many insurance plans limit the reimbursement or restrict access to certain analgesics (Gordon, 2003). Patients who do not have sufficient prescription coverage may find the financial burden of purchasing analgesics intolerable. In addition to encouraging multidisciplinary teams to use affordable analgesic choices in analgesic regimens, case management nurses function as patients' links to many pharmaceutical companies that provide patient assistance programs. These programs are often accessible based on need or financial criteria (Vallerand, 2003).

Patients who have complex acute pain or who are facing the challenge of chronic pain may benefit from receiving pain management care from pain management specialists. Patients may feel overwhelmed or inadequately prepared to undertake the task of identifying and selecting their pain management specialist to provide ongoing pain care. Case management nurses assist patients by providing listings of pain management specialists in the patient's locale. In some geographical locations pain management specialists are not readily available. As an alternative, case management nurses may assist patients in finding primary care physicians or independent nurse practitioners recognized as good pain managers who are willing to provide ongoing care.

CLINICAL NURSE SPECIALIST AND EDUCATOR

Nurses functioning in roles of clinical nurse specialists (CNS) or educators are vital to support the ongoing learning of student nurses and nurses practicing at the bedside. Generally prepared with a master's degree or doctoral degree in nursing, CNSs and educators are recognized experts in the practice of nursing. As faculty members, nurses are responsible for developing curricula and conducting the education of the adult learner in the professional practice of nursing. In a position to influence curricula throughout all phases of the nurses' training, educators are responsible for ensuring that student nurses are schooled in the appropriate principles and practices of pain management. CNSs function primarily in health care institutional settings. The rapid changes and advancements in the science of pain management make it difficult for practicing nurses to assimilate new practices into the busy pace of everyday work without educational offerings and supportive mentoring that CNSs provide. Nurses in CNS roles are often responsible for developing and reviewing algorithms or protocols and directing quality improvement activities. CNSs and educators conduct ongoing review of current health care literature, participate in or direct nursing research, and contribute to the body of literature through publication. CNSs and educators who are passionate regarding the central role that nurses play in the success of pain management can be remarkable and positive forces in improving the quality of pain management nursing.

ADVANCE PRACTICE NURSES

Nurse Practitioner and Certified Registered Nurse Anesthetist are advanced practice roles in which nurses functions with greater autonomy in a supervised or collaborative relationship with physicians. Rather than collaborating with physicians for orders prior to initiating changes in the pain management plan, advanced practice nurses collaborate with physicians when determining diagnoses and treatment plans, but maintain independent decision-making authority (Brown & Draye, 2003). Although the role of advanced practice nurses was first described in the 1960s, it is not unusual for these nurses today to find that the jobs they are considering may not have well-defined descriptions and roles. Nurses are embracing these challenges and opportunities that come with defining their advanced practice roles. Advanced practice nurses in many states are able to obtain prescriptive privileges for controlled substances. Prescriptive practice allows these nurses to fill a much-needed role in settings and locations where access to pain management specialists or health care providers with pain management expertise is limited. The role of advanced practice nurses has improved access to services for patients and specifically for patients in vulnerable populations such as minorities, those with low incomes, and the uninsured (Brown & Draye, 2003). Advanced practice nurses may specialize in pain management and fill roles within an interventional pain management clinic or multidisciplinary pain management center.

RESEARCHER

The National Institute of Nursing Research (NINR) encourages nursing research to focus on building nursing knowledge for the improvement of care to patients. The organizational mission statement calls for nursing research to establish a scientific basis for the care of individuals across the life span including all aspects of care from recovery to end of life (NINR, 2001). There are many unanswered questions in the practice of pain management, and nurses need to be involved in research regarding the physical, psychological, social, and financial impact and outcomes related to interventional pain management technologies (St. Marie, 2003). Nurses in pain management often fill the roles of primary investigators or co-investigators for pain management studies in addition to enrolling participants and gathering data. The rapid expansion of the science of pain management provides opportunities for nurses to be contributors to the future knowledge that will define nursing practice in pain management.

PAIN MANAGEMENT SPECIALIST

Nurses who specialize in pain management often are members of acute or chronic inpatient pain services and serve as staff for interventional pain clinics or multidisciplinary pain management programs, in addition to a variety of other settings where the focus is on the management of complex pain conditions. Pain management nurses combine the skills encompassed in the roles of the bedside nurse, pain resource nurse, case manager, clinical specialist, educator, and researcher into one demanding role. Expert skills in the assessment of pain in complex patient situations utilizing multiple tools and methods are necessary to ensure that pain complaints are recognized and appropriately treated. In addition, skills such as an in-depth understanding of analgesic medications, equianalgesia, and drug–drug interactions are essential. Pain management nurses provide routine assessments and oversight of the nursing care for patients, ensuring patient safety and providing support to the greater nursing staff when advanced pain management technologies are used, such as intravenous PCAs, epidural or intrathecal infusions utilizing external or implanted infusion pumps, and spinal cord stimulators. In turn, the nursing staff depends on the expertise of pain management nurses to assist when identifying unusual analgesic side effects and complications associated with pain treatments. Pain management nurses provide expertise as educators and mentors for nursing staff. There is beginning evidence to suggest that the expertise of a pain management nurse in health care settings and the nursing staff's interactions with a pain management team have a positive influence on the knowledge and beliefs of the nursing staff (Mackintosh & Bowles, 2000). Pain management nurses are generally well respected for a willingness to educate and mentor those just joining the specialty as well as those who express disdain regarding the principles of effective pain management. Indeed, within the specialty of pain management, nurses are among the most respected and recognized educators and advocates. Pain management nurses, who are editors of professional publications and members of editorial boards, author many case studies, journal articles, reports of research studies, and reference books.

SUMMARY

Although nurses practice in a variety of specialties and settings and provide patient care in collaboration with many different professions, nurses' skills are unique to the health care team and central to the optimal delivery of appropriate pain management care. Nurses more commonly hold master's and doctoral degrees and capably perform in advanced practice roles. As leaders, nurses stand out in roles that establish long-range plans influenc-ing the delivery of health care and directly providing needed services that bring relief to those in pain. From the provision of proper patient assessments to decision making at the bedside to establishment of treatment efficacy, nurses are the frontline soldiers in the army of health care providers that battle against pain.

Allopathic Specialties

B. Eliot Cole, MD, MPA

INTRODUCTION

Allopathic medicine is the health care practice combating disease through the use of treatments producing effects different from those produced by the disease, producing a second condition that is antagonistic to the first (Arizona Medical Board, 2004). Allopathic physicians, as doctors of medicine (M.D.s), routinely do physical examinations to be able to diagnose, prevent, and treat illnesses, injuries, and other disorders, often using highly technical procedures. Allopathic physicians, as medical doctors, are not just one homogeneous group that provides the same services to all patients, but a large group of extensively educated practitioners who have initially trained in the common areas of medical science and primary medical specialties before pursuing different specialty areas of interest. Physicians working in pain management/medicine serve as valuable members of treatment teams providing multidisciplinary care for those in pain and work to prevent, remove, or control pain through the provision of unique, often highly specialized skills and therapeutics. This chapter describes for non-allopathic pain practitioners the background and training of allopathic physicians. It identifies the specialty implications for managing pain and the range of pain-related services provided by these different types of practitioners.

BECOMING A PRACTICING ALLOPATHIC PHYSICIAN

Formal education and training requirements for allopathic physicians are among the most demanding of any occupation (Bureau of Labor Statistics [BLS], 2004). To be eligible for admission to an allopathic medical school in the United States one must generally complete a 4-year undergraduate college-degree program (granting a B.A. or B.S.) with a strong emphasis on the basic sciences (American Medical Association [AMA], 2000). Entrance requirements for most American medical schools include completion of course work in biology, mathematics, chemistry, physics, and English, so the traditional "premedical" education minimally covers these areas. To keep the undergraduate experience well rounded, studying humanities and the social sciences is strongly encouraged, as the "ideal physician" understands how society works and is able to communicate and write well (American Association of Medical Colleges [AAMC], 2004a). Those wishing to apply to medical school must possess grade point averages (GPAs) well above the mean and score well on the Medical College Admission Test (MCAT), which analyzes knowledge of the basic sciences, reading and writing abilities, and overall problem-solving skills.

Having the right personality to be an allopathic physician usually requires caring deeply about other people, their problems, and their pain(s); enjoying helping people with medical skills and knowledge; enjoying the process of learning and gaining new understanding; and being interested in how the human body functions (AAMC, 2004b). Key factors affecting acceptance to medical school include completion of required undergraduate courses, GPA, score on the MCAT, extracurricular activities, letters of recommendation, and interviews with medical school faculty members. Only half of those applying to U.S. medical schools are accepted (AAMC, 2004a).

The usual 4-year medical education leading to the M.D. degree consists of preclinical and clinical training. Preclinical education involves the mastery of many basic medical sciences: anatomy, biochemistry, embryology, his-

tology, human behavior, microbiology, pathology, physiology, pharmacology, and more. Until medical students are able to demonstrate mastery with these areas during their first 2 years of medical school, they are generally not permitted to have significant clinical contact beyond learning how to perform thorough medical histories and physicals. During their second 2 years of clinical training, allopathic students learn about the "primary care" specialties of family medicine, internal medicine, obstetrics and gynecology, pediatrics, and surgery (general and specialized), plus a few other core specialties (e.g., neurology and psychiatry) by actually working with patients under the continuous supervision of resident and attending physicians. While the education is not all-inclusive in scope, allopathic students have wide exposure to the breadth of medical practice during their 4 years of medical education and leave medical school with one or more identified interest areas.

Immediately upon completing their medical education newly graduated medical doctors serve at least 1 year of postgraduate training, commonly referred to as "internship" or postgraduate year 1 (PGY-1), putting their textbook knowledge and rudimentary clinical skills into actual clinical practice by assuming progressively greater roles in the care of patients assigned to them. Physicians are usually eligible for medical licensure after completion of an internship.

Medical licensure is always necessary for allopathic physicians to practice medicine and provide direct patient care. This licensure is unique to a jurisdiction; usually a state within the United States requires passage of a licensure examination reviewing the basic medical sciences and clinical specialties, background checks, and in some states, even letters of reference from current in-state license holders. While temporary or training licensure is available without much difficulty and required for those in training programs, unrestricted medical licensure usually requires some specified period of postgraduate training and passage of an examination. Many allopathic physicians become fully licensed during their training years, once they have completed the minimum training necessary for licensure and have passed their examinations. This may allow them to continue their own residency training while beginning to work part of the time as practicing physicians ("moonlighting").

Those planning to specialize in one or more of the major disciplines of medical practice continue their professional education by performing residency training for 2 to 6 additional years, PGY-2 to 7 (American Board of Medical Specialties [ABMS], 2002; AMA, 2000). To obtain independent licensure necessary to practice medicine, resident physicians generally remain under initially continuous direct and then increasingly indirect supervision from fully licensed senior educator physicians (attending physicians) who have already completed their training and are usually "board eligible" or fully board certified.

For many physicians, becoming knowledgeable about one of the major disciplines of medicine (family practice, internal medicine, pediatrics, neurology, obstetrics and gynecology, psychiatry, and surgery) is not enough, so they continue their training into areas of subspecialization within the larger specialties by spending additional time, usually 1 to 3 years, in fellowship programs (ABMS, 2002; AMA, 2000). Having completed 4 years of college, 4 years of medical school, 3 to 7 years in residency training, and 1 to 3 years in fellowship (12 to 18 years in training), allopathic physicians are eligible for medical licensure and voluntary specialty and subspecialty certification.

Becoming voluntarily certified or subspecialty certified requires completion of an approved residency and/or fellowship training program, having an unrestricted medical license, submission of an application to the appropriate specialty board describing the scope of training received, and then successfully passing a written examination, oral examination (15 of the 24 boards), or both (ABMS, 2002). Only those allopathic physicians who have taken and passed their board certification or subspecialty certification examinations are permitted to describe themselves as being "board certified" in the United States. Those claiming to be "board eligible" have completed only their training, but have not yet passed their certification examination(s).

MEDICAL SPECIALTIES AND CERTIFICATION PROCESSES

In the United States, the primary overall certifying body for most allopathic physicians is the American Board of Medical Specialties (ABMS). There are 24 specialty constituent boards within the ABMS that provide certification in 36 general medical specialties and an additional 88 subspecialty fields (ABMS, 2002; AMA, 2000). In the past, certifications were given for the lifetime of practitioners passing the examination(s). Certifications and subspecialty certifications are now time-limited, requiring renewal (recertification) about every 6 to 10 years (ABMS, 2002).

General medical specialties include the core clinical areas of medicine: family and internal medicine, pediatrics, neurology, obstetrics and gynecology, psychiatry, and surgery. Today, the certifying medical specialties include allergy and immunology, anesthesiology, colon and rectal surgery, dermatology, emergency medicine, family practice, internal medicine, neurological surgery, neurology, nuclear medicine, obstetrics and gynecology, ophthalmology, orthopedic surgery, otolaryngology, pathology, pediatrics, physical medicine and rehabilitation, plastic surgery, preventative medicine, psychiatry, radiology, surgery, thoracic surgery, and urology. Certified practitioners in these specialties are given certificates bearing the name of the granting authority, the "American Board of" and the name of the specialty.

Subspecialty certification, available to allopathic physicians after becoming certified in one of the major medical specialties, requires additional training and competency beyond that necessary for initially becoming specialty certified and requires passing another examination in the subspecialty area (e.g., addiction psychiatry, child neurology or psychiatry, endocrinology, gastroenterology, hematology and oncology, infectious disease, nephrology, pain medicine, pulmonary medicine, or rheumatology). Those achieving certified subspecialty status have reached the zenith in their professions, with few other honors considered more prestigious.

Certified allopathic physicians often refer to themselves as "Diplomates" of their boarding organization when they become certified, or simply "Boarded." Those using the term "Fellows" are board-certified physicians belonging to a professional society (e.g., American College of Surgery, American College of Obstetrics and Gynecology), requiring board certification for full membership, that is dedicated to furthering standards, practice, and professional and public education within individual medical specialties (ABMS, 2002). Being a "Fellow" is another way of recognizing distinguished specialty physicians, and this frequently is abbreviated as "F" plus the initials of their professional organization (i.e., F.A.C.P. for Fellow, American College of Physicians; F.A.C.S. for Fellow, American College of Surgeons; F.A.C.O.G. for Fellow, American College of Obstetrics and Gynecology).

The declared purpose of certification, according to the ABMS (2002) is to "provide assurance to the public that a certified medical specialist has successfully completed an approved educational program and an evaluation, including an examination process designed to assess the knowledge, experience and skills requisite to the provision of high quality patient care in that specialty" (p. 4). Certification does not directly establish how physicians clinically practice but is an independent "check" of allopathic physicians. In fact, certification is much like obtaining a commercial driver's license; it establishes that the holder of certification knows some prospectively agreed upon minimal set of data, which exceeds the minimum required for medical licensure, while never entirely establishing the breadth of the certificant's knowledge. However, not having certification prevents one from practicing some aspects of medicine, just as not having the specialized driver's license makes it illegal to operate a commercial vehicle.

In general, allopathic physicians after completing their training continue to work long, irregular hours; almost one third of physicians worked 60 or more hours a week in 2002 (BLS, 2004). Because of the tremendous costs associated with starting medical practice, most new allopathic physicians work as salaried employees of group medical practices, clinics, hospitals, or health networks before considering solo practice (BLS, 2004).

In the past decade it has been possible for allopathic physicians in certain specialties (anesthesiology, neurology, physical medicine and rehabilitation, and psychiatry) to obtain subspecialty certification in pain medicine from the same ABMS boards that initially credentialed them. The first boarding organization to subspecialty certify its members was the American Board of Anesthesiology (ABA, 2004) in 1993. The American Board of Psychiatry and Neurology (ABPN, 2004) and the American Board of Physical Medicine and Rehabilitation (ABPMR, 2004) added subspecialty certification for their constituent members in 2000, allowing their members to take the ABA subspecialty examination. All three of these boarding organizations initially offered a "grandfathering" practice option for establishing eligibility to take the examination during the first 4 years, before mandating completion of an Accreditation Council for Graduate Medical Education (ACGME, 2004) approved fellowship in pain medicine.

In addition to the ABMS route described above, two other credentialing options exist. Allopathic and osteopathic physicians completing allopathic residency programs leading to certification by an ABMS board are able to take the pain medicine certifying examination given by the American Board of Pain Medicine (a self-designated, voluntary credentialing organization not recognized by the ABMS) (American Board of Pain Medicine, 2004). Allopath physicians are allowed to take the American Academy of Pain Management's (a self-designated, voluntary credentialing organization not recognized by the ABMS) credentialing examination in multidisciplinary pain management after 2 years of clinical experience working with patients in pain with or without prior ABMS certification (American Academy of Pain Management, 2004).

THE ROLE OF MEDICAL SPECIALISTS IN PAIN MANAGEMENT

ALLERGY AND IMMUNOLOGY

Allergist-immunologists are trained (2 years in a fellowship) in disorders of the immune system. They are particularly knowledgeable about adverse reactions to food, insect stings, medications; asthma; eczema; immune deficiency disorders; and problems related to autoimmune disease, organ transplantation, and malignancies of the immune system. Some allergist–immunologists also are additionally trained in rheumatology or pulmonology (ABMS, 2002). Pain disorders associated with disorders of the immune system often require the collaboration of allergist–immunologists with pain practitioners.

ANESTHESIOLOGY

Anesthesiologists are trained (4 years in a residency) to provide pain relief and maintenance, or restoration, of a

stable condition during and immediately following an operation or an obstetric or diagnostic procedure (ABMS, 2002). Beyond these duties, anesthesiologists diagnose and treat acute, persistent noncancer and cancer pain problems. Those practitioners with particular interest in pain medicine often provide specialized "blocks" for patients in pain (described in the Invasive Procedures section of this book).

COLON AND RECTAL SURGERY

Colon and rectal surgeons are trained (6 years of residency and fellowship) to diagnose and treat diseases of the intestinal tract, colon, rectum, anal canal, and perianal area by medical and surgical means. They also deal with other organs and tissues involved in the digestive process. These surgeons typically manage painful conditions such as hemorrhoids, fissures, abscesses, and fistulae, along with disorders of the intestine and colon. Colon and rectal surgeons perform endoscopic procedures to diagnose and treat cancer, polyps, and inflammatory conditions (ABMS, 2002).

DERMATOLOGY

Dermatologists are trained (4 years of residency) to diagnose and treat people with benign and cancer-related disorders of the skin, mouth, external genitalia, hair, and nails, as well as many sexually transmitted diseases. These physicians are experienced in the management of skin cancer, moles, tumors of the skin, contact dermatitis, and the skin manifestations of systemic and infectious diseases (ABMS, 2002). While not primary physicians for the management of pain per se, they are involved in the management of patients with painful skin conditions and do recognize the dermatological manifestations of serious underlying medical conditions.

EMERGENCY MEDICINE

Emergency physicians are trained (3 years in residency) to focus on the immediate decision making and action needed to prevent death or any further disability in the prehospital and hospital settings. These physicians are trained to recognize, evaluate, treat, stabilize, and make dispositional decisions for patients with acute illnesses and injuries (ABMS, 2002). They are the "frontline" practitioners for patients in pain both at the beginning of the process and often for months to years as chronic pain develops.

FAMILY PRACTICE

Family physicians are trained (3 years in residency) to address the total health care of the individual and the family, and to diagnose and treat a wide variety of ailments in patients of all ages. Special emphasis is placed on prevention and primary care of entire families by using consultations and community resources when necessary (ABMS, 2002). Many patients with painful disorders obtain their ongoing medications from these physicians.

INTERNAL MEDICINE

Internists train (3 years of residency) to provide long term, comprehensive medical care for adolescents, adults, and the elderly. They are particularly skilled in the diagnosis of cancer, infections, and diseases of major organ systems and have an understanding of disease prevention, wellness, substance abuse, and other issues (ABMS, 2002). Like family physicians, internists commonly follow patients with painful disorders, providing medication renewals and coordinating care with different specialists, and are frequently trained themselves in many different subspecialties (cardiology, endocrinology, gastroenterology, geriatrics, hematology, infectious disease, oncology, nephrology, pulmonology, rheumatology, and sports medicine).

MEDICAL GENETICS

Medical geneticists are trained (2 or 4 years of residency) in the diagnosis and therapeutic procedures for patients with genetically linked diseases. They are often involved in screening programs for inborn errors of metabolism, hemoglobinopathies, chromosomal abnormalities, and neural tube defects (ABMS, 2002). Painful disorders that are hereditary in nature may necessitate the involvement of medical geneticists for family planning purposes.

NEUROLOGICAL SURGERY

Neurosurgeons provide operative and nonsurgical management of disorders of the central, peripheral, and autonomic nervous systems; evaluate and treat processes modifying the function of the nervous system; and manage pain. Their training (7 years of residency) enables them to treat all of the structures of the nervous system and the supporting structures and vascular supply (ABMS, 2002). These are the physicians who perform surgical therapies (decompressive or destructive in nature) for the management of pain arising from the structures and surrounding tissues of the nervous system. Many neurosurgeons are involved with the implantation of medication delivery systems (pumps) and stimulators used for the management of intractable pain.

NEUROLOGY

Neurologists train for 4 years of residency to diagnose and treat all types of disease or impairment of the brain, spinal cord, peripheral nerves, muscles, autonomic nervous system, and the vascular supply to these structures (ABMS,

2002). They do not perform surgical procedures, but do perform a variety of diagnostic (EEG, EMG, NCV, SSEP) and therapeutic (lumbar puncture, nerve blocks) procedures. Some neurologists now subspecialize in pain medicine and take the same examination as anesthesiologists. As they are well trained in the use of anticonvulsants and other adjuvant medications, many have a particular interest in the management of neuropathic pain.

NUCLEAR MEDICINE

Nuclear medicine physicians are trained (3-year residency) to employ the properties of radioactive atoms and molecules in the diagnosis and treatment of disease. They are able to detect disease as it changes the function and metabolism of normal cells, tissues, and organs (ABMS, 2002). Many of their approaches are used in the treatment of cancer, so patients with malignancy-related pain often have some of their care provided by these practitioners. Additionally, these specialists have considerable knowledge about the effects of radiation exposure, fundamentals of physics, and principles of operation for radiation detection and imaging systems.

OBSTETRICS AND GYNECOLOGY

Obstetrician/gynecologists specialize in the medical and surgical care of the female reproductive system and associated disorders. They are commonly the primary care physicians for women (ABMS, 2002). They are best trained (4 years in residency and 2 years in clinical practice before certification) to manage pain-related disorders of the pelvic area for women and to work collaboratively with other medical specialists.

OPHTHALMOLOGY

Ophthalmologists provide comprehensive eye and vision care, and are medically trained (4 years of residency) to diagnose, monitor, and medically or surgically treat ocular and visual disorders. They also address problems affecting the component structures, eyelids, orbits, and visual pathways (ABMS, 2002). They are best able to address many of the painful conditions involving the eyes, periocular structures, and surrounding structures.

ORTHOPEDIC SURGERY

Orthopedists are trained (5 years of residency) to preserve, investigate, and restore the form and function of the extremities, spine, and associated structures by medical, surgical, and physical means. They are typically involved in the care of those with musculoskeletal problems, deformities, injuries, and degenerative disorders of the spine, hands, feet, knees, hips, shoulders, and elbows (ABMS,

2002). They provide care for acute and chronic painful conditions when bones, joints, and muscles are implicated.

OTOLARYNGOLOGY

Otolaryngologists (ear, nose, and throat, ENT) are surgeons caring for disorders of the ears, nose, and throat; respiratory, and upper alimentary systems; and related structures of the head and neck. They are trained (5 year-residency) to diagnose and provide medical and/or surgical therapy. Many focus on hearing- and voice-related conditions (ABMS, 2002), so may provide the decompressive surgical techniques needed for 8th cranial nerve tumors and other painful conditions of the ears or throat. They are inevitably involved in the care of people suffering from cancers of the head and neck. Working collaboratively with anesthesiologists and specialists in medical and radiation oncology, ENTs manage the pain experienced by their patients and continue to provide them with analgesic medications as part of ongoing postoperative care and monitoring.

PATHOLOGY

Pathologists are trained (5-year residency) to address the causes and nature of disease through the application of the biologic, chemical, and physical sciences. Pathologists use microscopic examination of tissue specimens, cells, body fluids, and secretions to diagnose, evaluate, and monitor diseases (ABMS, 2002). While rarely directly involved in the treatment of those in pain, pathologists provide much needed diagnostic services and help to define broadly the care necessary for many patients.

PEDIATRICS

Pediatricians train (3 years of residency) to care for the physical, emotional, and social health of children from birth into young adulthood. They are able to provide preventative care, diagnosis, and treatment of acute and chronic illnesses (ABMS, 2002). Their focus of care addresses the biopsychosocial and environmental influences on developing children. Children with painful disorders are usually first evaluated and managed by pediatricians; pediatricians are the primary care practitioners for many children. Numerous subspecialties within pediatrics include cardiology, critical care, endocrinology, neonatology, neurology, psychiatry, sports medicine, and others.

PHYSICAL MEDICINE AND REHABILITATION

Physical medicine and rehabilitation (PM&R) physicians (physiatrists) are concerned with the diagnosis, evaluation, and management of patients who have been injured or are physically disabled. These physicians are

trained (4 year-residency) to address the needs of those having maladies involving the musculoskeletal system, sports-related injuries, and other painful conditions. They provide the primary direction for rehabilitative programs helping patients with neurological trauma and diseases of the spine, spinal cord, and brain (head injury and stroke). Increasingly, these physicians are becoming more involved in pain management to assist patients obtain maximal restoration of physical, psychological, social, and vocational function. They are well versed in the use of therapeutic exercise, prosthetics, orthotics, and other physical modalities (ABMS, 2002). They are able to take the subspecialty examination in pain medicine given by the ABMS after becoming certified in PM&R.

PLASTIC SURGERY

Plastic surgeons repair, reconstruct, or replace physical defects involving skin, musculoskeletal system, facial structures, hand and extremities, and other areas. They have special training (5 to 7 years of residency training) in the design of grafts, flaps, free tissue transfers, replantation, and use of implantable materials (ABMS, 2002). While not directly managing patients in pain, situations that cause pain (cancer, injuries, and other diseases) are commonly addressed by plastic surgery.

PREVENTIVE MEDICINE

Preventive medicine physicians address the health of individuals and defined populations to protect, promote, and maintain health and well-being (3-year residency). They work to prevent disease, disability, and premature death. These physicians may also be specialists in public health, occupational medicine, aerospace medicine, and undersea and hyperbaric medicine (ABMS, 2002). While not direct providers of pain management services, they may be the best trained to identify potentially dangerous situations that could cause painful illnesses and injuries if not addressed.

PSYCHIATRY

Psychiatrists prevent, diagnose, and treat mental, addictive, and emotional disorders after completing a 4-year residency. They understand the biopsychosocial components of illness and are prepared to treat the whole person. These physicians order and interpret laboratory tests, prescribe medications, and intervene with patients and their families coping with stress, crises, and issues in living (ABMS, 2002). They are increasingly involved in the care of patients with chronic painful disorders and are now able to take the ABMS subspecialty examination in pain medicine. Many are also subspecialists in addiction medicine, geriatric psychiatry, and neurophysiology.

RADIOLOGY

Radiologists use a variety of imaging modalities and radiological methods to diagnose and treat illnesses. Some focus primarily on diagnostic methods while others provide radiation therapy. After 4 years of residency, some radiologists subspecialize in neuroradiology, nuclear radiology, and vascular and interventional radiology (ABMS, 2002). Many patients with pain have their diagnostic and therapeutic procedures performed by radiologists.

GENERAL SURGERY

General surgeons are trained (5 years of residency) to manage many different surgical conditions involving virtually any part of the body. They establish diagnoses and provide pre-, peri-, and post-operative care for patients having surgery. Many provide overall care for the victims of trauma, perform a range of diagnostic techniques, and coordinate care with subspecialty surgeons (ABMS, 2002). Patients with pain often are, or have been, treated by surgeons before their referral to pain management practitioners.

THORACIC SURGERY

Thoracic surgeons train (7 to 8 years of residency) to manage surgical conditions within the chest. They address coronary artery disease; cancer of the lung, esophagus, and chest wall; and abnormalities of the trachea, great vessels, and heart, as well as many other conditions (ABMS, 2002). These specialists working in collaboration with other physicians may be involved in all aspects of pain management from initial diagnostic evaluation to definitive surgical treatment and, by doing so, bring much relief for those with painful conditions involving the organs and structure of the chest.

UROLOGY

Urologists train (5 years of residency) to manage benign and cancer-related medical and surgical conditions of the genitourinary system. They provide comprehensive evaluation of urinary and reproductive systems and their contiguous structures (ABMS, 2002). Pelvic pain, pain involving the genitourinary system, and conditions involving the adrenal gland often lead to urological referral.

CONCLUSION

While allopathic physicians are not the only pain practitioners, they are commonly involved in all phases of care for those suffering from painful disorders. Allopaths represent a heterogeneous group of health care providers, offering a wide array of diagnostic and therapeutic options for the management of pain. Working within allopathic

medicine, they are able to offer treatments including oral medications, surgery, rehabilitative measures, and more. Working beyond allopathic medicine per se, allopathic physicians as members of multidisciplinary treatment teams are able to complement the wonderful efforts of many different types of pain practitioners and bring relief from suffering for those in pain.

Pain Management in Dentistry

Christopher R. Brown, DDS, MPS

It is unfortunate that one of the most common sensations known to humanity is also one of the least understood. Besides love, throughout history there has been no other motivator stronger than pain. Pain can change one's life in an instant, completely turning the direction of an individual's course and those with whom he or she comes into contact. Pain, or the avoidance thereof, whether physical, psychological, or emotional, motivates every living entity from humanity to single cell organisms.

In 1979, the International Association for the Study of Pain set forth the following working definition of pain: "An unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage" (Wall & Melzack, 1984, p. 1). Dental pain has always held special loathing in all known civilizations. All ancient cultures had theories of dental pain origin and proposed treatments often linked with religious ceremony. It was not until the times of Henry VIII in England that practitioners began to emerge whose practices were limited to removing teeth — a truely rudimentary form of pain management.

In 1840, the first true dental college was opened in Baltimore, ushering in the modern era of dentistry and raising the level of dentistry beyond basic exodontia and expanded into other aspects of dental treatment (Glenner, Davis, & Burns, 1990). In 1997 the American Dental Association (ADA) House of Delegates adopted the following definition of Dentistry:

> Dentistry is defined as the evaluation, diagnosis, prevention and/or treatment (non-surgical, surgical or related procedures) of diseases, disorders and/or conditions of the oral cavity, maxillofacial area and/or adjacent and associated structures and their impact on

the human body; provided by a dentist, within the scope of his/her education, training and experience, in accordance with the ethics of the profession and applicable law.

In spite of its late start into a specialized field of medicine, dentistry often took the lead in many aspects of pain management beyond that of the teeth and periodontium. In fact, a dentist's, Dr. Horace Wells, demonstration of nitrous oxide in 1845 helped lead the way in analgesia and anesthesia in the field of medicine (Glenner et al., 1990).

As a result of relentless dedication from the dental profession, dentistry has emerged as a true science for the control of one of the most common sources of pain known to humanity since time began — the toothache. People in all modern societies learn from childhood if there is pain in the mouth, a dentist should be initially consulted as, to borrow a current term, the "primary care physician."

In fact, dentistry has developed the reputation few other professions can claim. In the public mind, dentists are the sole practitioners to seek first for dental pain. Other aspects of the healing arts do not have the distinction of this reputation. Back pain, for example, which is probably the second most common source of pain in the United States, provides a list of possibilities for treatment from which a patient must initially choose. The result is an often confusing, confrontational system that produces high costs and uncoordinated care. The dentist, as a portal of entry physician, provides quick, cost-effective pain relief in a logical, coordinated manner. The lines of distinction between general dentists and associated specialties have been proven to work consistently.

A doctor of dental surgery (D.D.S.) or a doctor of dental medicine (D.M.D.) indicates the degree awarded

upon graduation from a dental school to become a general dentist. There is no difference between the two degrees per se, only a reflection of the prerogative of the individual schools. Both degrees use the same curriculum requirements set by the ADA's Commission on Dental Accreditation. Generally, 3 or more years of undergraduate education plus 4 years of dental education are required for either degree. State licensing boards must be successfully completed according to state laws (ADA, 2004a).

Dental specialties that require additional training have been organized and recognized by the American Dental Association and approved by the Council on Dental Education and Licensure (ADA, 2004b).

Dental Public Health: Dental public health is the science and art of preventing and controlling dental diseases and promoting dental health through organized community efforts. It is that form of dental practice that serves the community rather than the individual as a patient. It is concerned with the dental health education of the public, with applied dental research, and with the administration of group dental care programs as well as the prevention and control of dental diseases on a community basis. (Adopted May 1976)

Endodontics: Endodontics is the branch of dentistry concerned with the morphology, physiology, and pathology of the human dental pulp and periradicular tissues. Its study and practice encompasses the basic and clinical sciences including biology of the normal pulp, the etiology, diagnosis, prevention, and treatment of diseases and injuries of the pulp and associated periradicular conditions (Adopted December 1983)

Oral and Maxillofacial Radiology: Oral and maxillofacial radiology is the specialty of dentistry and discipline of radiology concerned with the production and interpretation of images and data produced by all modalities of radiant energy that are used for the diagnosis and management of diseases, disorders, and conditions of the oral and maxillofacial region. (Adopted April 2001)

Oral and Maxillofacial Surgery: Oral and maxillofacial surgery is the specialty of dentistry that includes the diagnosis and surgical and adjunctive treatment of diseases, injuries, and defects involving both the functional and aesthetic aspects of the hard and soft tissues of the oral and maxillofacial region. (Adopted October 1990)

Orthodontics and Dentofacial Orthopedics: Orthodontics and dentofacial orthopedics is the dental specialty that includes the diagnosis, prevention, interception, and correction of malocclusion, as well as neuromuscular and skeletal abnormalities of the developing or mature orofacial structures. (Adopted April 2003)

Pediatric Dentistry: Pediatric dentistry is an age-defined specialty that provides both primary and comprehensive preventive and therapeutic oral health care for infants and children through adolescence, including those with special health care needs. (Adopted 1995)

Periodontics: Periodontics is the specialty of dentistry that encompasses the prevention, diagnosis, rehabilitation, and maintenance of the supporting and surrounding tissues of the teeth or their substitutes and the maintenance of the health, function, and aesthetics of these structures and tissues. (Adopted December 1992)

Prosthodontics: Prosthodontics is the dental specialty for diagnosis, treatment planning, rehabilitation, and maintenance of the oral function, comfort, appearance, and health of patients with clinical conditions associated with missing or deficient teeth and/or oral and maxillofacial tissues using biocompatible substitutes (Adopted April 2003).

Dentists unfortunately still carry the label of being the causation of pain more often than being true healers. On any given day, one can find difficult situations being referred to by individuals or the media as "as bad as a root canal" or "as painful as going to the dentist." This is in spite of the fact dentistry has made tremendous strides in minimizing or alleviating the pain involved in many dental procedures.

Within those stereotypes, however, are opportunities for dentists to provide care that sets individual practices beyond what is expected by the public. The technical aspect of dentistry when properly performed may be little appreciated by most patients. One of the true tests of a "good" dentist in the public eye is whether the patient feels any pain as a result of procedures. Often the patient's co-workers (or classmates) have already heightened a patient's apprehension with horror stories from their own past dental experiences raising the level of anxiety, and, in the truest sense, lowering the expectations of what level the care deliverer can perform. Many patients expect dentistry to hurt, being convinced that it is the norm for our profession. Delivering careful, pain-free procedures actually surprises and delights patients. Modern dental techniques allow properly trained dentists to do so on a predicable bases. Often anticipation of a painful procedure that turns out to be nonpainful can lead to acceptance of preventive care, which is the best form of pain management.

The costs dentists charge patients for pain management is not the true cost to society. Dental fees are minuscule when considering the actual costs involved. For every dollar spent in the office, there are hours of lost time in industrial production, hours of lost sleep, a reduction in the overall work force, and mistakes made at work that have to be corrected. The staggering costs to society for dental pain could be measured in the billions of dollars when all factors are considered.

Even though dentistry has led the way in cost-effective pain management and preventive care, there is still an almost unlimited number of easily preventable, painful dental problems occurring every day in the United States. For example, diseases of the periodontium are estimated to affect more than 90% of the adult American population.

That presents a need of epidemic proportions. Dental practitioners have to be well skilled in the diagnosis, treatment, and prevention of periodontal disease. Along with successful treatment comes the need for knowledge of pain control. Whether periodontal therapy is surgical or nonsurgical, patients need to have proper advice for pain control, or treatment may not be successful due to incompletion or noncompliance on the patient's part. The finest clinical procedures meet ultimate failure if the patient does not follow the dentist's proper advice. As much as we think our patients are motivated on a higher plane of thought, the truth is many still judge clinical management of periodontal disease by how much the therapy hurts them. With such an overwhelming percentage of the population affected by this problem, the knowledge of proper preoperative and postoperative pain management becomes a vital part of a successful practice.

Tied into the complexity of dental pain management are problems associated with dysfunction of the temporomandibular joints. TMJ dysfunction, or what is now currently referred to as TMD, is estimated to affect more than 25% of the American population (Zarb, Carlsson, Sessle, & Mohl, 1995). While this broad statement encompasses everything from sore mastication muscles to advanced degenerative joint disease, it is safe to say TMD in one form or another is a commonly occurring disorder. The role of the dentist in the treatment of TMD pain is vital. Dentists are the only health care providers capable of providing an adequate differential diagnosis based on proper education and clinical skills. No other profession has the training to evaluate factors such as occlusion, mandibular position, biomechanical forces, and parafunctional habits as various etiologies of the resulting facial pain. The complexity of pain control in this patient population is often exacerbated by both the acute and chronic nature of the pain complaints. The management of acute pain may present the initial challenge, but diagnosing the perpetuating factors that affect the chronicity may prove to be the ultimate key to successful clinical pain management.

Because of the multifactorial nature of TMD, dentists may be placed in the position of either a primary care physician or a team member with other health care providers. This presents situations in which dentists must become comfortable in communicating with other professional practitioners. These opportunities allow for professional growth and understanding between professions, providing a more thorough continuity of care for the pain patient. Continuity of care, or what is commonly called "teamwork," is often lacking in acute and chronic pain treatment. The dental model of care has long established itself as being effective and successful.

The dental model of care inherently gives dentists the ability to treat TMD/facial pain from their individual level of skill. While the treatment of TMD is not a recognized specialty within the American Dental Association, there are many dentists who have chosen to limit their practice to the diagnosis and treatment of these collective disorders. The education system is now established to allow dentists to pursue advancement of their clinical skills to the level they desire. Courses are now available, through universities and other organizations that train dentists, in the diagnosis and advanced treatment of muscular trigger points, various diagnostic and therapeutic nerve blocks, computer-aided adjunctive diagnostics, radiology, pharmacology, and physical supportive medicine.

Along with advanced training come opportunities to provide pain management beyond the traditional concepts of dentistry allowing dentists to function as true oral physicians. Dentists who wish to pursue this aspect of pain management can often provide the needed link between medicine and dentistry offering a unique perspective to pain control, resulting in cost-effective successful treatment.

The advent of third-party managed care has dictated a new catchphrase: "outcomes measurement." Outcomes measurement is nothing new to dentistry in the traditional sense. The treatments provided, such as crowns, bridges, and fillings, are usually judged against true measurable outcomes. There are certain criteria that need to be met for clinical success. The parameters are measured by treating dentists, patients, and third-party providers.

As dentists move into the realm of less measurable entities, such as pain management, new paradigms must be established if the profession is to prove viable as a cost-effective avenue of health care delivery. Within those paradigms, outcomes measurement must be used. The concept of using a ruler and fingertip palpation as the "gold standard" of measurement and verification is no longer acceptable if the dental profession is to advance. Objective standards and measurements must be adopted and routinely used, or a dentist's role in pain management erodes and delegates to the role of technician.

The American Academy of Pain Management, the largest pain management organization in the world with more than 5000 members, has a computerized outcomes measurement system in place that fits the needs of modern dental pain practitioners. The use of standardized intake and outcome formats allows offices that practice pain management to compare all aspects of their programs with other participating practices throughout the nation. The tracking system allows not only comparisons within the dental profession, but with other disciplines as well. In other words, the cost-effectiveness of alleviation of headaches via "dental" procedures can be compared with medical, chiropractic, physical therapy, etc. The parameters measured are consistent within the various disciplines. This is the only program that measures the total true outcomes, which are pain alleviation, cost, and individual dental versus medical components.

A conference in Bethesda, MD, sponsored by the National Institutes of Health and the National Institute of

Dental Research decried the lack of measurable outcomes available to determine the effectiveness of pain management procedures commonly used by dentists and challenged the profession to respond. As a result, several major dental groups formed "The Alliance of TMD Practitioners" to help coordinate the various dental special interest groups that have formed over ideology. A representative from each dental group has been invited to become a member to help form cohesive leadership beyond each individual member's group focus. The alliance provides an entity that allows for dissemination of information without prejudice to all member organizations.

For dentistry to compete in the new cost-effective atmosphere of today's society, high standards must be met. Dentistry has been extremely effective in cost containment when compared with allopathic medicine. With the expansion of dentistry into aspects of pain management beyond teeth and their supporting structures, the challenges of the future lie not only in its scope of treatment but also within the realm of multidisciplinary diagnosis and treatment. The term *multidisciplinary* indicates all aspects of the dental profession and its various specialties as well as all aspects of the healing arts. The unique training and abilities make dentistry a viable partner in the alleviation of one of humankind's pain and suffering.

Podiatric Medicine and the Painful Heel

Paula Gilchrist, DPM, PT

PODIATRIC MEDICINE

What is a doctor of podiatric medicine? By strict definition, a podiatrist is a medical specialist who functions specifically to diagnose and treat a variety of maladies, illnesses, and problems as they are manifest in the lower extremity, especially at the foot and ankle complex. Surgically, depending on individual residency training, board certifications, and state licensure laws, the podiatrist can operate on the ankle and the foot to repair and or remove bony and soft tissue structures. Fixation devices, bone grafts, and amputations are well within the skill and training of the podiatrist. There is no medical practitioner who is better trained in lower extremity anatomy, pathology, and biomechanics than the doctor of podiatric medicine.

There are two questions of interest. How does one become a podiatrist? Exactly what academic, clinical, and residency training does a podiatrist have? There are many course requirements for medical, dental, osteopathic, and podiatry schools. Ironically, the mandatory prerequisite courses needed for entrance to any of these schools are academically similar. From 90 to 135 college course hours are needed. Great emphasis is placed on the sciences. The curriculum includes 12 credits of biology with laboratory, 12 credits of inorganic chemistry with laboratory, 12 credits of organic chemistry with laboratory, 12 credits of physics with laboratory, 9 credits of English, and 6 credits of mathematics, which are the minimal course requirements. On occasion, a school may require an introductory-level course in anatomy and physiology. Generally, applications to the schools of podiatric medicine are made in the second term of the third year of college or in the fall of the fourth year. The Medical College Admission Test (MCAT) or the Graduate Record Examination (GRE) serves as the entrance exam for admission to podiatry school. Applicants to the schools of podiatric medicine also go through the process of entrance interviews. This can be done on a one-to one basis or with a committee interview.

Once accepted to a podiatric program, the student now begins to enjoy an intense curriculum of academic and clinical medicine. Most schools of podiatric medicine will award the doctorate degree (Doctor of Podiatric Medicine or D.P.M.) in 4 years. There are some schools that couple the doctor of podiatric medicine with a doctor of philosophy in certain preapproved areas. Overall, whether the curriculum is that of traditional coursework or problem-based education, the basic subject matter must be presented. Core curriculum is used in all seven U.S. schools of podiatric medicine (Temple School of Podiatric Medicine; Ohio College of Podiatric Medicine; Scholl College of Podiatric Medicine; New York College of Podiatric Medicine; Barry School of Podiatric Medicine; Des Moines College of Podiatric Medicine; and California College of Podiatric Medicine). This curriculum is quite similar to that used in medical schools. In fact, several schools of podiatric medicine actually share the faculty of adjoining medical schools.

The following discussion is a representation of the curriculum used in shape and form in all the schools of podiatric medicine; individual program modifications certainly do occur. During the first year's first term, course work includes gross anatomy (including dissection), histology, biochemistry, podiatric medicine, and introduction to general medicine. During the first year's second term, lower extremity anatomy (with laboratory), neuroanatomy and physiology, microbiology and immunology, physical diagnosis, and biomechanics are covered.

In the second year's first term, microbiology, infectious disease pathology, pharmacology and therapeutics, biomechanics and physical medicine, physical diagnosis, and rehabilitation medicine are taught. The second year's second term is generally reserved for intense courses in general and podiatric radiology, pathology and case studies, pharmacology and therapeutics, and podiatric medicine and skills of podiatric medicine.

At the completion of the second year of study, the student must take Part I of the National Board Exam. A passing grade on this examination is necessary before clinical studies can continue.

During the third year of study, clinical rotations are introduced and the student must complete studies in business administration, general medicine, sports medicine, traumatology, and podiatric surgery. In the first term of the third year, the student takes coursework in public health, jurisprudence, neurology, dermatology, and podopediatrics.

The fourth year of podiatric study is entirely clinical in nature. A total of 24 weeks of clinical externships and rotations in podiatric medicine and surgery rotations are possible at the Ohio College of Podiatric Medicine; 20 are mandatory and 4 are optional. These can be scheduled at the school clinics as well as with outside individual practitioners and surgery centers. There is also an 8-week rotation required in physical medicine and diagnosis. Podiatrists are skilled in the use of ophthalmoscopes, stethoscopes, and other medical instruments. An oral exam and a written cumulative exam are common requirements for graduation from schools of podiatric medicine. This is in addition to individual course requirements.

During the time of this fourth year of study, the student is also heavily engaged in applying and interviewing for residencies. The postdoctorate training is heavily responsible for practice formation in future years. Certified podiatric residencies are approved by the Council on Podiatric Medical Education.

In podiatric medicine, there are generally three types of residencies available. These are in the areas of podiatric medicine, podiatric surgery, and podiatric orthopedics. The terms of the residencies mostly range from 1 to 3 years in length. For those students who are fortunate to be accepted into surgical training, it is quite common to work with well-trained orthopedic surgeons after the hospital rotations in general medicine, anesthesia, dermatology, rheumatology, emergency medicine, and ophthalmology are completed.

At the completion of all formal training, the student must then sit for state licensure examinations. States can have a reciprocity agreement for licensure, but most states require a candidate to be tested in the state where practicing as a skilled podiatrist is a possibility. Once licensure is granted, the doctor of podiatric medicine must consider board certification. Many insurance companies require board certification or board eligibility status before pay-

ment for services duly rendered is considered. In the field of podiatry, there are many certifications. The Council on Podiatric Medical Education approves some board certifications, though not all. Examples of podiatric certification boards are surgery, podiatric medicine, risk management, acupuncture, and orthopedics and wound care. These certifications are not multidisciplinary, as is the credentialing given by the American Academy of Pain Management.

The next step in the career of the podiatrist is to become very familiar with licensure requirements of the state. After obtaining malpractice insurance, the podiatrist must attend continuing education seminars in order to keep the license active. A fixed number of continuing education credits per year set by the licensure board of each state is required. Failure to comply with this requirement will result in suspension of the license to practice podiatry.

Now the fun of practice really does begin. Podiatrists have the flexibility and training to take the practice in any of many directions. Memberships in many professional organizations are possible. Occasional networking and association with colleagues occur. The American Academy of Pain Management has a wealth of information in the membership of the academy alone. Sports medicine, pain management, general practice, dance consultant, acupuncture, biomechanics, surgery, dermatology, podopediatrics, and rheumatology are just a few of the areas in which a well-trained and dedicated podiatrist will have no problems finding a niche. Sometimes the real problem is in the attempt to narrow the scope of the practice. Yes, it does take years of training, sleepless nights, and thousands in school loans, but the benefits outweigh the problems. The satisfaction outweighs the risks.

HEEL PAIN

By way of example, let me tell you about a typical podiatric problem and how it is addressed. Heel pain (calcaneal pain) is one of the most common foot problems presenting to the clinical practitioner. In 1999, more than 2 million doctor visits were involved with the treatment of heel pain. Age is not a discriminating factor. Heel pain can occur in any age group, but is most frequently found from the age of 8 to 80 years of age. Heel pain is noted in women, men. and children. It is responsible for loss of workdays, loss of school days, and loss of income.

Disability from heel pain can be short term and mild to long term and fully debilitating. Problems with the heel can be associated with activity change (so-called weekend warrior), increase in weight, and change of shoe gear. Poor preparation for activity, such as running without stretching or improper shoe gear, can result in injury to many body areas, but especially to weight-bearing structures such as the heel. Foot type (pronated or supinated foot) as well as atrophy and distortion of the infracalcaneal fat pad and the presence of muscle spasm can contribute to heel pain.

In 2002, a MedLine search produced more than 12,000 "hits" with questions on heel pain. These questions ranged from the definition of heel pain, to causes, treatments, and support groups. In 2001, a news release from a survey undertaken by the American Podiatric Medical Association suggested that heel pain was present in epidemic proportions (www.apma.org).

Care for heel pain can range from the most conservative to the most radical. A myriad of treatments exist. Treatments such as rest, ice compression, elevation, medication (oral anti-inflammatories, oral steroids, vitamin therapy), steroid injections, orthotics, physical therapy modalities, exercise for strength and flexibility, massage therapy, myofascial therapy, acupuncture, acupressure, splinting, strapping, and casts are but a few of the conservative care measures. Steroid creams, magnets, and anti-inflammatory creams have also been used. Extracorporeal shock wave therapy (ESWT) is now finding a place in nonsurgical care for the treatment of infracalcaneal heel pain. Radical care, generally reserved for the most resistant of cases, does include surgical measures. Plantar fasciotomy, plantar fasciectomy, exostectomy, bursectomy, calanceal osteotomy, neurolysis and lysis of adhesions, and tendon rebalancing, shortening, and lengthening are all within the surgical realm of possibility.

Practitioners from many areas of traditional medicine and complementary care medicine treat heel pain. We all have our niche. Medical physicians tend to give medication for pain and inflammation. Podiatrists offer use of medication, orthotics for foot and joint balancing, strapping, splinting, casting, injections, and surgery. Osteopaths offer medication and bony adjustment (such as for a short leg). Chiropractors offer spinal alignments. Acupuncturists and acupressurists offer pain-blocking care. Therapists such as physical, massage, and others offer deep soft tissue relief, myofascial care, scar reduction, flexibility, and body awareness. All have similar goals: reduction of pain and inflammation and increase of normal function. There is no single line of treatment and no simple rate of cure for patients who experience heel pain.

Infectious processes as well as systemic diseases can cause heel pain. Diseases such as gout, rheumatoid arthritis, psoriatic arthritis HLA-B27 disorders, and Reiter's syndrome can cause heel pain. However, for the purpose of this discussion, the following pathologies are reviewed:

1. Plantar fasciitis
2. Heel spur syndrome
3. Haglund deformity
4. Retrocalcaneal exostosis/Achilles tendon calcification
5. Achilles tendonitis
6. Tarsal tunnel syndrome
7. Flexor hallucis longus tendonitis

For an anatomical review of the foot as well as thorough illustrations, the reader is advised to consult a standard anatomy text. *Gray's Anatomy* and *Grant's Anatomy* are excellent and clear sources for review. There are 26 mostly irregularly shaped bones in the adult human foot. This amounts to one fourth of the bones found in the entire human body. The foot itself is divided as follows:

Three bony sections:
1. Rearfoot: Consisting of talus and calcaneus
2. Midfoot: Consisting of navicular, cuboid, and cuneiform bones 1, 2, 3
3. Forefoot: Consisting of metatarsals 1, 2, 3, 4, 5

Five proximal phalanges
Four middle phalanges (hallux or great toe does not have a middle phalanx)
Five distal phalanges

The sesamoid bones found under the area of the first metatarsal are not part of the foot proper

In terms of the foot musculature, there are four distinct layers of plantar muscles. The layers ranging from superficial (plantar) to deep (dorsal) are:

First Layer: Abductor digiti quinti, flexor digitorum brevis, abductor hallucis
Second Layer: Tendon of flexor hallucis longus, tendon of flexor digitorum longus, four lumbricales, and the quadratus plantae
Third Layer: Adductor hallucis, flexor hallucis brevis, flexor digiti minimi brevis
Fourth Layer: Three plantar and four dorsal interossei (the tendon of the peroneus longus muscle and the tendon of the posterior tibialis muscle in the posterior half of the foot are close to this fourth layer)

The plantar fascia, often discussed as an inflamed area in heel pain, consists of three separate compartments: medial fascia (encompasses abductor hallucis muscle), central fascia (encompasses flexor digitorum brevis), and the lateral fascia (encompasses abductor digiti minimi). The medial fascia, which has a very broad band, is often implicated in cases of plantar fasciitis. The attachment of the fascia onto the anterior medial calcaneal tubercle takes a great deal of pressure when standing and walking. The configuration of the calcaneus itself is partially responsible for this problem.

The tarsal tunnel, located on the medial side of the ankle, is often implicated in impingement syndromes that can cause heel pain. The tarsal tunnel has four distinct canals that have the laciniate ligament (flexor retinaculum) as the roof and two septa that form the borders of the canal.

Canal 1: Contains tibialis posterior muscle (primary function is to assist in plantar flexion and inversion of the foot)

Canal 2: Contains flexor digitorum longus muscle (assists in bending of the toes)

Canal 3: Contains posterior tibial nerve (L4, L5, S1, S2, and S3 nerve roots) plus the posterior tibial artery and vein

Canal 4: Contains flexor hallucis longus muscle (responsible for flexion of the great toe and assists in the push-off phase of gait; this muscle also assists in deceleration of forward motion of the tibia in a stance phase limb)

These four soft tissue canals are prevented from bow-stringing (bulging out) during standing and walking by the flexor retinaculum (laciniate ligament). The medial calcaneal nerve, a branch from the posterior tibial nerve, is noted to pierce through the retinaculum and give sensory innervation to the medial side of the heel.

PLANTAR FASCIITIS

Plantar fasciitis may perhaps be the most common heel problem presenting to the clinician. It is often associated with repetitive stress injuries and is not usually the result of direct trauma. It is a soft tissue problem that can be present for years, to some degree, before the patient seeks any type of treatment. Heel spurs can be present on radiograph without symptoms of plantar fasciitis. In fact, endoscopic plantar fasciotomy serves to relieve traction at the anterior medial calcaneal tubercle by severing fascial attachments. Spur, if present, is generally not removed. The lateral attachments of the plantar fascia remain intact.

Poststatic dyskinesia is often noted. Pain occurs with great intensity when the patient arises from a resting posture or sleep. Inflamed soft tissues and muscles are tight after rest. Weight bearing stretches these areas and pain results. Pain is noted to diminish with activity. As the course of the day progresses, so does the pain. Still, the greatest pain is noted after rest.

Inflammation can be detected at any area of the fascia. It is most commonly noted at the medial calcaneal tubercle attachments of the fascia onto the calcaneus. This bony prominence serves as the point of origin of the anatomic medial band of the plantar fascia and the abductor hallucis, flexor digitorum brevis, and abductor digiti minimi muscles. Pain is generally elicited with deep palpation in front of the medial calcaneal tubercle. Pain is also greatest at the push-off phase of gait when the already inflamed fascia is stressed and is stretched as the forefoot begins to accept more body weight and the propulsive phase of gait begins.

It is important to remember that the plantar fascia assists in maintaining the arch height of the foot; it connects the rearfoot to the forefoot. With pathology present, the medial longitudinal arch of the foot can lower. Passive toe extension with the ankle in full dorsiflexion and the knee in extension can elicit pain at the heel.

Pain from plantar fasciitis can be noted to increase when there is a decrease in the flexibility of the gastro-soleus (triceps surae) complex at the calf area. The gastrocnemius muscle assists in plantar flexion of the foot and in knee flexion; the soleus muscle assists in plantar flexion of the foot. The triceps surae sends a plantar attachment under the heel and into the plantar fascia. However, remember that when the plantar fascia is stretched, inversion of the heel occurs to a slight degree. Peroneal muscles (evertors of the foot) can be involved. These muscles are working harder to perform their function. As a result, it is easy to note that evaluation cannot always be contained to the heel itself. Soft tissue attachments to the heel and around the heel must be assessed.

One method to assess for calf tightness is to apply a heel lift (on the painful foot) that does not compress to less than 1/2 to 1 in. If the plantar heel pain eases, then calf tightness must be addressed in the process of eliminating heel pain. If calf tightness is noted, it is best to stretch the Achilles tendon bilaterally. The stretch should be done with the subtalar joint of the foot in neutral position. This helps to maximize the stretch of the Achilles tendon. The stretches should be done with static holds, without bouncing. If heel lifts are needed, then the lifts should be worn in both shoes to reduce the risk of back pain until the flexibility of the gastro-soleus complex is restored. When bouncing instead of static stretching is done during exercise, shortening of the gastro-soleus muscle area is apt to occur. This shortening may cause a secondary Achilles tendonitis.

Plantar fasciitis can occur in either a supinated (cavus high-arch-type; Figure 15.1) foot or in a pronated (planus low-arch-type; Figure 15.2) foot. In pronation, the foot is noted to be quite flexible. This position is sometimes referred to as "a loose bag of bones." A cavus-type foot is inherently more rigid, an excellent propulsive foot. The cavus-type foot may require extra cushioning for relief of pain. The planus-type foot (Figure 15.2) may require only a heel lift. Note that a hint for balancing the foot is to assess the foot in neutral, that is, to assess the foot with the subtalar joint in neutral and the midtarsal joint in pronation. Either foot type can respond nicely with the use of a mechanically balanced custom-made orthotic device that controls subtalar joint motion (Figure 15.3).

In the early stages of treatment, a foot strapping to lock the first ray and transfer pressure away from the fascia and onto the tendons and toes may help relieve heel pain. It is not uncommon to find scar tissue formation on the medial side of the heel due to repetitive stress and an unbalanced foot. Lateral shift and atrophy of the infracalcaneal fat pad can occur. A heel cup may eliminate lateral shift and a heel lift may assist in cushioning. Scar tissue may be eradicated with deep soft tissue massage and fascial release therapy.

FIGURE 15.4 Infracalcaneal heel spur, traction type spur located anterior to the medial calcaneal tubercle.

HEEL SPUR SYNDROME

Infracalcaneal heel pain (heel spur syndrome) can occur if plantar fasciitis progresses and microtears of the proximal fascia occur at the attachment areas to the heel. Low-grade periostitis occurs along with thickening in the area of trauma. Edema and fibroblastic inflammatory cell infiltration can also occur. Periosteal calcification occurs near fascial and tendonous attachments. The infracalcaneal heel spur forms in this manner (Figure 15.4). A "traction" type of spur from excessive pulling of the soft tissue is noted on lateral radiograph of the foot.

Lateral, oblique, and calcaneal axial radiographs of the foot are helpful to assess heel pain. However, for infracalcaneal spurs, the lateral view often yields the most information as to type and extent of spur. Direct bony alignment of the foot can also be evaluated with radiographs. Weight-bearing radiographs in angle and base of gait are preferable.

Pain presentation is very similar to that of plantar fasciitis. Etiology can be overuse or excess weight in a pronated or a supinated foot type. Conservative treatment is the same as in plantar fasciitis. The physical therapy modalities of iontophoresis, phonophoresis, and electrical stimulation may be of great help to reduce inflammation. Special attention to the thickness and placement of the infracalcaneal fat pad is needed to assist in pain relief. This fat pad acts as a shock absorber for the heel. Soft shoes with a long medial counter for cushioning and shock absorption may be helpful. Medial longitudinal arch support may also assist in easing inflammation. Note that not all infracalcaneal heel spurs are symptomatic. Occasionally, if the foot is well compensated, an infracalcaneal heel spur can be an incidental finding on radiographic examination.

HAGLUND DEFORMITY

Synonyms for Haglund deformity include pump bump (from female high-heel shoes) and retrocalcaneal bursitis. This bony problem (Figure 15.5) located on the lateral side of the heel is often confused with Achilles tendonitis

FIGURE 15.5 Haglund deformity. Note enlargement of the posterosuperior aspect of the calcaneus.

or bursitis. This condition can occur in patients with a prominent posterosuperior aspect of the calcaneus who wear tight or rigid counter shoes. Instability of the rearfoot can be noted.

The counter refers to that part of the shoe that "cups the heel" and gives the foot stability inside the shoe. The lateral foot radiograph helps to assess the Haglund deformity. In this entity, the counter of the shoe rubs the heel and causes pain and further enlargement of the posterosuperior aspect of the calcaneus. Clinically, the examiner should view the posterior aspect of the heels from behind and with the patient standing. The bulge is quite evident and is seen lateral to the insertion of the Achilles tendon.

Pain symptoms are generally reported as dull aching at the posterior aspect of the heel, lateral to the attachment of the Achilles tendon. The pain is greatest when the foot is dorsiflexed. A possible etiology for this pain is the pinching of the retrocalcaneal bursal sac between the Achilles tendon and the calcaneus. An adventitious (not an anatomically correct) bursal sac can form at the superficial surface of the Achilles tendon. This can further enhance pain.

Conservative care for this problem includes rest, trigger point therapy, soft heel lifts, soft counter shoes, and nonsteroidal anti-inflammatory drugs (NSAIDs). Open-back shoes can be used. Heel lifts of 1/2 to 3/8 in. are used to raise the point of the heel irritation just superior to the counter of the shoe. Ice massage may be of help. If conservative care fails, then removal of the inflamed bursal sac and partial calcaneal exostectomy may be required. Some clinicians may advocate steroid injection into the bursal sac only; however, this must be done with great caution and skill. If steroid is inadvertently placed into the Achilles tendon, spontaneous rupture of the tendon can occur.

RETROCALCANEAL EXOSTOSIS/ACHILLES TENDON CALCIFICATION

In this malady, heel spur or calcification is noted at the insertion of the Achilles tendon onto the posterior aspect

FIGURE 15.6 Retrocalcaneal exostosis. Note the spur formation at the superior aspect of the calcaneus.

of the calcaneus or within the tendon itself (Figure 15.6). This problem can be isolated or can be found in combination with retrocalcaneal bursitis or Achilles tendonitis. The Achilles tendon itself can become thick and wide; lateral radiographs reveal calcification in the calcaneal attachment of the Achilles tendon.

Pain symptoms include dull aching, especially near the insertion of the Achilles tendon onto the heel. Pain frequently occurs in the patient who is involved in athletics or dancing activities. Range of motion of the ankle is altered. Slightly less dorsiflexion of the involved ankle can be noted due to bony block caused by the exostosis. Crepitation of the Achilles tendon can occur due to chronic inflammatory and fibrous deposition throughout the tendon.

Conservative care consists of rest and modalities. Great emphasis is placed on stretches for the triceps surae. The use of ice can decrease edema as well as poststatic dyskinesia. Surgical exostectomy can require splitting of the Achilles tendon or detaching the Achilles tendon from the calcaneus in an attempt to gain exposure of the spur. The muscle does tend to lose strength with this radical approach.

ACHILLES TENDONITIS

Tendon disabilities can be caused by irritation around a tendon sheath (paratenosynovitis), pathology of the sheath itself (tenosynovitis), lesions between the sheath and the tendon (such as lipoma or xanthoma), and lesions within the sheath itself (tenosynovitis). Peritendonitis is a term used to describe inflammation of a tendon with or without a sheath. The Achilles tendon, which is the largest and strongest tendon in the body, is surrounded by a paratenon.

FIGURE 15.7 Achilles tendonitis. Note the swelling of the Achilles tendon.

Tendons, in general, receive blood supply from four areas: muscles, bone, paratenon, and mesotenon. The Achilles tendon has little supply from bone or muscle; much of the blood supply and hence nourishment is via the paratenon. Tendonitis is an inflammation of the tendon itself. It is generally caused from repetitive stress experienced by athletes, dancers, and jumpers. Tendonitis crepitans can be noted due to chronic inflammation of the area. Some practitioners describe this as the sound of crackling in the tendon itself.

Achilles tendonitis (Figure 15.7) is generally noted to be posterior on the heel with the greatest tenderness noted approximately 3 cm proximal to the insertion of the Achilles tendon onto the heel. Pain is noted with dorsiflexion of the ankle due to tension on the heel cord (Achilles tendon) itself. The patient may not be able to unilaterally rise up and down on the toes. Tenderness can be associated with swelling, redness, and thickening of the tendon. In dancers, pain can be noted in the propulsion off the foot, as well as during landing. During landing the triceps surae also act as a decelerator of foot motion.

Treatment consists of longer warm-ups, heel lifts, flexibility training, cross-fiber massage, modalities, NSAID medication, and possible foot strapping. Stretching is the key to care. The patient should stretch with the foot in multiple positions, both weight bearing and non-weight bearing.

TARSAL TUNNEL SYNDROME

The tarsal tunnel is located on the medial side of the ankle. The roof of the tunnel consists of the laciniate ligament (flexor retinaculum). There are four distinct canals in the tarsal tunnel, which are formed by two individual septa. The contents of the canals are posterior tibialis tendon, flexor digitorum longus tendon, posterior tibial nerve artery and vein, and flexor hallucis longus tendon. Tarsal tunnel syndrome is generally the compression or entrapment of the posterior tibial nerve as it courses under the laciniate ligament. The posterior tibial nerve divides into the medial and lateral plantar nerve and is responsible for great areas of sensory innervation in the foot. As a result,

patients may not be able to pinpoint the source of heel pain. Patients may only be able to describe the pain in general, such as inferior to the medial malleolus.

Pain with this syndrome is generally of gradual onset and is described as aching, burning, and unremitting. The triad of pain, paresthesia, and numbness are not uncommon with nerve injury. Pain is noted with weight bearing and non-weight bearing. Pain can begin in the posterior aspect of the heel and continue forward to just below the medial malleolus and onto the toes. A positive Tinel (pain radiation to the toes) or Vallieux sign (pain radiation to the calf) can be noted with percussion and compression of the posterior tibial nerve as it courses around the medial malleolus. Causes for tarsal tunnel syndrome include the pronated (flat) foot that is decompensated, hypertrophy of the abductor hallucis longus muscle (causing nerve pressure), cysts of the nerve itself, or a poorly applied cast that incorporates the foot. An electromyogram may help to establish the diagnosis. Differential diagnoses include plantar fasciitis, medial calcaneal neuroma, digital plantar nerve entrapment, vascular disease, and lumbosacral radiculopathy.

Conservative care of this lesion can include a medial longitudinal arch support, strapping, and control of the subtalar joint with a custom-made biomechanical orthotic device. The goal is to control pronation and relieve stress from the medial heel structures. Medication and steroid injection can help when pathology is diagnosed early.

FLEXOR HALLUCIS LONGUS TENDONITIS

The flexor hallucis longus muscle assists in plantar flexion of the great toe. During the push-off phase of gait, the muscle locks the proximal phalanx of the great toe and assists in ease of weight distribution. This muscle helps accelerate the forward motion of the tibia onto a weight-bearing foot. When tendonitis occurs here, it is generally the result of a mechanical disturbance. Overuse is a common etiology. The patient will complain of discomfort in the sole of the foot.

Tendon pain is not generally noted with passive stretch or dorsiflexion of the great toe. Pain is noted with local pressure and palpation at the point of pathology. On examination, the flexor hallucis longus tendon stands out when the toe is passively dorsiflexed (Figure 15.8). Pain can occur the length of the tendon, but is more commonly noted at the proximal portion of the tendon. Tenderness is detected more superficially and distal to the area where heel spur tenderness is expected. The medial calcaneal tubercle is generally not tender.

Treatment for this lesion consists of soft sole shoes, modalities, and massage. A transverse arch band may also help. Tendon injection with steroid is questionable and may cause tendon rupture (Figure 15.9).

FIGURE 15.8 Flexor hallucis longus tendonitis. Note the bulge of the flexor hallucis longus.

FIGURE 15.9 Did somebody mention heel pain?

SUMMARY

A final comment concerning the practice of podiatric medicine is in order. It is not uncommon to see "an older student" attend a school of podiatric medicine. Some students are looking for an adjunct to a current career, and some are looking for a new career. Some students are searching for more independence in their work experience. Some feel a need for individual and independent job satisfaction. Podiatric medicine offers all of this. If interested, each of the seven schools has a well-designed Web site for information.

As for the role of the podiatrist, heel pain is a common malady treated by many types of practitioners. It is hoped that this chapter has provided the opportunity for one to gain new insight exploring the differential diagnosis of heel pain. Once the accurate diagnosis has been made, it is necessary to follow with appropriate care. Given the potential for overlap in clinical presentation and diagnosis, reevaluation of the etiology of the pain is always a consideration, especially if the patient is not responding as expected.

Chronic Spinal Pain: Mechanisms and a Role for Spinal Manual Medical Approaches to Therapy and Management

James Giordano, PhD, Alfred V. Anderson, MD, DC, and Michael J. Nelson, DC

INTRODUCTION

Pain is a major public health problem in the United States; 50 million Americans are partially or totally disabled from intractable pain. According to the American Pain Society, approximately 45% of all Americans seek care for persistent pain at some point in their lives. Back pain syndromes substantively contribute to the overall epidemiologic prevalence and fiscal gravity of pain disorders. As the leading cause of occupational disability in Americans below the age of 45 (Borenstein, 1998), the economic toll of back pain exceeds $16 billion in costs dedicated to therapeutic and/or management intervention (Burton & Erg, 1997). A significant issue is the progression of acute and subacute back pain to a condition of chronicity. Chronic back pain involves physiologic, psychologic, and sociocultural variables that exacerbate the scope of its effects and complicate both the clinical picture and amenability to intervention. Although an in-depth discussion of pain taxonomy, thoroughly detailed elsewhere in this text, is beyond the scope of the present chapter, it is important to note that persistent (back) pain can be perpetuated through numerous factors and can lead to maldynia (Table 16.1). Maldynic spinal pain involves heterogeneous mechanisms of peripheral and central sensitization, frequently produces a cognitive constellation in excess of apparent organic pathology, and increases the need for (and often the paradoxical inefficacy of) multidisciplinary management approaches.

Chronic and maldynic spinal pain may be underevaluated and/or inadequately treated. Such disparity can lead to patients' frustration that reflects dissonance with patients' subjective suffering, models of spinal pain diagnosis and treatment, and clinicians' capacity to evaluate provocative mechanisms objectively and apply appropriate, case-based therapeutic intervention(s). This chapter is dedicated to a mechanistic depiction of spinal pain and its therapeutic management utilizing manual/manipulative procedures. It must be understood that the technical application of these procedures is possible across both allopathic (physical medicine and rehabilitation) and non-allopathic (osteopathic, chiropractic, and physical therapeutic) disciplines. Part I reviews substrates producing spinal pain relevant to spinal manual medicine (SMM); Part II presents an overview of SMM (across disciplines of use) from a clinical and research perspective.

PART I

INNERVATION OF SPINAL STRUCTURES

Fibers from the dorsal and ventral horns converge into roots that conjoin upon exiting the intervertebral foramina (IVF) into the common spinal nerves. These nerves are contained in dural sleeves that attach to the rim of the IVF. Beyond this point, spinal nerves bifurcate into dorsal and ventral rami containing both sensory and motor fibers. The

capable of transducing and conducting nociceptive impulses. Second, the activation of these fibers either specifically or together with concomitant input from related structures should produce pain that reflects the clinical picture. Third, these structures must be shown to be vulnerable to insult and/or trauma that can initiate and perpetuate a relevant pain syndrome. Last, strong correlation should exist between clinically identified pain syndromes and the involvement of these underlying substrates. These last two points may be somewhat problematic in light of known mechanisms of peripheral and central sensitization that may lead to activation of the afferent nociceptive neuraxis despite the absence or resolution of a provocative anatomical cause (Giordano, Chapter 3, this volume; Woolf, 2000). The following structures meet Bogduk's criteria and are thus capable of at least initiating the nociceptive process (that may lead to sensitization and maldynia).

Vertebrae

The periosteum of the vertebral bodies and arches are innervated by unmyelinated nerve fibers derived from the plexi of the anterior and posterior longitudinal ligaments. These plexi also innervate the articular capsule, aponeuroses, deep paravertebral fascia, and tendons (Groen et al., 1990; Jackson et al., 1966; Wyke, 1970). These nerves penetrate the vertebral body and innervate both the vasculature and the cancellous bone (Hirsch et al., 1963). Thus, both the vertebral periosteum and bone itself may be sensitive to inflammation, mechanical distention, and therefore, pain. As well, intraosseous hypertension can dilate the penetrant blood vessels of the vertebrae stimulating perivascular nerves and evoking pain (Arnoldi, 1972, 1976).

The vertebral periosteal elements are sources of pain secondary to two biomechanical conditions. Principal among these is spondylolysis, a fatigue fracture of the pars inter-articularis (O'Neill & Micheli, 1989) that can be acutely painful and be a source of chronic afferent sensitization. The chronic condition is the result of postfracture fibrous scarring with proliferation of nociceptive free nerve endings that are reactive to, and sensitized by, biochemical substrates of the inflammatory cascade and may directly induce neurogenic inflammation and pain (Schneiderman et al., 1995). Additionally, Bogduk (1997) suggests that bilateral pars fracture produces pain due to

dorsal ramus divides into the medial branch that innervates the capsular and intra-articular areas of the zygapophyseal (ZP) joints, the interspinous ligaments, and the mutifidi muscles (Wyke, 1987). The lateral branch of the dorsal ramus innervates the iliocostalis and longissimi muscles in the lumbar region, and courses through these muscles to become the cutaneous cluneal nerve(s) (Edgar & Ghadially, 1976).

The ventral ramus is the source of the recurrent meningeal (sinuvertebral) nerve, which is joined by the gray ramus communicantes of the sympathetic chain to innervate the posterior longitudinal ligament, periosteum of the posterior zone of the vertebral bodies, anterior dura, epidural and basivertebral vessels, and posterolateral annulus fibrosus (Porterfield & DeRosa, 1991). Fibers of the ventral ramus directly innervate the lateral aspect of the annulus of the intervertebral discs (Bogduk, 1983). This innervation is summarized in Table 16.2.

MECHANISMS OF SPINAL PAIN

Spinal Pain Generators

Numerous anatomical structures are capable of directly or indirectly producing spinal pain. According to Bogduk (1992), an anatomical structure can be a locus of spinal pain providing it satisfies four essential criteria. First, the structure must be innervated with both receptors and fibers

the action of the multifidi muscles pulling upon the loose, fractured pars segments, creating displacement and excessive mechanoreceptor activation within the related zygapophyseal joint(s).

Vertebral spinous processes, particularly those of the lumbar vertebrae, are susceptible to Baastrup's disease (Baastrup, 1933) in which spinal hyperextension leads to anterior (longitudinal) ligamentous laxity and compression of the interspinous ligament(s), and allows contact of the spinous processes of adjacent vertebrae. This can inflame the involved ligaments, cause periostitis of the contacting spinous processes, and produce pain (Jackson et al., 1966; Rhalmi et al., 1993).

Zygapophyseal Joints

The fibrous capsules of the zygapophyseal (ZP), or facet joints, are extensively innervated by unmyelinated fibers derived from the medial branches of the dorsal rami (Bogduk et al., 1982, Jackson et al., 1966) and meet proposed criteria for generating spinal pain (Bogduk, 1997). Diagnostic studies have confirmed the contribution of ZP joint pain to the epidemiologic prevalence of chronic back pain (Schwarzer et al., 1994, 1995a, 1995b). The ZP joints are susceptible to numerous pathologies such as osteoarthritis (Lewin, 1964; Magora & Schwartz, 1976), rheumatoid arthritis (Lawrence et al., 1964; Sims-Williams et al., 1977), and epiphyseal disintegration of the articular processes (King, 1955). It should be noted, however, that ZP osteoarthrosis is frequently asymptomatic for pain (Magora & Schwartz, 1976), but may incur biomechanical effects in other spinal structures that are the actual source of pain generation.

Traumatic insult to the ZP joints can produce pain. Hyperextension can result in impaction of the articular processes causing disruption of the joint capsule, inflammation, and activation of nociceptive afferents (Yang & King, 1984). Similarly, capsular disruption leading to tears, avulsion, or fracture–avulsion can be caused by rotary and/or rotation–compression torque–stress at the ZP joint (Farfan, 1985; Farfan et al., 1970; Sullivan & Farfan, 1975).

The meniscus of the ZP joint is susceptible to distortion during flexion-extension articulations (Bogduk & Engel, 1984; Bogduk & Jull, 1985). Hypothetically, mechanical entrapment of the fibro-adipose meniscus, which has been overstretched during flexion and buckled within the joint space during postural normalization/extension, could activate nociceptive fibers directly (via mechanical disruption or inflammation) or indirectly by disrupting the biomechanics of ZP joint stability and provoking compensatory muscular spasm. Additionally, it has been proposed that avulsion of articular cartilage can interfere with ZP meniscus function, disrupt ZP biomechanics during flexion/extension, and physically distend the joint capsule (Bogduk & Jull, 1985). This would pro-

duce localized inflammation, biomechanical ZP joint aberration, and pain.

The Intervertebral Discs

The intervertebral discs are innervated by a plexus of nerve fibers that weaves within the outer (loose) connective tissue of the annulus fibrosus and is continuous with the innervation of the vertebral periosteum (Hirsch et al., 1963; Roofe, 1940; Yoshizawa et al., 1980). The innervated outer portion of the annulus (known as the ligamentous region) is normally shielded from mechanical loading and chemical stimuli occurring within the central nuclear zone by the structural and functional arrangement of the inner component of the annulus fibrosus (known as the nuclear envelope region; Bogduk, 1997). Four pathologies of the disc are considered to be principally provocative for pain. These are disc degradation/internal disruption, nuclear herniation, torsional-load injury, and discitis.

Internal disc degradation involves progressive change of the matrix of the nucleus pulposus. A number of etiologic possibilities may lead to degradation. One hypothesis is that fracture of the discal-vertebral endplate may induce an autoimmune inflammatory response (Bogduk, 1991; McCall et al., 1985; McCarron et al., 1987); however, there are equivocal arguments against this possibility (Gronblad et al., 1994; Olmarker et al., 1989). It is more probable that endplate fractures directly disrupt the biochemical equilibrium of the nuclear matrix, lower nuclear pH, and engage metalloproteinases to incur disc degradation (Maroudas et al., 1975; Melrose & Ghosh, 1988). The endplate fracture itself is frequently asymptomatic and often spontaneously heals. Furthermore, degradation of the nucleus is often limited. However, if nuclear metabolic changes (due to age, nutritional status, or disease) have begun to occur, proteolysis can disrupt the water-binding and cohesive ability of the nucleus to maintain and respond to load pressures. This transfers load forces abnormally through successive layers of the annulus. Such loads can exceed the stress/strain dynamics of annular fibers and induce tears of the annulus (Scott et al., 1994; Skaggs et al., 1994; Stokes, 1987). In this condition, the internal arrangement of the disc is deranged by radial fissures (Bogduk, 1991). Such fissures are graded to characterize the degree of penetration through successive architectural layers of the annulus (Sachs et al., 1987). This grading system is provided in Table 16.3.

With progressive internal disc disruption, annular fissures may extend through the periphery of the annulus and lead to frank disc herniation. As the fissure advances to the outer layers of the annulus, chemo-inflammatory substances (e.g. phospholipase-A_2, prostaglandin E_2, adenosine-ATP, hydrogen ion, enzymes, and cytokines released from locally infiltrating inflammatory cells) may stimulate chemoresponsive C-fiber afferents in the annular perimeter (Elves et al., 1975; Jaffray & O'Brien, 1986; Olmarker et

TABLE 16.3
Possible Sites of Spinal Pain Generation

Structure	Innervation
Zygapophyseal joints	Medial branch, dorsal ramus
Periosteum of vertebral arch	Medial branch, dorsal ramus
Spinous and transverse ligaments	Medial branch, dorsal ramus
Ligamentum flavum	Medial branch, dorsal ramus
Deep paraspinal musculature	Medial branch, dorsal ramus
Intermediate and superficial musculature	Lateral branch, dorsal ramus
Skin	Lateral branch, dorsal ramus (cuneal nerve)
Periosteum of posterior vertebral body	Recurrent meningeal nerve
Posterior anulus fibrosus of disc	Recurrent meningeal nerve
Internal and basivertebral veins	Recurrent meningeal nerve
Anterior dura mater	Recurrent meningeal nerve
Posterior longitudinal ligament	Recurrent meningeal nerve
Anterior/lateral anulus fibrosus	Sympathetic trunk and gray ramus
Anterior longitudinal ligament	Sympathetic trunk and gray ramus

al., 1995). Alternatively, distention of the outer fibers of the disc, both by extrusive nuclear material and by increased pressure under load, evoked by structural disruption of the inner architecture of the nuclear envelope, are capable of activating high-threshold mechanoresponsive A-delta and polymodal C-fibers (Crock, 1986). Thus, a grade-3 disc disruption may or may not be painful, depending on the relevant involvement of nociceptive fibers in outer disc layers. Frank herniation can produce local spinal pain without radicular signs or symptoms or may advance to radicular presentation if the herniation is significant enough to compress or inflame the nerve roots. In addition, nerve endings in the dura and epidural adipose tissues may be activated by inflammatory substances released by the degenerative or herniated disc (Melmon et al., 1967; Nachemson, 1969; Zvaifler, 1973). Thus, disc degeneration and herniation may sensitize the innervation of adjacent spinal structures and produce pain and hyperalgesia.

Age-related changes, primarily in the biochemistry of the nucleus pulposus, can lead to loss of the discs' functional capacity to bear and distribute load forces, thereby increasing pathologic diatheses in older patients. With age, a progressive shift to anaerobic metabolism results in decreased synthesis and concentration of proteoglycans (Scott et al., 1994; Sedowfia et al., 1982), change in collagen content (Buckwalter, 1995), and loss of elastic fibers (Johnson et al., 1985) within the nucleus and nuclear envelope. These changes result in decreased water-binding capacity of the nucleus (Hirsch et al., 1953), diminished resiliency, and an increased capacity for deformation and pathologic distortion (Vernon-Roberts & Pirie, 1977). In contrast to previous reports suggesting that loss of discal height is a cardinal feature of age-induced pathology

(Lawrence, 1969), in actuality there is an approximate 10% increase in the height of most intervertebral discs with age (Twomey & Taylor, 1985). The decrease in the imbibitive capacity of the disc appears to be a more significant contribution to pathology of the subchondral bone of the vertebral bodies (Twomey & Taylor, 1983). These changes may contribute to endplate failure, advancing the process of intervertebral disc degradation as described above (White & Panjabi, 1978). Such synergistic changes in the disc and vertebral body may be responsible, at least in part, for an increase in spinal pathology and pain in the geriatric population. Co-morbid disease (e.g., osteo- and rheumatoid arthritis, osteopenia, Paget's disease of bone) also contributes to this clinical scenario in the aged, and can predispose these patients to discal injury as described below (*vide infra*).

Torsional–rotational injury of the disc occurs when it is stressed in lateral shear beyond its rotary limit when in flexion (Farfan, 1985; Farfan & Sullivan, 1967; Pearcy, 1990). The stress forces are greatest where the annular lamellae are maximally curved and where the most torsional strain is incurred (Bogduk, 1997). This tends to occur in the posterolateral area of discs with concave posterior surfaces, while circumferential distortion (annular tears) occurs posteriorly in discs with convex posterior surfaces (Farfan et al., 1972). In torsional injury, the circumferential tear involves the superficial, ligamentous layers of the annulus, which is innervated and therefore provocative for pain (during flexion and rotation; Farfan, 1985). The nucleus pulposus or nuclear envelope fibers are not affected per se; however, it is possible that torsion–rotation injury can occur (perhaps with higher frequency) in circumstances where the outer annulus is pre-stressed due to existing grade 2 or 3 circumferential fissures.

Discitis is a relatively rare, inflammatory condition caused by microbial infection subsequent to medically invasive procedures (e.g., discography). The infection and inflammation is limited to the disc and is evoked by the direct action of pro-inflammatory and pro-nociresponsive substances (e.g., cytokines, hydrogen ion, adenosine, histamine) on nociceptive small fiber afferents (Guyer, et al., 1988).

Dura and Nerve Roots

Dura mater is innervated by a plexus of unmyelinated nerve fibers from the recurrent meningeal (sinuvertebral) nerve. Innervation is greater in the anterior areas of the dural sac and root sleeves than in the posterior dural sac and epidural adipose (Edgar & Nundy, 1964; Groen et al., 1988). Inflammation of the dura has been shown to elicit both back pain and peripheralized, referred somatic pain (Bogduk, 1997; Walton, 1977). Inflammation of the dural sleeve subsequent to disc herniation can also occur as a consequence of chemical activation of dural nociceptive afferents by components of the extrusive nucleus pulposus

(McCarron et al., 1987). Disc herniation has been proposed as a mechanism through which inflammatory fibrosis can produce adhesions that tether the dura and evoke high-threshold mechanical stimulation and pain (Spencer et al., 1983). The phenomenon of peripheralization, in which there is a spread of perceived pain to a distal somatic structure from focal spinal insult, has been reported as a consequence of dural pathology (see Aina et al., 2004, for review). Pathologic involvement of the dura or the dural sleeve may produce this centrifugally, referred type of pain due to convergent inputs of sinuvertebral and somatic pain afferents within the dorsal horn. This process involves the co-terminal activation of second-order afferents producing a dermatomal referral pattern that may be independent of, or co-morbid with, specific radiculopathy (Merskey & Bogduk, 1994).

Bogduk (1997) explicitly contends that radiculopathy, a decrement in neural conduction caused by axonal compression and/or ischemia, characteristically causes weakness, but not uniformly pain. In contrast, radicular pain may arise from sequelae of radiculopathy or may be an independent event evoked by irritation of a spinal nerve or its root (Merskey & Bogduk, 1994). The most likely mechanism of radicular pain involves chronic inflammation following exposure to nuclear material and compressive ischemic activation of neurovascular nociceptive afferents (Franson et al., 1992; Saal et al., 1990). Leakage of phospholipase-A_2 can provoke significant inflammatory responses leading to radiculitis, edema of the nerve roots, immunocyte activation, and radicular/perineural fibrosis (Cooper et al., 1995; Olmarker et al., 1989, 1993). The fibers of the sinuvertebral nerve can become sensitized, leading to subsequent mechanical hyperalgesia produced by movement of the dural sleeve and nerve roots during even normal articulation of the spine.

Muscles

The muscles of the spine are extensively innervated; the majority of the deep paraspinal musculature is innervated by the medial branch of the dorsal rami. Intermediate and superficial musculature is innervated by the lateral branch of the dorsal rami and the intertransverse muscles are innervated by the dorsal and ventral rami (Bogduk et al., 1982; Cave, 1937). The spinal musculature can evoke both focal back pain and somatic, referred pain (Bogduk, 1997) as a consequence of micro/macrotrauma (strain/sprain), compensatory spasm, and myofascial trigger points.

Microtrauma and/or macrotrauma to superficial and intermediate muscles of the spine can produce local hyperemia, and the extravasation of pro-algesic substances that activate both A-delta and C-fiber afferents in these tissues (Newham, Jones, Ghosh et al., 1988; Vecchiet et al., 1983). Local hyperemia disrupts endomysial circulation and leads to accumulation of metabolic end products, reactive oxidative species, and disrupted ATP metabolism

(Bogduk, 1997). These biochemical factors have been shown both to directly stimulate afferent nociceptive fibers and to produce subsequent sensitization such that normal eccentric loading and contraction may evoke firing of high-threshold mechanoreceptors to produce pain (Newham et al., 1988). While these variables appear to be a cause of acute and subacute back pain, their role in the instigation and maintenance of chronic pain is less clearly defined (Garrett et al., 1989).

The pathophysiology of muscle spasm contributory to, and reciprocal with, back pain is somewhat controversial (Bogduk, 1992; Roland, 1986). The neuromechanical basis of spinal muscular spasm has been proposed and discussed relative to articular disorders of the spine (Porterfield & DeRosa, 1991). Briefly, afferent input (from fibers innervating spinal structures, spinal musculature, or both) can feedforward to influence firing rate and patterns of motor units involved in the maintenance of spinal stability, postural architecture, and/or biomechanical articulation. Volleys of afferent input are capable of generating aberrant activation of motor neurons driving the spinal musculature, and produce abnormal increases in spinal muscle tone and/or contractility (Roland, 1986). Bogduk (1997) states that these contractile differences may represent a transitory hyperreflexia. It remains unclear whether spasm is a consequence *of* chronic back pain, a contributory variable *to* chronic back pain, or both, dependent on circumstance.

The seminal work of Travell and Simons has described the etiology, pathology, and effects of myofascial trigger points in detail (see Travell & Rinzler, 1952, and Simons & Travell, 1981, for early reviews). It has been suggested that ZP joint pathology and activation of spinal nociceptive afferents may incur changes in efferent motor output. This can evoke both compensatory postures and articulations capable of affecting the physiology of the spinal and paraspinal musculature and producing trigger points (Schimek & Schimek, 1984; Simons, 1988), most specifically in the multifidi, longissimi, iliocostalis, and quadratus lumborum (Sola & Kuitert, 1954; Travell & Rinzler, 1952).

Ligaments

The paraspinal ligaments (anterior and posterior longitudinal ligaments, ligamentum flavum, interspinous, and iliolumbar ligaments) are differentially innervated by free nerve endings (Jackson et al., 1966; Wyke, 1970). However, these ligaments do not uniformly meet Bogduk's criteria for sites of pain generation and, therefore, must be considered individually regarding their possible role in spinal pain. The anterior longitudinal ligament is innervated by fibers from the sympathetic branches and gray rami communicantes, while the sinuvertebral nerves innervate the posterior longitudinal ligament (Groen, Balijet, & Drukker, 1990; Pederson et al., 1956). The longitudinal ligaments are structurally conjoined to the outer ligamen-

tous layer of the annulus of the intervertebral discs (Bogduk, 1997). The elastic nature of the ligaments and their responses along the stress–strain curve of (even excessive) spinal movement makes it improbable that they are a primary source of spinal pain. Rather, discogenic pain, as described above, may activate common afferents that innervate both the annulus and its overlying longitudinal ligaments such that, if sensitized, these afferents could discharge in response to mechanical input from the ligament (Bogduk, 1997).

The ligamentum flavum is only sparsely innervated and may actually lack afferent innervation in some regions (Yahia & Newman, 1989). As well, the highly elastic composition of the flaval ligament and its biomechanical tensile range do not render it easily vulnerable to traumatic injury (Bogduk, 1997; Kirby et al., 1989). The interspinous ligaments are considerably innervated by the medial branches of the dorsal rami (Yahia & Newman, 1989). Rissanen (1960) has shown that interspinous ligaments can degenerate and atrophy with age, increasing their vulnerability to biomechanical creep, distortion, and micro- or macrotears with spinal flexion. However, local anesthetic perfusion of interspinous ligaments was only modestly effective in reducing back pain in patients showing focal midline sensitivity upon postural flexion, suggestive of interspinous ligament pathology (Wilk, 1995). It is more reasonable to assume that degenerative laxity of the interspinous ligaments increases the vulnerability of other spinal structures (paraspinal muscles, intervertebral discs), recognized as viable pain generators, to injury.

The iliolumbar ligament is diffusely innervated by fibers of the dorsal and, to some extent, ventral rami (Bogduk, 1997). It is not well known whether this ligament fulfills the criteria for generating spinal pain in that it is difficult to clinically isolate, (anatomically) lying within the multifidi and erector spinae (Bogduk, 1997); is differentially developed across age groups and individual adults (Luk et al., 1986); and may functionally affect and be reciprocally affected by both the deep and intermediate musculature of the spine and the lower lumbar and lumbosacral joints (Collee et al., 1991; Ingpen & Burry, 1970). Macintosh and Bogduk (1986) maintain that the lumbar intramuscular aponeurosis, which forms a common tendonous attachment for the tendon of the lumbar longissimus to the posterior superior iliac spine (PSIS), may be the principal pain generator during lumbar flexion, rotation, and lateral bending. Thus, it seems that ligamentous pathology is only minimally contributory to primary spinal pain, but may exacerbate existing pathologies in other structures to produce postures and articulations that recruit these substrates to be nociceptive.

In sum, despite some disparity in the literature, it appears that pain arising from deep spinal structures (e.g., vertebral bodies, ZP joints, intervertebral discs, ligaments) is capable of affecting motor output to the spinal muscu-lature (putatively causing physiologic dysfunction and perhaps pain) and that primary pathology of the spinal muscles may be a source of pain. In either case, increased activity of mechanoreceptor afferents within spinal muscle tissue contributes to sensitization of second-order nociceptive neurons within the dorsal horn that may result in the phenomenon of maldynia. It has also been proposed that normalizing the tone of these mechanoreceptor populations may help to restore vertebral muscular activity, stabilize existing compensatory biomechanics, and perhaps induce specific pain modulatory mechanisms. At least hypothetically, mechanoreceptor-mediated feedforward and feedback axes appear to play a role in the maintenance of spinal biomechanics, pain generation, and pain modulation along a continuum of effect(s) from functionality to pathology.

Pain Pathways

Irrespective of what structures generate nociceptive input in the spine, this afferent information is conducted along A-delta and C-fibers that enter the dorsal horn of the spinal cord. The transduction, conduction, and transmission of pain and the anatomy of the nociceptive and analgesic pathways are discussed in considerable detail elsewhere in this volume. Briefly summarized, primary nociceptive afferents synapse upon both nociceptive specific (NS) and wide-dynamic range (WDR) neurons in laminae I, II, IIa, and V of the superficial dorsal horn. Significant modulation of the nociceptive signal is possible within the dorsal horn, and low- to moderate-level nociceptive afferent input is attenuated by spinal interneuronal mechanisms involving GABAergic, glycinergic, opioid (dynorphin, enkephalin), nitric oxidergic, and anadamidergic inhibition.

Second-order afferents aggregate in the dorsal horn, and the majority of these fibers decussate within the cord and ascend contralaterally as the (paleo- and neo-) spinothalamic tracts within the anterolateral column. The paleospinothalamic tract projects to the brainstem reticular formation (i.e., the spinoreticular subtract), with specific projections to the serotonergic raphe nuclei of the rostroventral medulla and the noradrenergic reticulomagnocellular nuclei of the caudal pons. As well, paleospinothalamic fibers project to the opioid-rich, mesencephalic periaqueductal gray (PAG) and periventricular gray (PVG) regions (i.e., the spinotectal subtract). These brainstem structures may be activated singularly or in synergy to evoke bulbospinal and centrifugal analgesia, respectively. Paleospinothalamic neurons ascend to project somewhat diffusely within several thalamic nuclei, which subserve distinct qualitative and quantitative components of the nociceptive signal, and which activate cortical and subcortical limbic structures to engage affective dimensions of pain. In contrast, the neospinothalamic tract

projects directly to the ventroposterior lateral (VPL) nucleus of the thalamus, an area involved in the somatotopic localization and intensity discriminative features of the pain signal(s). Thalamolimbic and thalamocortical pathways engage neuroanatomical regions including the cingulate, frontal and temporal cortices, amygdala, hippocampus, and hypothalamus, which subserve the cognitive, expectational, emotional, and perceptual aspects of pain. Cortical and limbic regions may also activate the PAG/PVG to facilitate "top-down" mechanisms of pain control that are co-terminal with, and contingent upon, specific expectational, emotional, or cognitive states (see Giordano, Chapter 3, this volume, for review). A basic overview of these pathways is schematically depicted by Figure 16.1.

Factors Affecting Spinal Pain: Sociocultural Influences

The complexity of the algesic neuraxis and the interactive involvement of several structures subserving cognition, memory, and emotion reveal that "pain" is phenomenologically greater than the somatosensation of nociception. Furthermore, patients are persons and do not live in sociocultural vacuums. As persons, they are embodiments of the ongoing interaction between genotype and phenotype and the influences of the time, environment(s), and cultures in which they live. This is compounded by the pre- and/or co-morbidity of disease; any or all of these variables can affect the biological, psychological, and behavioral extent to which the persistent somatosensory occurrence of nociception may progress to the multicomponential *illness* of maldynia. The ontology of pain, in general, and back pain specifically must account for the relative roles these variables contribute to the patients' pain experience.

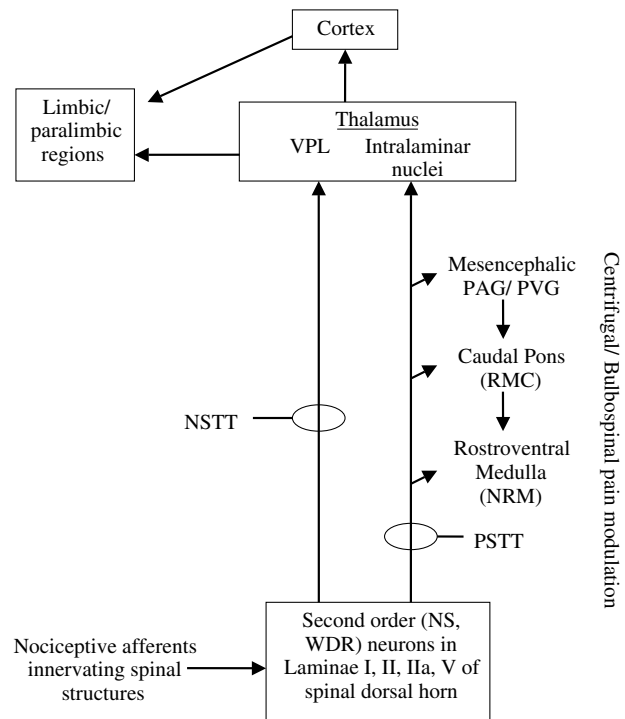
Scarry (1985) states that chronic pain deconstructs patients' (and perhaps families' and social cohorts') lives. This can certainly be true of back pain, and the classic triad of the "3-D pain patient," *d*isabled, *d*ependent (upon medicalization, remuneration, and others) and *d*epressed, is a common entity in the offices of primary and specialty care providers and pain management centers. The reciprocal relationship between depression and pain is well known and well understood. Although somewhat beyond the scope of this chapter, suffice it to state that neurochemical mechanisms of chronic pain can be directly contributory to the pathogenesis of depressive illness, particularly among patients in whom there is a defined predisposition or pre-morbidity (Williamson & Schulz; 1992). The circumstantial disability of chronic pain can also precipitate depressive symptoms (Williams & Schulz, 1988), and the pain experience has been shown to be greater in patients with depressive co-morbidity (Herr et al., 1993). Of course, there are patients that exacerbate symptoms in order to achieve sec-


FIGURE 16.1 Schematic diagram of afferent pain-transmitting and efferent pain-modulating systems. A-delta and/or C-fibers innervating spinal pain-generating structures project to the superficial dorsal horn and form synaptic contact with NS and WDR neurons. Considerable modulation of the afferent signal occurs by local and segmental inhibition within the cord (not shown). Axons of NS and WDR neurons decussate and ascend in the anterolateral columns as the paleo-and neospinothalamic tracts. The differential projections of these spinothalamic pathways are illustrated. PSTT activation of mesencephalic and/or midbrain substrates can engage descending inhibitory control (centrifugal-bulbospinal analgesia). Thalamic projections to somatosensory cortex mediate sensory components of pain. Activation of S-II, cingulated, limbic, and paralimbic regions subserves cognitive, emotional and expectational aspects of pain. (Details in text.) Abbreviations: NRM: nucleus raphe magnus; NS: nociceptive-specific neurons; NSTT: neospinothalamic tract; PAG-PVG: periaqueductal/periventricular gray region; PSTT: paleospinothalamic tract; RMC: reticular magnocellular nuclei; VPL: ventroposterior lateral nucleus; WDR: wide dynamic range.

ondary or tertiary gain, and such behaviors often reflect ongoing psychological enfranchisement with, and expression of, distress. (At worst, symptomatic overexpression for the achievement of secondary gain may reflect malingering and fall within the medicolegal purview).

However, this pattern is not universal and Carron et al. (1985), Raspe et al. (2004), Smith and co-workers (2004), and others have shown significant cultural and community-based distinctions in the perception of, behaviors, responses to, and acknowledgment of back pain. Socioeconomic status (SES) may influence a number of variables relevant to patients' presentation and

experience of back pain (Smith et al., 2001a, b; Thomas et al., 1999). Most obviously, SES is a strong determinant of access to health care, the absence or paucity of which could lead to progressive exacerbation of subacute pain to a more chronic, sensitized condition. Yet, this is not uniformly the case, and there is evidence that characteristics of hardiness, locus of control, and social cohesiveness can strongly contribute to low prevalence of back pain, even in lower SES communities (Thomas et al., 1999). Interestingly, one of the strongest contributory variables to pain is the notion of cultural pain-permissivity or a social expectation for both pain exacerbation and its expression (Mechanic, 1986; Smith et al., 2004). This appears to be particularly true among individuals with pre-morbid disease, pain, or both, for whom the sociocultural effect seems to perpetuate and augment both pain and treatment expectations (Raspe et al., 2004; Smith et al., 2004).

Hadler (2004) posits that sociocultural influence on illness is a component of the process of medicalization (see also Morris, 1998). This may well be true for maldynic back pain: while socioculturally acknowledging its existence, it remains something of a diagnostic and therapeutic enigma and thereby creates considerable discord in the social relationship between the medical community and persons who have become "patients."

This latter point speaks to Scarry's second tenet that chronic pain defies language (Scarry, 1985). There is not an effective semantic for pain, and back pain, by its complex, multifocal nature, emphatically reinforces this issue. The clinical semiotics of pain assessment often fails to convey objective value to the first-person experience of pain, leading to dissonance and frustration between patient and clinician. Many pain patients may overexpress their pain in an effort to convey the first-person impact of suffering across domains of their existence and in an attempt to recruit subjective pathos and objective unity with their clinician(s). For the clinician, understanding these dynamic variables is essential, and assessment of the patient with chronic back pain may require the development of semiotics for symptoms that are meaningful to both patients and clinicians. Equally important, however, is the establishment of semiotics that are resonant *across* medical disciplines that are based on mechanistic evaluation of the biologic, psychologic, and social factors contributing to the back pain specific to individual patients. Scarry's perceptivity of the linguistic defiance of pain may be well illustrated by the relative discord between clinical disciplines in defining and "naming" the locus and nature of the spinal lesion or dysfunction that is provocative for pain. A more uniform, mechanism-based terminology might allow for improved interdisciplinary heuristics and facilitate enhanced cooperativity of back pain care in a progressively pluralist medical society.

PART II

SPINAL MANUAL MEDICINE

As addressed elsewhere in this volume, there are numerous approaches and techniques to treat and manage chronic back pain. When examining the overall therapeutic armamentarium against maldynic spinal pain, it is important to consider the relevant specificity (and therefore the relative efficacy) of these approaches, whether used alone or in combination. Paradigmatically, it is best to take a mechanistic approach to the pathology, a patient-centered approach to its manifestations, and a combined or integrative approach to care and management. While the majority of studies suggest that acute and subacute back pain regularly resolves with stabilizing exercise, short-term rest, and conservative use of nonsteroidal anti-inflammatory agents (Cady et al., 1979; Nachemson, 1983; Waddell, 1987), chronic back pain may require more extensive therapeutics or management. Diagnosis is critical, and it is important to reiterate that evaluation of underlying pathology may not be identical to identification of pain generators that might be responsive to intervention. Often, a defined organic cause of pain is non-identifiable. Therefore, it is vital to address pain from a mechanistic viewpoint and engage in therapeutic approaches that effectively target these mechanisms. There is a significant body of literature to demonstrate the efficacy of anesthesiologic procedures in cases where ongoing pain is contributory to the cycle of dysfunction and neural sensitization. As well, prudent use of systemically administered anti-inflammatory and low-grade analgesic agents has utility in diminishing central or peripheral sensitization. In cases of defined orthopedic or neurologic instability, surgical approaches may be warranted; however, there is some controversy regarding the use of surgical intervention for patients who do not present with progressive neurological signs and symptoms.

The source of chronic spinal pain may be due to aberrant and hypertonic musculature, ZP joint dysfunction, and symptomatic disc extrusion without frank herniation. The former two conditions are obviously amenable to spinal manual medicine (SMM), and there is evidence to support that SMM may produce force-relevant distraction of vertebral segments in patients with disc extrusion, allowing for resumption of annular architecture and producing symptomatic resolution (Browning, 1988). Interestingly, there is also evidence to suggest that SMM may produce a more global, nonspecific analgesia (*vide infra*), although the mechanism(s) for such effects remain speculative.

Spinal manipulation is a historically old therapeutic tradition. Ancient writings and depictions display manipulation as a part of the healing practices used in widespread locations and cultures throughout the Old World and Eurasia. In the 1800s, spinal manipulation "re-

emerged" as part of folk healing traditions in Europe and the United States. At the turn of the century in the mid-western United States, two practitioner-level healing professions developed that relied on spinal manipulation as a primary means of treatment. Palmer and Still, the founders of the chiropractic and osteopathic professions, respectively, differed in their beliefs of the therapeutic effects and processes of spinal manipulation, but both acknowledged and promoted the beneficial role that spinal manipulation played in the health and restorative well-being of patients.

Despite the castigating climate fostered by the Flexner report, these professions survived through the 20th century and have established distinct niches within the post-modern medical community. While osteopathic medicine has become more assimilative to and integrated within the allopathic model, an expanding examination and progressive acceptance of chiropractic is becoming evident as a consequence of medicosocial and political support for application(s) in broader scope of public health care. Yet, it should be noted that spinal manipulation was not the sole domain of the chiropractic and osteopathic professions during the 20th century. Considerable work in the application, utilization, and refinement of various forms of SMM was conducted by Mennell, Cyriax, Paget, and many others, and types of SMM are components of physical therapy and physical medicine.

BASIC MECHANICS OF SMM

Spinal manual techniques essentially involve both soft tissue and hard tissue (i.e., joint relevant) components. The longitudinal work of Triano and colleagues (Triano, 1989, 1991, 1992, 2001; Triano & Gudavalli, 1990; Triano & Luttges, 1985; Triano & Schultz, 1997; Triano et al., 1997a, b; Triano et al., 2002) has shown that the mobilization component primarily effects elastic soft tissue elements while the low-amplitude impulse (i.e., manipulation) component predominantly effects spinal joints. It is unclear whether these components function individually or synergistically to effect spinal substrates. Application of manual techniques can involve moving a tissue or joint through its passive range of movement. This may engage the tissue to its elastic barrier and thereby activate mechanoreceptors beyond the physiologic limit incurred during active motion. This mobilizing phase is of obvious utility in instances of a defined muscular pain focus (e.g., spasm, trigger points, hypertonicity), which may incur restrictive barriers to movement or posture and produce compensatory motor recruitment and resultant alteration in biomechanics (Beal, 1953; Bourdillon & Day 1982). Mobilization techniques are characteristically applied with low velocity, engage a minimal thrust or impulse, and are frequently used as the basis of osteopathic SMM (DiGiovanna & Schiowitz, 1991; Lamax, 1975; Stiles, 1975).

Extending the application of manual force beyond the passive range into what is known as the paraphysiologic space moves the tissue to approach its anatomic barrier, reflecting the osseous contours of the joint and the ligamentous and tendonous end-range (Sandoz, 1976). The restrictive barriers within this range may include spinal/paraspinal muscular hypertonicity and mechanical impediments of the ZP joints (Giles, 1986). Although somewhat simplistic, and certainly not reflective of practice philosophy, the major distinctions between osteopathic and chiropractic SMM involve the principal use of mobilizing versus manipulative techniques, respectively. It should be noted that the specificity of one form of SMM as compared with another may be a function of the mechanism and substrates of pain generation and/or the ability of a particular technique to engage local or nonlocal pain alleviating or modulating mechanisms.

The osseous and soft tissue components of the spine may be conceptualized as a combined mass-damped and elastic biomechanical system (Gudavalli & Triano, 1999; Triano, 2001). The mobilizing phase of SMM engages soft tissue mechanoreceptors, while the peak velocity, impulse-manipulative phase engages joint-space mechanoreceptors (Triano, 2001). Although contradictory viewpoints exist, the cavitation caused by biophysical gas-phase shifts within the ZP joint synovial fluid appears to be generally an artifact of the velocity movement and not responsible for mechanoreceptor activation or mechanical restoration of the ZP meniscus (D. Meyers, & J. Giordano, unpublished observation). A variety of conceptual and practical systems of SMM have been developed and implemented. These use non-impulse mobilization as well as a number of impulse based approaches that employ variable velocities and distinctions in the biomechanics of tissue contact (Haldeman et al., 1992). Examples of these are provided in Table 16.4.

Spinal manual medicine is predominantly used against musculoskeletal conditions in which the major constellation of features are biomechanical and the principal symptoms are reciprocal pain and dysfunction. Within this treatment category the majority of SMM is employed against low back pain (Chapman-Smith, 2000). Studies examining the efficacy of SMM against chronic (noncervical) back pain have yielded somewhat varied results. A recent systematic review by Bronfort, Haas, and colleagues (2004) assessed the efficacy of manipulation and mobilization for both acute and chronic back (as well as neck) pain. The study focused on multinational randomized clinical trials (RCTs) published through 2002. The authors concluded that moderate evidence exists to support the efficacy of manipulation and/or mobilization and that both forms of SMM afford pain outcomes that are superior to placebo and at least equivalent to combined physical and pharmacotherapy. An earlier study illustrated generally effective trends but noted conflicting evidence regarding the effects

---

of manipulation versus placebo (van Tulder, 2001). Weiner and Ernst (2004) reviewed the literature addressing spinal manipulation (and other complementary and alternative approaches to persistent musculoskeletal pain) and drew attention to the similarity of outcomes between manipulative treatment and placebo (i.e., sham SMM) groups. These authors also expressed concern regarding safety issues relevant to adverse effects after SMM, although the majority of adverse effects cited were consequential to cervical manipulation (see also Ernst, 2002; Ernst & Harkness, 2001). Cagnie et al. (2004) report that while minor adverse effects were frequent the predominance of these were related to cervical SMM, with lesser effects observed for other spinal regions. As well, this study raised contention that direct correlation of effects of (noncervical) SMM might be difficult to ascertain as other treatments were frequently co-administered. Jonas (2000) emphasized that while serious adverse effects of SMM are rare, such adverse sequelae can occur and strategies for identification of pre-existing risk factors and guidelines for specific application of SMM need to be developed to reduce this risk potential.

Whether attempting to illustrate trends of efficacy or incidence of risk, a uniform advocacy is for further out-comes-based and mechanism-oriented research. Giordano et al. (2002, 2003) have discussed the need to develop and expand complementary medical research as a means to facilitate medical integration that maximizes utilization and efficiency within a public health model. However, the methodology of such research may be equally as important as its focus. While the RCT remains the *sine qua non* of biomedical research, its application beyond the disease-centered and/or pharmaceutical model may have some limitations (Jonas, 2002). Relevant to this, an important recurrent issue is what constitutes a sham treatment for SMM. This has been addressed by Triano et al. (1997a, b) and Triano and colleagues (Gudavalli & Triano, 1999; Rogers & Triano, 2003). Important considerations are the biomechanical parameters necessary to constitute SMM. In other words, what forces are required for therapeutic effect(s), and what are the nature and mechanisms of those effects? This becomes crucial when attempting to discern significant clinical outcomes produced by "real" SMM versus placebo. The question has been raised whether SMM may represent a nonspecific treatment or "placating" effect (Chapman-Smith, 2000). Refutation of such nonspecific effects was fortified by reports of distinct physiologic events induced by SMM including overall analgesia, altered muscle tone, and change in immunocyte activity (Brennan et al., 1994; Terrett & Vernon, 1984; Vernon et al., 1990). We posit that such effects may reflect a cascade of "top-down" mechanisms similar to those seen in other therapeutic approaches that are capable of eliciting a patient-centered response (Stefano et al., 2001). These putative pathways are depicted in Figure 16.2.

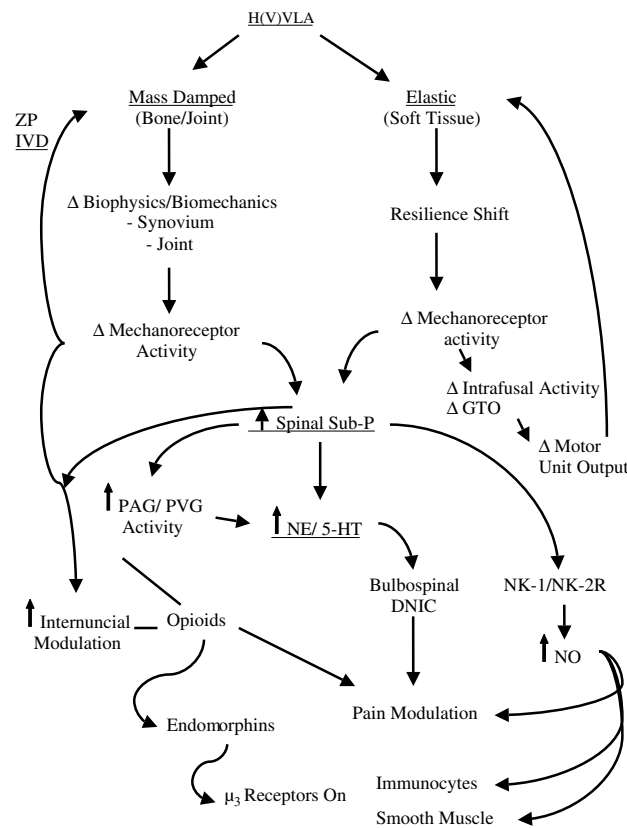
Such patient-centered responses are also referred to as the placebo response and involve discriminable neural and extra-neural mechanisms capable of affecting pain sensation, pain perception, cognitive state, and endocrine and immunologic processes (Lazar et al., 2000; Spiro, 1997; Stefano et al., 2001). The occurrence of such outcomes and mechanisms does not discount the therapeutic efficacy of a treatment that engages them; to the contrary, there is a building body of evidence to suggest that such mechanisms underlie diverse therapeutic approaches (Benson, 1996; Fields & Price, 1997). It may be that particular forms of SMM engage peripheral substrates to activate central neuraxes that produce both specific pain modulatory, physiologic, and salutary responses (refer to Figure 16.2). As knowledge of the network hierarchical properties of brain–body systems becomes increasingly well understood, the expanding epistemic framework allows for a more thorough evaluation of such "bottom-up"/"top down" (i.e., body–brain/mind–body) mechanisms. However, to effectively move in this direction, it is critical that academic and clinical institutions abandon political and parochial dogmatism that could restrict the ongoing reevaluation of scientific knowledge and impede progress (Flanagan & Giordano, 2002). Taken together,


FIGURE 16.2 Diagrammatic representation of putative mechanisms of pain modulation and physiologic responses evoked/induced by manual therapeutics of spinal substrates. High- or variable-velocity, low-amplitude manual force may affect both mass-damped and elastic spinal components. Respective changes in the biophysics or biomechanics of these structures affect mechanoreceptor activity to produce local mechanical effects and evoke an intraspinal substance-P pulse. Such afferent mechanoreceptor input and the resultant substance-P pulse may engage supraspinal mechanisms to induce centrifugal pain modulation. As well, substance-P may act locally within the cord to engage interneuronal afferent modulation via opioid and/or nitric oxidergic mechanisms. Systemic effects of opioids may include immunocyte and smooth myocyte modulation. This tentative diagram is representational of existing data and hypotheses and therefore remains a speculative model. (Refer to text for details and reference citations). Abbreviations: DNIC: descending noxious inhibitory control; GTO: Golgi tendon organs; H(V)VLA: high (or variable) velocity, low-amplitude manual force; 5-HT: 5-hydroxytriptamine, serotonin; IVD: intervertebral discs; NE: norepinephrine; NK-1/NK-2R: neurokinin-1 or -2 receptors; NO: nitric oxide; PAG/PVG: periaqueductal/periventricular gray regions; ZP: zygapophyseal joints; μ_3: refers to an opioid receptor.

epistemic, philosophic, and technologic developments become viable tools to more stringently define the effects, limitations, risks, and applicable benefits of SMM. However, it is also important that this research not be limited in scope to a single evidence domain, such as the RCT.

Future research needs to be conducted that uses rigorous mixed-methods to assess both qualitative and quantitative outcomes of SMM, and that affords new applications for existing strategies and develops new and novel methodologies to investigate mechanisms that subserve these more broadly defined outcomes.

Occupational Therapy

Lori T. Andersen, EdD, OTR/L, FAOTA, Barbara L. Kornblau, JD, OT/L, FAOTA, DAAPM, and Jill Broderick, MS, OTR/L

OCCUPATIONAL THERAPY HELPS PEOPLE PARTICIPATE IN THEIR LIVES

Occupational therapists play a significant role on the pain management team as the members who look at how pain affects one's everyday life and one's ability to participate in the important everyday task of life or "occupations." Pain treatment teams benefit from the occupational therapist's contribution regarding how the individual functions in the everyday activities of his or her life. Occupational therapy is so named because the term *occupation* refers to "everything people do to occupy themselves, including looking after themselves (self-care), enjoying life (leisure), and contributing to the social and economic fabric of their communities (productivity or work)" (Law, Polatajko, Baptiste, & Townsend, 1997).

Pain can hinder participation in life roles and associated activities. For example, Phyllis had to give up her job as a computer operator due to severe neck pain, which also compromised her role as a homemaker. Jane is not able to hold her new grandchild due to severe arthritic pain in both her shoulders. George is unable to bend at the waist to tie his shoes due to a work injury, which left him with chronic low back pain. Occupational therapy can help people like Phyllis, Jane, and George resume their life roles and daily activities or, in other words, regain their ability to participate in life.

Occupational therapists must graduate from an accredited academic occupational therapy program, pass a national certification examination, and meet requirements of individual states for licensure or certification. Occupational therapists have a minimum of a bachelor's degree in occupational therapy. Some have master's or doctoral degrees in occupational therapy.

ROLE OF OCCUPATIONAL THERAPY IN PAIN MANAGEMENT

An essential aspect of occupational therapy is in the creation of a therapeutic milieu during both evaluation and treatment of the client. This includes creating a subtle shift in the client's expectations from being "treated" to a process in which he or she must actively participate in occupational therapy intervention. Occupational therapy is not a "passive" therapy, but rather a "doing" therapy, actively involving the client. All intervention actively involves clients performing, responding, and using feedback from the process to enhance positive change in behavior as it pertains to their perceptions, cognition, or ability to perform tasks in various environments or contexts. In this chapter, a case study illustrates how occupational therapy intervenes with clients experiencing pain to enable them to participate in their life roles and daily activities.

CASE STUDY

John Smith was living the American Dream. He was working for the power company as a power line installer and repairer. He was earning a good salary, so Mary, his wife of 15 years, no longer had to work. She could stay at home to care for their two children, one boy (age 7) and one girl (age 4). For the first 6 years of their marriage, John attended school and then worked various jobs with electrical contractors. Mary worked as a receptionist to help

make ends meet. When John landed the job with the power company, they realized their dream of buying a house and starting a family.

The new house had plenty of room for family "additions" and was perfect for entertaining their close-knit family and friends. A dedicated family man, John coached his son's Little League team. He recently built an outdoor "club house/doll house" for his daughter using his woodworking skills. To him, woodworking was a relaxing occupation — one that he valued and helped define him. John used his computer to search for and draw up plans for his construction projects. He was planning to build a new wood deck on his house when he was injured on the job.

John hurt his back when a heavy toolbox started to fall off a slow moving company truck. Reaching out to try to prevent the toolbox from falling, he twisted his back and was thrown to the ground. John was hospitalized for a few days with severe back pain and then sent home. He was unable to return to work.

John's doctor referred him to therapy with the goal of returning to work. He started attending therapy every day, but he feared reinjuring himself and he feared what might happen when he returned to work. He knew he wouldn't be able to climb poles or pick up the heavy tools and supplies and he didn't have the flexibility in his back to get into "tight" areas. He soon quit attending therapy sessions.

John was still experiencing severe, chronic back pain 6 months later. He was having difficulty with some of the simplest tasks — rolling and moving in bed, getting in and out of the bathtub, bathing and dressing himself, including tying his shoes. Because of the pain he experienced while bathing and dressing, he dreaded these tasks, and usually delayed his morning routine or even avoided it for the day. His appearance suffered. John was uncomfortable in most any position — sitting, standing, or lying. When standing or walking he would often try to brace himself to minimize the pain by using his extended arms on a table or countertop. His movements were painful and awkward. He tried to avoid reaching for or picking up anything, restricting his participation in many daily living tasks. The pain made it difficult to sleep at night. He was tired constantly. The lack of sleep made him cranky and contributed to family arguments. Unable to sit for more than 20 minutes at a time without discomfort, John avoided trips in the car and trips in airplanes. Family outings and vacations were compromised. Friends and family came less frequently to visit. His plans for the wood deck, and many pleasurable afternoons with his family, came to a halt. He had to quit his volunteer work as coach of his son's Little League team. His son did not understand why.

As John was not able to go back to work, he collected worker's compensation. He filed suit against the toolbox manufacturer for wrongful injury from a defective product. His worker's compensation case and his third-party action dragged on through the administrative process and the courts. Eventually, the family's financial situation suffered and Mary had to go back to work to make ends meet. While it was a difficult adjustment to become the "breadwinner," she was happy to get out to the house as her relationship with John had suffered. John now became the "homemaker," reversing roles with Mary, albeit on a limited basis. Because of the pain, he was not able to perform all the chores that Mary did, such as meal preparation, housekeeping, shopping, and driving the children to various activities, not to mention the handyman activities he used to do. This further strained the marriage and family life. Mary felt overworked and resentful. The children didn't understand why their father was acting differently toward them. John felt useless, depressed, and hopeless. The American Dream had become a nightmare, and he didn't know what to do about it.

The devastating effects of pain are quite evident in this case study. Not only is pain a physical problem, but pain also restricts an individual's participation in various life roles and activities, what one wants to do and what one needs to do. For example, in the case of John Smith, participation in his roles as "husband," "father," "worker," "productive member of society," "volunteer" (Little League coach), "friend," and "family member" had been restricted. Participation in daily living tasks such as simple self-care, household management, parenting, work, and hobbies was also restricted. John not only suffered physically, but financially and psychologically as well. The effects of pain reached beyond the individual to affect the entire family and social system of the individual.

OCCUPATIONAL THERAPY EVALUATION

Occupational therapists look at the person, the tasks he or she must perform, and the environment in which performance occurs to determine if the factors involved in the person, task, and environment will support participation. To do this, the occupational therapist works in collaboration with the client to identify the client's everyday roles and the environments in which the client needs to function. The occupational therapist also analyzes the tasks or activities in which the client wants and needs to participate.

The evaluation process in occupational therapy is a two-step, client-centered, collaborative process (American Occupational Therapy Association, 2002). During the first step, the occupational therapist develops an occupational profile by looking at the client's needs, problems, and concerns about how he or she performs desired and expected daily activities. In the second step, the occupational therapist evaluates the client's abilities in all areas of occupational performance — activities of daily living (ADL), instrumental activities of daily living (IADL), education, work, play, leisure, and social participation (American Occupational Therapy Association, 2002). The occupational therapist may use interviews, observations,

informal testing, and formal testing such as functional capacities evaluations, the Canadian Occupational Performance Measure (a client-centered measure of self-perception of abilities), and various pain scale measures.

The John Smith case study example illustrates this part of the evaluation process. Using a client-centered approach, the therapist would determine why John is seeking occupational therapy services. What is John's occupational history — his values, interests, and meaningful occupations? What are John's priorities and expected outcomes? Does he want to improve his occupational performance? Does he want to prevent further injuries? Does he want to improve his quality of life? Does John see the need to change his roles or adapt to his new situation?

A significant factor that often interferes with performance and participation is the role change that often accompanies chronic pain. A perfect example of this role change happened to John. After finding himself unable to work for more than 6 months and his family in severe financial trouble, his wife returned to work and he took on the roles of "homemaker" and "mom." The occupational therapist will also find that some of John's life roles have been disrupted. He no longer is able to participate with his son's Little League or other hobbies, his social participation with friends has declined, and his family life has suffered.

During the second step, the occupational therapist assesses the client's occupational performance using various assessment tools. What areas of occupation can John perform successfully? Which ones cause John problems or put him at risk for reinjury? During this step, the occupational therapist focuses on occupational performance issues and looks at factors that might support performance or hinder performance. This step of the evaluation includes looking at motor skills, process skills, and client factors or abilities (American Occupational Therapy Association, 2002). In John's case, as in many other cases of clients experiencing chronic pain, pain is one of the factors that can hinder performance and limit flexibility, strength, and endurance. John fatigues quickly, has difficulty lifting and carrying items, and has difficulty with simple tasks such as tying his shoes and rolling over in bed. Also in John's case, as with many others, the depression that accompanies chronic pain can hinder performance, affecting motivation and self-esteem. Inadequate coping skills, stress, medication side effects, and sleep disturbance that accompany chronic pain can also hinder performance.

From the onset of occupational therapy intervention, goals for discharge are discussed. The client must start to develop an image of participating and reengaging in former or new roles. Again, the collaborative process is at work as client and occupational therapist identify what the client hopes to accomplish in occupational therapy. Together they develop long-term and short-term goals to lead the client back into activities and roles. An orga-

nized and sequential process is devised using clear behavioral objectives that serve as an unstated contract about expectations of performance for the client and therapeutic outcomes.

OCCUPATIONAL THERAPY INTERVENTIONS

Occupational therapy intervention generally focuses on "changing" the person, adapting the task, adapting the environment, or helping to redesign lifestyle to facilitate a person's participation in life roles and activities.

CREATING A "CHANGE" IN THE PERSON

Bearing witness to the client's pain is a critical part in the development of the therapeutic relationship in occupational therapy. The client with pain often experiences a great deal of grief and loss. Many times the process of identifying the impact of occupational performance problems during the evaluation crystallizes clients' awareness regarding their inability to perform as they did before their accident or injury. The occupational therapist's ability to validate clients' experience and frustrations helps clients to develop more realistic perspectives on their functional status while fostering a respectful and trusting relationship. For many clients, past encounters with the medical community resulted in failure to alleviate pain or improve status and inadvertently may have contributed to greater feelings of helplessness. The occupational therapist can play a pivotal role in changing the client's perspective from acceptance of the helplessness characteristic of the sick role to active participation required in other life roles. Centering treatment on "occupation" (as defined by everyday activities and organized by role choices), acknowledging loss, and the use of a collaborative approach in occupational therapy sends a powerful message to clients that they are entering into a dynamic phase of managing their chronic pain and returning to function.

Such is the case with John, who terminated therapy as he feared reinjury. His life spun out of control. The occupational therapist will establish a respectful and trustful relationship, giving him control and actively involving him through use of occupations and goals important to him.

Client Education — Modifying the Perception of Disability

The initial assessment provides a reference point regarding clients' perceptions of disability as well as functional status as they pertain to occupation. The occupational therapist is challenged to provide methods to alter this perception and enhance motivation as well as participation in daily activity. Maladaptive behavioral responses such as fear of movement (due to fear of exacerbating pain),

posturing, expectations of failure, anxiety, and related stress responses serve as barriers to progress. Client education directed at breaking down these barriers is used to help the client regain control and enhance motivation in all areas of performance.

Energizing Sense of Control

Client education involves teaching individuals that there are many different ways to be successful. Whether the occupational therapist chooses to use a restorative approach or teach skills to compensate for functional loss by using an alternative method to perform a task or adapt tasks and/or environment, all modes seek to create the client's ability to accomplish tasks. Problem-solving techniques and new skills provided in occupational therapy add to the client's belief that he or she has options and can effect change. There are many skills the occupational therapist can help a client to develop:

- Altering perception of function/loss
- Time management skills
- Organization skills
- Habit exploration/modification
- Role modification/role balance
- Use of relaxation techniques (diaphragmatic breathing, visualization, imagery, biofeedback)
- Use of proper body mechanics
- Incorporation of ergonomics
- Improving functional capacities
- Incorporating energy conservation techniques
- Pacing skills
- Assertive communication

Martensson, Marklund, & Fridlund (1999) found that a rehabilitation program focusing on developing ego-strength, awareness of resources for pain control, education on body functions, relaxation techniques, and ergonomics increased clients' self-confidence. These clients were able to manage symptoms of pain, they were less fearful of pain, and they returned to previous activities with fewer pain complaints (Martensson et al., 1999). The belief in the ability to be successful as well as feeling confident about using new skills adds to the client's motivation to participate in occupational therapy and pursue therapeutic goals both in the clinic and in the home environment. The therapist and the client explore these skills during the occupational therapy process. The question of improving function becomes less about what the person can do but rather how he or she can do it.

Another core aspect of client education for the client with chronic pain is providing an understanding of behavioral changes that happen during the course of coping with chronic pain. Client education about specific aspects of a diagnosis appears less useful than developing an aware-

ness of how people react to pain and develop subsequent stress-related responses (Rogers, Shaer, & Herzig, 1984). Educating clients about pain behaviors such as bracing, holding maladaptive postures, and reducing active movement in an attempt to limit pain helps break the pain cycle from becoming a downward spiral of further loss of physical capacity and function. Occupational therapy education provides information about these areas via use of body awareness activities such as videotaping movement or using photography during functional tasks and biofeedback to demonstrate faulty movement patterns. Posture and body mechanics instruction is provided and applied to daily activity with an emphasis on restoring movement and function while using motor patterns that reduce the likelihood of further injury, strain, or exacerbating pain. Studies show that education in good body mechanics during lifting can change behavior, improving lifting styles and incorporating good body mechanics (Lieber, Rudy, & Boston, 2000; McCauley, 1990). Clients are taught they have options regarding how to use their bodies and often gain a greater sense of confidence with movement.

To enhance perception of control, occupational therapy also provides education regarding techniques to improve self-regulation, in particular to reduce stress and pain-related symptoms. Relaxation training, using diaphragmatic breathing, body scans, visualization, imagery, and shifting attention (Fehmi, in press), can be taught in the clinic to reduce excessive autonomic nervous system output that contributes to excess muscle tension and feelings of anxiety. Occupational therapy intervention considers lifestyle factors that contribute to stress alongside relaxation training to focus on establishing a healthy balance between work (including self-care and home care initially then branching to other work-related roles), rest, and leisure.

Clients learn to take a wider view of the pain experience, looking into premorbid and current behavioral patterns that may influence stress and pain. All these factors effect arousal of the central nervous system. The concept of self-regulation can be expanded to include the choices people make in lifestyle and balanced activity — factors also considered in fostering "wellness." Certainly occupational therapy seeks to address many goals — from increased function to resuming roles to a life lived well.

Making Use of Feedback

Inherent in the process of engagement and collaboration is the use of feedback. The occupational therapist may initially provide feedback about changes in perception regarding stress, pain behaviors, goal choices, etc., but eventually encourages clients to start to use information about control of symptoms and function on their own. For example, using electromyographic (EMG) biofeedback may initially help clients reduce muscle tension and/or

bracing patterns. Over time, clients learn to increase body awareness to know they are tensing muscles and can then alter that behavior. For example, the occupational therapist observes John's posture and notes he is shifting his weight to the right, flexing his trunk to the right side, holding the torso forward, and flexing the neck toward the right shoulder. The occupational therapist determines he is creating additional muscle imbalance with this posture and tensing of muscles, which is likely to create additional pain over the time. John may not even realize that he favors his left side. However, using EMG biofeedback, John can learn to gradually correct this posture and reduce excessive muscle tone in numerous muscle groups involved in holding this position. The reduction in muscle tension and regained symmetry may help to reduce overall levels of pain.

Pain itself can be used as feedback to the person who has returned to many activities but starts to "overdo" participation and flares up symptoms. Clients may use pain as feedback and decide to pace their participation in activity so they can remain active but include short rest breaks when they feel fatigued. The use of various types of feedback, particularly during routine daily activities demonstrates the integration of therapeutic concepts and provides the impetus to facilitate change, return to function, and regain a sense of self-confidence.

ADAPTING THE ACTIVITY

Modification of an activity is an intervention approach used by occupational therapists (American Occupational Therapy Association, 2002). Working closely with the client, the occupational therapist analyzes the demands and component parts of activities the client wants and needs to do. By analyzing the activity and taking into consideration client preferences, an occupational therapist identifies various ways to modify or adapt an activity. Participation in an activity in spite of a limitation in body function or structure is the focus of the modification or adaptation. The occupational therapist may recommend doing the activity in a different way, such as incorporating good body mechanics, joint protection techniques, or energy conservation techniques into the activity. The occupational therapist may also recommend using a tool or an adaptive device that protects joints, saves energy, or minimizes pain during an activity.

Use of an adaptive device helps to break the pain cycle and helps the client regain functional abilities. The occupational therapist evaluates which adaptive devices the client will benefit from, assists the client to obtain these devices, and educates the client in the use of the devices.

For example, a "reacher" is a tool that extends one's reach when grabbing/picking up items. It eliminates the need to bend to the floor or to reach up over head if trunk flexibility or reaching ability is limited because of pain.

Use of this tool minimizes stress on the spine. John can use a reacher to extend his reach to put his pants on over his feet or to reach up overhead in the kitchen to get a food item. A sock aid and a long-handled bath brush are other adaptive aids that are used to extend reach for lower extremity dressing and bathing, respectively, minimizing stress on the spine. Other examples of adaptive aids are the long-handled shoe horn and elastic shoelaces, which eliminate the need for reaching to tie shoes. Properly adjusted, the elastic shoelaces create slip-on shoes that John could put his feet into with the help of the long-handled shoe horn.

Pain limits energy and participation in activity. One study found that clients with pain report temporal imbalances in activities, activities require more effort, and clients become stressed and tense because of the pain (Mullersdorf, 2002). Clients can often learn to be sensitive to the different aspects of their pain and use this information to modify activities and facilitate participation (Peolsson, Hyden, & Larsson, 2000). Use of energy conservation techniques enables a client to complete all daily living tasks within his or her energy reserve or pain limit. The occupational therapist works with a client to determine in which activities the client wants and needs to participate. The occupational therapist analyzes the activities and assists the client to plan his or her daily or weekly activities to distribute high-energy and/or physically demanding activities throughout the day or week.

For example, John may distribute his morning self-care activities throughout the morning. He might take a shower and wrap himself in a terry cloth robe to dry, modifying how the activity is done. This would eliminate the task of using a towel and bending to reach all areas of his body, also eliminating stress on the spine. John could rest while eating his breakfast and dress himself after breakfast. The energy conservation technique of sitting on a chair or a stool while performing grooming activities such as shaving and brushing his teeth will also protect his back by minimizing pain from standing and bending forward over the sink.

In another example, John may be able to complete high-energy or physically demanding tasks such as a household repair or woodworking activity on one day and play catch with his son on another day. To enable John to play catch with his son, the activity could be modified by having John sit in a chair that facilitates good postural alignment. This would minimize stress on his spine. Facilitating return to his occupational role of being a father and coach, it could also help improve the skills of his son and son's teammates who would have to be more accurate in their throwing.

Other energy conservation techniques include using equipment that minimizes energy output. This equipment frequently protects the joints of the body as well. Use of a rolling cart will help John to transport items that he

needs to use for various activities such as transporting tools for handyman repairs. He will avoid lifting and carrying items, limiting stress on the spine while participating in activities.

When modifying or adapting any activity, it is important that the person practice the activity in the new way so it becomes habit and routine. Ensuring that the new method of performing the task becomes routine or habit assists the client to resume normal activities and normal occupational roles.

Modifying the Environment

Modification of the environment is another intervention strategy used by occupational therapists. Activity priorities are again determined by the client. The occupational therapist analyzes each activity and the environment in which the activities take place to determine if environmental modifications will facilitate the client's participation. Environmental modifications, as with activity modifications, may assist in saving energy, protecting joints, and minimizing pain.

Organizing one's work area so that it is easy to gather tools and materials for a task saves energy and minimizes stress on the spine. Items used together should be stored together. Most frequently used items should be stored in an easy-to-reach location that does not require bending or reaching overhead — generally around waist to shoulder height. For example, shoes can be placed in a shoe bag over a closet door between waist and shoulder level. This concept can be applied to certain tools and supplies John might use for handyman activities. These tools and supplies should be stored in a location, around waist level, so that John is able to reach them without bending. If used frequently, tools and supplies, such as drills, miter saws, may also remain setup, saving energy from setup and restoration each time.

In John's case, consideration may need to be given to the height of work surfaces to encourage proper musculoskeletal alignment. Analysis of activities and activity demands will help determine appropriate height of work surfaces. Changing the height of work surfaces may be accomplished by placing blocks under a table to raise the height or perhaps providing a chair or stool to position the client at the appropriate work height. Provision of the chair or stool saves energy as well. The work area can also be set up so items are within easy reach while working, thereby avoiding bending and stress on the spine.

Setting up John's computer workstation to support musculoskeletal alignment is another example of adapting the environment to prevent and/or reduce pain. The workstation chair should be designed to provide support for John's lower back while positioning the head neck and trunk in line with each other, to support his elbows and position his forearms in line with his wrists, and be adjust-

able so his feet are flat on the floor. The top of the monitor should be around eye level (Occupational Safety and Health Administration, 2004). It is also important to ensure that other aspects of the environment, lighting, temperature, noise minimize stress on the person using the workstation.

Life Style Redesign

Clients who experience pain show deficits in their occupational performance from role changes, barriers to their performance, and difficulties adapting to their lives. In addition to changes to the environment, which can facilitate performance and participation, changes in the daily tasks one performs or in one's lifestyle make a difference in one's health and one's ability to participate in life activities.

Clients experiencing pain often find themselves lacking in the daily meaningful activity in which they had participated. For example, John believes he can no longer participate in woodworking, a significant preinjury meaningful activity. He finds himself unable to coach his son's Little League. He has adopted the role of "homemaker." The lack of meaningful activities in his life and the role changes put John's pain in the forefront and allow his pain to take over his life.

Research shows that incorporating meaningful activities into daily routines in one's life promotes heath, wellbeing, and participation in life. In occupational therapy we refer to this as "lifestyle redesign." Lifestyle redesign is an occupational therapy intervention process that provides clients with strategies to control their own lives by adopting daily routines of meaningful activities to promote health, well-being, and participation in life. Lifestyle redesign has proved successful in a variety of treatment contexts (Clark et al., 1997; Luebben, 2000).

Lifestyle redesign structures a person's day with meaningful activities that remove barriers to performance. For clients who experience chronic pain, barriers that require removal include pain, stress, lack of coping skills, the belief that one's pain prevents participation in life's activities, and others. Lifestyle redesign takes a collaborative effort between the occupational therapist and the client. Together they find activities that are meaningful to the client and can thus break down the barriers to participation. People participating in purposeful activities have longer tolerance for pain than those participating in nonpurposeful activities (Heck, 1988). Participation in meaningful tasks helps to break the pain cycle and get people back to "doing."

Some of the activities clients with pain need to incorporate into their routine include activities and strategies that relieve symptoms associated with chronic pain. These activities need to become an integral part of the daily routine activities in one's life — not just a "therapy experience." Some of these activities one might include in lifestyle redesign for individuals with chronic pain include aquatic therapy, Tai Chi, and yoga.

Aquatic Therapy

Aquatic therapy takes advantage of the buoyancy and resistive properties of water, and the soothing properties of heat to promote increased movement with decreased pain. Water walking, water dancing, or other water exercises incorporated into one's daily routine can increase one's participation in life while increasing pain-free movement and decreasing pain. Research has shown the benefits of aquatic therapy for individuals with fibromyalgia, osteoarthritis, rheumatoid arthritis, low back pain, and a variety of musculoskeletal disorders (Hall et al., 1996; Konlian, 1999; Mannerkorpi, Ahlmen, & Ekdahl, 2002; McNeal, 1999; Prins & Cutner, 1999; Sim & Adams, 2002; Wyatt et al., 2001. These studies show benefits that include increases in range of motion, pain-free movement, self-esteem, and endurance; improved sleep; and decreased pain, stress, and symptoms of depression. Occupational therapy intervention incorporates aquatics into one's daily routine, not merely for the sake of exercise but to facilitate an overall, big-picture lifestyle redesign.

Tai Chi

Tai Chi is a centuries-old form of exercise that combines slow, gentle, coordinated movements with focused deep breathing and relaxation. Tai Chi is usually done in a group setting. Occupational therapists recommend incorporating Tai Chi into one's daily routines as part of the lifestyle redesign process for clients experiencing chronic pain. Although most of the studies to date have used small sample sizes, these studies have shown that regular Tai Chi decreases the pain intensity scores in older adults with chronic arthritis pain (Adler et al., 2000), decreases perception of joint pain and stiffness and perceived difficulties in physical functioning in older woman with osteoarthritis (Song et al., 2003), and achieves significant improvement in symptom control and health-related quality of life in individuals with fibromyalgia (Taggart et al., 2003). Although these and several other studies support Tai Chi's role in improving quality of life and decreasing pain, Wang, Cellet, and Lau's (2004) recent systematic review of 47 studies of Tai Chi's effect on health outcomes in people with chronic conditions suggests that more rigorous studies are needed to properly evaluate the effects of Tai Chi on health.

Incorporating Tai Chi into one's daily routine contributes to one's lifestyle redesign by giving clients experiencing chronic pain a starting point to participate in mild, relaxing exercises in a social environment. Decreasing pain and other symptoms, combined with increased participation, can give meaning to clients such as John who have not been able to participate in any of their normal everyday activities. This may be the first step to establishing new routines of everyday life.

Yoga

Yoga is a centuries-old mind–body–spirit intervention practiced though different methodologies, which all, to some degree, focus on movement, postures, concentration, consciousness, healthy lifestyle, and controlled breathing. Yoga can occupy a significant role in the lives of individuals experiencing chronic pain by decreasing pain symptoms and thus increasing the ability to participate in normal routine activities.

Research shows that yoga can contribute to the relief of pain-related symptoms in a number of contexts. In one study, clients with osteoarthritis in their hands reported a decrease in pain during activity and an increase in finger range of motion following a regularly scheduled course of yoga intervention (Garfinkel et al., 1994). Garfinkel and colleagues (1998) found that individuals with carpal tunnel syndrome experienced, among other things, a reduction in pain and an increase in grip strength following a regular series of yoga-based intervention. Researchers report that individuals with chronic pain from migraines, osteoarthritis, neck pain, and other sources, who participated in regularly scheduled yoga classes all reported some improvement. The improvement was measured by clients' reports of a decrease in the use of pain medication, decreased levels of anxiety, and an increase in the ability to participate in everyday activities at home (Linz, 2004; Martin, 2001).

While these studies look promising and a plethora of anecdotal reporting exists to back up those findings, as with the Tai Chi research, more rigorous research is needed to further support yoga's efficacy with clients in pain. A systematic review of more than 300 articles on the potential health benefits of yoga reports that while preliminary evidence shows yoga may be beneficial when used in conjunction with traditional treatment interventions for, among other conditions, stress, anxiety disorder, and depression, further research is needed in better-designed studies with larger samples of participants (Harvard Medical School, 2003).

If clients experiencing chronic pain find yoga helpful to their symptom control, it can be a meaningful activity to incorporate into a lifestyle redesign program as a step back toward the goal of participation. Participation in yoga, Tai Chi, and aquatics also functions to begin a role change back to a participating individual in society as part of the lifestyle redesign process.

SUMMARY

Occupational therapy's focus — to ensure a match between the person, environment, and occupation (task) — relies on interventions that can change the person and modify the task or environment so people can participate in their life roles and activities. Occupational therapy plays

a vital role in the pain management team, to bridge the gap between individuals identifying themselves as people in pain and as participating members of society.

Physical Therapy and Pain Management

Tom Watson, DPT MEd, PhD, DAAPM

INTRODUCTION

Physical therapy intervention dates to the ancient Greeks, ancient Egyptians, Chinese, and Romans, who used heat, sunlight, electric eels, massage therapy, and manipulation. Physical therapy today utilizes physical agents including modalities such as heat or cold, electricity, light, magnets, ultrasound, traction, manual therapies such as manipulation or mobilization, and therapeutic exercises. Pain management is always a team approach and coordination among medical doctors, physical therapists, chiropractors, psychologists, pharmacists, and other health care practitioners is of primary importance for the patient to reach an optimal level of function with adequate pain resolution or control.

Physical therapy today consists of proper evaluation and examination of the body's musculoskeletal and neurological systems. This will include a history, a review of related diagnostic interventions such as x-ray and laboratory, and a structured examination of range of motion, strength, sensory integrity, gait, locomotion, balance, joint mobility and function, posture, and location of pain in order to identify the tissue in lesion. Low back pain is the most frequent diagnosis seen by physical therapists. Part of this chapter is directed toward low back pain.

Following a thorough evaluation and examination, therapeutic interventions are based on the findings or the tissue(s) in lesion. Therapeutic interventions consist of alleviating the impairments, functional limitations, or pain and improving motion, function, and life activities. These interventions include but are not limited to physical agents; electrotherapeutic modalities; manual therapy techniques including manipulation, mobilization, and soft tissue massage; therapeutic exercise including strengthen-ing–coordination–function, activities of daily living, use of proper body mechanics, self-care/home program and pain management techniques, instruction in adaptive devices such as orthotics or prosthetics, and instruction in prevention of further injury or pain.

To treat pain, one must understand the process of pain. Various modalities and procedures are used to inhibit or alleviate pain based on the category of pain and the type of nerve fiber transmitting the nociceptive information. Pain, according to the IASP (International Association for the Study of Pain), is "an unpleasant sensory or emotional experience associated with actual or potential tissue damage and described in terms of such damage." Pain is the primary reason for visits to a clinician, according to Watson (1995a). Pain always evokes a sensory or emotional response. When pain occurs, suffering and pain behaviors follow. Pain is classified in three categories: (1) acute: lasting 4 to 6 weeks; (2) subacute: lasting 6-weeks to 6 months; and (3) chronic: 6 months or symptoms lasting longer than the anticipated time for recovery. The brain records pain experiences in the thalamus, sensory cortex, and limbic system. Pain is transmitted to the brain through the neurological process of nociception. Nociception occurs when tissue is damaged and chemical or endogenous agents are released. These agents include bradykinins, serotonin, cytokines, protons, sensory neuropeptides, and arachidonic acids that include leukotrienes and prostaglandins. Special nerve endings or type IV mechanoreceptors, i.e., free nerve endings, absorb these chemicals and transfer the information to the spinal cord. The main nociceptor acting nerves are A-beta fibers, which are thickly myelinated, mostly sensory, and 10% transmit pain; A-delta fibers, which are thinly myelinated and transmit sharp/lancinating pain; and C-

fibers, which are nonmyelinated fibers usually associated with dull or chronic pain. Pain transmission enters the spinal cord via the dorsal horn. Information from nociceptor fibers is transferred through the dorsal horn to one of six lamina or levels. Information from A-delta fibers terminates in lamina V and I, C-fibers terminate in lamina II, and A-beta fibers terminate in lamina III, IV, and VI. There are exceptions and crossovers that occur. Pain information ascends through the spinal thalamic tract or Lissaurs track and terminates in the thalamus, somatosensory cortex, limbic system, midbrain, hypothalamus, or thalamic nuclei. These areas of the brain respond, causing a pain memory, a response, and/or a pain behavior. In other words, the patient will respond to the pain based on past history and react according to the type and severity of the pain.

Developing a treatment intervention must begin with identification of the problem, the needs of the patient, and the outcome goals for the patient. An appropriate evaluation procedure to identify the tissue in lesion, according to Cyriax (1982), is the first step in physical therapy pain management. This will allow for proper selection of the manual therapy techniques, exercise protocols, modalities, and patient education intervention that are necessary.

EVALUATION

The Ola Grimsby Institute (OGI, 1998a) developed the "diagnostic pyramid" for the purpose of identifying a "tissue in lesion" and arriving at the proper treatment format (Figure 18.1). The proper flow of this pyramid requires that all the suspect tissues be provoked to reproduce the symptoms, thereby eliminating normal tissue and arriving at the pathology. Cyriax (1982) originally described this concept. The top of the pyramid lists 13 different tissue types and the vertical column represents 12 evaluation categories of this pyramid allowing examination of all tissues available to a physical therapist. Therapists can begin with very basic observation and questioning, and then use hands-on techniques to examine the tissue involved. Active range of motion tests all anatomical structures. Passive range of motion tests structures such as nervous, ligaments, capsules, bursa, bone, blood vessels, and connective tissue. When examining muscles and tendons, Cyriax stated that when active and passive motion is restricted or painful in opposite directions, this indicates contractile or muscle tissue as the tissue in lesion. When active and passive motions are restricted and/or painful in the same direction, there is an arthrogenic or joint tissue lesion. The pyramid examines strength, palpation, joint play, and neurological testing, and concludes with specific laboratory, electrophysiological, and radiological results. Cyriax goes on to state provoked (aggravated) tissue minus normal (healthy) tissue equals pathological tissue. Pathological tissue (the tissue causing the problem) minus

contraindications (treatments not allowed) equals the treatment approach. The treatment is based on the information obtained through the diagnostic pyramid and directed specifically to the tissues identified in the evaluation. Another advantage to using evaluation procedures is to assess both the patient and the referring clinician in arriving at an appropriate to diagnoses.

There are times that physical symptoms will be manifested by tissues or conditions other than orthopedic, musculoskeletal, or neurological. Symptoms of sciatica, for example, may be caused by intermittent claudication, dissecting aneurysms, neoplastic conditions, osteoporosis, congenital conditions, or genital–urinary disorders. The experienced physical therapist may also assist in identifying certain psychological syndromes, as described by Martelli, Zasler, Nicholson, Pickett, and May (2002), such as factious disorders, somatoform disorders, hypochondriasis, or conversion disorders. Furthermore, Waddell signs such as overreaction, widespread hypersensitivity, axial loading sign, rotation sign, and differences between straight leg raise from sitting to supine should be identified. Other non-organic signs may be found during examination/history, including lower extremities giving way, no pain-free episodes in the past year, treatment intolerance, and frequent number of hospital admissions for the same condition.

After evaluating and analyzing the entire intake information including physical findings, psychological findings, laboratory, x-ray and other testing, the physical therapist can develop an appropriate treatment program. This treatment program may include modalities, manual therapy, therapeutic exercise intervention including a home exercise program, self-pain management techniques, instruction in adaptive devices, patient education regarding present condition, and injury prevention.

Pain can be treated by physical therapy with various uses of modalities, manual therapies, therapeutic exercises, and assisted devices. High-intensity afferent stimulation will cause pain inhibition. Manipulation causes a fast stretch in collagen tissue resulting in a response in the basilar neuron; GABA inhibits NMDA, directly affecting the gamma loop leading to the muscle spindle resulting in inhibition of pain and muscle tension. Slow stretch deforms collagen and also inhibits pain but not muscle tension. Electrical stimulation at 110 to 140 Hz is a very powerful high-intensity afferent stimulation. Other high-intensity afferent stimulators include alcohol, pain, Baroque music, and having sex (OGI, 1998).

MODALITIES

The majority of modalities including heat, cold, ultrasound, traction, galvanic stimulation, interferential current, and transcutaneous electrical nerve stimulation (TENS) are for pain management. A few modalities such

as microcurrent stimulation, sympathetic therapy systems (STS), and laser therapy may have therapeutic value.

The use of heat dates to the ancient Greeks and Romans, who used hot rocks, hot water, open fires, hot sand or oils, or the sun. Therapeutic heat includes radiant heat — sun, open fires, glowing coals, or metals — and agents conductive of heat — hot water, thermal springs, and heated agents (oils, sands, grains). The ancient Greeks believed sweating was very helpful as it caused body poisons to run out through the pores of the skin. Therapeutic cold agents include ice and chemical freezing agents such as ethyl chloride. Both are high-intensity afferents and will inhibit pain in as little as 5 minutes. Various sources recommend not using either heat or cold for more than 5 minutes as it may cause tissue damage, damage collagen fibers, or increase edema as the body tries to either cool or warm itself. There currently is insufficient evidence to support or refute the previous statement.

ULTRASOUND

Ultrasound is a type of therapeutic heat generated by sound waves. A deep heating effect occurs by the transmission of sound waves through a coupling medium into the tissues. A meta-analysis published in the journal *Pain* (Gam, 1995), "Ultrasound Therapy in Musculoskeletal Disorders: A Meta-Analysis," reviewed 293 papers published since 1950, and none showed evidence of pain relief achieved by ultrasound versus a sham. The article concluded that the use of ultrasound treatment for musculoskeletal disorders is based at empirical experience, lacking firm evidence and well-designed controlled studies. The journal *Physical Therapy* published two articles on ultrasound by Baker et al. (2001a, 2001b). "A Review of Therapeutic Ultrasound: Effectiveness Studies" evaluated 35 randomized controlled studies published between 1975 and 1999 using ultrasound for treating people with pain, musculoskeletal injuries, and soft tissue lesions. Of the studies, 10 were judged to have acceptable trial methods. Of those, 2 trials suggested therapeutic ultrasound is more effective in treating some clinical problems (carpal tunnel syndrome or calcific tendonitis) than placebo ultrasound, and 8 trials suggested it was not effective in treating clinical problems. This article concluded, "there's little evidence that active therapeutic ultrasound is more effective than placebo ultrasound for treating people with pain, musculoskeletal injuries, or promoting soft tissue healing" (Baker et al., 2001a). The second article, "A Review of Therapeutic Ultrasound: Biophysical Effects" (Baker et al., 2001b), examined the literature regarding the physical effects of therapeutic ultrasound and whether these effects might be considered sufficient to provide a biological reason for the use of ultrasound for the people with pain or soft tissue injury. The article

concluded, "there is currently insufficient biophysical evidence to provide scientific foundation for the clinical use of therapeutic ultrasound for the treatment of people with pain or soft tissue injury."

INTERFERENTIAL CURRENT

> The Austrian physicist Nemec developed interference current therapy (IFC). Two electrical currents, each with a different frequency, 4000 and 4100 Hz, are applied to the skin through surface electrodes and an interference pattern is established at the intersection of the two currents. (Fernando, 2002.)

Other frequencies of greater than 2000 Hz and less than 10,000 Hz with a sweep range of 0 to 200 Hz are now being used. The skin's resistance (ohms) to electricity significantly drops at 2000 Hz. The theory is that although frequencies greater than 2000 Hz and less than 10,000 are classified as "medium frequencies" and have no direct therapeutic effect on the body, medium frequencies appear to penetrate deeper into the tissues and carry the lower-frequency current (0 to 200 Hz) theoretically causing a greater impact on A-delta fibers and stimulating endorphin release, resulting in significant pain reduction. The result of this interference pattern is that the targeted tissue receives a net frequency of 0 to 200 Hz of low-frequency current. The main advantage of this type of current is that lower-intensity output is required. Also, this low-frequency current produces superficial muscle contractions and tends to depolarize the muscle membrane to a great extent. Moreover, motor nerves and sensory nerves are more readily depolarized at lower frequencies. Therefore, deep stimulation of muscle and nerve is possible by the selective application of IFC using from 1 to 200 Hz.

At frequencies of 0 to 10 Hz, motor nerves are readily depolarized and muscle contractions initiated. This frequency can be used for muscle contraction, muscle relaxation, muscle strengthening, and muscle reeducation. Also, smooth muscles surrounding blood vessels reportedly respond well to stimulation at these lower levels. IFC also allows the therapist to effectively reduce and treat edema in acute conditions, and pain relief is possible from frequencies of 110 to 140 Hz. The specific features of interference current are no polar effects, as pure sinusoidal current is used; stimulation of cell division; increased adenosine released through depolarization of the cell membrane leading to adenosine triphosphate; improved microcirculation due to increased adenosine release; and ATP splitting, which results in an increase of free phosphate ions beneficial for mineralization (Fernando, 2002). Interferential current is effective for a temporary decrease of pain and may be used as a home unit for pain management. There are no significant long-term outcomes.

TRANSCUTANEOUS ELECTRICAL NERVE STIMULATION

In 46 A.D., Scribonius Largus described the use of the torpedo fish, an electric eel, to control pain. This was the beginning of the technique of electrical stimulation for the relief of pain. TENS uses electrodes to stimulate the skin in the treatment of acute and chronic pain conditions. In 1967, Drs. Shealy and Mortimer (1970) developed a dorsal column stimulator for surgical implantation in patients with chronic intractable pain. At the time, they used TENS as a screening device for their patients. Eventually, they eliminated the surgery because they found that the screening process alone brought relief. At that point, TENS, as an alternative method of pain management, became a reality. In addition, Drs. Melzack and Wall's Control Therapy of Pain Perception convinced the medical community of the benefits of electrical neuromodulation of pain. The physiological basis for the treatment is the stimulation of large myelinated afferent fibers, a-delta fibers, which at the level of the spinal cord tend to block the passage of painful impulses carried by smaller unmyelinated afferent fibers – c fibers. (Fernando, 2002.)

There is no consistent information to demonstrate that TENS "cures" anything. It can be highly effective in managing pain with patients suffering from chronic orthopedic or neurological pain. It does not appear to be effective in managing pain of fibromyalgia or neuropathies. It should not be used transcranially.

HIGH VOLTAGE GALVANIC STIMULATION

High voltage galvanic stimulation is based on positive and negative polarity. The primary function has been for reduction of edema and pain management. Interstitial fluid accumulation, edema, is mostly negatively charged fluids. By placing a negative electrode over the area of edema and a positive electrode proximal or distal to the edema site, electronic stimulation can disperse some of the negatively charged fluids from the site of edema. It can also temporarily inhibit pain.

MICROCURRENT STIMULATION

Joseph M. Mercola, D.O., and Daniel L. Kirsch, Ph.D., D.A.A.P.M., coined the term "microcurrent electrical therapy" (MET) to define a new form of electronic intervention using biocompatible waveforms as opposed to previous uses of electrical therapy as an application of force (Mercola & Kirsch, 1995).

Microcurrent stimulation is based on the Arendt–Schultz physics principle of low-intensity stimulation's causing profound biophysical response. This device works on the cellular level using milliamp current. It appears to be highly effective through research with

peripheral neuropathies and post-operative pain (Kirsch & Smith, 2000).

Cranial electrical stimulation (CES), also a type of microcurrent, has been researched and proved effective in reducing chronic headaches and improving serotonin levels. It was initially used for the treatment of patients with closed-head injuries. It can prevent or abort migraine headaches (Brotman, 1989) and significantly decreases the pain of fibromyalgia. Patients with depression, insomnia, chronic pain, chronic headaches, and fibromyalgia have reported increased energy and a feeling of well-being. It may also have an effect on the pain neural matrix in the cerebral cortex. The device is applied through ear clips or on the scalp (Kirsch & Smith, 2000).

SYMPATHETIC THERAPY SYSTEMS

Sympathetic therapy systems (STS) was developed and patented by Dr. Donald Rhodes, a pain specialist in Corpus Christi, TX, in August 2000. This device was marketed and distributed by Dynatronics and has been approved by the FDA for use in "symptomatic relief of chronic intractable pain and/or management approach post traumatic or post surgical pain." This device uses medium-frequency current to affect the sympathetic system by treating the pain systemically rather than locally. Guido (2001, 2002) studied the effects of STS patients with peripheral neuropathy. He reported 80% of 20 patients reported an overall improvement in their quality of life and sleep and 40% reduced their medications. These patients had previously not responded to other therapeutic interventions. This chapter's author has used the STS on more than 150 patients with fibromyalgia, chronic intractable headaches, and peripheral neuropathies. The majority of patients have reported significantly decreased pain, decreased medication usage, and improved functional ability. This device did not appear to work with diabetic neuropathy.

LOW-POWER LASER

LASER is an acronym for Light Amplification by Stimulated Emission of Radiation. Laser therapy dates to the 1950s when it was first used in Europe for the reduction of pain and inflammation. There was inadequate and insufficient evidence to support its continued use; however, empirical evidence seemed to support its function. Laser therapy, like microcurrent stimulation, is also based on the Arendt–Schultz physics principle of low-intensity stimulation's causing profound biophysical response and supports the theory that less energy rather than more causes the body cells to exhibit a greater physiological response. The laser works on a photobiostimulation principle. Laser output is measured in nanometers. It was called cold, soft, or low-level laser therapy when used during the 1970s to the 1990s. The helium neon laser, 632.8 nm, and the

gallium aluminum arsenide laser, 810 nm, were used for superficial wound healing and acute and chronic pain with or without inflammation. The gallium arsenide or infrared laser, at 904 nm, was used for deep pain and deep wound healing, scar tissue, and calcium deposits. Either laser could be used for auricular therapy or on body acupuncture points. Low-power cold laser technology appears to reduce inflammation, improve range of motion, engage proprioception, and integrate locomotive process. There are no actual contraindications to cold laser therapy. Relative contraindications include pregnancy, malignant melanoma, or general illness. Direct radiation in the eyes must be avoided as this can cause damage to the retina (Watson, 1995). Laser therapy appears to decrease swelling and acute traumatic soft tissue injury conditions (Oschman, 2004).

MAGNETIC THERAPY

Magnetic therapy has been used for thousands of years for treating acute and chronic pain. Many professional football teams, golfers, and other athletes utilize various forms of magnetic chairs, belts, and treatment devices. Magnetic therapy is also useful in treating animals in pain as it emits a subsensory sensation. It is covered in much greater detail in Chapter 84 of this book.

PHONOPHORESIS

Phonophoresis is the process of driving medication into the subcutaneous tissue using ultrasound. The studies done have been poor and limited, and had minimal controls. Anecdotal responses, however, are good (Watson, 1995). The medications listed as used included corticosteroids, salicylates, nonsteroidal anti-inflammatory drugs (NSAIDs), DMSO, Manitol, insulin, anesthetics, vitamins, antibiotics, and antispasmodics.

IONTOPHORESIS

Iontophoresis is the process of electrically transmitting ions through the skin into the underlying tissues through the cellular membranes. The process is based on the principle that like charges repel like charges. A positive current will drive positive ions and negative currents will drive negative ions into the body through the cellular membranes. Knowledge of the chemical solutions being driven in and the tissues being treated is absolutely necessary. All types of extremity and trunk myofascial pain, strains, inflammatory orthopedic pain, and neuritis can respond to iontophoresis. The following chemicals are indicated for these conditions: dexamethasone for inflammatory conditions, magnesium as a muscle relaxant, acetic acid for calcium deposits, sodium chloride to soften scars, copper sulfate for fungal infections, salicylates for edema and pain reduction, lidocaine and marcaine for painful bursitis

or neuritis, and zinc to assist with wound healing. Iontophoresis is also used in dermatology, otorhinolaryngology, ophthalmology, and on the spinal cord.

Iontophoresis is the introduction of medicinal ions through the skin into the tissue using direct electrical current (Garzione, 1968). It is used to deliver a locally high concentration of the drug with little systemic side effects, as the hepatic first pass elimination is bypassed. The concept, simply put, is that like poles repel. The charged ion is repelled into the tissue by the same pole of the direct current stimulator. In 1908, Leduc conducted an experiment putting two rabbits in series with the same direct current so the current had to pass through both rabbits. The first rabbit was connected by the positive electrode soaked in strychnine sulfate with the current leaving by the negative electrode soaked in plain water. The second rabbit was connected to the positive pole soaked with water and by the negative pole soaked with potassium cyanide. The first rabbit was seized by tetanic contractions, indicative of strychnine poisoning, and the second rabbit died rapidly with symptoms of cyanide poisoning. The two animals were replaced with two new rabbits and the current flow was reversed. Neither animal was harmed, as the ions were not repelled by the opposite charge (Banga & Chien, 1998; Garzione, 1968).

Studies using radiolabeled tracers have shown that 3 to 32% of the drug is delivered by iontophoresis (Glass, 1980; Zunkel et al., 1959). The most common drug studied is dexamethasone. Studies have shown that this drug can be phoresed into the tissue and is effective in reducing symptoms (Li et al., 1996; Nirschl et al., 2003). There are more than 200 case reports of using iontophoresis with alternative ions, but there is little double-blind, placebo-controlled evidence that these other ions are efficacious.

The drug must be in an ionized state, have a charge or be able to have a charge introduced on it by pH manipulation, be soluble in water for good ion formation, and be soluble in fat for good tissue penetration and permeability (Garzione, 1968).

The advantages of iontophoresis or phonophoresis are there are no needles, medication stays locally versus systemic, the stomach and liver are bypassed, the medication is not degraded or absorbed, and the chances of overdosing are greatly reduced.

EVIDENCE-BASED MODALITIES EFFECTIVENESS

The effectiveness of modalities must be based on evidence. Therapeutic exercise programs and massage are addressed later in this chapter. Evidence-based practice for the treatment of low back pain is of growing concern in the field of rehabilitation. Low back pain is a leading cause of workers' compensation claims in the United States and Canada. It is estimated that 60 to 90% of the adult population will experience low back pain and 30%

of all low back pain will become chronic. A special article entitled, "Philadelphia Panel Evidence-Based Clinical Practice Guidelines (EBCPG) in Selected Rehabilitation Intervention for Low Back Pain" (Scalzitti, 2001) was published in *Physical Therapy*. The correct management of low back pain is extremely relevant to outcome. This panel evaluated random control studies, observation studies as defined by the Cochrane Collaboration, and literature review using meta-analysis. The results were compared with the Québec Task Force on spinal disorders (QTF) and the Agency for Health-Care Policy and Research (AHCPR).

Multiple interventions were used by a variety of clinicians for treatment of low back pain. The Philadelphia Panel evaluated nine interventions for the treatment of low back pain: thermotherapy, therapeutic exercise, therapeutic massage, electromyographic (EMG) feedback, mechanical traction, ultrasound, TENS, electrical stimulation, and combined rehabilitation intervention. The practitioners responding included family physicians, orthopedic physicians, physical therapists, members of the American College of Rheumatology, physiatrists, and neurologists. The purpose of the article was to describe EBCPGs developed by the panel for rehabilitation intervention of low back pain and in acute low back pain and in subacute low back pain. Strengthening exercises in flexion and extension were effective in subacute, chronic, and postoperative low back pain. Mechanical traction, ultrasound, and EMG biofeedback demonstrated no consistent clinical outcomes with acute, subacute, chronic, or postoperative patients with low back pain. There was insufficient evidence for or against therapeutic massage, electrical stimulation, or combining rehabilitation interventions.

The QTF and *British Medical Journal* recommended therapeutic massage based on clinical practitioners' preferences and not on contributed clinical trial results. The article cited unpublished studies suggesting therapeutic massage may have a clinical therapeutic benefit. The lack of well-designed and controlled random studies limited the assessment of the effectiveness of the rehabilitation of patients with low back pain. EBCPGs support the use of therapeutic exercise in acute, chronic, subacute, and postoperative low back pain, and continuation of normal activities in acute low back pain. There is at present a lack of evidence to support the use of other modality interventions.

Modalities can be very effective in managing pain but are predominantly ineffective in resolving or curing pain.

MANUAL THERAPY

The evaluation process determines the tissue lesion or what structure needs treatment. Manual therapy techniques including massage, mobilization, and manipulation are highly effective in reducing pain, muscle guarding, and producing increased range of motion. The evaluation will determine whether there is a hypermobility or a hypomobility of a joint and the amount of tension in the muscles surrounding the joint. Hypermobilities, or excessive motion, in a spinal or extremity joint are effectively treated with stabilization exercises and are addressed later in this chapter. Hypomobility, or restricted motion, at a spinal or extremity joint is effectively treated with manual therapy. Manual therapy philosophies include Mennell's — there is a pathological condition or joint disease; osteopathic structure governs function according to Cyriax — all pain has an anatomical source and with correct diagnosis and treatment directed at the cause a positive outcome will occur. The majority of information covered is a combination of osteopathic and Cyriax philosophies.

Dorland's Medical Dictionary (1965) defines manipulation as "skillful or dexterous treatment by the hand and in physical therapy, the forceful pressure/movement of a joint within or beyond its active limit of motion" (p. 873). Manipulation and mobilization date back to Hippocrates in 460 B.C. Basmajian documented "laying on of hands" in the Old Testament of the Bible as described by Harris (1993) in "History and Development of Manipulation and Mobilization." Hippocrates advocated several types of manipulation, including single force thrust, prolonged pressure by sitting on the patient, shaking movement, and a foot being applied to the bony prominence. The Turks advocated manipulation during traction as recorded in a textbook of the renaissance era.

Other writings from Arabia, China, Germany, and France list various forms of manipulation from the 17th and 18th centuries. Ambrose Pare, during that same era, introduced the terms "subluxation of the spine" (Harris, 1993, p. 14). Andrew Taylor Still introduced osteopathic manipulation in the late 1800s. He believed diseases were due to abnormal bony situations. Bonesetters were prominent in Mexico and famous for "stamping or trampling" techniques that are still practiced today. Sarah Mapps, also known as Crazy Sally or Cross Eyed Sally, was in high demand in London during the early 1700s for her "bone setting ability" (Harris, 1993, p. 10).

James Cyriax, a famous orthopedic surgeon in the 1900s, defines manipulation as "a method of treatment that consists of different sorts of passive movement performed by the hand in a definitive manner for prescribed purpose" (Harris, 1993, p. 14). The main reason was for correction of internal derangement. He believed a displaced fragment could be moved and the disc could be "sucked up" by distraction. He disagreed with osteopathic techniques and advocated manipulation to be done by physical therapists. Cyriax further states, "for thousands of years manipulation treatment for low back pain has been common practice, Hippocrates straightened kyphosis, Galen replaced outward dislocated vertebrae, and Pare wrote about sublux-

ation of the spine" (Harris, p. 14). He further states, "bone setters replaced out of place bones, osteopaths treated the osteopathic lesion, orthopedic surgeons manipulated the sacroiliac (SI) joint, chiropractors replaced subluxed vertebrae, and neurologist have stretched the sciatic nerve" (Harris, 1993, p. 13). There has been success met by all clinicians performing these techniques. Cyriax concludes, "clearly the mechanism has been a fragment of disc that has become dislocated and put back into place, a protruding disk sucked up, a jammed or blocked joint was unlocked, or a nerve root was shifted off a prolapsed disc" (Harris, 1993, p. 13). He referred his patients to physical therapy for heat treatment, massage, and exercise. Orthopedists and physical therapists complement each other in dealing with all types of soft tissue lesions.

There are various types of manipulation and mobilization as described by Nyberg (1993) in *Rationale for Manual Therapies*. The basis for doing manipulation or mobilization is detection of motion impairment or a biomechanical problem of spinal movement. This biomechanical problem may be hypomobility (restricted motion) or hypermobility (excessive motion). Each produces motion around a nonphysiological axis. There is ambiguity and no clear definition among health care practitioners on the term "manipulation." It may be a vigorous high-speed maneuver to reduce displacement resulting in a pop or crack or gentle motion to improve range of motion and soft tissue extensibility. Nyberg (1993) lists nine types of manipulation:

1. General (original)–specific
2. Localized
3. Indirect–direct
4. Noncontact–contact
5. Soft tissue–joint mobilization (nonthrust)– manipulation (thrust)
6. Application
   Graded oscillation   Under anesthesia
   Progressive loading   General
   Sustained loading   Specific
7. Mobilization
   Joint mobilization
   Soft tissue therapy
   Soft tissue mobilization
   Myofascial release
8. Neuromuscular therapy
   Proprioception neuromuscular facilitation
   Muscle energy
9. Positional release therapies
   Strain/counterstrain
   Functional or active
   Assisted motion therapy

A general spinal manipulation involves a load applied to more than one joint or spinal segment with pressure transmitted to a number of joint/segments that have been determined to be hypomobile. Specific spinal manipulation is force applied to one segment or spinal joint and minimal force transmission through an involved spinal segment. Direct manipulation is a force applied in the direction of motion restriction or barrier. Indirect manipulation involves movement in the opposite direction of motion restriction. Contact manipulation requires hand or finger placement on the involved area or spinal segment, which may include spinous process, laminae, facet joints, or transverse processes. Noncontact manipulation involves hand or finger placement away from the spinal segment or area in lesion (also known as Maignes treatment). Noncontact manipulation may be used because an area is too painful or because additional leverage is needed to achieve a soft tissue or joint release. Soft tissue therapy does not involve high-velocity motion and therefore is defined as soft tissue mobilization myofascial release.

Graded oscillation is a form of cyclic loading whereby alternating pressure, off and on, is delivered at different parts of the available range with either small- or large-amplitude motions in the beginning, middle, or end of range. Progressive loading mobilization involves a series of short-amplitude, spring-type pressure applications. Sustained loading is continuous, uninterrupted pressure where the force may remain at the same intensity or increase or decrease depending on the patient reaction.

Joint mobilization is nonthrust manipulation and the pressure varies from gentle to vigorous, but is imparted slowly as opposed to thrust or high-velocity manipulation. Soft tissue therapy involves manual contact, pressure, or movements primarily to myofascial tissues. It is defined as manual manipulation of soft tissue administered for the purpose of producing effects of the nervous, muscular, lymph, and circulatory systems. The techniques involve classical massage, connective tissue massage, Rolfing, acupressure, and soft tissue stretching. Myofascial release is a form of soft tissue therapy based on a reflexive responsive that reduces tissue tension.

Proprioceptive neuromuscular facilitation, developed by Kabat and Knott (Nyberg, 1993, p. 33), is a method of promoting or hastening the response of the neuromuscular mechanism through stimulation of proprioceptors. Muscle energy is a form of manipulative treatment using active muscle contraction and varying intensities from a precisely controlled position in the specific direction against a distinctly executed counterforce. Neuromuscular motion disorders are the basis for the use of positional release therapies. Improper neuromuscular mechanisms are responsible for establishing and maintaining joint motion abnormality.

The two types of positional release therapies are strain/counterstrain and a functional technique known as active assisted therapy. Strain/counterstrain, developed by Jones (Ward, 1993), is the passive placement of the body in the position of greatest comfort to reduce pain. Pain relief is achieved by the reduction of continuing inappro-

priate proprioceptive activity that maintains the motion dysfunction and is carried out away from the motion restriction or in the direction of motion ease and comfort. Positional therapy or active assisted motion therapy is performed by the patient and is based on the fact that motion response is the result of a demand placed on the body and that demand causes a response from each motion segment.

The criteria for manipulation are based on the assessment, type of dysfunction, and the patient's attitude. Minimal manipulation is indicated for acute conditions. Subacute, settled, or chronic conditions respond to nonthrust and sustained loading to increase joint range of motion. There is little overall evidence to validate one type as more effective for any specific dysfunction. The therapist must be aware of the restricted motion and the direction of restriction or hypermobility, control the force or amplitude of the technique, be aware of the tissue recruitment, and expect specific tissue response to the techniques performed.

The application of specific manual therapy can be partly determined by the type of mechanoreceptors located in the specific regions to be treated. Type I and type II receptors are located throughout the body. Type I mechanoreceptors are slow adapting and can be used to inhibit pain. They are predominately at the neck, hip, and shoulder region. They respond to slow collagen stretching. Collagen stretching assists in increasing range of motion and reducing pain. Type II mechanoreceptors are fast adapting, and predominate in the lumbar spine, hand, foot, and temperomandibular joint (TMJ). Oscillation techniques assist in lubrication of a joint and in pain reduction. Either of these techniques, oscillation or collagen stretch, can be applied at any of the spinal or extremity joints. (OGI, 1998b) The ultimate goal of joint mobilization/manipulation techniques is to lower the threshold of activity at a joint or muscle via dorsal horn inhibition. EMG studies demonstrated that following manipulation/mobilization increased active range of motion and decreased muscle tone and following massage/stretching demonstrated increased range of motion but increased EMG activity.

There is evidence that specific mobility testing of the spine will reveal loss of functional mobility or hypomobility and increased mobility or hypermobility. Fritz's (2004) research suggests that hypomobilities respond better to manipulation/mobilization and hypermobilities respond more to stabilization exercises. Furthermore, Jewell (2004) suggests that patients with sciatica will achieve a greater therapeutic benefit when receiving joint mobility treatments or general exercises as compared with other interventions according to his research.

Risk Factors

How effective is spinal manipulation therapy (SMT)? Powell, Hanigan, and Olivero's (1993) article in neuro-

surgery online, "A Risk/Benefit Analysis of Spinal Manipulation Therapy for Relief of Lumbar or Cervical Pain," attempts to answer that question. SMT is performed on more than 12 million Americans each year. The authors reviewed 140 cases in the literature and determined six risk factors associated with complications of SMT. The risk factors were misdiagnosis, failure to recognize the onset or progression of neurological symptoms or signs, improper technique, SMT performed in the presence of coagulation disorders, herniated nucleus pulposus (HNP), and manipulation of the cervical spine. Most of the clinical trials reviewed had flaws, but the data suggested that SMT demonstrated consistent effectiveness as an alternative treatment for adults with acute low back pain. SMT, according to the authors, has not been shown to be superior to other conservative methods or provide long-term benefits. The risk/benefit analysis for SMT is acceptably low for adults with low back pain of less than 1-week duration. The ratio, however, was unacceptably high for patients with radicular symptoms or signs associated with prolapsed disc or with neck pain.

The evidence supports the use of spinal manipulation for low back pain. Some patients do not respond to manipulation of the low back. Fritz, Whitman, Flynn, Wainner, and Childs's (2004) study published in *Physical Therapy* included 75 patients with nonradicular low back pain. Of the patients, 20 (28%) did not improve with manipulation. The study identified six variables for a nonresponse to manipulation: longer symptom duration, having symptoms in the buttocks or leg, absence of lumbar hypomobility, less hip rotation range of motion, less discrepancy in left-to-right hip internal rotation range of motion, and a negative Gaenslen's sign. Utilizing appropriate evaluation techniques will ensure a greater positive outcome when administering manual therapy.

Soft Tissue Massage

How does massage therapy or soft tissue mobilization (STM) work? Grodin and Cantu (1993) describe the history, physiology of soft tissue mobilization, scar tissue formation, and the effects of massage. The term "soft tissue massage" includes myofascial release, muscle energy, traditional massage, Rolfing, and movement therapies such as Feldenkrais, Traegering, and proprioceptive neuromuscular facilitation (PNF). STM rationale is based on the structure and function of soft tissue, taking into account the histology, biomechanics, and gross morphology. Histologically, the body has five types of connective tissue and compounds including ordinary connective tissue, blood cells, cartilage, adipose tissue, and bone. STM is directed at ordinary connective tissue, superficial and deep fascia sheaths, nerve and muscle sheaths, supporting framework of internal organs, aponeurosis, ligaments, joint capsules, periosteum, and tendons.

The most abundant cell in connective tissue is collagen. Type 1 collagen, of 19 types of collagen, is found in ordinary connective tissue. Also found in connective tissue are glycosamino-glycans and water (Grondin & Cantu, 1993), which serve as a mechanical barrier for foreign matter, acts as a medium for diffusion of nutrients and waste products, provides lubrication, and maintains space between collagen fibers. The ground substance is composed of glycosaminoglycans (GAG) and water. Studies performed on animals have shown the deleterious effects of immobilization on soft tissue structures. Analysis of the cells and chemical components reported changes in water content and no significant loss of collagen in connective tissue immobilized less than 9 weeks. There was a 30 to 40% loss of GAG, primarily in hyaluronic acid. The loss of GAG theoretically results in approximation of adjacent collagen fibers and/or increase in abnormal cross-linking. Normal collagen has a half-life of 300 to 500 days, and GAG has a half-life of 1.7 to 7 days. There were demonstrated actual increases in cross-link formation of fibers after 9 weeks of immobilization. The consequence of cross-linking was decreased tissue pliability. Decreased tissue pliability was the result of fatty infiltration and increased microscopic cross-linking.

Movement is the primary factor in maintaining homeostasis between collagen synthesis and tissue degradation. Normal mechanical pressures on tissue promote biological activation for alignment of fibroblast and muscle cells in the line of stress. This also helps maintain normal biochemical activity in connective tissue. Movement inhibits contractures by facilitating proteoglycan synthesis that maintains lubrication and space between collagen fibers. When trauma or injury occurs, scar tissue formation may result. Scar tissue formation occurs in four phases. In the *inflammatory phase,* which begins immediately and lasts 24 to 48 hours, blood clotting occurs and macrophages rush to sites to breed, clean, and prevent infection. Immobilization is important in this phase to prevent further damage. The *granulation phase* results in increased vascularization for removing necrotic tissue and providing nutrition. The time varies depending on the tissue damage and extent of trauma. The *fibroblastic phase* results in collagen and ground substance increases; collagen is laid down in an irregular pattern, and the collagen has weak hydrogen bonds. During the *maturation phase,* lasting 3 to 8 weeks, the collagen shrinks, matures, and solidifies.

The collagen can absorb more stress and significant tissue remodeling can occur with proper mobilization and therapeutic techniques if stresses are applied appropriately in the line of stress. If nothing is done or if treatment is not appropriate, then there is significant loss of tissue extensibility, scar tissue may form, and abnormal alignment of collagen fibers occurs. Massage or soft tissue mobilization can be used during the maturation phase, and

has an effect on circulation, blood flow, cutaneous temperature, and morphology of blood vessels.

There are several types of STM. The connective tissue massage or Bindegewebmassage, described by Dicke in the 1920s (Grondin & Cantu, 1993), involved stroking a hypersensitive area until it was warm and superficial circulation reappeared. This became known as the visceral somatic response. Hoffa massage (traditional effleurage and petrissage) consists of upward stroking or gliding over the muscle in the direction of the muscle fibers. Rolfing involves manual manipulation of myofascia in order to "balance the body in the gravitational field." It focuses on the different aspects of positional integrity. Other soft tissue work included movement approaches such as PNF and Feldenkrais.

The best approach is based on the condition being treated. Hypermobility responds to stabilization and an autonomic approach. Hypomobility responds to soft tissue mobilization. Menell (cited in Grondin & Cantu, 1993) states there are only two effects of any type of massage: reflexive and mechanical. Movement or mobilization rehydrates connective tissue, stimulates ground substance production, aides in collagen fiber orientation, and breaks up fatty adhesions. Mobilization causes plastic deformation of the connective tissue resulting in improved extensibility, lengthening, and mobility. The histological changes produced mechanically by myofascial manipulation are decreased muscle tone and increased extensibility. The patient is ready for postural reeducation and therapeutic exercises following intervention of STM/mobilization. STM is contraindicated over tissues in the state of acute inflammation and should be avoided over hypermobile or unstable spinal segments such as in spondylolisthesis.

NEURAL MOBILIZATION

David Butler (Grondin & Cantu, 1993) introduced the concept of neural mobilization in 1989. There is at present inadequate and inconsistent validity and efficacy in the literature to substantiate this technique. These mobilization techniques are directed at peripheral nerves and utilize stretching exercises, gliding exercises, or both. There is minimal indication that neural mobilization may provide some relief of symptoms for mechanical allodynia of the hand (Kietrys, 2003). Anecdotal responses are encouraging, but lack scientific validity.

OTHER TYPES OF MANUAL THERAPY

There are other types of manual therapy beyond the scope of this chapter which are addressed more thoroughly in other chapters of this book. ASTYM (advanced soft tissue therapy) system, for example, utilizes various mechanical tools and applies specific pressure to certain body areas

to stimulate fibroblast recruitment and activation, guiding and aligning the healing of collagen, decreasing pain, and producing stronger healthier tissue.

IMMOBILIZATION

Prolonged immobilization and bed rest have a devastating effect on all body systems. Immobilization of patients in pain should be avoided. Early movement and motion utilizing manual therapy techniques and structured exercise are important in reducing the morbidity of patients in pain. Morris (1999), in the *British Journal of Therapy and Rehabilitation*, outlined the effects of immobilization on the musculoskeletal system. Prolonged immobilization or bed rest affects muscle, bone, cartilage, connective tissue, joint capsule/synovial membrane, ligaments, and tendon structures.

Muscle tissue suffers from disuse atrophy and a 10% loss of strength can occur within 1 week. Disuse atrophy affects antagonistic or slow-twitch muscle fiber. There is a decrease in protein synthesis and a decrease in the size of muscle fibers. Immobilization in a shortened position will lead to overall loss of muscle length and a loss of sarcomeres. Immobilization in a lengthened position will add length to sarcomeres. This can lead to an imbalance of agonist and antagonist. The research, described by Morris (1999), has shown that early controlled mobilization improved the quality and rate of repair of damaged muscle tissue.

Disuse osteoporosis, or bone loss, begins within days of immobilization and is measured by increased urine calcium levels in patients on prolonged bed rest. The bone loss is a result of decreased loading on bone. Cartilage becomes weaker and can deteriorate rapidly as the result of the loss of GAG and waste from the collagen matrix. This degeneration results from loss of motion and loss of loading on the cartilage. Further cartilage damage may occur due to impairment of nutrition to the cartilage. Cartilage changes due to immobilization can occur within a few weeks and the damage is largely irreversible.

Periarticular connective tissue, including joint capsule, ligaments, and tendon, loses water and GAG during immobilization. There is an increase in collagen synthesis and degradation results in more immature collagen, with a change in the overall collagen mass. When there are no stresses placed on immobilized immature collagen, its overall structure is weaker, the fibers are randomly laid down, and more cross-linkage occurs. Adhesions form that can lead to contractures as a result of increased cross-linking of collagen.

Joint capsule immobilization leads to capsular contracture, thickening and shortening on the flexed side, lengthening and thinning on the extended side, and loss of GAG and water. This leads to stiffness of the joint, hypertrophy of the synovial membrane, and increased potential for adhesions between the synovial membrane and cartilage.

Ligaments undergo marked atrophy, loss of tension strength, and weakness at insertion sites as a result of immobilization. Full recovery of strength in immobilized ligaments can require more than a year. Tendon and ligament immobilizations are very similar. Recovery of strength in tendons requires several months. Tendon repair recovery is improved by early controlled mobilization.

Immobilization affects quality and quantity of life, as the musculoskeletal system does not respond well to immobilization. The end result is the deterioration and weakness of the body's tissue. Recovery is a slow process and care must be taken during activity and exercise to avoid further tissue damage.

THERAPEUTIC EXERCISE

Therapeutic exercise programs are aimed at reducing pain and increasing stability. Programs begin with exercises aimed at increasing circulation into a muscle, improving endurance, and facilitating coordination so motion occurs around a normal physiological axis, and increasing strength and power.

SCIENTIFIC THERAPEUTIC EXERCISE PROGRESSIONS

The Ola Grimsby Institute (1998c) introduced the concept of Scientific Therapeutic Exercise Progressions (STEP). The concept is that each patient benefits most fully from an exercise plan individually tailored to the pathology and the tissue tolerance of the particular individual. This program provides the optimal exercise progressions each patient requires at every level of rehabilitation. It is divided into three phases:

Phase 1. This is the pain free-phase that focuses on coordination, mobility, and stability around a physiological axis throughout the range of motion. The emphasis here is reducing pain, reducing symptoms, and increasing circulation. This is normally the subacute stage. There is minimal resistance, range, and repetition.

Phase 2. This is the restoration of function phase that focuses on increasing tissue tolerance to levels corresponding to the demands of activities of daily living and restoring function. The methods employed will consist of increasing one or more of the following: strength, endurance, range of motion, speed, weight-bearing capability, and coordination. It is estimated that it will take 5,000 to 6,000 repetitions to regain the former coordination of the tonic or phasic muscles in a joint system following an injury.

The principle of overload, which states that habitually overloading a system will cause it to respond and adapt, is utilized in phase 2. The Holten diagram displays the relationship between the number of repetitions until fatigue and a percentage of the "resistant maximal" (RM)

used in each repetition. This is valid for either isotonic or isometric exercises. RM describes the resistance a group of muscles is capable of overcoming in one repetition. Endurance, according to the Holten curve, is defined as the functional quality that increases with more than 30 repetitions or using less than 60% of 1 RM. Coordination, as used in STEP, is defined as "the contraction and relaxation of muscles in a specific consecutive order and with a specific magnitude to produce movement around those axes of motion that are best suited for a specific function" (Ola Grimsby Institute, 1998). Coordination therefore refers to the quality of motion. The three criteria used in testing for one 1 RM are fatigue, pain in either the primary or secondary site of pathology, and loss of coordination in the required motion. Testing and training are not done in the same session.

There are three types of muscle contraction. Concentric contraction occurs when a muscle shortens and generates tension. Mechanical work is positive because the movement is in the same direction as the tension and joint movement. Eccentric work occurs when a muscle lengthens as a result of a force external to the muscle stretching. Mechanical work is negative because the net muscle movement is in the opposite direction of the muscles force. Isometric work occurs when the muscle neither lengthens nor shortens and produces tension. The greatest contractile tension in a muscle occurs in the length–tension curve. In concentric contraction the muscle is weakest at its beginning length of tension (actively insufficient), strongest 20% into its length to 20% past its mid-length, and weakest at the end of range.

Factors affecting the length–tension relationship are histological, biomechanical, and neurophysiological. Histological factors occur as a result of minimal overlap of a sarcomere's actin and myosin filaments at full extension, which allows for the production of very little tension in a muscle or at the end of range when no more overlap can occur. This is considered active insufficiency. Biomechanical factors are described as the motion of the lever where the angle of the tension insertion into the bone directs where the greatest contractile force from the muscle is produced. When the muscular forces are perpendicular to the lever arm, such as the biceps to the forearm, the greatest muscle force will be generated. The neurophysiology of joint mechanical receptors influences muscle facilitation around a joint. Type I mechanical receptors facilitate tonic muscle and type II facilitate phasic muscle. The beginning range of collagen tension is the only range of tension where both types of mechanoreceptors fire; type II fires in mid-range, and type I fires at the end of range. The beginning range of collagen tension in clinical terms is the resting or loose-packed position. This is the only range where both type I and type II mechanoreceptors fire together to facilitate the greatest amount of both tonic and phasic fibers.

The important component of STEP is to utilize collagenous tension specifically to recruit and facilitate muscle fibers. The pulley system is recommended in the STEP program as acceleration and deceleration can be controlled. Speed and resistance remain consistent with pulleys throughout the range of contraction for fiber recruitment and physiological coordination. Both concentric and eccentric contractions occur during pulley exercises. The lower extremities will not strengthen as consistently eccentrically as the upper extremities will. Eccentric exercises produce hypertrophy of a muscle, venous flow, and removal of waste products between contractions. Concentric exercise will increase capillary density, and 75% of metabolic activity in a muscle occurs during the concentric phase.

Phase 3. This phase involves combining concentric and eccentric contractions such as in PNF patterns to finalize strengthening and coordination. The patients are pain free and are preparing to return to their preinjury levels of activity or sports participation at this time.

BALL THERAPY

There is no single treatment that is successful in treating low back pain. One possible approach is the Swedish gym ball for rehabilitating spinal dysfunction as described by Irion (1992). Lumbar stabilization techniques, including balance, strengthening, and proprioceptive activities, as performed with a 55- to 65-cm Swedish ball, can be part of a comprehensive program in patients with low back pain and dysfunction. The gym ball allows the patients to develop proper and pain-free movement patterns. The goals of lumbar stabilization and the gym ball are to promote healing and develop appropriate movement patterns.

Treatment progression is divided into the acute phase, lasting 2 to 3 days, and the training phase, lasting through the remainder of the rehabilitation program. The initial exercises include abdominal isometrics and gluteal sets, which give the patient instruction in proper lumbo pelvic motion. Education in safe movement patterns is the goal of the training phase. Appropriate exercise equipment for improving flexibility, endurance, and strengthening is left to the therapists' discretion. The training phase progresses to dynamic lumbar stabilization using the gym ball for improving balance, coordination, strength, and stability. Correction of muscle imbalance, controlled motion, and good posture are implemented in this phase. The techniques used with the gym ball promote smooth, coordinated movement patterns and maintain correct, appropriate lumbo pelvic alignment, resulting in good movement patterns and postural control.

To use the gym ball, patients must find a functional position of the spine, described as the most stable and asymptomatic position for the task at hand. Patients are trained to stay in this midrange of lumbo pelvic motion,

also known as a neutral position. However, variation may occur based on the underlying pathology. Conditions such as spinal stenosis or spondylolisthesis may prevent patients from assuming this mid-range pain-free position. Dynamic stabilization is a complex neuromuscular skill in which a more neutral spine position is maintained by continuous fine adjustments in muscle tension in response to fluctuating loads. The patient must master the functional position and lumbar stability before starting a gym ball program. The gym ball must not reproduce the pattern that initially brought the patient in for treatment. The intensity of the program should be to the point of fatigue, almost losing control of the quality of moment or functional position, but not actually losing control. Quality of movement is more important than quantity of movement.

Indications for the gym ball program include general poor conditioning, improper posture/body mechanics, psychomotor conditions, sacroiliac dysfunction, post-lumbar laminectomy, degenerative disc disease, post-spinal fusion, herniated or bulging disc, thoracic strain, cervical pathologies, spinal stenosis, and spondylolisthesis. Relative contraindications include pulmonary dysfunction, cardiac problems, hypertension, and obesity. The exercises are performed sitting or lying on the ball. Increasing the length of lever arm while on the ball results in the progression of exercise. Patients move arms and/or legs in traditional movements, working agonist and antagonistic muscles in alternating motions while maintaining the functional position of the spine. The motions are begun in the sagittal and coronal planes and progress to oblique and torsional patterns. The measurable outcome is to regain appropriate movement patterns.

PILATES

Pilates exercise programs are based on Joseph Pilates's training techniques developed in the 1920s. These programs can be used for general conditioning and fitness or recovery from orthopedic injury or trauma of surgery. There is no current evidence-based information on Pilates programs. Pilates has become increasingly popular and is used by many physical therapists. Pilates developed specific principles and performing specific active stretching movements that include breath, awareness, concentration, balance, centering, control, flowing motion, and precision. The emphasis of these exercises is directed at the trunk and abdomen for stability. There is also extremity motion that helps to facilitate active stretching. Therapeutic exercise programs must be supervised and directed by a qualified therapist (Lombardo, 2003).

OTHER FORMS OF THERAPEUTIC EXERCISE

Other forms of exercise that may help reduce pain include Feldenkrais, yoga, and plyometric training. Yoga, very

simplified, involves placing the body in specific nonpainful positions and meditating. It is spiritually "getting in touch with yourself" or some other focus such as Jesus or other god. It is not pure mysticism. Plyometric training is used to train the eccentric activity for lengthening contraction of a muscle's action. Although it places a greater strain on the tendons and ligaments, it may be beneficial in reducing pain and facilitating endurance, motion, and strength.

HOME PROGRAMS

Home programs are a vital part of the treatment schedule of any patient with pain. A home program should include instructions of do's and don'ts for body mechanics, lifting, sitting, lying down, and any kind of activities of daily living. For example, a patient with low back pain standing at a sink or ironing might benefit from using a footstool to rest one foot on and alleviate pressure on the low back. Home exercise programs are used for lubrication of joints, increasing range of motion, reducing pain, and reducing muscle tension. The patients must be actively instructed in the exercises, given a copy of the exercises with the appropriate dosage, and told to stop the exercises if their pain increases or they feel tired.

ADAPTIVE EQUIPMENT

Physical therapists are in a unique position to provide many adaptive devices for patients to use at home. These devices may be felt inserts for shoes; instruction in using braces or supports on lower extremities, backs, or upper extremities; supports for sleeping at night to position the body in a more comfortable position; instruction in the use of walking devices such as canes, walkers, crutches, and home pain management devices such as TENS, STS, CES, IFC, or EGS (electro-galvanic stimulation) units, in short, any kind of device that will help patients function more normally and reduce their pain.

PREPARATION FOR COURT TESTIMONY

Physical therapists may be called to testify in a court of law or provide depositions for patients who are suffering from pain and are seeking financial compensation (Watson, 1995). The purpose of court testimony as a physical therapist may be as a treating therapist, expert witness, or defendant. A *treating therapist* will be asked to present evaluation findings, treatment administered, and outcome of the treatment program. The documentation of all findings and treatments will be thoroughly scrutinized in court. The therapist should not answer opinion questions or speculate on other outcomes. The *expert witness* is a consultant qualified to address pain conditions and treatment programs. Testimony should be based on evaluation findings and treatment administered, audiovisuals and

models, KISS (keep it simple, silly), and the therapist must be prepared to give an opinion. The therapist must be relaxed, compassionate, and noncombative even when assaulted by an opposing attorney. The *defendant physical therapist* is in court as a result of malpractice. The best course of action to not become a defendant physical therapist is prevention, having good communication and clear documentation, being professional and cautious when working with the opposite sex, and receiving informed consent from a patient. Always get an attorney and listen to the attorney's advice.

INDICATIONS FOR PHYSICAL THERAPY

Physical therapy is indicated for the major types of acute and chronic pain. Acute pain may include sprains or strains, postsurgical or post-traumatic events, acute-onset headaches without neurological complications, and orthopedically caused pain. The treatments utilized here include heat or cold, electrotherapy to manage pain or reduce swelling, manual therapies, and pain-free exercises. Chronic pain conditions such as failed back or neck surgeries, fibromyalgia, chronic headache syndromes, and general chronic pain syndromes may also be managed and/or sometimes treated with various modalities: TENS, manual therapies, and pain-free exercises. Certain types of chronic pain such as cancer pain, chronic headaches, and peripheral neuropathies may respond to laser therapy, microcurrent therapy, or STS therapy.

CONCLUSIONS

Physical therapy is a skill and an art using the head, hands, and heart. The head learns the anatomy, physiology, pain symptoms, and what evidence-based outcomes various types of modalities, exercises, and manual therapies produce. The hands apply the modalities, the manual therapies, and exercises. The heart supplies the empathy and the understanding that patients with pain need more than just modalities and exercise. Patients with pain need someone to lay hands on them, talk to, and listen, someone who cares. Physical therapists who treat patients with pain must have very big hearts.

Remember: "Pain does not have to be a way of life."

Social Work

Terry Altilio, LMSW

INTRODUCTION

Since the late 1970s, social work experts have been articulating and encouraging a role for the profession in the complex and rich specialty of pain management (Altilio, 2004; Hamilton, 1967; Holden et al., 1999; Hudgens, 1977; Kelley & Clifford, 1997; O'Neill, 2003; Roy, 1985a; Subramanian, 1991a, 1991b, 1994; Subramanian & Rose, 1988a). In many respects the profession has reflected the attitudes of the larger society as well as the field of health care wherein the treatment of pain has been viewed as a choice rather than an essential responsibility mandated by ethical principles such as beneficence and respect for the dignity of persons. Social workers practice in a range of settings, including hospitals, nursing homes, facilities for senior centers, hospices, correctional facilities, chemical dependency programs, mental health facilities, social service agencies, and private offices, providing extensive opportunity to advocate for, and promote and provide competent, compassionate pain management. This opportunity creates a mandate that clinicians become knowledgeable of the myriad issues that inform pain-related experiences. Social work authors have encouraged this potential for professional contribution and advocacy as it easily evolves both from our presence in multiple settings and from historical traditions and values such as commitment to vulnerable populations, social justice, and respect for the worth and dignity of the individual. An assessment of the person in the environment, which might include social, economic, cultural, and spiritual aspects of his or her experience, is fundamental to social work practice. These values infuse the profession's approach to clinical care, research, and policy work, and they have become increasingly important as the care of persons with pain has moved beyond the medical model to a multidimensional focus and most currently beyond the clinical relationship to the political, regulatory, and legislative arenas.

SOCIAL WORK AND PAIN MANAGEMENT: A UNIQUE FIT

The management of pain is often a shared responsibility — shared with patients and families, shared between disciplines. The care is enriched when disciplines come together bringing their unique perspectives, knowledge, and values. Social workers bring a worldview that is based in the belief and value that a "*person in environment*" perspective is the essence of comprehensive assessment and that the engagement process "*starts where the client is*" (Hamilton, 1967). These key social work values are also embedded in the treatment principles that pain is a multidimensional experience and that competent and compassionate care begins with a belief in the patient's report of pain. Acceptance of the patient's report, his or her language and metaphors, implies acceptance of the person and the perception of his or her experience; this is the basis of a beginning trusting and therapeutic relationship. The ongoing exchange, assessment, and expertise of the clinicians adds richness and depth to that report — expands and informs the multidimensional work that is often indicated and necessary. Identification of strengths is basic to the clinical and problem-solving approach of social work. This emphasis on strengths and competence is often key to assisting people who have been overwhelmed by pain to recover their voice, restore self-esteem, maximize their abilities, and create avenues of hopefulness and meaning in their lives. The unique heritage of social work creates

an expectation of holistic assessment and interventions which may range from the practical to the clinical to policy aspects of the pain experience.

The social work profession has a rich tradition and commitment to social justice, advocacy, and empowerment. These values are relevant to any discussion of the underserved person with pain and to the many barriers that limit access to adequate management of pain. The identification of barriers can be viewed as the beginning of the systemic diagnostic assessment that guides interventions whether they are on an individual, family, system, or policy level. The increasing presence of social work practitioners in advocacy organizations such as the American Pain Foundation, Alliance of Cancer Pain Initiatives, and many state pain initiatives speaks to the emerging recognition that the undertreatment of pain is the shared responsibility of many disciplines. Our commitment to self-determination, empowerment, and social justice mandates that the profession respond not only at the clinical level but also on the policy, political, and institutional level (O'Neill, 2003). The policy and regulatory focus of social work in the area of pain is most celebrated in the efforts of David Joranson, who has worked for decades to study and improve the national and international regulatory environment surrounding the use of opioids and the management of pain. The merging of social work values with key issues and principles of pain management is striking, and it informs the advocacy efforts of many social work clinicians who challenge their peers to become knowledgeable and expert, and to expand the presence of the profession in the field.

A HISTORICAL REVIEW

In 1981, Golden and Steiner published "Unique Needs of People with Chronic Pain" in the *Journal of Health and Social Work*. Reflective of the unique professional perspective, the authors discussed the individual, societal, and professional response to a multidimensional health problem that was cloaked in stigma. The article was intended to make practitioners "aware of the prevalence and nature of chronic pain so that their subjective and even unconscious relationship to this condition takes on new form and meaning" (p. 47). The authors noted increased patient vulnerability by virtue of minority or poverty status and/or gender as well as the potential for cultural variation in the pain experience. In addition to the societal and financial impact, chronic pain was described as a hidden epidemic often accompanied by threats to autonomy and competence, positive identity, and meaningful social relationships. Clinicians were challenged to recognize that social values and professional attitudes can create and reinforce isolation and stigma of chronic pain sufferers. The proposed factors that contributed to the social reluctance to accept the phenomena and prevalence of chronic pain

included the absence of methods to measure and prove pain and the inability to understand the cause, compounded by the fact that cures are elusive, reflecting and reinforcing feelings of practitioner incompetence.

Although the first pain clinic was established in 1961, many persons with chronic pain continued to receive care through local health and welfare agencies, reinforcing the need for social work clinicians to establish specialized skills to assist persons with pain. Suggested roles included therapist/teacher, broker/advocate; all were based on a therapeutic alliance intended to foster the restoration and enhancement of autonomy and competence. Therapist and teacher tasks included increasing the ability to describe, partialize, and manage the pain experience within the context of maintaining role function, minimizing strain in relationships, enhancing the environment to nourish and facilitate, and increasing coping skills. Advocate and broker roles involved a guide and liaison function driven by problem identification and focused on accessing available and needed resources and developing a plan to create a responsive treatment system (Golden & Steiner, 1981). The roles of advocate and broker, while important in 1981, are crucial today when health care systems have become more complex, inaccessible, and challenging for patients, families, and many clinicians as well.

Additionally, in 1981, Roy described the global nature of the psychosocial effects of chronic pain and suggested that the complex and multidimensional factors that infuse the chronic pain experience are a natural fit with a profession that incorporates comprehensive assessment of emotional, family, social, and environmental issues. A social work assessment is intended to identify relevant etiologic data, determine the effect of pain on psychological and social functioning, understand coping style, and create a diagnostic formulation to be used with medical input for the development of a treatment plan. Roy (1981) maintains, "the essential element — and the special if not unique focus that social work can bring to bear upon an assessment of a patient with chronic pain — is the understanding of the person-environment paradigm in all its complications" (p. 56). In chronic pain this may include such complicated and interconnected issues as a feeling of failure after numerous investigations and interventions, a sense of not being believed, and misunderstood when clinicians introduce the concept that psychological issues may impact the pain experience.

Precise exploration of roles, function, and the multiple aspects of family structure and dynamics is followed by a developmental history, which often informs the comprehensive understanding and the formulation of a treatment plan based on the individual, family, conflicts, and sociocultural factors. Suggested therapeutic interventions include client-centered, short-term educational and problem-solving approaches that foster coping and adaptation, improved family relationships, resumption of roles, resto-

ration of autonomy, and diminishment of maladaptive pain behaviors. While acknowledging the absence of outcome data on specific treatment strategies, Roy (1981) reinforces the importance of the social work perspective of addressing social, psychological, and environmental dimensions of the chronic pain experience and sees the integration of social work clinicians into multidisciplinary pain centers as an opportunity for the profession to both challenge traditional methods and demonstrate efficacy.

In 1986, Marcus proposed a social work view of chronic pain based in systems theory, which complemented team perspectives and integrated data from relevant frames of reference to provide a context and map that served to guide assessment and target interventions. In an effort to capture a visual representation of the complexity of interacting factors that contribute to the chronic pain experience, Marcus created a model that included pain, limitations and consequent emotional response, the reactions of others (including health care professionals), psychosocial stresses, and financial issues, as well as a comprehensive exploration of the personality, attitudes, culture, roles, and health status of the person with pain. The systems map allowed for assessment of the individual in relation to each variable providing an overview of factors influencing the pain experience. The modality validated pain as a problem in itself and as a "part" of the individual's reality, which has social and emotional impact. Treatment involved engaging the patient in active participation to reduce the disabling effects of pain and to enhance control, coping, and ego functioning. Interventions might include exploration and adaptation of role, education, problem solving, relaxation training, family interventions, and alleviation of external stresses through patient empowerment or systems negotiation (Marcus, 1986).

During the 1980s these generic articles providing overviews of the social work role were accompanied by an eclectic group of publications in social work journals and included pain in the dying (Milner, 1980); incest and pelvic pain (Caldirola et al., 1983; Gross, Doerr, Caldirola, Guzinski et al., 1981); burn pain (Weinberg & Miller, 1983); headache (Roy, 1984); disability, pain, and narcissism (Rousso, 1985); pain and marital difficulties (Roy, 1985a); family and chronic pain (Roy, 1985b); chronic pain, depression, and elderly people (Roy, 1986); chronic pain and cognitive behavioral group intervention (Rose & Feldman, 1986; Subramanian, 1994; Subramanian & Rose, 1988a, 1988b); pediatric end-of-life care (Price, 1989); and end-of-life symptom management as a contributing factor to social work job satisfaction (Parry & Smith, 1987).

In 1996, Sieppert surveyed 212 medical social workers in Canada, addressing their attitudes toward and knowledge of chronic pain by combining focus group and survey techniques. Subramanian's social work publications in the late 1980s and early 1990s encouraged clinicians to transfer an ecological systems model to the assessment of personal, psychological, social, and situational factors that infuse the experience of pain. Social workers were providing services in many settings other than pain clinics, which created the potential to have an impact on chronic pain in a large population both clinically and through research (Rose & Feldman, 1986; Subramanian & Rose, 1988b; Subramanian, 1987, 1991a, 1991b). Sieppert's investigations explored preparedness of medical social work to maximize these opportunities.

Sieppert's study supported Subramanian's view that social workers were becoming more visible participants on pain teams, as 40 of 47 organizations that maintained chronic pain programs employed social workers, implying that their skills and theoretical perspectives were valued. Only three respondents identified chronic pain as their primary focus, indicating that the profession was just beginning to explore pain as an area of interest. Findings from this study indicated that medical social workers recognized the importance of chronic pain treatment and the significance of this work to their own professional practice. They confirmed the need for training and expansion of their practice to the field of pain, and the underlying themes pointed to the value of social work in the area of advocacy and in assessment and intervention in psychosocial issues and family disruption. This study suggested that the highly positive orientation toward nonmedical treatment of pain and social work involvement in chronic pain services was not matched by the knowledge base of medical social workers, a discrepancy that must be addressed from the individual practitioner level as well as the level of social work education.

Practitioners have the capacity to explore independently the extensive literature, and educators must assume responsibility for developing pain-related training (Sieppert, 1996). The need for education of social workers is consistent with and sadly reflective of the need for pain management education and training of our nursing and physician colleagues.

During this same decade, the role, responsibility, and scope of social work practice in the management of cancer pain was being articulated in the writing of Loscalzo and Amendola (1990). Psychosocial and cognitive behavioral interventions were recommended as adjuncts to medical management, which might include pharmacologic, surgical, anesthetic, and radiologic interventions. The multidimensional, practical, problem-solving orientation of social work was at the core of a comprehensive, humane approach to meeting the practical, psychological, and emotional needs of oncology patients and their families who were coping with pain (Loscalzo & Amendola, 1990). The oncology literature had identified numerous barriers to the adequate management of cancer pain, and Glajchen, Blum, and Calder (1995) extended the advocacy and clinical focus of social work to the prevention of unnecessary pain and to overcoming barriers through direct service,

education, advocacy, and research. Direct service roles included facilitating communication; assessing strengths, resources, and limitations; providing psychological support; and developing problem-solving approaches that extend beyond the medical model to the environmental realities of the patient/family experience. Education of patients and families might take place with individuals, in psychoeducational groups, and workshops and might include interdisciplinary discussion of specific patient family issues or discharge planning needs.

Advocacy is a shared responsibility with pain management colleagues and for social workers; the scope often goes beyond the patient and family to multiple systems such as organizations, policy arenas, and insurers. Also included is the empowering of patients and their families to act as their own advocates. Clinicians themselves are encouraged to pursue research both to enhance quality of life for patients and families and to advocate for the profession by developing a literature supportive of social work practice (Glajchen, Blum, & Calder, 1995).

During the 1990s in addition to generic articles exploring the expanding areas of practice, social work literature included research directed toward quality of life in patients with back problems (Claiborne et al., 1999) as well as psychosocial problems in urban and poor children with sickle cell anemia (Barbarin, Whitten & Bonds, 1994), sickle cell group intervention (Butler & Beltran, 1993), pediatric migraine (Gilbert, 1999), long-term breast cancer survivors (Polinsky, 1994), chronic illness in a therapist (Elliott, 1996), childhood sex abuse and chronic back pain (Pecukonis, 1996), narrative approaches in treatment of patients with fibromyalgia (Kelley & Clifford, 1997), the impact of a virtual environment on pain and anxiety (Holden et al., 1999), cognitive behavioral interventions (Loscalzo & Jacobsen, 1990), and COPE problem solving in pain-related problems (Loscalzo & Bucher, 1999).

Current literature addressing generic issues and the role of social work in pain management reflects the recognition of the complexity and multidimensional issues surrounding the clinical, social, economic, and policy aspects of pain. MacDonald (2000) in the article, "A Deconstructive Turn in Chronic Pain Treatment: A Redefined Role for Social Work" challenges the diagnostic and treatment processes applied to patients whose pain is described as idiopathic. Writing as an educator, social worker, and chronic pain sufferer, she suggests a reevaluation of a treatment approach that focuses on the management of behaviors and attempts to reestablish well behaviors through the withdrawal of reinforcing influences. The author applies a process of "deconstruction" to the contingency management model, taking "apart socially constructed categories as a way of seeing how a particular world view is constructed" (Ristock & Pennel, 1996, p. 114). Using the word *sufferer* is intentional and is chosen to identify the "chronic pain patients' existence — their

physical, emotional and spiritual struggle" (MacDonald, 2000, p. 52). The contingency management model is challenged first in the area of criteria for application.

MacDonald suggests that professional judgment of excess behaviors is an effort to gauge an unmeasurable pain experience against operationally defined behavior. The supposition that chronic pain sufferers experience "gains" through their experience of pain contradicts the language of sufferers who speak of multiple losses. Social workers and health care professionals are encouraged to "listen to the voices of sufferers" to recognize their losses, validate their struggle, and create a plan to assist in rebuilding a sense of control. The withdrawal of reinforcing behaviors by staff and/or family runs the risk of alienating sufferers and increasing isolation, a potential outcome that obviates the goal of supporting and building families. The contingency model is also challenged as an approach that demands compliance, seeks out discrepancies in sufferer's behaviors, and thus contradicts relationships built on trust and active involvement.

MacDonald reinforces the traditional values of social work, including social, political, and economic distribution of resources and power and the promotion of the self-determination, dignity, and worth of all people. She suggests that these values create both a mandate and an opportunity to engage some of the inherent conflicts and challenges in delivery of care to chronic pain sufferers. Practice suggestions include nonhierarchical modalities of individual and family empowerment counseling, advocacy, organization of sufferers, research, and program construction (MacDonald, 2000).

A paper by Mendenhall (2003) provides a framework for social workers that conceptualizes barriers to pain management as misinformed personal beliefs of health care providers, undeveloped and inadequate industry policies, and dysfunctional social mores rather than a lack of adequate science. These barriers, when framed as psychological, social, and cultural elements, become a focus for social work intervention. A review of the literature concerning vulnerable populations, barriers, and social policy explores how the inclusion of social work perspectives creates options for overcoming barriers. Empowerment practice principles are offered as a framework to expand the effectiveness of multidisciplinary efforts to improve access to pain relief. The author invites social work clinicians to participate with colleagues to create effective policy to influence psychological, social, and cultural barriers with particular attention to the most vulnerable populations. Social policy aspects, including the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) standards, federal regulations, and issues related to assisted suicide, are discussed, weaving in the important concerns emanating from the use of controlled substances and the impact of media and legislation on the use of medications for management of pain. A thorough review

of empowerment theory sets the framework for integrating the core values of social justice, integrity, competence, and service to guide the profession's participation in the multidimensional issues of pain management. For example, social justice relates to identifying and advocating for those who receive differential care and to accepting responsibility for working toward solutions. Integrity requires social workers to define proactively their role in management of pain motivated by the well-known implications of untreated pain in the lives of patients and their families. Competence demands that clinicians practice within an area of expertise and expand their knowledge base as needs arise. The value of service is both to the patient and to institution and may be reflected in multidimensional approaches to increasing the status and adequacy of pain management. In summary, Mendenhall challenges the social work profession to view pain and its psychological, quality of life, financial, regulatory, and social policy aspects as well within the mission of social work as articulated in the 1999 *Code of Ethics,* "enhance human well being and help meet the basic needs of all people, with particular attention to the needs and empowerment of people who are vulnerable, oppressed and living in poverty" (National Association of Social Workers, 1999, p. 1).

Over the past 4 years, the social work literature has expanded to reflect the multidimensional nature of the pain experience and the eclectic focus of the profession. Glajchen (2003) has written of the delayed recognition within the health care system of the effects on family caregivers who assist persons coping with cancer pain. The fact that the impacts of pain extend beyond the individual to family and caregivers and into the social, psychological, spiritual, and social realms reinforces the need for clinicians to extend their assessment and interventions beyond the patient. Recommended treatment strategies focus both on enhancing coping skills as well as professional interventions that reflect the responsibility of clinicians to engage the family in decisions and planning and to support, validate, and educate (Glajchen, 2003). Otis-Green and colleagues (2002) describe an integrated psychosocial spiritual model for cancer pain management, which involves the collaborative effort of multiple oncology mental health professionals to assess from their unique perspective and create a comprehensive treatment plan to optimize effective, holistic pain management. The emerging emphasis on palliative and end-of-life care has fostered a growing literature and educational programs that include pain and symptom management as an expected social work competency (Otis-Green et al., 2002). Postgraduate educational programs, fellowships, and Web-based learning modules have included pain and symptom management as an essential part of the curriculum.

In addition to the clinical aspect of end-of-life care, Roff (2001) in an article, "Analyzing End-of-Life Care Legislation: A Social Work Perspective," advocated the need for social workers to have a clear understanding of the political and social climate as well as the policy proposals that are designed to respond to end-of-life challenges, one of which is unrelieved pain. To that end, she discusses frameworks for evaluating the adequacy of legislation and applies it to the Pain Relief Promotion Act, the Conquering Pain Act, and the Advance Planning and Compassionate Care Act. The expectation that clinicians become informed and involved in the policy aspects of pain is a recognition that the experience of the patients and families is profoundly influenced by the social and political environment in which they find themselves and that holistic care requires involvement and attention on multiple levels.

WHO ARE SOCIAL WORKERS, WHAT DO THEY DO, AND HOW DO THEY DO IT?

The Substance Abuse and Mental Health Services Administration (2000) reported that professional social workers are the largest group of mental health providers. In 1998, it was estimated that there were 190,000 clinically trained social workers. About 600,000 people hold social work degrees at the bachelor's, master's, and doctoral levels http://www.socialworkers.org/pressroom/features/general/profession.asp. Social work has the same educational challenges as our colleagues in medicine and nursing — to infuse generalist curriculum with knowledge about pain as a multidimensional issue that affects the individual, family, and larger society; to create programs to train specialists; and to increase the number of ongoing continuing education opportunities. With that said, social workers approach problems from a biopsychosocial perspective seeking to understand not only pain but also the setting in which the person functions and lives. To that end, we will join patients and colleagues to understand

- Who the patient is
- What values, beliefs, hopes, goals, and history informs their experiences and perceptions
- The impact and meaning of pain in their lives and the lives of others
- The reciprocal relationship between biological, psychological, cultural, spiritual, social, economic, family, caregiver, social system, and political aspects of the person's experience

We will listen for

- Strengths, resources, areas of competence
- Metaphoric communication

- Language that diminishes the other and reflects sufferer and/or clinician helplessness and hopelessness such as "failed" and "noncompliant"
- Opportunities to empower and restore some small semblance of control or purpose

We will intervene, in collaboration with colleagues, from a recognition that pain, medications, and various adaptations such as filing for disability or using a walker have symbolic significance and ramifications in multiple areas such as self-image, role definition, and family structure. Interventions might include

- Psychodynamic therapy, family counseling, cognitive behavioral techniques, problem solving
- Individual, family, group modalities
- Education, advocacy, and negotiation of systems
- Resource finding or development, networking
- Practical needs
- Discharge planning and referral

SUMMARY

The enhancement and extension of social work professional presence into the clinical, advocacy, research, and policy aspects of pain management is a natural outgrowth of the values, skills, and perspectives that are at the core of the profession. We are in the valuable position of being employed in many settings beyond the health care system and have the consequent responsibility to ensure that our practitioners recognize and maximize the opportunity to intervene with pain-related issues. It is the respectful thing to do.

Vocational Rehabilitation

Fong Chan, PhD, CRC, Gloria K. Lee, PhD, Kacie Blalock, MS, CRC,
Denise E. Catalano, MS, CRC, and Eun-Jeong Lee, MA

Work is considered therapeutic and essential for both the physiological survival and psychological well-being of people in contemporary societies (Chan et al., 1997; Dawes, Lofquist, & Weiss, 1968; Perrone, Perrone, Chan, & Thomas, 2000). Recognizing the importance of work, vocational rehabilitation professionals have consistently advocated for work as a fundamental human right of people with disabilities (Rubin & Roessler, 1995; Wright, 1980). Thus, the primary goal of vocational rehabilitation is to assist individuals with disabilities gain or regain their independence through employment or some form of meaningful activity (Parker & Szymanski, 1998; Rubin & Roessler, 1995). Several major vocational rehabilitation systems have been established to help people with disabilities achieve their employment goals, including, most notably, the state–federal vocational rehabilitation program and the private sector rehabilitation system.

Vocational intervention is also considered appropriate in medical rehabilitation programs (Chan, Parker, Lynch, & Johnson, 1986). However, Fawber and Wachter (1987) argued that traditional vocational rehabilitation, which typically occurs at the end of the treatment continuum, is insufficient for effecting successful job placement for persons with chronic illness and disability. Rather, they proposed a treatment-oriented placement process that seeks to distribute responsibility for vocational rehabilitation outcomes among all interdisciplinary team members throughout the entire treatment continuum. The important benefit of aggressive vocational rehabilitation programming within the overall operation of any treatment program is its capacity to provide direction, focus, and meaning to other therapies or services. Vocational rehabilitation

is therefore best regarded as a "pull factor" (i.e., providing direction and meaning) and, as such, is distinguished from other "push factor" therapies (i.e., those from which the hope is the client will become independent) (McMahon & Fraser, 1988). The probability of successful vocational outcome is enhanced when all therapies can be related to work and when work can be related to therapy. McMahon and Fraser provided specific suggestions regarding how interdisciplinary team members might approach their respective duties to maximize the level and stability of ultimate job placement.

The interplay between vocational adjustment and psychological adjustment is well documented in the rehabilitation and counseling literature (Perrone et al., 2000). Without any doubt, vocational rehabilitation can play an important role in enhancing psychosocial and vocational outcomes of people with disabilities including people with chronic pain. Hence, it is imperative for health care professionals who work with patients with pain in rehabilitation to become familiar with the philosophies, processes, and systems of vocational rehabilitation in order to incorporate return-to-work as one of the major rehabilitation goals for their clients and to utilize vocational rehabilitation as major treatment resources.

The purpose of this chapter is to (1) provide an overview of the state–federal vocational rehabilitation program, the private sector rehabilitation system, and the rehabilitation processes associated with these systems; (2) review best practices and outcomes of vocational rehabilitation within the context of evidence-based practice; and (3) discuss qualifications of vocational rehabilitation professionals in a multidisciplinary rehabilitation team.

VOCATIONAL REHABILITATION SYSTEMS

STATE–FEDERAL VOCATIONAL REHABILITATION PROGRAM

The state–federal vocational rehabilitation program was established on a federal level in 1920, with the passage of the Smith–Fess Act (Public Law [PL] 66-236). This rehabilitation legislation offered grants-in-aid to state vocational rehabilitation agencies to provide vocational services to people with physical disabilities. The Vocational Rehabilitation Amendments of 1943 (PL 78-113), referred to as the Barden-LaFollette Act, extended state vocational rehabilitation services from serving only people who had physical disabilities as their primary disabilities to services for people with mental retardation and mental illness (Parker & Szymanski, 1998). Currently, vocational rehabilitation is defined by the 1998 Amendments to the Rehabilitation Act as a comprehensive sequence of services, mutually planned by the consumer and rehabilitation counselor, to maximize employability, independence, and integration and participation of people with disabilities in the workplace and the community.

Prior to 1973, the rehabilitation philosophy of the state–federal vocational rehabilitation program could be described as an economic-return philosophy. The emphasis was on returning as many people with disabilities to work as possible and at a minimal cost in order to demonstrate the cost-effectiveness of vocational rehabilitation programs. Therefore, the priority was to serve people with mild and moderate disabilities. With the passage of the 1973 Rehabilitation Act Amendments emphasizing services to people with *severe* disabilities, the philosophy of rehabilitation has evolved from an economic-return philosophy to a disability-rights philosophy — that is, working and living independently and assertively in the community is considered a civil right of people with disabilities. As expected, consumerism and empowerment become central to the vocational rehabilitation process in the state–federal program in recent years.

Rehabilitation counselors have the direct service responsibilities for working with people with disabilities in the rehabilitation process and are central to the success of the state–federal vocational rehabilitation program. Specifically, rehabilitation counseling has been described as a process where the counselor works collaboratively with the client to understand existing problems, barriers, and potentials to facilitate the client's effective use of personal and environmental resources for career, personal, social, and community adjustment following disability (Parker & Szymanski, 1998). In carrying out this multifaceted process, rehabilitation counselors must be prepared to assist individuals in adapting to the environment, change environments to accommodate the needs of the individual, and work toward the full participation of individuals in all aspects of society, with a particular focus on

independent living and work (Jenkins, Patterson, & Szymanski, 1998).

To be eligible for services, an applicant for vocational rehabilitation services must (1) have a physical or mental impairment, which for such individual constitutes or results in a substantial impediment to employment, and (2) be able to benefit in terms of an employment outcome from vocational rehabilitation services. In addition, because of limited financial resources, vocational rehabilitation programs in their respective states are required to develop "order of selection" plans to prioritize services for people with disabilities (e.g., people with several significant functional limitations requiring multiple services over an extended period of time may receive the highest priority for services, while people with less severe disabilities may be placed on a waiting list). Currently, the federal government provides for 78.7% of the budget for state-run vocational rehabilitation programs, which translates roughly into about $2 billion in federal grants, matched by $645 million in state and local funds. Because of the federal reporting requirements, state-run vocational rehabilitation programs all follow a fairly standard rehabilitation process:

- Eligibility determination
- Rehabilitation plan development
- Service provision
- Job placement

During the eligibility determination phase, the focus of rehabilitation services is on diagnoses. Typically, a vocational rehabilitation client will be referred to diagnostic services such as general and specialty medical examinations, psychological evaluation, and vocational evaluation. The purpose of these diagnostic examinations is to determine functional limitations related to disability; to identify psychosocial, educational, and economic factors that might interact with disabilities to impede ability to work and live independently; to identify the strengths of the client; to develop appropriate vocational goals; and to identify services needed to achieve the client's immediate objectives and long-term vocational rehabilitation goals. During the service provision stage, the majority of the services provided to people with disabilities include restoration of physical function (e.g., surgery, prosthesis, or assistive technology); restoration of mental function (e.g., psychotherapy); academic, business, or vocational training; personal or vocational adjustment training; employment counseling; and job placement and job referral (Spitznagel, 2002).

As mentioned, the interplay between vocational adjustment and psychological adjustment is well documented in the rehabilitation and counseling psychology literature (Perrone et al., 2000). Rehabilitation health professionals working with clients with chronic pain condi-

tion should consider state-run vocational rehabilitation program as a potential resource for referral, especially if the client is interested in vocational assessment and counseling, vocational training, and job placement. State-run vocational rehabilitation programs are particularly appropriate for clients with limited financial means.

WORKERS' COMPENSATION AND INSURANCE BENEFITS SYSTEMS

The impetus for private sector rehabilitation (also known as proprietary rehabilitation and insurance rehabilitation) can be traced to the skyrocketing cost of workers' compensation in the 1970s (Chan & Leahy, 1999; Shaw, McMahon, Chan, Taylor, & Wood, 1997). Private sector rehabilitation grew in response to the demand for vocational rehabilitation services by workers' compensation insurance carriers (Matkin, 1995). Federal legislation also promoted the growth of private sector case management services. The 1970 Federal Occupational and Safety Health Act (OSHA) (PL 91-596) required the development of a National Commission on State Workmen's Compensation Laws. This commission issued a report in 1972 with 84 recommendations for improvement of the workers' compensation system, including recommendations related to vocational rehabilitation (Parker & Szymanski, 1998). The report suggested that not enough was being done to help injured workers to return to work and acknowledged the apparent problems in attempting to have the state–federal rehabilitation system serve the workers' compensation caseload (Matkin, 1995). It recommended the creation of specific rehabilitation units with medical/rehabilitation divisions. Funding for vocational rehabilitation was paid by employers, which resulted in many states enacting mandatory rehabilitation programs (Jenkins et al., 1998). By 1976, 27 states had developed some type of vocational rehabilitation program and, during the late 1970s and early 1980s, many more enacted mandatory provision of vocational rehabilitation within their workers' compensation laws. As a result, fewer and fewer workers' compensation and insurance benefits programs relied solely on the public rehabilitation program to return their claimants to work. The primary goal of private sector rehabilitation services is an early return to work and to minimize loss of earnings capacity by the injured worker to help mitigate insurer and employer losses. Since the 1970s, rehabilitation nurses and rehabilitation counselors have been hired in increasing numbers to provide medical and vocational case management services to workers' compensation recipients. As expected, the majority of injured workers served in private sector rehabilitation reported injuries to the head, neck, back, trunk, and the extremities, with back injuries appearing to be most prevalent, consisting of at least 50% of the workers' compensation cases (Davidson, 1994).

1. Return to work: same job, same employer
2. Return to work: same job modified, same employer
3. Return to work: different job (capitalizing on transferable skills), same employer
4. Return to work: same job, different employer
5. Return to work: same job modified, different employer
6. Return to work: different job (capitalizing on transferable skills), different employer
7. Return to work: different job with re-training, same or different employer
8. Return to work: self-employment

FIGURE 20.1 The return-to-work hierarchy. Adapted from R.E. Matkin (1995) in Foundations of the rehabilitation process, 4th ed. Austin, TX: Pro-Ed.

Historically, the vocational rehabilitation process within the context of the workers' compensation system is similar to the federal–state vocational rehabilitation process of eligibility determination, rehabilitation planning, treatment/intervention, and job placement. Vocational rehabilitation is defined as the array of services designed to facilitate and ease the return to work (Berkowitz, 1990). Typical services include, but are not limited to, vocational training, general skills upgrading, refresher courses, career counseling, on-the-job training program, job search, and consultation with employers for job accommodation and modification. It generally follows a path of least resistance and, inherently, minimal cost to the employer, while seeking to return the injured worker to preinjury vocational functioning. The return-to-work philosophy in private rehabilitation differs somewhat from the federal–state vocational rehabilitation program in that it is based on an economic model and not a human rights model. The optimal outcome for workers' compensation rehabilitation is to return the injured worker to his or her former employment capacity and not his or her optimal potential. The return-to-work hierarchy in private rehabilitation is presented in Figure 20.1.

After several decades of explosive growth, private sector rehabilitation has now witnessed a reduction in the use of vocational rehabilitation services in workers' compensation due to lack of concrete evidence for its efficacy (Berkowitz & Berkowtiz, 1991; Habeck, Kress, Scully, & Kirchner, 1994). As pointed out by Habeck (1996), the fundamental problem for this less than successful experiment of private sector rehabilitation is precisely due to the traditional vocational rehabilitation process it follows. Unfortunately, services from rehabilitation professionals most often are brought to bear after the critical, early period of intervention has passed, and the barriers to rehabilitation posed by time delay, litigation, and the demotivating effects of disincentives have occurred. Vocational rehabilitation in work disability is most often used as a "last-ditch effort" after all other attempts have failed. The rehabilitation process is typically controlled by third parties and removed from the worksite, and the essential relationship between employer and the employee in the

rehabilitation process has been lost. In addition, the weakening of the work injury programs can be attributed to the failure of the rehabilitation counseling profession to carefully document justifications for rehabilitation services and the lack of empirical data to justify vocational rehabilitation (Chan et al., 2001; Currier, Chan, Berven, Habeck, & Taylor, 2001).

Disability management, a proactive work rehabilitation approach, is now touted as an alternative service paradigm to the reactive traditional individual-focused service approach in private sector rehabilitation. Akabas, Gates, and Galvin (1992) define disability management as follows:

> A workplace prevention and remedial strategy that seeks to prevent disability from occurring or, lacking that, to intervene early following the onset of disability, using coordinated, cost-conscious, quality rehabilitation service that reflects an organizational commitment to continued employment of those experiencing functional work limitations. (p. 2)

From the onset, employer commitment and involvement in disability prevention and management are considered central to the success of disability management. According to Habeck (1996), the practice of disability management can be differentiated from traditional private-sector vocational rehabilitation in terms of the ability of disability management specialists to (1) provide early intervention and return-to-work programming at the onset of injury or illness, (2) provide services at the workplace to a greater extent, and (3) maintain a proactive employer–employee focus. In response to the need to diversify private sector rehabilitation services, private rehabilitation specialists are beginning to change their practice approach to embrace the proactive approach of disability management in workers' compensation.

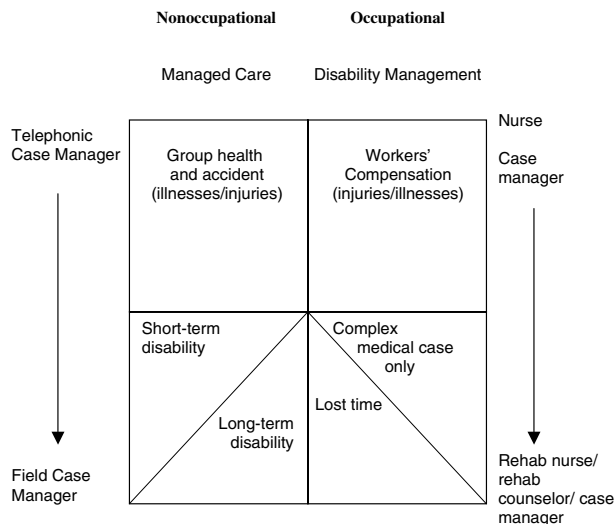
The evolvement of disability management practice can be best demonstrated within the 24-hour care (integrated benefits systems) framework of the managed care movement (Lui, Chan, Kowk, & Thorson, 1999). In general, 24-hour care means an employee is covered around-the-clock under a managed care package, whether or not an accident or illness is job related (Knight, 1997). Knight suggested group health (HMO) and workers' compensation carriers have much to learn from each other. She cited back injury as an example of how the same injury may be approached very differently by the two benefit systems. For example, rehabilitation professionals in workers' compensation benefit systems often recommend more frequent therapy and move aggressively to other methods, whereas group health practice stays with a treatment for a much longer time. She believes that return-to-work techniques would also help group health contain costs. In addition, the use of a single provider to treat an employee's occu-


FIGURE 20.2 Case management interventions in an integrated health care system. From *Health Care and Disability Case Management* (p. 106), edited by F. Chan and M. Leahy, 1999, Lake Zurich, IL: Vocational Consultants Press. Reprinted with permission.

pational and non-occupational injuries would prevent duplicate claims and services.

Lui et al. (1999) provides a framework for conceptualizing health care and disability case management services that includes vocational rehabilitation counselors within an integrated health care system. Figure 20.2 depicts the relationship between occupational and non-occupational injuries/illnesses, the roles of vocational rehabilitation counselors in the intervention process, and a continuum of health care and disability case management interventions.

Under this model, a 24-hour care plan could benefit from both the advent of case management interventions developed for managed care (group health) and disability management (workers' compensation). At the highest level, the concern of the employers is the physical and mental health of their employees. Case management interventions at this level include wellness programs, health education, stress management training, and employee assistance programs to foster a healthy life style. Safety education and the design of an ergonomically sound workplace can help prevent work-related injuries. Case managers with a rehabilitation counseling, nursing, occupational therapy, or physical therapy background could be responsible for handling these prevention activities. A rehabilitation case manager who is also a certified rehabilitation counselor or a licensed professional counselor could also provide in-house vocational and psychosocial adjustment counseling.

Case management interventions at the time of illnesses and injuries would focus on *early* medical intervention and conflict resolution to avoid an adversarial

relationship between the employee and the employer. Early intervention requires the cultivation of easy access to a network of quality providers such as rehabilitation counselors, who understand occupational health and return-to-work issues. Telephonic medical case management would be appropriate for most situations; the resulting compressed timeframe in medical management would reduce the number of cases that become lost-time cases. However, field-based case management may be required for catastrophic injuries or complicated medical cases (e.g., chronic pain). Examples of cases considered to be catastrophic include amputations, traumatic head injury, spinal cord injuries, severe burns, multiple factures, and crushing injuries. Other indicators that a field-based case manager/rehabilitation counselor intervention may be needed include when:

- The physician reports that the injured worker is unlikely to return to his or her former job
- The physician labels the period of disability as indefinite
- There is prolonged physical therapy
- There is prolonged excessive chiropractic treatment
- The physician cannot offer a specific treatment plan
- The medical diagnosis or prognosis is unclear
- Medical complications develop in addition to injury
- There are coexisting medical problems (e.g., epilepsy)
- The employee is unhappy with the treatment program, fails to follow the treatment plan, or seeks a second medical opinion
- Experimental, alternative, or otherwise unsubstantiated medical procedures are included in the treatment plan
- There is a psychiatric reaction to the injury or condition (e.g., depression)

Nursing case managers would be responsible for this level of care. For cases of severe injuries/illnesses resulting in disabilities (short/long-term disability or lost time), intensive medical case management would be required to ensure optimal medical rehabilitation. At the same time, the use of rehabilitation counselors to promote early *safe* returns to work may be extremely important. As soon as the client is medically stable and the functional capacity of the person can be accurately predicted, a vocational rehabilitation counselor would be assigned to conduct a functional job analysis, identify job accommodation needs, determine transitional alternative duties, and provide disability adjustment counseling to help the client cope with his or her disabling conditions. The goal is to help the client return safely to his or her previous level of

employment as soon as possible. If unfeasible, the goal would be to help identify alternative job placement and/or retraining needs. In addition, the rehabilitation case manager would be involved in training job supervisors and co-workers regarding the on-the-job support needs of the disabled worker.

Recently, McMahon et al. (2000) documented a phenomenon of the progression of disability benefits (PODB). They defined PODB as the migration of workers with work-limiting disabilities as they move through a system of economic disability benefits resulting in their ultimate placement into the Social Security Disability Insurance (SSDI) system. An effective way to control the growth of the SSDI enrollees is to initiate programs that would reduce the flow of new persons onto these rolls. In this context, one could argue that health care and disability case management could be construed as one form of "service intervention." The Social Security Administration is currently exploring innovative ways (e.g., the ticket-to-work initiatives) to return SSDI recipients to gainful employment. It is clear that rehabilitation counselors can play a significant role in providing upstream services such as disability prevention, disability management, disruption of PODB, and downstream services such as vocational rehabilitation services for recipients of short-term disability, long-term disability, and SSDI benefits.

Vocational rehabilitation counselors in the private sector also play a significant role in forensic rehabilitation as vocational experts. Rehabilitation counselors can be retained to assess the preinjury work capacity/earning capacity and post-injury work capacity/earning capacity of clients as well as the life care planning needs of clients in workers' compensation, medical malpractice, third-party liability, and other personal injury litigations. The vocational expert plays a vital role in the hearing process by presenting evidence on behalf of either the plaintiff (injured worker) or the defendant (insurer, employer) (Lynch, Lynch, & Beck, 1992; Matkin, 1995; Weed & Field, 1994). This "forensic" role of the vocational case manager is becoming more common although recent legislative and policy initiatives have sought to diminish this litigious environment.

EVIDENCE SUPPORTING THE EFFECTIVENESS OF VOCATIONAL REHABILITATION

Evidence-based practice can be defined as a total process beginning with knowing what clinical questions to ask, how to find the best practice, and how to critically appraise the evidence for validity and applicability to the particular care situation (Chronister, Cardoso, Lee, Chan, & Leahy, 2005). The best evidence then must be applied by a clinician with expertise in considering the patient's unique values and needs. The final aspect of the process is eval-

uation of the effectiveness of care and the continual improvement of the process. Ottenbacher and Maas (1999) indicate that the "best evidence" for evidence-based practice is derived from a series of research study results that form an empirical consensus regarding the effectiveness of a specific treatment approach. Within the field of medicine, with its positivist scientific methods tradition, the "gold standard" for scientific evidence is randomized clinical trials, and the method of choice for determining the cumulative evidence of the effectiveness of a treatment is meta-analysis. Holm (2000) and Gray (1997) describe a hierarchy of levels of evidence from which professionals can formulate an empirical consensus and determine "best evidence" regarding the effectiveness of a treatment approach:

- Level 1 evidence is defined as strong evidence from at least one systematic review of multiple well-designed randomized controlled trials.
- Level 2 evidence is defined as strong evidence from at least one properly designed randomized controlled trial of appropriate size.
- Level 3 evidence is defined as evidence from well-designed trials without randomization, single group pre–post, cohort, time series, or matched case-controlled studies.
- Level 4 evidence is defined as evidence from well-designed non-experimental studies from more than one center or research group.
- Level 5 evidence is defined as opinions of respected authorities, based on clinical evidence, descriptive studies, or reports of expert committees.

EVIDENCE FOR THE FEDERAL–STATE VOCATIONAL REHABILITATION PROGRAM

As discussed, vocational rehabilitation services typically include several of the following: diagnostic evaluation, medical restoration, personal adjustment training, independent living training, job readiness training, vocational training, and job placement. The use of experimental research to validate the effectiveness of vocational rehabilitation is, unfortunately, uncommon due to the complex and holistic nature of the rehabilitation process (Johnston, Stineman, & Velozo, 1997). Contemporary vocational rehabilitation intervention encompasses a broad scope of services, spans along the medical–vocational rehabilitation continuum from acute care to community based services, and is provided through an array of disciplines (e.g., nursing, social work, and rehabilitation counseling) for individuals with diverse and complex impairments and disabilities. The process typically involves a range of personal and environmental processes and the interactions thereof, making it difficult to determine what aspects of

service delivery contribute to what outcomes (Johnston et al., 1997). Bolton (2004) contends that it would be virtually impossible to design and implement a randomized study to examine the overall effect of state-run vocational rehabilitation programs because clients who are eligible for services must be served and clients who are placed on waiting lists according to "order of selection" criteria are clients with less severe disabilities and therefore are very different from clients who receive vocational rehabilitation services immediately.

Conversely, counseling is a central, integrative activity that serves to unify the rehabilitation service delivery process. Within this context, there does exist a variety of *indirect* Level 1 evidence that suggests that the counseling context of rehabilitation service provision results in benefits to clients. Literally hundreds of experimental studies of the efficacy of counseling have been reported in the research literature during the past 50 years. The initial meta-analysis of these investigations concluded that clients benefit considerably from the various types of psychotherapeutic and counseling interventions (Smith & Glass, 1977; Smith, Glass, & Miller, 1980; Wampold, 2001). In a meta-analysis of 475 controlled outcome studies, Smith et al. (1980) demonstrated an average effect size of .85 standard deviation on the outcome measure of the treatment over the control group, indicating that the typical client receiving counseling was better off than 80% of those untreated but in need of counseling.

Additionally, the working relationship between the client and counselor, which is most often referred to in the literature as the "working alliance," has gained overwhelmingly strong empirical support as a primary influence on rehabilitation and counseling outcomes. Working alliance can be defined as (1) the client's affective relationship with the therapist, (2) the client's motivation and ability to accomplish work collaboratively with the therapist, (3) the therapist's empathic responding to and involvement with the client, and (4) client and therapist agreement about the goals and tasks of therapy.

In a meta-analysis involving thousands of studies designed to investigate the efficacy of counseling interventions on client outcomes, Wampold (2001) determined that it is common factors such as working alliance, empathic listening, and goal setting that underlie all psychotherapeutic approaches that affect outcomes, not techniques associated with specific theoretical orientations. He found that at least 70% of psychotherapeutic effects are due to common factors, 8% are due to specific factors (i.e., different theoretical orientations/techniques), and the remaining 22% was partially attributed to individual client differences. In a review of extant meta-analyses related specifically to the efficacy of working alliance, Horvath (1994) found a "robust relationship" between working alliance and positive counseling outcomes, with an average effect size of $r = .26$. Working alliance is especially

conducive to active participation between clients and counselors in the rehabilitation process (Chan et al., 1997). Schelat (2001) surveyed 255 state vocational rehabilitation (VR) clients who were closed successfully or unsuccessfully in 1998 and found that all factors of working alliance (i.e., goal, task, and bond) are predictive of rehabilitation outcomes, with high scores strongly predictive of successful outcomes. Lustig, Strauser, Rice, and Rucker (2002) examined survey data of 2,732 VR clients during fiscal year 2000 and found that (1) employed clients had a stronger working alliance than unemployed clients ($d = .73$; large effect), (2) a stronger working alliance was related to a more positive client perception of future employment prospects ($r = .51$; large effect), and (3) a stronger working alliance was related to employed rehabilitation clients' satisfaction with their current jobs ($r = .15$; small effect). Donnell, Lustig, and Strauser (2004) surveyed 305 individuals with mental illness and also found working alliance to be related to employment outcomes and job satisfaction. The results of these rehabilitation studies suggest that the working alliance may be an important aspect of vocational rehabilitation services that can lead to positive rehabilitation outcomes.

Promoting self-efficacy is another important aspect of vocational rehabilitation. Although skills training is frequently used to promote the self-efficacy of individuals with severe and persistent mental illness and alcohol and other drug abuse problems, the concept of skills training in the areas of social skills, coping skills, general life skills, and specific job skills is also applicable to individuals with other disabilities. Bolton and Akridge (1995) conducted a meta-analysis of skills training interventions for people with disabilities in vocational rehabilitation and found that outcome measures resulted in an estimated true effect size of +.93, suggesting substantial benefit to the typical participant.

In psychiatric rehabilitation, numerous narrative reviews indicated that skills training using behavioral methods is effective in teaching a variety of social and living skills to persons with mental health problems. Benton and Schroeder (1990), in a meta-analysis of the efficacy of social skills training for individuals with schizophrenia, found that 69% of the people receiving social skills training were better off than people without social skills training. People with alcohol dependence receiving social skills training and coping skills training also were found to maintain a higher number of abstinent days than people without such training (Drummond & Glautier, 1994; Eriksen, Bjornstad, & Gotestam, 1986; Hester & Miller, 2003). Hester and Miller indicate that the social and coping skills training approach is the most efficacious treatment in substance abuse rehabilitation.

Although it is not possible to conduct randomized clinical trials for state-run vocational rehabilitation services as an independent variable, the state–federal vocational rehabilitation program is required by the Rehabilitation Act to conduct ongoing research to demonstrate the effectiveness of rehabilitation interventions on employment outcomes of people with disabilities. There is ample Levels 3 and 4 evidence that vocational rehabilitation is an effective intervention to enhance the employment outcomes of people with disabilities. For example, during fiscal 1995, state-run vocational rehabilitation programs provided services to 1.3 million people with disabilities (Kaye, 1998). In that year, 350,700 clients exited the system after receiving services. Of those who exited the system, 210,000 clients (60%) were considered to have been rehabilitated, and people with orthopedic impairments represented the largest group (21%) of successful cases. The 60% employment rate is significantly higher than the 33% employment rate for people with disabilities in the general population. Industrial (26%) or services jobs (25%) represented the most common job placement outcomes (Kaye, 1998). Dean, Dolan, and Schmidt (1999) conducted an independent study to examine the cost-effectiveness of the federal–state vocational rehabilitation program, using a quasi-experimental research design and found that vocational rehabilitation returns roughly $2.50 for each dollar spent. The Rehabilitation Service Administration (RSA) that administers the state–federal vocational rehabilitation program has reported to the Congress that every dollar spent on vocational rehabilitation to return people with disabilities to gainful employment generates $18.00 in tax payment to the government. Recently, RSA conducted a longitudinal study, using a random sample of 8,500 clients, to examine the effectiveness of vocational rehabilitation services (Research Triangle Institute, 2002). Clients of vocational rehabilitation services in the RSA study indicated the following:

- Their counselors were interested and concerned about their needs (70%) and were willing to listen to their ideas and suggestions (75%).
- They were given sufficient choice in the selection of their vocational goals (75%) and were satisfied with their goals (76%).
- Vocational rehabilitation services had helped them become employed (61%), and they obtained the job they wanted as a result of vocational rehabilitation services (63%).

Private Sector Rehabilitation

There is a paucity of outcomes research in private sector rehabilitation; no randomized clinical trail studies were found for private sector rehabilitation. Johnson, Chan, and Questad (1987) found that severity of disability, presence of an attorney, number of previous back injury claims, and lifting restrictions are strong predictors of case expenditures. Faimon, Hester, Decelles, and Gaddis (1987)

reported the following 10 variables to be significant in predicting return-to-work status of clients with long-term disability claims: type of financial support received due to the disability, level of education, percentage of wage replacement of the predisability earnings, predisability occupation, type of disability, type of predisability employer group, gender, age, population density of area of residence, and marital status. Lam, Bose, and Geist (1989) examined all 216 workers' compensation case file closures (from 1983 through 1987) of a proprietary rehabilitation company and found that the most frequent medical diagnosis was low-back pain (54%). The rehabilitation rate of the company was 61%, with 36% of the clients returned to work with the same employer after rehabilitation and 25% to a new employer. Preinjury physical demands of the job and the residual physical capacity of the client were found to be the two most important factors differentiating the employed and unemployed groups.

Zaidman and Clifton (cited in Davidson, 1994) examined the long-term effectiveness of workers' compensation rehabilitation in Minnesota. Results of their study indicated that at the time of program completion, 69% of workers in the study returned to work with an average wage of $360 per week (93% of the average preinjury wage). Of the remaining 31% who did not return to work, one third settled the cases and about two thirds eventually returned to work. Zaidman and Clifton indicated that early intervention significantly increased the probability of returning to work; an acceleration of the intervention by 6 months raised the likelihood of retuning to work by two percent. They attributed two factors, older age (older than 40 years) and living in rural areas, as the main reasons for unsuccessful rehabilitation.

There are some empirical evidences that disability management is effective in controlling costs in work injury programs (Daiker, 1995; Lui, 1993; Tabak, 1995). Habeck, Leahy, Hunt, Chan, and Welch (1991) found that an organization's workers' compensation experience may be affected by organizational factors and behaviors that can be controlled or influenced. Further, Habeck et al. (1991) found that reduced incidence of work injury was associated with certain employer behaviors that emphasized safety and prevention. They found a lower incidence of workers' compensation claims in organizations that were more actively involved in safety, in the prevention and management of work injuries/disabilities, and in open and participatory relationships with employees. In a subsequent study of a larger random sample of employers, Habeck and colleagues (Habeck, Hunt, & VanTol, 1998; Habeck, Scully, VanTol, & Hunt, 1998) found fewer incidents that resulted in lost workdays and a lower incidence of total lost workdays and workers' compensation claims in organizations that were more diligent and thorough in their safety efforts. These employers devoted management time and resources to support prevention, to provide a proactive approach to return to work beginning as early as possible and involving all the parties in the process toward accommodation, and to create a work climate that values people.

UNUM Insurance Company of America, a leading provider of disability insurance, employee benefits, long-term care, and retirement products, works with high-risk employers at the organization level to implement disability management programs. These programs include prevention activities such as job restructuring, ergonomic engineering, and job safety training and early intervention such as stay-at-work services and other vocational rehabilitation intervention for injured worker receiving short-term disability or long-term disability benefits. A cost–benefit formula is applied based on the cost of services, the cost of providing present and future benefits, and employer and employee benefits. Using this formula, UNUM has calculated that for every dollar expended, there is a return in the range of $5 to $7 (Hunt, Habeck, Owens, & Vandergoot, 1996). Similarly, United Health Care, one of the largest health maintenance organizations with more than 2.7 million enrollees, using an integrated disability management service approach, also reported a five-to-one return on investment, supporting the benefits of disability management services in private sector rehabilitation (Hunt et al., 1996).

VOCATIONAL REHABILITATION OF INDIVIDUALS WITH CHRONIC PAIN

There has been limited research conducted to determine the effect of vocational interventions on the rehabilitation outcomes of chronic pain patients. Allaire, Li, and LaValley (2003) conducted a randomized controlled trial study to study the effectiveness of vocational rehabilitation for patients with rheumatic diseases. The researchers found that at 48-month follow-up, 97 of 122 (80%) participants in the vocational rehabilitation intervention group remained employed with no job loss, as compared with 72 of 120 people (60%) in the control group. They concluded that early intervention is the key to the successful outcomes, as vocational rehabilitation intervention is more effective for individuals who are at risk of losing their jobs but less effective for individuals who had already lost their jobs.

Multidisciplinary pain treatment programs have been popular to treat chronic pain disability when other methods have failed. Loeser, Seres, and Newman (1990) report an exemplary 3-week, structured, outpatient program, staffed by an attending physician and psychologist, physical and occupational therapists, pharmacists, nurses, and vocational rehabilitation counselors. The program has a strong, operant-behavioral focus where pain behaviors are not reinforced by staff, while coping and competency behaviors are reinforced. Patients are taught about chronic pain disability and rehabilitation, and about increasing their

competency and perceived self-efficacy to cope with pain and the rehabilitation process through the cognitive-behavioral and psychoeducational components of the program. Aerobic exercise and strength-training, using quotas, are key components as well. Family members and/or significant others are required to participate to ensure that the environment to which the patient returns is modified. Vocational rehabilitation is frequently a significant component.

Aronoff, McAlary, Witkower, and Berdell (1988) also indicate that a multidisciplinary approach of chronic pain management involves specialists from various professions to modify pain and drug-seeking behavior and to interrupt the disability process as desirable. Aronoff et al. (1988) conducted a systematic review of various multidisciplinary pain treatment programs and reported return-to-work rates of these programs ranging from 50 to 100%. They found that vocational rehabilitation is an integrated component in many of these multidisciplinary pain programs. Vocational rehabilitation services provided by these programs typically include work hardening, job search, job placement, and job accommodations and modifications.

Recently, Turk (2002) reviewed the clinical effectiveness and cost-effectiveness of various medical and rehabilitation treatment programs for individuals with chronic pain. Some of the common treatment modalities include pharmacology, surgery, spinal cord stimulators, implantable drug delivery systems, and pain rehabilitation programs. He found that none of the single mentioned treatment modalities has a significant effect on the elimination of pain. However, multidisciplinary pain rehabilitation programs do provide comparable reduction in pain, in addition to having a significant improvement in other outcome measures such as decreased use of medication, decreased health care utilization, increased functional activities, increased rate of return to work, and higher closure of disability claims. In terms of vocational outcomes, Turk (2002) indicated that the return-to-work rates of patients participating in multidisciplinary pain rehabilitation programs ranged from 48 to 65%, as compared with other treatment modalities such as lumbar surgery (20%) and implanted medication delivery (5 to 31%). Turk (2002) remarked that most individuals who have been out of the workforce for a long period of time tend to have difficulty finding jobs due to the lack of updated vocational training, job search, and development skills and can therefore readily benefit from vocational rehabilitation interventions.

QUALIFICATIONS OF VOCATIONAL REHABILITATION PROFESSIONALS

As mentioned, rehabilitation counselors are central to the delivery of vocational rehabilitation services. Since 1967, rehabilitation counselor roles and functions studies have been conducted on a regular basis, with several receiving support from the Commission on Rehabilitation Counselor Certification (CRCC) and the Council on Rehabilitation Education (CORE) (Leahy, Chan, & Saunders, 2003; Leahy, Shapson, & Wright, 1987; Leahy, Szymanski, & Linkowski, 1993). Leahy et al. (2003) conducted the most recent roles and functions study, which involved a survey of a large random sample of certified rehabilitation counselors. This study examined the perceived importance of major job functions and knowledge domains that underlie contemporary rehabilitation counseling practice and credentialing. Results revealed seven major job functions as central to the professional practice of rehabilitation counseling in today's practice environment: (1) vocational counseling and consultation, (2) counseling interventions, (3) community-based rehabilitation service activities, (4) case management, (5) applied research, (6) assessment, and (7) professional advocacy.

The vocational counseling and consultation function was composed of four subfactors: (1) job development and placement, (2) career counseling, (3) employer consultation, and (4) vocational planning and assessment. The tasks associated with counseling interventions were organized into three subfactors: (1) providing individual, group, and family counseling; (2) building consumer–counselor working relationships; and (3) helping consumers cope with specific psychosocial issues related to disabilities. The community-based rehabilitation service function represents activities that involve such tasks as (1) researching resources and funding available in the community for consumers, (2) advocating for consumers and their families, (3) benefits counseling, (4) and marketing rehabilitation services to the community. The case management function involves such activities as (1) obtaining written reports regarding client progress, (2) developing rapport/referral network with physicians and other rehabilitation health professionals, (3) reporting to referral sources regarding progress of cases, and (4) making financial decisions for caseload management. The applied research function focuses primarily on applying research skills to evidence-based professional practice (e.g., reviewing clinical rehabilitation literature on a given topic or case problem). The assessment function represents assessment activities such as selecting and administering standardized tests and conducting ecological assessment. Finally, the professional advocacy function involves applying disability-related policy and legislation to daily rehabilitation practices. On a daily basis, the most frequently performed tasks fall under the functional domains of case management, professional advocacy, and counseling, followed by vocational consultation, assessment, utilization of community-based services, and applied research (for evidence-based practice).

Roles, functions, and knowledge validation research has been used to guide the development of graduate curriculum in rehabilitation counseling. Currently, there are

90 graduate programs in rehabilitation counseling accredited by the National Council on Rehabilitation Education. In addition, roles and functions studies have been used to develop national examinations for the certification of rehabilitation counselors with the certified rehabilitation counselor credential considered the "gold standard" for vocational rehabilitation professionals. The Certified Rehabilitation Counselor (CRC) credentialing process was the first, and considered to be the best, established certification mechanism in the counseling and rehabilitation professions within the United States (Leahy & Holt, 1993). The CRCC was officially incorporated in January 1974 to conduct certification activities on a nationwide basis. Since that time, more than 23,000 qualified professionals have participated in the certification process. Today, more than 14,000 CRCs are practicing in the United States and in several other countries (Shaw, Leahy, & Chan, 2005).

The primary purpose of certification is to provide assurance to rehabilitation counseling clients that services will be provided in a manner that meets the national standards of quality. Such standards are also considered by the profession to be in the best interest of the client (Leahy & Holt, 1993). To guide these standards, the CRCC established a Code of Professional Ethics for Rehabilitation Counselors, which delineates exemplary rehabilitation counseling as being a service that is client centered, is sensitive to an array of disabilities, is vocationally inclusive, encourages a collaborative and multidisciplinary focus, and is defined within the context of an established profession (Tarvydas, Peterson, & Michaelson, 2005). In addition to the CRC credential, many rehabilitation counselors hold related credentials such as the certified case manager (CCM), which has a strong focus on medical case management, or the certified disability management specialist (CDMS), which emphasizes vocational case management. The latter replaced the certified insurance rehabilitation specialist (CIRS) credential (Tarvydas et al., 2005).

There is good empirical evidence to support that counselors with a master's degree in rehabilitation counseling (the minimum requirement for a CRC) have better rehabilitation outcomes (Cook & Bolton, 1992; Szymanski, 1991; Szymanski & Danek, 1992; Szymanski & Parker, 1989). Szymanski and colleagues investigated the relationship of rehabilitation counselor education and experience to client outcomes in Arkansas, Maryland, New York, and Wisconsin. They found that counselors with master's degrees in rehabilitation counseling (or closely related fields) produce better outcomes for clients with severe disabilities as compared with counselors without such educational preparation. Frain, Ferrin, Wampold, and Rosenthal (2004) conducted a meta-analysis of rehabili-

tation outcome studies done between 1980 and 2004. They found a small educational effect of $d_+ = .20$, indicating that the average client who is served by a counselor with a master's degree in rehabilitation counseling is better off than 58% of those in the control group who are treated by a counselor without a master's degree in rehabilitation counseling. While the effect size of education is small, this is above and beyond the effect of interventions provided as part of the vocational rehabilitation process.

SUMMARY

There is some empirical evidence to support the efficacy, clinical utility, and cost-effectiveness of vocational rehabilitation in returning people with chronic illnesses or disabilities to competitive employment. Research reporting the cost-effectiveness ratios of public and private sector rehabilitation programs varies considerably, ranging from approximately a 3-to-1 ratio to an 18-to-1 ratio. Central to the delivery of vocational rehabilitation services is the rehabilitation counselor, with moderate support found for counselors with graduate training in rehabilitation counseling being more effective than counselors without degrees in rehabilitation counseling. There is strong empirical evidence to support the efficacy of certain components of the counseling process including working alliance and skills training. There is a paucity of research, however, addressing the efficacy of vocational rehabilitation for people with chronic pain. Yet, a high percentage of clients served by the public and private sector rehabilitation systems are reported to have orthopedic or back injuries indicating that vocational rehabilitation interventions might be useful for people with chronic pain. Nevertheless, programmatic outcome research conducted specifically to determine the effect of vocational rehabilitation on the psychosocial and vocational outcomes of people with chronic pain is warranted.

In closing, vocational rehabilitation services have been found to be underused and their values unappreciated in the treatment of patients with pain (Straaton & Fine, 1997). However, vocational rehabilitation represents a highly desirable alternative to a "work disability." Vocational rehabilitation can help prevent or minimize potentially devastating personal consequences of a work disability that often culminated in the loss of employment, reduce excessive dependence on other persons and health and social service agencies, and save enormous amounts of taxpayer and third-party money. For these reasons, rehabilitation health professionals need to be more knowledgeable and efficient in the early identification and referral of patients with pain to vocational rehabilitation.

The Pharmacist Role in Pain Management

Gregory L. Holmquist, PharmD, BCOP

INTRODUCTION

Surveys of public opinion have consistently ranked pharmacy as a highly respected profession. In general, pharmacists are respected for their knowledge, integrity, compassion, ability to provide "down-to-earth" relevant information about medications, and overall friendly, courteous demeanor. In an outpatient setting, pharmacists often represent the last professional seen by a patient prior to implementing a medical treatment. Having the last interaction affords an opportunity to prevent problems overlooked by other health care professionals. As opposed to the respect shown to the pharmacy profession by many, pharmacists may be viewed by some as obstructionists. Waiting in long lines to pick up expensive medications, for which the insurance company will not authorize coverage, may lead to patient frustration. Frustration intensifies if the prescription is not ready or if the prescriber does not authorize the refill. Patients who perceive that a "drug" is the only answer or the chief solution to their condition may view the pharmacist as a roadblock to successful procurement of their "miracle." Unfortunately, in many of these circumstances, the pharmacist is the one who is blamed as the responsible party.

The dichotomy of viewpoints of the pharmacy profession is most likely related to the perception of the role of the pharmacist. Pharmacy is both a business and a profession. For the most part, the "business" of pharmacy encompasses retail and wholesale aspects of marketing and selling medications (both over-the-counter and prescription products), ancillary products (including everything from sun-tanning lotions to condoms), and a variety of products unrelated to the medical world (e.g., greeting cards, candy, and books). The business side of pharmacy includes large and small chain stores, community pharmacies, pharmaceutical companies, wholesalers, and others. The "profession" of pharmacy, usually referred to as "clinical pharmacy," can take place in any of the aforementioned business models. Clinical pharmacy is a broad term that usually refers to pharmacist's involvement in assuring that medications are handled, stored, and dispensed in the safest, most efficacious, and most clinically sound manner and that drug-related problems are minimized. Another term often used to describe the clinical activities of pharmacists is "pharmaceutical care." The American Pharmaceutical Association defines *pharmaceutical care* as patient-centered, outcome-oriented pharmacy practice. Pharmaceutical care is designed to promote health, prevent disease, and assess, monitor, initiate, and modify medication use to assure that drug therapy regimens are safe and effective.[1] Activities pertinent to the provision of pharmaceutical care include prevention of drug-related problems through review of medication regimens, medical records, and charts of outpatients, nursing home residents, and hospitalized patients; consultation with members of the health care team to assist in the design of clinically efficacious and cost-effective drug regimens; education of the lay public and health care providers on the appropriate use of medications and methods to prevent the occurrence of adverse effects; design and oversight of drug research; and numerous other clinical interventions that ultimately serve to enhance the medical care of patients. Both the "business" and the "profession" of pharmacy have changed dramatically in the past century[2] (Table 21.1). This has led to a consequent change in the practice of pharmacy and the role of pharmacists.

Fulfilling the pharmacy needs of the more than 50 million persons in the United States who suffer from pain

TABLE 21.1
The Changing Role of Pharmacy

Time Period	Key Practice Points
Late 1800s	• Independently owned stores predominated • Most owners of pharmacies never attended pharmacy schools; training occurred through apprenticeship • Common name for owner was "druggist" • Main job was selling patent medicines and supervising the sale of sodas, candy, and cigars, with prescription drug business secondary • Most prescriptions were mixtures of opium, ipecac, quinine, iron, digitalis, belladonna • Hospital pharmacists only in the largest and most established institutions
Early 1900s	• Food and Drugs Act passed in 1906 • Harrison Narcotic Act passed in 1914 • First requirement for pharmacy school diploma for licensure in New York in 1905 • During prohibition pharmacies handled prescriptions for medicinal alcohol; hospitals hired pharmacists to provide inventory control and safeguard of medicinal alcohol supplies • Drugstore soda fountains replaced taverns as social gathering places during prohibition (1920–1933) • Hospital pharmacists made effort to differentiate themselves from community pharmacists via associations • American Association of Colleges of Pharmacy (AACP) adopted a 4-year bachelor's degree as the national requirement (1928)
Mid-1900s	• Pharmacists the only medical professionals exempted from service in World War II • Supreme Court ruled that FDA could enforce its designation of prescription-only status for certain medications (1948) • Durham–Humphrey Amendment to the Food, Drug and Cosmetic Act resulted in removing almost all discretionary latitude of pharmacists in determining prescription versus nonprescription status • Mass manufacturing reduces need for pharmacist to compound prescriptions leading to the era of "count and pour" • American Pharmaceutical Association (APhA) (1952) code of ethics for pharmacists delineates pharmacist role as "safeguarding the preparation, compounding and dispensing of drugs and the storage and handling of drugs and medical supplies"; the pharmacist is instructed to "not discuss the therapeutic effects or composition of a prescription with a patient" but instead to send the patient to the physician for such discussions • In addition to numerous penicillin derivatives, introduction of numerous new medications in the 1950s that influence the outcomes of diseases (warfarin, chlorpromazine, methotrexate, reserpine, tolbutamide, hydrochlorothiazide, hydrocortisone, and imipramine) • Five-year degree instituted as the norm for pharmacists (1960)
Late 1900s	• Clinical pharmacy role emphasized at Hilton Head conference (1985) • Model of pharmaceutical care established that defines the role of pharmacists to identify and prevent drug-related problems • State and federal laws allow for expanding the role of pharmacy technicians to free pharmacist time for clinical interventions • Omnibus Budget Reconciliation Act of 1990 (OBRA '90) recognized pharmacists as professionals whose expertise can be effectively utilized to promote rational outcomes from drug therapy • Institution of automated prescription filling machines separates the pharmacist farther from the "count and pour" functions • Doctor of Pharmacy degree (Pharm.D.) established as the national requirement for pharmacists • Most states mandate that pharmacists provide education (counseling) to patients receiving new prescriptions

Note: Adapted from Higby, G. J. (1997). *American Journal of Health-System Pharmacy, 54,* 1805.

can be complex, challenging, and time-consuming. Most patients with chronic pain syndromes will at some point in their life require palliation with multiple medications including simple analgesics (acetaminophen, aspirin, nonsteroidal anti-inflammatory drugs [NSAIDS]), adjuvant agents (antidepressants, anticonvulsants, local anesthetics, N-methyl-D-aspartate [NMDA], receptor antagonists, muscle relaxants, topical agents, etc.), and opioids. Furthermore, patients with pain conditions often require the prescribing (and endless refilling) of large quantities of multiple medications for a myriad of associated symptoms such as insomnia, depression, anxiety, and muscle spasms. Guidelines and expert opinion[3-24] suggest that medications should not be used as a sole strategy in the comprehensive

management of pain syndromes, nor should they be viewed as "quick fixes." Unfortunately, many patients with pain syndromes have inflated, and often unrealistic, expectations for the chief purpose of medications. Pharmacists must recognize that there are many opportunities to affect the care of these patients, both positively and negatively, as well as to play a fundamental role in reinforcing key messages regarding the role of medications for pain.

Despite reports of pain-focused pharmaceutical care services,[25-29] studies of practicing pharmacists have generally shown an inadequate level of knowledge about the therapeutics of pain management[30] and the laws and regulations governing the use of opioid analgesics[31]. Before discussing the potential positive roles of the pharmacist

in pain management, it is vital to present a brief discussion of one key area in which the pharmacist can be a barrier to effective pain management. This area is the conflict in the pharmacists' perceived roles in advocating for strong pain medications (i.e., opioids) versus their stewardship of controlled substances. For example, from the patient perspective, it seems that some pharmacists are excessively suspicious of them and their motivations for having pain or "wanting" a pain medication, excessively worried about "addiction," and excessively nervous about dispensing a prescription for anything other than small quantities of widely recognized pain medications. The patient is often scrutinized in a suspicious manner whenever a prescription for a pain medication is presented.

Granted, an appropriate role of the pharmacist is to ascertain the safety, validity, and clinical appropriateness of prescribed medication(s). However, suspicions may be exaggerated for certain pain medications, the number of refills listed, the perceived legality of the prescription, and among other things, the number of pills prescribed (perhaps pharmacists wondering to themselves, "Was it supposed to be 100 tablets or was that '10' changed to a '100' by the patient by the addition of a '0'?"). Furthermore, without adequate clinical information relating to the patient's pain condition, the pharmacist may become nervous about the patient taking the medication on a "regular basis." Counseling the patient, the pharmacist may erroneously state, "Only take this medication when and IF you have pain" (giving the subliminal message, "These 100 pills better last a lifetime!"). Pharmacists who focus their role toward being "drug police" versus being patient advocates also increase the reluctance of physicians to prescribe pain medications. Using the drug police mentality, pharmacists sometimes turn their suspicions to the prescriber, (perhaps muttering to themselves, "Wow, that doc sure does prescribe a lot of pain meds!").

Practitioners who were once willing to provide pharmacological interventions become frustrated with justifying the validity of pain medication prescriptions to this type of pharmacist. Pharmacists who do not possess an in-depth understanding of up-to-date pain management principles and current controlled substances policies may compound the problem further. Drawing the wrong conclusion, the pharmacist may consider that the chronic use of certain pain medication prescriptions (e.g., opioids) is "poor practice," "marginally legal," or "not in the patient's best interest." Ultimately, the pharmacist who envisions his or her role more in the realm of drug police may deem it necessary to interrogate the physician regarding the validity of the prescription, may make skeptical, condescending comments to patients regarding their intent for use of the medication(s), or may even go so far as to report the physician to the medical board or Drug Enforcement Agency. Obviously, these actions are time-consuming and costly to the prescriber, are intimidating and unsettling to the patient, and do not further the goals of care.

While the above discussion may give the appearance that the pharmacist's role in managing pain is mainly counterproductive, it is the author's opinion that the majority of pharmacists provide a benefit to the interdisciplinary team approach. The remainder of this chapter highlights key roles for pharmacists in pain management, from both the "business" and the "professional" side of pharmacy.

Americans spend more than $75 billion per year on prescription and nonprescription drugs. Problems associated with improper use of medications are illustrated by the following:

- Improper use of prescription medicines due to lack of knowledge costs the economy an estimated $20 billion to $100 billion per year.[1]
- American businesses lose an estimated 20 million workdays per year due to incorrect use of medicines.[1]
- The failure to have prescriptions dispensed and/or renewed has resulted in an estimated cost of $8.5 billion for increased hospital admissions and physician visits — nearly 1% of the country's total health care expenditures.[1]
- Documented records indicate that medication errors are responsible for more than 7,000 deaths annually[32]
- An FDA review found that there were more than 56,000 emergency room visits a year due to acetaminophen overdoses, about a quarter of them unintentional. Additionally, it found that there were about 100 deaths annually associated with acetaminophen.[33]
- Conservative estimates from U.S. data suggest that on an annual basis more than 100,000 people are hospitalized for gastrointestinal bleeds secondary to NSAIDS and, of those, 16,500 die.[34]
- In 2001, of 22,242 poisoning deaths in the United States, 14,078 (63%) were unintentional. In an analysis of 11 states, the substances associated most frequently with unintentional and undetermined poisoning deaths were cocaine (15%), alcohol (8%), heroin (7%), antidepressants (5%), benzodiazepines (5%), and methadone (5%). Nonspecific categories, such as "other opioids" (e.g., codeine, morphine, oxycodone, and hydrocodone), "other synthetic narcotics," "other and unspecified narcotics," and "other and unspecified drugs, medicaments, and biological substances" accounted for approximately half of all the documented substances associated with unintentional and undetermined poisoning deaths.[35]

- In an unpublished study, two out of three terminally ill persons experiencing moderate to severe pain refused additional pain treatment. The top reason patients with cancer refused additional pain treatment was fear of addiction.

EDUCATION

All the above and other problems could perhaps be influenced by one of the most important and influential roles of the pharmacist: education. Patient and family education is a vital component of the pharmacist's professional and ethical duty. A position statement by the American Society of Health System Pharmacists affirms, "Pharmacists can contribute to positive outcomes by educating and counseling patients to prepare and motivate them to follow the pharmacotherapeutic regimens and monitoring plans."[36] The general broad-based goals of patient education surrounding pain medications are to ensure that the patient fully understands (1) the role of the medication for their pain syndrome; (2) the potential benefits, risks, and side effects; (3) what action to take should a side effect occur; (4) how to properly use, store, and if needed, dispose of the medication; (5) potential drug–drug interactions with current therapies, newly prescribed medications, and any subsequently purchased over-the-counter medications; (6) action to take in the event a dose is missed; (7) the availability or lack of refills and the process to obtain refill authorizations; and (8) techniques for self-monitoring of drug therapy. And, of course, the pharmasist needs to answer any questions the patient might have.

In addition to broad-based educational objectives, there are specific pain medication–related teaching opportunities that the pharmacist is the ideal professional to address. First, prior to implementation of any pharmacological intervention, pharmacists can assist patients to clearly understand key concepts regarding the appropriate role for analgesics and adjunctive medications in the overall treatment plan. Second, because many patients have fears of taking medications in general and these fears are often magnified with opioid analgesics, pharmacists can be key to allaying unwarranted fears. Key discussion/education topics to meet these two specific areas include teachings on physical dependence versus addiction risks, tolerance concerns, medication agreements (also referred to as "medication contracts"), "trial-and-error" approach to adjuvant medications, benefits versus risks of simple analgesics, role of maintenance opioid therapy and adjuvant medications, pharmacological rationale of short-acting versus long-acting time-release opioids, role of topical therapies, and nonpharmacological alternatives. The fear of addiction is so engrained in the minds of patients and families that it often becomes the greatest barrier to the willingness of patients and family members to administer these medications, even when pain is at a high level during

the final weeks, days, and hours of life. A frank and open discussion between the pharmacist and the patient/family will not just allay fears, but will increase the likelihood of proactive pain management.

The pharmacist can also be a valuable asset in reinforcing key concepts and messages conveyed by other members of the pain team. When a patient hears a message consistently repeated by various respected health professionals, the message can become a powerful influence to changing behaviors that ultimately will improve the functioning and care of the patient. For example, many patients with chronic pain have inflated views of the role of a medication for improving their pain and functioning. Some patients may opt out of lifestyle modifications, physical therapy, and rehabilitation programs if they can "just take a pill to feel better." This erroneous mentality, a very passive approach, can lead patients to becoming more dysfunctional over time. Passive activities (taking medications, massage therapies, etc.) may provide a certain level of comfort, but they often do not improve the functionality of the patient over the course of time. A chief strategy of many pain clinics is to assist patients improve their functioning by establishing exercise, physical therapy, socialization, and recreational goals, and then, over a period of time, having the patient incrementally increase activities in these areas. From a behavioral viewpoint, it is suggested that therapies that divert the patient's attention from their pain are more likely to improve function, and vice versa.[37] The pharmacist, by reinforcing the message that "medications are only one part of the strategy to deal with chronic pain" and emphasizing "the need to engage in active strategies (e.g., regular exercise, weight loss, physical therapy)" can assist in balancing the patient's perceptions and behaviors regarding the use of pain medications. This ultimately will improve patient adherence to a comprehensive interdisciplinary plan, resulting in improvements in functioning and pain. Examples of key messages that pharmacists can reinforce are summarized in Table 21.2.

The members of the pain team or hospice team, including the physician, psychologist, nurse, physical therapist, physiatrist, social worker, and others, look to the pharmacist as the definitive source of medication information. Providing education to these professionals affords an opportunity to positively affect the use of medications to manage pain. Today's graduating pharmacist has undergone 6 years of college and graduate education to attain the Doctor of Pharmacy degree. Additionally, after graduation, many pharmacists attend 1- or 2-year general or specialty residencies and/or fellowships. The training the pharmacist receives not only focuses on drug knowledge, but also includes courses on literature evaluation, research methodology, biostatistics, pathophysiology of diseases, and much more. The advanced training adapts the pharmacist well to the role of providing education to the other

TABLE 21.2
"Key Messages" to Patients with Pain Regarding Medications

Message

1. The pain team uses many methods to help control your pain. Medications may or may not be the best method for your pain condition.
2. Medications alone typically are not able to totally relieve your pain. Based upon the type of pain you have, we may use medications other than opioids (narcotics) to help control your pain.
3. In order for the pain team to obtain the most effective pain control for your condition it is important that you help us monitor your level of comfort, sleep, exercise, and activities by keeping a daily diary. Bring this diary with you to each doctor appointment.
4. Many of the medications we use to help control your pain take several weeks to work. You must continue taking the medications as directed in order for the pain team to know if this medication will work for you. Also, report any bothersome side effects to your doctor.
5. If it is decided that the use of an opioid (narcotic) is the best choice for your pain condition, it is important that you follow all directions exactly. Having to take opioids (narcotics) for pain does not mean that you automatically will become an "addict."
6. Medications more commonly used to treat depression or seizures can be effective in certain pain conditions. Using one of these medications for your pain condition does not necessarily mean that we think you are depressed or that the pain is only in your mind.
7. Because pain conditions change over periods of time, we may need to change medications, increase the dose of your current medication, and/or attempt to decrease the amount of pain medication you are taking.
8. The right dose of a pain medication is the lowest dose that works.
9. Constipation is one of the most frequent side effects of pain medications. The pain of constipation can sometimes be worse than the pain we are treating with the medications. It is important that you take stool softeners and mild laxatives prescribed by your physician. The goal is to have one bowel movement every day or every other day.
10. Taking medications other than those prescribed by your physician can cause serious side effects. Let the pain team know of all medications you are taking (including those medications you buy over-the-counter).
11. Anxiety can be caused by pain as well as cause more pain. However, it is best not to use medications to control anxiety.
12. Taking too much over-the-counter pain relievers such as acetaminophen (Tylenol) or ibuprofen (Advil, Motrin) or naproxen (Alleve) can be harmful to your kidneys and liver. Let your doctor or pharmacist know if you plan on using any of these medications.

health care providers on the team. Education can occur as one-on-one consults, formal lectures, informal in-services, continuing education articles, written and oral summaries of published studies, formulary reviews, written educational materials for patients, treatment algorithms, and a host of other activities that add value to the care of the patient with pain. The use of medications, especially opioids, for managing pain can be a controversial issue. Pharmacists lend credibility to medication decisions by factual analysis of studies. Evidenced-based decisions are becoming a hallmark of good medical practice. Pharmacists are well trained to quickly review the medical literature, offer a science-based critique, and distill key points of the literature into a clinically sound recommendation.

Finally, advocacy represents an indirect, but very important educational opportunity. Patient advocacy uses the knowledge and compassion of a pharmacist to informally educate practitioners. Because of the inherent trust in pharmacists, patients will often disclose information to a pharmacist that would not be shared with other members of the health care team. Advocacy is an active role in which the pharmacist, in listening to the patient or in reviewing the medication record, uses his or her extensive drug knowledge to compassionately encourage and persuade a practitioner to prescribe a needed medication or discontinue an unneeded or side-effect-prone medication. Advocacy centers on the patient's palliative care needs and uses good communications skills to educate the practitioner, allay myths and fears, and instill a confidence in the pre-

scriber that the care of the patient will be improved if the pharmacist's recommendation is implemented.

COLLABORATION

Collaborative drug therapy affords an opportunity for the pharmacist to work directly with the physician and others to design regimens that are safe and clinically effective. The team approach is designed to maximize the patient's quality of life, reduce the frequency of avoidable drug-related problems, and improve the overall benefits of medications. Collaboration puts the patient at the center of a team that includes a pharmacist, a physician, and other health care professionals. It includes basic dispensing functions, drug information services, the solving of patient-related and medication-related problems, and decision making regarding drug prescribing and monitoring and drug regimen adjustments.[38] While there are no published studies suggesting direct measurable benefits of collaboration in the area of pain management, several studies have assessed pharmacist participation in drug therapy decisions in a variety of settings, including pharmacy-based disease management and on hospital rounds.[39,40,41] In these and other published studies, pharmacist collaboration in drug therapy has been deemed successful, leading to improved patient care and safety and lowered medical costs.

Physicians collaborating with pharmacists regarding complex pain management cases have an opportunity to

simplify drug therapy choices, minimize the risk of drug-related problems, and co-develop unique medication regimens. Patients with chronic pain or those who are terminally ill with end-of-life pain often are receiving multiple medications. Patients with pain are at higher risk for drug interactions and adverse effects, as they often require the simultaneous administration of multiple medications for pain, other symptoms, and underlying conditions not related to pain, yet all are often vital to the overall care of the patient. Collaboration implies that the pharmacist will provide recommendations to the physician regarding several aspects of therapy, including (1) selection of new medications that will not interact with current medications; (2) discontinuance of medications that are ineffective or that have a high risk of interacting with current medications deemed as essential; (3) dose reduction or dose increase of interacting drugs to avoid toxicities and maintain maximal efficacy; (4) route selection and information on how to administer medications via unique routes (e.g., inhalation therapy, buccal absorption, transdermal delivery) to ensure adequate serum levels and clinical efficacy; and (5) information on third- or fourth-line options, when other evidence-based, standard-of-care options have failed to improve the quality of life of the patient with pain. The pharmacist is skilled and adept in reviewing complex medication scenarios and making recommendations for modifications not just to simplify the administration of the medication regimen, but also to minimize adverse effects and drug interactions. Collaboration with a pharmacist can greatly assist the physician who has exhausted "standard" options.

DRUG SAFETY

Medications have the power to heal and the power to cause tremendous harm. For the patient with pain, the goal of any medication is to improve the overall quality of life more than the side effects of the medication diminishing it. Many patients with chronic pain and cancer pain will require the use of multiple medications for years, potentially decades, and perhaps even the rest of their lives. Given the longevity of medication use, patients with pain are at risk for serious adverse events. Given the multiple medications prescribed, they are at risk for drug–drug interactions. The pharmacist is in a unique position to be a guardian of drug safety. The pharmacist is mandated by law to maintain comprehensive medication profiles for every patient. Because most medication profiles are computerized, it is a simple process to examine for patterns of dangerous drug use. Additionally, most pharmacies have computerized prescription entry systems that are programmed to readily identify serious and potentially serious drug interactions.

A key example suggestive of how pharmacists can use information from medication profiles to improve drug safety in patients with pain relates to acetaminophen toxicity. Many patients are unaware of the risk of developing hepatotoxicity from the consumption of excessive doses of acetaminophen products or from the combination of chronic alcohol consumption and acetaminophen. Many patients with pain are also unaware that trade name analgesic combination products such as Vicodin®, Lortab®, Norco®, Lorcet®, Tylox® contain large amounts of acetaminophen. Furthermore, patients often do not make the connection between the common brand name of acetaminophen (Tylenol®) and the warnings given by the pain team regarding not to exceed the maximal daily doses of acetaminophen. The pharmacist, via computerized patient profiles, can easily review months and years of medication use, readily compute the average daily amount of acetaminophen (from all sources) that the patient is consuming, and instantly determine if the patient is at risk for acetaminophen-induced toxicity. Collaboration with the physician to develop a treatment plan to reduce average daily acetaminophen consumption can prevent 1 of the 100 plus deaths associated annually with this commonly used analgesic.

Another key drug safety measure that pharmacists can influence includes recognition and differentiation between patient behaviors that are typical of drug abuse, diversion, or addiction versus those of untreated pain. While the vast majority of patients who use opioids for pain do so in a manner consistent with the directions prescribed by the physician and only a small percentage of patients receiving opioids for pain become iatrogenically addicted, pharmacists have an ethical obligation to ensure that all drugs are used in the safest possible manner and only for the medical condition prescribed. There is a fine balance that a pharmacist must walk between being compassionate and being duped.

Pharmacists should not overbalance their perceived duty as drug police with their duty to ensure that patients are respected, believed, and given the dignity that everyone deserves. Pharmacists should be outspoken on both the negative aspects of drug abuse and the shortcomings of poor pain management. Pharmacists understand the pharmacological basis for "physical dependence" and that it is not to be equated with "addiction." Pharmacists understand how "tolerance" influences drug dosing. Patients who are erroneously labeled "drug seekers," when in fact they have a legitimate pain that is not being managed, are often denied prescriptions for opioid analgesics or have received very limited quantities. Patients denied appropriate analgesics often desperately consume excessive dosages of over-the-counter analgesics (including alcohol), which can lead to serious adverse effects.

Other drug safety activities performed by pharmacists include verifying medication dosages and correcting errors; interpreting and confirming poorly legible or illegible handwritten prescriptions; ensuring appropriate use

of medication delivery systems; calculating and verifying opioid dose conversions, reviewing medication profiles for medications that might be contraindicated due to patient specific factors (e.g., age, renal dysfunction, allergies); recommending therapies to counteract the adverse effects of analgesics; ensuring the integrity of sterile products for intravenous, intrathecal, or epidural use; and correcting erroneous and mythical pain management information that patients receive from uninformed health care practitioners, fearful family members, and unscrupulous Internet sites.

COMPOUNDING

In the 1930s and 1940s, pharmacists compounded about 60% of all medications. During the 1950s and 1960s, as more drugs were mass-produced, compounding declined. Beginning in the 1980s, compounding began to reemerge as a way to meet specific patient needs. Today, according to the Professional Compounding Centers of America, some 43,000 prescriptions — about 1% of all prescriptions — are compounded each day. A "compounded medication" is a customized medication prepared by a pharmacist according to a doctor's specifications to meet an individual patient need. Compounded medications can be specialized preparations for oral, sublingual, transdermal, topical, intravenous, subcutaneous, intra-articular, inhalation, and spinal use. Conventional medicine has usually accepted the idea that some patients are not good candidates for mass-produced drugs. They may be allergic to preservatives or dyes in the drugs or sensitive to standard drug strengths. In these cases, a compounding pharmacist can prepare a drug to alter its strength, eliminate the allergens, or make it more digestible or palatable. A compounding pharmacist can also put a drug in a form that does not have to be taken orally, thus avoiding systemic side effects.

The advantages of a compounded medication can be significant. Many medications used for pain and palliative treatment are commercially available in only oral or parenteral formulations and in standard strengths. For a patients with chronic pain, having a product that can be prepared for a topical application may mean lack of systemic side effects. For end-of-life patients who are unable to swallow, having a product compounded into a buccal, transdermal, or rectal formulation may allow a family member or the patients to continue to administer medications at home, thereby allowing them to live their final days, weeks, or months in the comfort of their home setting.

There are risks associated with the use of compounded medications when they are prepared without the specialized services of a pharmacist trained in the compounding process. Infections and deaths can occur if preparations of parenteral therapies occur without the use of appropriate equipment and sterile techniques. Efficacy can be compromised or toxicities can occur if products are compounded without rigid quality control standards. In spite of numerous anecdotal reports and cases suggesting efficacy of compounded topical analgesics such as gabapentin, dextromethorphan, and amitriptyline, there is a lack of controlled trials demonstrating clear benefits, appropriate application techniques, or approved dosages. Pharmacists can assist in providing recommendations for the use of topical products and direct physicians to products that have support in the literature to suggest efficacy.

DISPENSING, STOCKING, FILLING

Over the past 20 years the role of pharmacists has evolved to one that spends less time with "product" and more time with the patient. While the expanded role of technicians and advancements in technology have freed the pharmacist from many of the duties traditionally associated with the "count, lick, and pour" role, the pharmacist is still a critical link in the chain of drug distribution to the patient. To dispense opioid analgesics, pharmacists must comply with the requirements of federal and state drug, pharmacy, and controlled substances laws. Federal and state laws mandate that the pharmacist is responsible for the inventorying and accountability of all scheduled (controlled) substances. Most patients with pain will be prescribed some form of a controlled substance and the pharmacist is key in ensuring that all legal requirements are fulfilled with the filling and dispensing of the product. Beyond what the law allows, pharmacists have little discretion in refill authorization, telephone/fax prescriptions, emergency authorizations, etc. The pharmacist serves a role as "gatekeeper" who must determine whether dispensing a prescription order will serve a legitimate medical purpose and be in the usual course of professional practice.

The pharmacist's role in inventory control also has potential ramifications for patients with pain. Studies suggest that if pharmacies do not stock certain controlled substances, it is often due to fear of robbery. In 1986, Kanner and Portenoy[42] reported that 29% of pharmacies randomly sampled in New York City did not stock Schedule II opioid analgesics because of a fear of being robbed; only 3% stocked oral morphine. In 1989, Kanner and Cooper[43] found that 38% of a national sample of pharmacies stocked oral morphine. Those that did not stock the drug indicated that the reasons were a lack of prescription demand and fear of robbery. The results from these two studies generally mirror those from surveys of pharmacies in other states, such as New Mexico (1992)[44] and South Carolina (1993),[45] and from a 2000 survey of New York City pharmacies.[46] Pharmacists play a pivotal role in ensuring patient access to controlled substances.

The pharmacist who dispenses medications is in the unique position of being the last health care professional to have contact with the patient prior to the administration of the medication. Patient fears and concerns are often expressed and the pharmacist has one last opportunity to

dispel myths and allay unwarranted fears. Ascertaining the patient's level of understanding of therapy decisions can also occur at this time. Finally, the dispensing pharmacist has an opportunity to recommend any appropriate over-the-counter medications (e.g., laxatives, analgesics) that might benefit the patient.

PAIN TEAMS, HOSPICE CARE, AND SPECIALIZED PHARMACIES

Pharmacists are increasingly well recognized for their critical role on multidisciplinary pain management teams across a variety of health care settings. Depending on the setting, pain management teams consist of a combination of disciplines such as physicians, nurses, physical and occupational therapists, psychologists, social workers, chaplains, nursing assistants, and pharmacists. The pharmacist role on chronic pain teams includes a combination of many of the roles discussed earlier in this chapter (e.g., education of patient, family, and pain team members; advocacy for appropriate drug therapies; collaboration with team members; assurance of drug safety; decisions on the role of compounded medicines; and occasionally, drug-dispensing duties). As a member of the pain team, the role of the pharmacist is formalized, and recommendations are dictated and transcribed into the medical record. Having a pharmacist on the pain team ensures that medication decisions are evidence-based. As a member of a pain team, the pharmacist usually has additional responsibilities for broad-based clinical activities such as developing, or co-developing with medical leadership, treatment algorithms; writing formulary drug reviews and monographs; and organizing patient-centered medication education. These activities increase the odds that a consistent medical plan will be in place for patients and strengthen patient perceptions and compliance with pain team therapy recommendations.

Hospices, similar to pain clinics/teams, employ the pharmacist for his or her skill in designing clinically effective and cost-effective therapy regimens for patients with pain and other end-of-life symptoms. The roles of a pharmacist in hospices are similar to many of those on the pain team with two exceptions. As part of the hospice team the pharmacist will not just focus on pain, but will provide recommendations on managing a variety of other symptoms common to patients during their terminal phase (e.g., breathlessness, edema, itching, nausea, cachexia, delirium, myoclonus). The other variation in the role of the pharmacist on the hospice team is the great focus on palliation of symptoms versus improvement of functioning in the patient with chronic pain. Granted, a chief goal in the care of a hospice patient is to maintain or improve functioning whenever possible, and it is accepted that the means to obtain both palliation and functional improvement can be similar. However, in the care of the hospice

patient the overriding goal of care is palliation, and often this means a more aggressive approach with the use of strong opioids. Pharmacists use their expertise not only to advocate for aggressive palliation of pain and other end-of-life symptoms, but also to provide the information for how to do so in a safe manner.

Finally, with specialization occurring in many areas of pharmacy practice (e.g., oncology, cardiology, psychotherapeutics, nuclear medicinals, and others), it makes sense for specialized practices in pain management. One area of specialization that is occurring in the area of pain management is the use of electronic prescribing systems (eR$_X$) in concert with specialized pain management pharmacies. Coupled with the risks and complexities of prescribing medications for patients with chronic pain syndromes, there are reasonable expectations that the use of eR$_X$ could provide favorable benefits to pain specialists and other practitioners who prescribe large numbers of analgesic medications.

Some eR$_X$ system benefits in this setting could reasonably include improving clinical decisions and time efficiencies for assessing, treating, and monitoring patients with pain; reducing physician liabilities; eliminating prescription fraud; and providing meticulous prescribing record documentation to meet and exceed that required by regulatory agencies. Currently, most eR$_X$ systems utilize a laptop computer or wireless, electronic prescription writing and transmitting device such as a handheld computer or a PDA. Many of the systems have been designed to be user friendly, secure, Health Insurance Portability and Accountability Act (HIPAA) compliant, and able to provide complete medication prescribing and utilization documentation. eR$_X$ hardware devices eliminate the need for traditional prescription pads by incorporating software that offers numerous functions for managing patient records and enhancing medical office productivity.

The electronic system eliminates the potential of handwriting errors and the risk of prescription counterfeiting. Unlike an ordinary prescription pad, the handheld prescription unit directly transmits the dispensing order to the pharmacy, which checks for frequency of use and/or potential misuse by the patient. Most systems allow the physician to select from the self-contained list of applicable medications after entering an authorization code for the medication. The device, by eliminating the need for a handwritten prescription, avoids prescription loss, alteration, copying, and forgery. Coded access to the prescription unit ensures that if the physician misplaces the unit or leaves it unattended, it is useless to another party and cannot be utilized to transmit prescriptions falsely.

When the patient arrives at the pharmacy, the prescription is often ready, in advance of patient arrival, minimizing lengthy waits. Other benefits to some eR$_X$ systems include (1) the electronic screening of new prescriptions against the patient's profile to prevent adverse drug events

related to dosage errors, known allergies, and drug–drug interactions, and to minimize errors with look-alike and sound-alike names; and (2) the provision of monthly activity reports, which among other things, identifies those patients who have failed to pick up their prescriptions. One key value-added service offered by some of the eR$_X$ systems is a "Refill Management Service." This service reduces physician office phone calls and associated frustrations because of the involvement of pharmacy staff proactively reviewing electronic patient medication records and telephoning patients several days prior to the anticipated refill date. Some systems allow patients a choice of coming in to pick up new and refilled prescription(s) or having the prescription(s) home-delivered via the U.S. mail service or via a bonded courier. Physicians who prefer to authorize refill prescriptions at an office visit discover the convenience and time saved by renewing medications via a few mouse clicks on the electronic device, instead of manually recopying multiple medications on paper prescriptions.

FINAL THOUGHTS

Indeed, the pharmacist has an important role in pain management. The right drug, at the right dose, administered to the right patient, monitored for appropriate outcomes, may afford tremendous functional improvement for a patient with pain. The pharmacist, as the "drug expert" can influence the patient's perspective on the medication, and whether or not he or she will comply. The pharmacist can positively influence the prescriber's selection of a medication, dosage, or route, thereby improving the benefit-to-risk ratio. In our search to improve the quality of life in our patients we must remember that we have many options, of which medications are but one option. The pharmacist is the ideal professional to assist the physician and other health team members, as well as the patient and family members, in developing the best medication plan for improving the lives of pain patients.

Medications are not perfect. The decision to use a medication or not can be an emotional decision for both the professional and the patient. Many patients blame themselves or are blamed by others for having pain and for having an ulterior motive for wanting a medication. In our search to improve the quality of life in our patients, we must remember that medications themselves have no inherent morality. It is the inappropriate use of medications, or lack of use, that oftentimes is the essence of the morality of medicines. Ultimately, the pharmacist's role in pain management comes down to one phrase: "to ensure that medications are used appropriately."

The Role of the Chaplain

Rev. Mr. Randol G. Batson, BS

It was the summer of 1986 and Ruth was dying, her body ravaged by malignancy. The pain seemed intractable, but for the chemical agent that transported her conscious mind to a precious state of relief somewhere between reverie and restless slumber. Brief interludes of clarity that had become increasingly less frequent were angry, bitter, and demanding.

During their presence in the home of the daughter who cared for Ruth, the hospice team observed many strange dynamics that appeared to be a way of life for the patient and her adult children. Ruth's two sons and one daughter were perceived as cold, indifferent people, yet each, in his or her own way, appeared possessive of the others.

One afternoon when Ruth seemed to be experiencing a more conscious episode, the chaplain asked what in her memory was the source of her intense pain. As though she had awaited that invitation for 43 years, Ruth slowly unraveled her story.

It was World War II and she was the young bride of a U.S. Navy flyer who in 4 short years of marriage had given her three hungry mouths to feed and mountains of diapers to wash. The stresses were many, and all too frequently erupted into a private battlefield on the home-front. One Sunday afternoon Ruth and her husband were engaged in yet another angry confrontation when he was required to leave for a scheduled training maneuver.

Frustrated at being left alone again with three demanding babies and feeling cheated over the issue that remained unresolved, Ruth shouted after her husband, I wish you were dead! Can you imagine the rest of the story? There was an apparent mechanical failure, the plane went down, and the young husband was killed. Believing she had set his fate, Ruth turned her guilt inward to self and a bitter,

undemonstrative, controlling mother raised three angry, undemonstrative, controlling children.

It was the first time in 43 years that Ruth had shared the depth of her pain with another human being, and in the catharsis there was a release of tears that had been bottled up beyond her remembrance. The chaplain helped Ruth find forgiveness for herself and reconnect with the tenderness of the love she had shared so briefly with her husband. The next time her three children gathered at their mother's bedside, they found a stranger who, for the first time in many years, reached out to touch them tenderly. Even amidst the physical pain that screamed from Ruth's body, her face displayed a softer demeanor, her voice free of its characteristic harshness. Ruth drew her children closer to her and repeated the dark secret she had revealed to the chaplain. Slowly, haltingly, she omitted no detail, punctuating each revelation with her tears. Before she finished her children too were crying. Ruth told them for the first time in their collective memory that she loved them, and she asked forgiveness for the many ways she had formed their lives by her own negativity. They responded with expressions of love and forgiveness toward her, and toward one another. There were embraces, positive affirmations, and more tears.

Within a week the hospice medical director discerned that Ruth was overmedicated for pain, and her morphine was reduced. It appeared as though the pain in her body had retreated as the festering boil in her memory continued to heal.

There was consensus among the hospice team that Ruth had been healed. That she died 2 weeks later seemed almost insignificant. Most people with cancer of the pancreas and liver do, after all, die from the disease process. More certainly, all people die sooner or later. Unlike many,

however, Ruth died with peace of mind. She found forgiveness of self that enabled her to accept the forgiveness of God, whoever or whatever she perceived God to be. She died with hope and with a sense of completion that gave rebirth to her children, thereby empowering them to release some of their own painful, emotional baggage and live with greater joy.

Ruth's story and the somewhat dramatic conclusion of her life pose certain questions, which many clinicians and researchers are no longer content to ignore. What was the complex relationship between her painful memories, replete with unforgiveness and self-condemnation, and the pain that a terminal disease process expressed in her body? Was it coincidence, or did the emotional catharsis and spiritual healing at the end of her life have any direct bearing on the ability of clinical caregivers to manage her pain effectively and yet maximize for herself and her family the quality of her final days? What is spirituality and spiritual care? Of what consequence is such an ethereal dimension to medical science?

These questions prompt many more, and the answers often seem beyond empirical evidence. In the past 30 years, however, medical scientists with strong interest in the spiritual dimensions of life have increasingly dared to ask such questions and to seek answers within the scope of clinical trial. Although still only comprising a small percentage of total research, such trials and/or considerations have become so common, and the interest in spiritual possibilities so universal, that it is no longer extraordinary to find them reported in the most mainstream medical journals, including *Journal of the American Medical Association, Southern Medical Journal, New England Journal of Medicine,* and *American Journal of Psychiatry.* Many medical scientists now understand that each human person is a total entity, a very complex communion of various dimensions, physical and nonphysical, compounded by psychological, familial, and social history; that among those is a component commonly called "spiritual" that has the power to profoundly affect the rest, a component that may even be a foundation block of total health. From the interest in possibility and evidence has risen an annual continuum of seminars, workshops, and conferences such as Harvard Medical School's *Spirituality and Healing in Medicine.* Those possibilities have also become a major focus of the work of such prestigious entities as the National Institute for Healthcare Research founded by the late David B. Larson, M.D., M.S.P.H., and the John Templeton Foundation.

It is important to establish that this discussion is not an effort to verify or support the existence of deity or divinity — God — as it were. Larry Dossey, M.D., a leader in the new frontier of spiritual consciousness in medicine and author of *New York Times* bestsellers, which include *Healing Words: The Power of Prayer and the Practice of Medicine* (Harper, San Francisco, 1993**)** and *Reinventing*

Medicine: Beyond Mind–Body to a New Era of Healing (Harper, San Francisco, 1999), asserts that to try to prove the existence of God is like nailing Jell-O® to a wall. Nor is this an attempt to further any religious agenda, although it may not be possible to consider comprehensively spirituality and the role of the chaplain without acknowledging religion, and religious practices, as a component of the spiritual dimension. That may be especially true because a preponderance of clinical research in spirituality and medicine has surrounded the religious identity and practices of test subjects.

Rather, this chapter is intended to raise consciousness of spiritual reality and the power it holds over health and wellness, pain management, healing, ease, and disease. Dale Matthews, M.D., F.A.C.P., of Georgetown University School of Medicine and coauthors (1993) of *The Faith Factor: An Annotated Bibliography of Clinical Research on Spiritual Studies* estimate that about 75% of spirituality studies have confirmed health benefits.

It is now regarded by many that all people have spiritual needs. It may even be possible that the most abject atheist has spiritual needs. Why? How? Because an inherent need for meaning, and to experience purpose in life, seems to be universal. Even the most seemingly negative demonstrate a basic need to give and receive love. This need seems present at birth, regardless of how it may be masked or pushed from consciousness by the psychosocial circumstances of this world. Forgiveness is widely believed to be a universal need, and avenues to transcendence appear likewise to be needed by people of every land and culture. Clifford C. Kuhn, M.D., of the Division of Behavioral Medicine at the University of Louisville School of Medicine, who advocates a spiritual inventory of the medically ill patient, defines spirituality as those capacities that enable a human being to rise above or transcend any experience at hand (Kuhn, 1988). In the case of the previously discussed hospice patient, forgiveness appears to have enabled Ruth to rise above, to transcend, the pain of cancer and the certainty of her impending death.

SPIRITUALITY: WHAT IS IT?

How do we define spirituality? Definition may be as elusive as the dimension itself. Many have found enlightenment, however, in a demonstration used by Marcia Baumert, F.S.P.A. (pers. commun.), a chaplain at Genesis Medical Center in Davenport, Iowa. When teaching about spirituality, Sister Marcia places a wide-mouth jar before her group and says, "This is Charlie." She then adds stones sufficient to fill the jar to the top and explains that the stones represent Charlie's total physical composition, DNA to organs, bones to skin, hair, and even eye color. She asks the question, "Is this all there is of Charlie?" The audience usually responds "No" with total acclamation.

Sister Marcia then adds small pebbles to the jar, explaining that they represent Charlie's mental capacities. When the jar will hold no more pebbles, she asks, "Is this all there is to Charlie?" Most will still respond "No." Sister Marcia then pours sand into the jar, carefully filling it and shaking the sand down into the empty space between the pebbles and the larger stones. She explains that the sand represents the psychosocial composition of Charlie's life, including all that is retained in Charlie's memory bank, conscious and unconscious. At the completion of that phase of the demonstration many in the room will deliver an affirmative response to Sister Marcia's inquiry as to whether that's all there is of Charlie. She then takes a pitcher of water from under the table and pours the water into the jar. The audience watches with interest and amazement to see how much water Charlie can hold. When the jar is filled to the top, Sister Marcia explains that the water represents Charlie's spirituality, and she invites them to observe the way the water changes the total context of the other ingredients. There are color changes, the pebbles and sand move and settle in ways that they seemed unable to do before. The water creates the appearance of mortar, as though it were a bonding agent for the other components. Sister Marcia invites her audience to observe that there is no place within the jar, Charlie, not affected by the water, and she explains that as the true nature of spirituality.

The word *spirituality* derives from *spiritus*, a Latin root that means "breath of life," and has historically been understood mainly within the context of religion. In the latter half of the 20th century, however, there arose a consciousness of spirituality as broader and more comprehensive than organized religion, integral to all people whether or not they recognize it, and irrespective of their identity with deity or religion. For many, religion is merely a piece of the pie, and the size of that piece corresponds to the importance that person places upon religion. For others, religion is the total pie. Determination of which position is more accurate may be as elusive as Dr. Dossey's image of nailing Jell-O to the wall. For the purpose of this discussion it really doesn't matter. What does matter is that health care providers — physicians, nurses, and all other members of the interdisciplinary care group — recognize that every patient may have a spiritual composition with the power to influence his or her total health. Often understood as energy, even as electric energy, spirituality can be our friend or our enemy, depending on the care with which it is respected, channeled, and used. That possibility should be of prime concern to all who practice healing arts and science.

RELATIONSHIP

My 25 years experience in spiritual health care has given me the consciousness that spirituality is, to a great extent, about relationship — the relationship of each person to self, to God or Higher Power, to family, to society. It is about one's relationship to the macrocosm of life. The personal experience shared by so many spiritual health care providers, e.g., chaplains, is now supported by studies that in various ways affirm or indicate the possibility that these "relationship factors" may have a role in some disease processes, and in healing. Excellent collections of such studies are to be found in *Scientific Research on Spirituality and Health: A Consensus Report,* edited by David B. Larson, M.D., M.S.P.H.; James P Swyers, M.A.; and Michael E. McCullough, Ph.D. (1997) as well as in *The Faith Factor: An Annotated Bibliography of Clinical Research on Spiritual Subjects* (Mathews, Lawson, & Barry, 1993).

Returning to Sister Marcia's, demonstration, if there were within the jar "Charlie" any area where the water did not flow, Charlie would not be totally integrated. That one dry pocket within the jar would be "out of relationship" with the rest of its components, and would have power to affect the total context of the other ingredients. Charlie would be out of balance, out of relationship. The same would be true of spirituality. If we cannot prove that it is so, we can also not prove that it is not so. The possibility evidenced by Ruth's story and countless similar cases experienced daily by multidisciplinary caregivers offers powerful motivation for physicians to seek a spiritual assessment of their patients, and to integrate spiritual care into their total care continuum.

SPIRITUAL PAIN

With the emergence of a consciousness for the critical role of spirituality in total health has come consideration of a phenomenon called spiritual pain. Like spirituality, spiritual pain may not lend itself easily to definition. If, however, spirituality is, as I have come to understand, about relationships, it would follow that spiritual pain is a manifestation of broken relationships. Surely we've all known its symptoms: a hollow feeling in the pit of the stomach, or a tight sensation, even nonphysical pain, in the heart region of the chest. It can be reflected in chronic anger, in bitterness, or in negativity. It can express as a fearful, mistrusting attitude, and it may be present in acute loneliness or depression. Tears, fatigue, and nonverbal body language can represent spiritual pain. It is irrefutable that such symptoms may have their basis in clinical psychosis and can often be treated with medical interventions. Clinical examples such as Ruth, however, suggest that many may be the sole result of spiritual pain or a combination of spiritual pain and clinical psychosis. Dare we even to ask ourselves the ages-old question, "Which came first, the chicken or the egg?"

Spiritual pain is beyond the scope of traditional medical interventions, save for mood-altering drugs, which serve as a Band-Aid® rather than a cure, and it is healed

only in the reestablishment of healthy relationship. The outcome of spiritual healing may be renewed self-esteem, forgiveness, peace of mind, the infusion of joy, reconnection to love, and the return of hope, meaning, and purpose. It may be characterized by renewed faith consciousness, the courage to endure challenge and to reach for victory. There can be renewed vitality and a resurgence of energy.

A contemporary supposition yet unproven, perhaps beyond proof, but held by many clinicians to be worthy of consideration is that spiritual pain can be a precursor to physical pain. Certainly, it would have seemed so in Ruth's case. When her spiritual pain was relieved, i.e., when she found the healing of memories that facilitated forgiveness and the restoration of her relationship to self, to her family, and to her deceased husband, the physical pain quotient generated naturally by the ravages of her physical disease process was reduced. She required less pain medication to be comfortable. She was more lucid and was thereby able to enjoy a greater quality of life for the remainder of her days.

WHY SPIRITUAL CARE?

Recognition of the power of the spiritual dimension and the importance of spiritual care is of vital importance to health care providers because it can be a complementary tool or therapy that is useful for most patients, regardless of their faith consciousness or religious practice. That the vast body of clinical studies on spirituality to date surround religion and people of faith can be viewed as both negative and positive. The danger is that they may reinforce the consciousness that spiritual needs are always religious in nature and spiritual care is always religious care. Because religion does not fit for some people, patients and caregivers alike, there is a risk that such understandings may result in the deprivation of therapeutic opportunity.

Amidst the ethereal, however, religious practices do provide some concrete basis for comparison. Were we to attempt to nail fruit Jell-O to the wall, it would at least be possible to spear a piece of fruit as the Jell-O dropped away. Perhaps the fruit within the Jell-O is a valid metaphor for religion within spirituality. People of faith do provide a basis for measurement and comparison to those without faith or religious practice. The studies increase annually, and their effect is being profoundly felt in Western medicine. In 1993, only 3 of the 123 colleges of medicine in the United States offered courses on spirituality and spiritual care. According to Dr. Larry Dossey (1998), that number had grown to 50 in 1999, and in 2003 Dr. Dossey believed the number to be greater than 90. At a collaborative conference in Dallas, Texas in September, 2000, the Association of American Medical Schools and the National Institute for Healthcare Research sought ways to more effectively integrate spiritual care into academic medical curricula.

A PATIENT MANDATE

Beside the existence of clinical indications for spiritual care, personal beliefs and practices of a majority of patients would seem to mandate the attention of health care professionals.

A 1990 Gallup study found Americans to be a highly religious people:

- 96% reported belief in God
- 75% claimed to pray at least once a day
- 58% said, "religion is very important in my life"
- 43% claimed to have attended worship services within the past week

One national poll of 1,000 adults found that 63% wanted their physicians to talk to them about spiritual health, but that only 10% reported their physicians having done so (McNichol, 1996.) In another national poll, 82% of 1,004 adults reported belief in the power of prayer, and 64% said physicians should pray with patients who so request (Wallis, 1996). According to a statement of the late Elisabeth Targ, M.D., quoted in the *Western Journal of Medicine,* December 1998, "Eighty-two percent of Americans believe in the healing power of prayer. Research indicates that they may be right" (Sicher et al., 1998).

Doubly blessed, perhaps, are patients who want such care and are so fortunate as to have a physician able and willing to participate. With the increasing body of evidence in favor of spiritual care, together with professional dialogue, it would seem that many physicians are now entering into spiritual "communion" with their patients in more visible and discernable ways. For others, however, it just does not fit — even for many who embrace personal spiritual or religious practices. Nor should that be subject to judgment. My own perspective throughout many years of spiritual health care, however, is that all caregivers should be spiritual caregivers. The key is consciousness. It is of critical importance that even those without religious identity be clearly conscious of the role that the previously named "relationship factors" may play in sickness and health, and that they be mindful and respectful of the importance that many, perhaps most, patients place upon spirituality.

Some, physicians and chaplains alike, argue that spiritual care should be left to the professional spiritual caregivers, the chaplains, that there are too many inherent risks for physicians to wear "chaplains' collars." While there may be credibility to that position, there are surely many personal variables, which will not be considered here. The bottom line should again be the consciousness of all physicians to consider spiritual factors and, at the very least, to make an appropriate referral to the chaplain who is equipped to do a spiritual assessment and to work together

with the physician in providing the highest possible level of total care for the patient.

Chaplains are privileged caregivers within the hospital environment in that they have freedom to move among patients at will, without medical orders. That is due in part to the historical role of the chaplain as a religious minister whose activities were governed by patient preference. It is also influenced by the fact that spiritual care is not currently, and never has been, a chargeable service. Therein, a double-edge sword exists. Non-requirement for a medical order has given autonomy to the chaplain, and has afforded opportunity for spontaneous relationships and "ah-ha" moments, which have led to meaningful outcomes. It has, however, enabled the presence of some chaplains whose skills and practices were not equal to professional standards, while failing to develop avenues of communication between chaplains and physicians.

Until 30 years ago it was not at all uncommon for hospital chaplains merely to be ordained ministers or members of religious orders. Completion of an accredited continuum of clinical pastoral education, including internship, is now the standard to which most health care institutions aspire. Professional organizations such as the Association of Professional Chaplains, the National Association of Catholic Chaplains, and the National Association of Jewish Chaplains establish high standards of clinical practice for professional accreditation and require continuing education for renewal of credentials. As spiritual care becomes more broadly accepted as a valid component of total care, institutional providers are more commonly requiring that their chaplains be certified professionals. While most accrediting organizations require that certified chaplains receive and maintain ecclesiastical endorsement, membership now comprises both ordained persons and laity, male and female. The quality of professional spiritual care has been greatly enhanced by the expanded playing field of acceptable candidates, and it has helped spiritual care to move beyond the "box" of traditional religion to a model that is more compatible with all patients and members of the multidisciplinary care team.

A professional chaplain puts aside his or her personal agenda. Rather, the patient's needs and the patient's agenda are the primary focus of the chaplain's work. A skillful chaplain may "invite" the patient to opportunities that result in the opening of pathways to memory and doorways to spiritual consciousness. It is the patient, however, who leads, and the patient who determines the direction and the outcome of the intervention. Beyond the right to accept or reject the care of a physician, an institution, or a particular intervention, the chaplain as facilitator may well represent the patient's greatest opportunity for personal autonomy in allopathic care.

The evolution of health care into the age of controlled reimbursements, preferred provider organizations, and health maintenance organizations has affected the opera-

tion and practice of many providers. Chaplains, like professionals in all other disciplines, have been affected by the ensuing changes. It is now a rare institution that can afford to maintain a spiritual care staff sufficient to routinely see all new admits and follow them to discharge. Chaplains must often triage patients and rely upon referrals from other caregivers. Nursing rounds and discharge planning conferences are avenues through which patients are routinely identified for spiritual intervention.

Some of the best opportunities I have known, and the ones that enabled me to facilitate the most positive outcomes, are those that have come from physicians, either by way of a personal contact or through a referral in the patient medical record. In my experience as a hospice chaplain, it was the norm to receive personal communication about patients and specific requests for spiritual care from the hospice medical director. Within the hospital setting, my experience has found such referrals to be outside the norm. Nonetheless, they seem to occur with greater frequency each year. When a physician and a chaplain take the time to develop a relationship of trust, and communicate together in the patient's behalf, insightful opportunities for total healing are often found.

I remember a patient several years ago who was what hospital staff called a "frequent flyer." A fine-looking and healthy-appearing man in his early 70s, he presented every few months with heart symptoms that his cardiologist seemed unable to manage effectively at home. While his pathology was supported by clinical evidence, his cardiologist was nonetheless stumped by his apparent inability to effectively control symptoms that normally respond well to medical intervention. While visiting the patient at the time of one of his hospitalizations, I engaged him in a "walk down memory lane." During that time together I learned that his mother had died when he was about 7 years old. His father worked out of town and, rather than take his son along or arrange for him to stay in the home of family members or friends, had placed him in one of the old-time state orphanages. For the remainder of his childhood he rarely saw his father. In a lucky year his father would show up once, maybe twice, for a brief visit as though he were making a courtesy call to a hospitalized acquaintance. There were no special remembrances at Christmas or birthdays. The patient spoke of understanding that times were hard. It was during the years of the Great Depression, and as a father and grandfather himself, he had come to accept that his father might have done the best he thought he could at the time. Still his eyes brimmed with tears when he recalled those years of loneliness, and the feeling of disconnection from the two people who had been the foundation of his life and his security.

Later that day I chanced to see his cardiologist, with whom I had a friendly but casual relationship, and I asked him if he could spare me a couple of minutes to share an insight I had gained about his patient. We sat together in

a charting area at the nurse station and I began to relate to him what I had learned. Imagine my surprise and personal satisfaction when, after relating the story of the patient's unhappy childhood, the physician exclaimed enthusiastically, "A broken heart! What a metaphor that is for the physical malady I am trying to treat." Excitedly, we developed a plan whereby I would work with the patient to help him find healing for his painful memory and to access forgiveness for his father. The success of such a plan was contingent on the patient's willingness to participate. He was, and he did, with an observable outcome. His damaged physical heart was, of course, not mended. His doctor and I presumed, however, that his broken spiritual heart found the healing it needed because his condition became manageable by the medical means the physician could provide. He enjoyed a life of renewed quality, and he was no longer a "frequent flyer" at the hospital. As pleasing an outcome for me personally was that the physician and I developed a much more collegial relationship, and we found ourselves working together often to effect better patient outcomes.

In-depth spiritual care can be a great deal like peeling an onion. Human beings are such incredibly complex lifeforms, and who and what we are is governed by so many factors beyond genetic predisposition, that there are may be layers upon layers to be peeled away in order to effect spiritual healing sufficient to influence physical outcomes.

How well I remember Elizabeth, a swollen, pathetic-looking woman with unkempt gray hair and sad eyes. Yet, the stage photograph that she always brought with her to the hospital depicted a vibrant, slender, dark-haired beauty in a flowing taffeta gown. Elizabeth had been an opera star of no small renown. The only child of foreign-born parents of modest means, she had climbed the ladder to success by her own wit, talent, and sheer determination. She had sung at many of the more famous opera houses of the world, including New York City's Metropolitan, and she was intimate with people whose names were household words in America. Her parents took little pride in show business "nonsense," however. Aging with poor health, frightened, and alone, they begged her to come home and settle down where she could be near them in their declining years. Succumbing to their pressure, Elizabeth put her career on hold and came home with the intent to return to the stage after her parents had died. She declined many opportunities during the years when her parents lived longer than expected and, ultimately, the exciting life she had known became history.

Hungry for a life beyond the mundane responsibility of caring for sickly parents, Elizabeth found companionship in George, an uninteresting accountant some years her senior. She married George and he shared the responsibility of caring for her parents during their few remaining years. Elizabeth and George had one daughter, Sylvia, a materially indulged child who, as an adult, presented as self-centered and resentful. When Sylvia was 10 years old, Elizabeth developed a close friendship with Joyce, a sweetly assertive woman. The friendship soon encompassed an inordinate quantity of Elizabeth's time, at the expense of George and Sylvia. Elizabeth and Joyce began to call themselves "sisters," and after a couple of years Joyce moved into Elizabeth and George's home and became "Aunt Joyce" to Sylvia. As the bond between the "sisters" grew stronger, the space between Elizabeth and George became a chasm. Ultimately, by mutual agreement of husband and wife, a room at the rear of the large home was made suitable for George. He lived somewhat the life of a boarder in his own home and died prematurely.

After George's death Elizabeth's own health declined. Her joints began to swell and ache, symptomatic of osteoarthritis, and she developed a litany of ailments considered by her physician to be somatic in nature. Among those, an asthmatic condition became chronic and, together with the osteoarthritis, limited her mobility. She became sedentary, obese, and frightened. Deprived of sleep, unable to breathe easily, and wracked with pain, Elizabeth started using prescription sleep aids at night, and later during the daytime. A self-generating cycle seemed to have been set into motion.

As chaplain of the unit where Elizabeth was hospitalized for several days out of every month, I had developed a relationship with her, and with Joyce, who was faithfully at her side from early morning until visiting hours ended in the evening. They were women who professed Christian faith, and they always seemed encouraged by a visit and a prayer. It was difficult, however, to accomplish anything at a deeper level with Elizabeth because Joyce was always present, often assuming the responsibility of Elizabeth's spokesperson. I had heard the story of her life more times than one, but I had the sense there was some deep spiritual pain, which influenced Elizabeth's current condition — a source too "sacred" to attempt to access in Joyce's presence.

One day I determined to work a swing shift, which caused me to be at the hospital after visiting hours were over and Joyce had gone home. I went to Elizabeth's room and engaged her in conversation during which I gently invited her down memory lane, into her relationship with George. I had already secured Elizabeth's trust through my previous ministry to her. The time was apparently right, and it was a place where she was ready to go. It soon became apparent that Elizabeth was burdened by guilt for the way she had replaced George in his own home and in their marriage. She wept with remorse that she had not had the opportunity to tell George that she truly did love him, and that she was sorry for the ways she failed him.

Moved by Spirit from within, I suggested to Elizabeth that there was a way in which she could communicate the things she needed to say to George, and the stage was set for an elementary Gestalt intervention. I helped her get

up, and positioned her in the bedside recliner. I then moved a guest chair and seated myself opposite her, knees to knees. I invited Elizabeth to close her eyes as I led her into a short relaxation exercise. I then suggested to her that through the power of the Holy Spirit, in which she professed faith, she could speak to George. I told her that I was George's surrogate. She should say to me whatever things she needed to say to him, and George would hear.

Elizabeth slowly began to speak just as though she were talking to George. Before long, her words poured forth in sobs, a waterfall of tears cascading down her swollen face. She told George that she was haunted by the memory of how she had hurt him and Sylvia, and that she was filled with grief. She told him that she did love him more than she realized at the time, and that she was most appreciative of the many ways he had been such a good husband and father. Acknowledging that she was not worthy of forgiveness, she asked him nonetheless to find it in his heart to forgive her.

When Elizabeth's words ceased and she became calmer, I spoke as though I were George. I told her that from where I lived in Eternity I had the ability to see circumstances clearly. I told her that I understood the things that motivated her to make choices that had caused me to be so disappointed, and that with all my heart I forgave her. Acknowledging that it takes two to fail as well as to succeed, I asked her forgiveness for all the ways in which I had failed her, and I professed my continued love for her. I also assured her that I was waiting for her, and that she could talk to me whenever she needed, just the same way she prayed to God. Reaching forth, I wrapped my arms tightly around Elizabeth, and she enfolded hers about me. She wept softly on my shoulder as she might have done with her husband in younger, happier days.

There was a remarkable change in Elizabeth by the next day. She had rested well. There was about her a discernable energy shift. She seemed almost serene and happy. On the following day she was discharged, never to reenter the hospital. Joyce phoned me early one morning after 5 weeks had passed and sobbed that Elizabeth had not awakened that morning. I was asked to do the funeral, which required a 2-hour drive to the cemetery where Elizabeth's parents and George were buried. Joyce rode alone with me, and she spoke of her wonder at the change in her companion during the weeks preceding her death. Elizabeth's attitude had become more as it was in the beginning of their friendship. She was peaceful and relaxed. She also seemed to have been healthier. The medications that her physician prescribed were more effective at controlling Elizabeth's pain. She breathed more comfortably and she slept without assistance. Elizabeth's improvement had, in fact, been so dramatic that Joyce was totally stunned to find that she had died during her sleep. I don't recall whether I suggested that her newly found peace of mind

might have enabled Elizabeth to release the attitudes and self-judgment that bound her to a life of misery, and go to wherever it was her spirit was being called.

SECURITY IN THE PRESENCE OF THE UNKNOWN

How unfortunate it is that the ones whom patients trust so implicitly, physicians and nurses who may even be responsible for the sustenance or preservation of life itself, must often be the ones who cause pain and suffering in order to accomplish or seek the outcome the patient desires. The most sensitive and compassionate caregivers must sometimes use implements, tools, and treatments that are uncomfortable, painful, and often very fearsome to their patients. The chaplain can represent a nonthreatening, caring presence to whom the patient can cling for temporary strength and comfort, especially if that chaplain has had an opportunity to develop a nurturing relationship with the patient.

It was in my first year as a hospital chaplain that I met George, a rugged, outdoors kind of man who, in his early 70s, still took great delight in his hunting and fishing trips, and pride in the large garden that he maintained for his wife at their rural retirement home. The progression of diabetes, however, resulted in a pedal wound that ultimately required amputation of his foot. Rugged as he was, George was a man of deep Christian faith and he bonded to me through the prayer and supportive presence I provided to him. Regrettably, the stump wound did not heal and the decision was made to amputate again, further up the leg. Before George was discharged, it became apparent that there was infection present in the second stump and, among the various procedures used to facilitate healing, a decision was made to lance the stump and clean out the infected substance that had collected inside. The procedure was to be accomplished in George's hospital bed, under local anesthesia. He was terrified and tearful, and was reticent to sign consent for the procedure. When I attempted to reassure him that the minor surgery was essential to his recovery, and that the physician would be as gentle with him as possible, he determined that he would only consent if I would be with him throughout.

The medical team welcomed the support and I was positioned in surgical gown at the patient's head where I could hold his hands firmly and speak words of encouragement. George's unit nurse was present, touching him and providing compassionate reassurance. However, she was also the one who gave him injections and, according to the nature of her duty, did a variety of invasive things to him. In my role as chaplain I was the only one who was totally nonthreatening, and therefore represented the security he needed for that occasion. Ultimately, George did recover and it was always a source of tremendous joy

whenever he stopped by the hospital to see me, walking on the prosthesis, which enabled him still to hunt and fish.

The chaplain's ability to provide security is also evidenced in my experience with Alma, a patient with severe coronary occlusions. At nearly 80 years old, Alma was a strong-appearing, physically attractive lady who, until the appearance of heart symptoms, had enjoyed a vital and productive life. Two cardiologists and a surgeon had, however, discerned that without multiple bypass surgery she was in danger of a major event that could end her life or render her a cardiac invalid. Alma was terrified. She had never previously been hospitalized, and the thought of having her chest invaded was overwhelmingly fearsome for her. When, after two consults, the surgeon was unable to reach verbal consent for the surgery to be scheduled, he asked her if she was a person who prayed. "Oh, yes," she responded, and then bore to him a firm testimony of what an important role faith played in her life. The surgeon was one with whom I had a collegial relationship, and whose patients I had often attended to provide prayer support during surgery, and so he asked her whether it would help her to know that a chaplain could be present in the room, praying for her safety and for the medical team throughout the surgery. Alma expressed interest in that possibility, and the surgeon wrote a referral to me.

After a very brief intervention, including prayer, Alma agreed that she would consent to the surgery with the assurance that I would provide on-location prayer support. I continued to pray with Alma for each of the next 2 days before the date of her surgery, and in pre-op holding on the morning of the big day. When it was time for her to be transported to the surgical suite, I helped push the gurney and I held her hand while the anesthesiologist put her to sleep. Then I took my place on a stool against the wall at the foot of the operating table and assumed an attitude of prayer for a very long time. There were complications, and what was expected to be 4 to 6 hours became 11 hours before Alma was moved to the Surgical Intensive Care Unit. The surgery was successful, however, and after a reasonable period of recovery, she was discharged to home. I followed Alma closely during the remainder of her hospitalization and maintained telephone contact with her for several weeks during her continued recovery at home. During that time she declared often that she would not have consented to the surgery without the security that there was a chaplain nearby who was praying continually for her safety and for the entire team in whose hands she had placed her life.

A CHAPLAIN TO SELF

Little evidence is more credible than that which we have, ourselves, experienced. So it was with me when I had spinal surgery in 1997. A congenital structural defect had, with advancing age, progressed to a condition that limited the quality of my life. I had for more than 2 years consumed maximum daily quantities of nonsteroidal anti-inflammatory drugs, and I used a cane to stand straight and to decrease the orthopedic stress that resulted in pain, which spiraled downward through my pelvis and my right leg whenever I walked or stood in one place. After extensive physical therapy and thorough neurological work-ups, I accepted the recommendation of a neurosurgeon who believed that vertebras L-4, L-5, and S-1 should be fused, and rods should be inserted to reinforce my lower spine. That surgery was totally successful, and my comfort level and personal stamina during the post-operative period and throughout my recovery were so dramatic as to amaze the surgeon and the entire care team.

I believe it noteworthy that as a spiritual care provider I consider the condition of my own spiritual health to be above average. I have no fear of death. My consciousness of self as a spiritual being, one who dwells in a physical "vehicle" during this life experience on planet Earth, frees me from any fear over what will happen to me whenever this vehicle, my body, can no longer sustain me. I know that I will just separate out of it, and that I will be as alive, more conscious perhaps, than before. While I prefer to remain with my family and friends in this Earth experience which I so enjoy, I live daily with confidence that whenever the phenomenon called death comes to me, it is okay. Having worked in hospitals for over 25 years, I trust medical procedures and the professionals who accomplish them. More than that, I trust God who is my constant and most intimate companion. I always expect the best for myself, and even though outcomes are not always as I desired them or designed them, the delivery of my higher good seems always evident. Armed with a positive attitude formed of faith and confidence, and supported by a prayer army — family and friends — I went to the operating room with no more anxiety than if I were taking an exciting journey. There was no expectation of any outcome less than total success and happiness.

When awakened in post-op, my first consciousness was a wave of nausea, feeling that I needed to vomit. That sensation could not have lasted more than 10 seconds, and it was the totality of my difficult symptoms following surgery. I was taken back to my room around 12:30 P.M., bright eyed and laughing. My wife and friends who waited could not believe it. Three shifts of nurses who thought I should sleep could not believe it either. I received visitors, talked on the telephone, and watched television continually until I finally closed my eyes to sleep sometime around 2:00 A.M. on the next day. For the first 24 to 48 hours after surgery I was given injections for pain. Those were soon discontinued, however, because, they simply weren't needed. The injections were changed to oxycodone that I took only in the late afternoon and evening when I experienced an unpleasant but tolerable sensation in my pelvic girdle and legs. On a scale of 1 to 10, it

probably never escalated higher than a 4, even without the drug.

I was out of bed and walking with the physical therapist on the morning after surgery, and on the fourth day I was discharged to home. My wife's anxiety over how I was going to ascend the stairs to our second-floor bedroom was replaced with astonishment when I simply walked up, changed into lounging pajamas, and got onto the bed. The oral oxycodone was flushed down the toilet within about 3 days after returning home. I found the consciousness-numbing effect of the medication to be far less tolerable than the mild afternoon and evening discomfort in my hips and legs, and within only about 10 days following surgery there was no longer any remaining sensation of pain. The incision itself, a "centipede" that ran from the center of my back to the top of my buttocks, was never more than slightly sore.

It is undeniable that as an employee of the medical center where my surgery was performed, I was the recipient of the best care available. Further, my anesthesiologist and neurosurgeon were recognized as the "A Team." I bless them for their good work on my behalf. Nor can we ignore the truth that every person is unique, each with a different pain threshold and with his or her own capacities to heal. Regardless, I know at the very core of my being that the condition of my spiritual health was instrumental in effecting the pain-free outcome that I experienced from such an invasive surgery. I have repeatedly seen evidence just as dramatic with patients who endured surgical procedures as radical as cardiothoracic and intracranial. As evidenced through the personal experience of spiritual caregivers the world over, and by the increasing body of clinical research, robust spiritual health disposes the patient to the most successful outcomes, and quality spiritual care enhances the efficacy of the medical interventions provided.

YOUR COLLEAGUE, THE CHAPLAIN

How often it seems that those things most obvious are the ones we overlook. Patients regularly receive referrals from one physician to another for specialized care. Likewise, doctors consistently utilize the skills of physical therapists, occupational therapists, psychologists, nutritionists, and social workers, to effect the most positive outcomes for their patients. It is still the exception, however, when a physician actually makes a referral to the chaplain. Old habits and old attitudes die slowly and hard. Far too often the chaplain is viewed as only the religious practitioner, the nice person who comes to pray or read scripture, or to encourage or "save souls." That model may be as archaic as the "country doctor" who rode the circuit from home to home and practiced out of a black bag. While there are still chaplains whose consciousness limits them to religious endeavors, or whose practice is exclusive and

self-serving, they are no longer well received within the mainstream of professional, spiritual health care. Despite the good they do, such practitioners may continue to feed attitudes that have for so long polarized science and religion, medical practice and spiritual care.

The few case studies considered in this chapter evidence the resource that the chaplain can represent to physicians who are willing to leave no stone unturned in affecting the greatest outcomes for their patients. We don't always understand, and may never understand, the true nature of the spiritual dimension and the power it holds over sickness and health, life and death. But if personal experience does not lend credibility, these examples, nonetheless, demonstrate the incredible value and potential of sound spiritual care that is now evidenced clinically at an annually increasing rate. Even those who attribute such outcomes to the placebo effect would be remiss to deny the value of placebo when the desired end is reached.

HOPE: A SPIRITUAL PLACEBO

In his book *The Anatomy of Hope: How People Prevail in the Face of Illness* (2004), author Jerome Groopman evidences the understanding of many scientists and health care professionals that the placebo effect is hope in action. He calls hope "the very heart of healing," and he asserts, "For those who have hope, it may help some to live longer, and it will help all to live better."

Throughout recorded history the power of hope has been evidenced by the ability of individuals to survive and to emerge victorious over the most insurmountable of difficulties. In our own age, survivors of death camps such as Auschwitz, prisoners of war, and persons subject to unthinkable economic, cultural, and political oppression have credited hope as the lifeline that enabled them to survive. Spiritually conscious health care providers are continuous observers of the mystery of hope. What enables an actively dying patient, even though comatose, to survive until the last or most important person arrives? How do some patients survive long after the ravages of a disease process medically allow? Why do some patients totally overcome or recover from injuries or diseases that offer no possibility of survival? The answers to such questions would again seem as attainable as "nailing Jell-O to the wall." But again the questions emerges, "So what?" Some things we may never prove, but they are no less worthy of consideration or acceptance. The evidence is clear that hope has power beyond our ability to define or to quantify. Whether it is placebo may be a non-issue so long as its outcome is positive and meaningful to the patient or family.

With people living longer, many well remember the days still glorified on the video screen when the physician was truly the "hope bearer" by his or her ability to come to the home with that wonderful little black bag of mira-

cles. "Doc" had time to sit by the bedside of a critically ill patient throughout the night, or to sit at the kitchen table and have pie and coffee with the family, sharing their burden, supporting them in their fear. With population growth, urban expansion, specialization, the evolution of society, and the control that third-party payers maintain over health care providers, such practices are now limited, if not virtually impossible for even the most spiritually conscious and caring physicians. Change is not without benefit, however. Today's health care chaplain is for many a hope-bearer and an extension of the physician. When partnered with a chaplain or a spiritual care team, physicians can devote their time and energy to the specialized demands of clinical patient care with confidence that their patients have a present resource to help them find hope where hope can be found.

A COAT OF MANY COLORS

Not just a resource for patients and physicians, professional chaplains interface closely with patient families, multidisciplinary members of the health care team, volunteers, and community members who are significant to the patient, or who can provide support in whatever challenges the patient may face. For patients whose life meaning and hope are founded in faith or religious practices, chaplains can represent the power, which is there to be found. When called to be religious practitioners, professional chaplains seek appropriate ways to transcend dogma and the boundaries that are often present in religion and denomination. The chaplain's job is never to proselytize nor to define truth. Rather, the chaplain provides the presence that the patient needs, or facilitates the patient's connection to the faith leader who can. Conversely, the chaplain reinforces the institution's duty to protect patients from visitors who represent religious agendas contrary to the patient's wishes.

The professional chaplain's services also extend to nonreligious needs of patients, families, visitors, physicians, volunteers, and other members of the multidisciplinary team. Common activities and responsibilities may include

- Spiritual assessment
- Spiritual risk screening
- Patient advocacy
- Crisis intervention and critical incident stress management
- Grief support
- Facilitation of advance directives
- Facilitation of organ/tissue donation
- Resource referral
- Facilitation of communication
- Conflict resolution

- Participation in patient care conferences and medical rounds
- Participation in multidisciplinary/interdisciplinary education
- Participation in bioethics consults and institutional review boards
- Staff support for both professional and personal crises
- Institutional support during times of organizational crisis or transition
- Implementation of the organizational mission

Having provided spiritual support and crisis intervention over the years to physicians, nurses, and a variety of staff persons, from housekeepers to administrators, dealing with issues ranging from personal grief to suicidal ideation, I have always considered one of the most vital roles of the chaplain to be that of keeping the rest of the team spiritually healthy.

A fairly common practice among bedside caregivers has for many years been to call the chaplain when all else fails or whenever things seem to be getting too out of control. Although flawed, that line of thinking has nonetheless given chaplains many opportunities to prove their worth, if in no other way than to provide a calm presence in the eye of the storm. As clinical consciousness for the value of spiritual care increases, however, chaplains are regarded more consistently as vital members of the care team, and their professional intervention is sought more proactively. Many physicians now include a spiritual assessment in their total care continuum. It is becoming increasingly more common for physicians to work collaboratively with chaplains in their dedicated efforts to accomplish desirable and lasting outcomes for their patients. Medical educators and practitioners of renown such as Larry Dossey, M.D., a Diplomate in the American Board of Internal Medicine; Harold G. Koenig, M.D, of Duke University; Christina Puchalski, M.D., of George Washington University; Herbert Benson, M.D., of Harvard University; Dale Matthews, M.D., of Georgetown University; and the late David B. Larson, M.D., of Duke University are but a few who have gained international recognition for their individual and collaborative efforts to bring spiritual consciousness to academic medicine. Together with countless others, they serve the cause of total care by being, themselves, spiritual caregivers and by espousing and utilizing the tremendous resource present in the professional chaplain.

Common Pain Problems

David Glick, DC, Section Editor

23

Acute Pain Management

Anh L. Ngo, MD, MBA, and Rainier Guiang, MD

INTRODUCTION

Acute pain serves as a warning system of potential or actual injury. It allows a person to sense when the body is physically threatened and to modify behavior to avoid further tissue damage. This evolutionary advantage is clear when one compares people who have impaired pain sensation with normal individuals. Those with congenital abnormalities, such as a lack of C nociceptive fibers, or acquired conditions such as diabetic peripheral neuropathy sustain more traumatic injuries.

Pain caused by surgical intervention or medical procedures, however, is maladaptive and does not serve any useful purpose. In fact, poorly treated pain is detrimental to several bodily systems, including immunomodulation, stress hormone levels, sympathetic tone, and the cardiovascular system (Ashburn & Ready, 2001; Carr et al. 1992; Max & Payne, 1999; Ready, 2000). Thus, while it is harmful to eliminate all pain when it serves its natural protective purpose, it is compassionate and medically appropriate to treat acute and postsurgical pain.

The Agency for Health Care Policy and Research released clinical practice guidelines in 1992, which set the standard for pain management for surgery and trauma (Carr et al. 1992). The American Society of Anesthesiologists formulated practice guidelines for acute pain management in the perioperative setting in 1995 (Ready et al. 1995). Protocols for acute pain management services in hospitals are available (Ashburn & Ready, 2001; Macintyre & Ready, 2001; Ready, 2000; Sinatra, 1998).

In 2001, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) published pain management standards for health care facilities (JCAHO, 2001). As providers became more aware of the standards,

in 2003, JCAHO provided follow-up recommendations for improving the quality of pain management through performance measures and suggestions for action (JCAHO, 2003). Health care facilities must now recognize the right of patients for timely assessment and management of pain. This process includes identifying inadequately treated pain during the initial assessment of patients and during subsequent reassessments. Patient, patient family, and caregiver education is central to the process as well.

Acute pain in the medical setting may be due to surgery, accidental injury, or exacerbation of a chronic medical condition. Examples include surgical incisions with attendant injury to skin, muscles, bones, and joints; distension of hollow abdominal or pelvic organs; and irritation of pleura or peritoneum. Acute pain may also be an exacerbation of a chronic condition, such as sickle cell crisis, gallstones, migraine headache, herpes zoster, ischemic tissue pain, and cancer. Regardless of the cause, acute pain is harmful to homeostasis and increases the risk of complications.

Untreated pain has negative effects on organ systems and the healing process. Pain can increase risk to problems such as myocardial infarction, congestive heart failure, and infection. Acute pain incites the body's reflex responses for a hypermetabolic state by increasing catecholamine and cortisol levels — which heighten protein catabolism, gluconeogenesis, lypolysis, and hypercoagulability. Pain can also stimulate the cardiovascular system causing hypertension, tachycardia, increased cardiac workload, and a higher cardiac oxygen demand. These physiologic changes place the patient at risk for perioperative ischemia, myocardial infarction, and stroke, particularly if the patient is elderly or has cerebral or coronary

artery disease. Pain also depresses the immune system, increasing the susceptibility of postoperative infections for patients (Sinatra, 1998).

Acute pain after upper abdominal or thoracic surgical procedures can lead to an increased risk of respiratory complications. Guarding and splinting in this area results in a decrease in vital capacity, tidal volume, and functional residual capacity while it increases respiratory rate. The result is an inability to effectively clear bronchial secretions leading to atelectasis, pneumonia, and respiratory failure. Effective pain control improves respiratory function in the postoperative patient, leads to earlier ambulation after surgery, and decreases the risk of deep vein thromboses and pulmonary emboli.

While there are many medical consequences for a patient after injury or surgery, acute pain also affects the institution of medical practice. Pain can cause increases in health care expenditures with prolonged hospital stays and increased pain-related visits. Therefore, prudent evaluation, identification, and treatment of acute pain are vital for the health of patients and the medical system.

EVALUATION OF THE PATIENT IN PAIN

Unfortunately, to date there is no objective test that can measure the severity of a patient's pain. Vital signs such as heart rate, blood pressure, and respiratory rate have been shown to be inconsistent with the subjective severity of pain. To infer severity, the verbal or visual analog scale has become widely accepted in modern medical practice. The scale ranges from 0 to 10, where "0" indicates no pain while a value of "10" indicates the worst pain imaginable. Prior to asking patients to assign a value, it is important to orient them to what characteristics define a score of 10. Examples of a 10 score could be equated to having a surgical incision without any anesthesia or described in terms of pain so severe they would be unable to tolerate it. Patients who can perform their activities of daily living or sleep soundly at night are unlikely to have pain levels of 9 or 10. These designations are reserved for patients who are in excruciating pain. Once determined, the pain score should be documented in the medical record and used to gauge the efficacy of future treatments.

Effective pain management strikes a balance between achieving adequate pain control and minimizing the potential physiological side effects associated with the chosen modality of treatment. A patient receiving a therapeutic dose of morphine may have significant pain reduction, but also develop sedation and, rarely, clinically significant respiratory depression. It is always safer to start with lower doses of pain medications and then titrate the dose to an acceptable level of pain control rather than be too aggressive and have to give a reversal agent. The goal of complete pain relief is rarely necessary and sometimes unreasonable. Recall that the sensation of pain is a pro-

tective mechanism and to completely inhibit this could mask other underlying pathology that may need to be addressed. A reasonable goal for pain reduction is to a level of 4 or less on the verbal or visual analog scale or to a level at which the patient can comfortably tolerate the pain without adverse side effects.

HISTORY AND PHYSICAL EXAMINATION

A detailed history and physical examination with special consideration of the pain history is the initial step in assessing the patient. The pain history should include inquiries into the characteristics of the pain, including location, quality (sharp, dull, aching, throbbing, burning, lancinating, etc.), duration, and factors that exacerbate or relieve it. The past medical and surgical history should pay special attention to disorders such as respiratory, renal, and liver disease, which may affect the choice of treatment modality. Current infection, coagulation disorders, or spine disease may contraindicate neuraxial (epidural or intrathecal) or regional modes of treatment. Tolerance from chronic pain medication use or a history of alcohol or illicit drug abuse must also be considered when determining an appropriate starting dose of pain medication. A patient's prior response to surgery and subsequent postoperative recovery course may give the provider insight into the patient's threshold for pain and the expected response to different pain treatment modalities.

The physical examination should start with an assessment of the patient's vital signs. In the acute postoperative setting, this may include blood pressure, heart rate, respiratory rate and peripheral oxygen saturation (pulse oximetry). Hypertension, tachycardia, and tachypnea may be objective signs of uncontrolled pain whereas a low respiratory rate, change in mental status, and hypotension may indicate respiratory depression from opioids. An observation regarding the patient's general appearance and condition should be documented. A patient found sleeping comfortably but reporting a pain score of 10 may indicate either a misunderstanding of the pain score or drug-seeking behavior. A focused, systematic physical exam should include an evaluation of mental status; auscultation of the heart, lungs, and abdomen; and gentle palpation of painful areas. In the postoperative setting, examination of the intravenous line and epidural catheter must also be documented as they are common sources of pain other than the primary surgical site. Thorough documentation of the initial history, physical, and pain score and then again with each subsequent patient encounter is the key to gauging the progress of a treatment plan objectively.

When acting on behalf of the primary (requesting) service, the consulting service (such as the pain service) should verify that all recommendations are documented in the medical chart and communicated directly to the primary service to avoid any confusion or misunderstand-

ings. Patients should be involved in the decision-making process regarding the pain management plan. For hospitalized patients, the pain service may follow the patient on a daily basis and adjust the treatment plan as necessary.

BASIC ACUTE PAIN MANAGEMENT STRATEGIES

The provider must first determine the severity of the pain (mild, moderate, or severe), choose an analgesic, and finally determine the optimal route of administration. There are several routes available to deliver pain medications: enterally, administered via the alimentary tract, or parenterally, administered by means other than the alimentary tract. Enteral administration involves the oral, sublingual, or rectal route whereas the parenteral route includes intravenous, epidural, intrathecal, subcutaneous or transcutaneous, and intramuscular administration. The choice of modality depends on the patient's condition, the availability of easy intravenous access, and the presence of a functioning gastrointestinal tract. Although technically easy to administer, intramuscular injections have fallen out of favor with many physicians for two reasons. First, intramuscular drug uptake is variable, and second, patients generally do not like receiving injections.

MILD TO MODERATE PAIN

Nonsteroidal anti-inflammatory drugs (NSAIDs) and acetaminophen are first-line medications for the patient in mild to moderate pain. The choice of which agent to start with depends on the existence of comorbidities, such as renal disease or bleeding diatheses in the case of NSAIDs or liver disease in the case of acetaminophen. Currently, there is only one NSAID, ketorolac, available for intravenous administration. Approval of a parenteral COX 2 selective drug, paracoxib, is anticipated in the near future. Failure to achieve adequate pain control with near maximal doses of these medications warrants the addition of an opioid.

Opioid medications differ from NSAIDs in that opioids do not have a strict ceiling dose; further dosage increase will provide incrementally more pain relief. In contrast, NSAIDs have a clear ceiling dose. Once exceeded, additional drug will not provide more analgesia, but will increase the risk of drug-induced side effects. Note that the concept of a "weak" opioid does not have much pharmacologic support and often simply means that the particular drug is combined with acetaminophen or NSAID. In such cases, using a weak opioid limits the amount of actual opioid that can be delivered, without potentially providing too much acetaminophen. Table 23.1

TABLE 23.1
NSAIDs: Dosing Data for Adult Patients

Drug	Usual Adult Dose	Comments
		Oral NSAIDs
Acetaminophen	650–975 mg q 4 hr	Acetaminophen lacks the peripheral anti-inflammatory activity of other NSAIDs; maximum dose of 4 g per day; may be contraindicated with alcohol use
Aspirin	650–975 mg q 4 hr	The standard against which other NSAIDs are compared; inhibits platelet aggregation; may cause postoperative bleeding
Celecoxib	100 QD to BID	COX 2 selective NSAID with improved platelet and GI profile
Diflunisal	1000 mg initial dose followed by 500 mg q 12 hr	Equivalent in strength to codeine 60 mg plus acetaminophen; fewer platelet effects than aspirin
Ibuprofen	400 mg q 4–6 hr	Available as several brand names and as generic; also available as oral suspension
Naproxen	500 mg initial dose followed by 250 mg q 6–8 hr	Also available as oral liquid
Naproxen sodium	550 mg initial dose followed by 275 mg q 6–8 hr	Sodium salt may have faster therapeutic effect
Salsalate	500 mg q 4 hr	May have minimal anti-platelet activity
Valdecoxib	10 to 20 mg q day	COX-2 selective NSAID
		Parenteral NSAID
Ketorolac tromethamine	30 or 60 mg i.m./i.v. initial dose followed by 15 or 30 mg q 6 hr Oral dose following IM dosage: 10 mg q 6–8 hr	Use not to exceed 5 days

Note: Modified and updated from *Acute Pain Management: Operative or Medical Procedures and Trauma.* Clinical Practice Guideline. Rockville, MD: Agency for Health Care Policy and Research, 1992.

QD = per day; BID = twice a day.

TABLE 23.2
Opioids: Dosing Data for Adult Patients

	Approximate Equianalgesic Doses		Recommended Starting Dose (adults weighing more than 50 kg)	
	Oral	Parenteral	Oral	Parenteral
Opioid Agonist Drug				
Morphine	30 mg q 3–4 hr	10 mg q 3–4 hr	30 mg q 3–4 hr	10 mg q 3–4 hr
Codeine	130 mg q 3–4 hr	75 mg q 3–4 hr	60 mg q 3–4 hr	60 mg q 2 hr (IM/SQ)
Hydromorphone	7.5 mg q 3–4 hr	1.5 mg q 3–4 hr	6 mg q 3–4 hr	1.5 mg q 3–4 hr
Hydrocodone (with acetaminophen)	30 mg q 3–4 hr	Not available	10 mg q 3–4 hr	Not available
Meperidine[a]	300 mg q 2–3 hr	100 mg q 3 hr	Not recommended	100 mg q 3 hr
Oxycodone	15–20 mg q 3–4 hr	Not available	10 mg q 3–4 hr	Not available

[a] Also see warnings with meperidine, listed in Table 23.3.

Note: The oral to parenteral ratio of morphine with chronic dosing is 3:1. The oral:parenteral ratio for hydromorphone is 5:1. These are only approximate doses, and clinical use of these tables demands caution. Doses should be titrated to effect. Modified and updated from *Acute Pain Management: Operative or Medical Procedures and Trauma.* Clinical Practice Guideline. Rockville, MD: Agency for Health Care Policy and Research, 1992.

displays the starting and maximum doses of NSAIDs and acetaminophen. Table 23.2 shows equianalgesic doses of opioids compared with morphine. NSAIDs and opioids are discussed in greater detail in Chapters 53 and 54, respectively.

MODERATE TO SEVERE PAIN

Patients who undergo major surgeries (cardiothoracic or open abdominal procedures) or procedures associated with intense postoperative pain (knee replacements) may require greater amounts of analgesics or more sophisticated analgesic delivery methods. For patients in severe pain, the intravenous administration of an opioid is usually the treatment of choice. An adequate intravenous dose of an opioid leads to rapid pain relief because a therapeutic blood level of drug is quickly achieved; this is facilitated by avoidance of the first pass effect in the liver.

Morphine, hydromorphone, and fentanyl are pure opioid agonists, available in oral and intravenous formulations. Pure opioid agonists, in contrast to partial agonists (and NSAIDs), have no theoretical dosage "ceiling effect." In theory, pure agonists can be titrated to pain relief without risk of end organ toxicity. However, one must keep in mind that all opioids are associated with dose-dependent side effects such as respiratory depression, sedation, and constipation. The actual dosage ceiling reached depends on the patient, clinical situation, patient monitoring (e.g., in the intensive care unit (ICU), and the physician's comfort with the analgesic protocol. Failure to achieve adequate analgesia for acute, nociceptive pain with a single opioid may be due to inadequate dosing, inappropriate frequency of administration, or onset of unwanted side effects, which prevents further titration.

Once pain control is achieved, pain levels should decrease over the first few postoperative or post-injury days, and the use of sustained-release opioids (e.g., MS Contin®, Oramorph®, OxyContin®, and Duragesic®) typically is not necessary or indicated. Although controlled-release preparations may be appropriate for patients who were on a stable opioid dose prior to the current episode of acute pain, the use of controlled-release analgesics is predicated on the need for a stable, around-the-clock dosage. The appropriate dose may be difficult to predict in a given patient, particularly in the acute pain or postsurgical situation.

ADVANCED PAIN MANAGEMENT STRATEGIES

Patient controlled analgesia (PCA) employs an electronic, programmable pump that delivers on patient demand a preset amount of pain medication, usually by the intravenous route (Macintyre & Ready, 2001). The health care provider generally must program a bolus dose, demand dose, lockout interval, hourly (or 4-hourly) maximum dose, and an optional basal rate. The bolus dose is the initial loading dose given to achieve a therapeutic level of medication. The demand dose is the dose that will be self-administered each time the patient pushes the button. The lockout interval is the time that must elapse before the patient will be allowed another dose on demand. The hourly maximum dose is the programmed total amount of drug that theoretically may be delivered within the given time period. The basal rate is an optional programmed hourly background infusion of opioid. An example of a typical regimen for hydromorphone would be the following: Demand dose 0.2 mg, lockout interval 10 minutes, hourly maximum 1.2 mg, basal rate 0 mg/h. See Table

TABLE 23.3
PCA Settings for Commonly Used Opioids

	Morphine	Hydromorphone	Meperidine	Fentanyl
Concentration	1 mg/ml	0.2 mg/ml	10 mg/ml	20 µg/ml
Demand Dose	1 mg	0.2 mg	10 mg	20 µg
Lockout interval	10 min	10 min	10 min	8 min
Basal Rate/hr	1 mg	0.2 mg	10 mg	20 mcg/hr
Hourly limit	7 mg	1.4 mg	70 mg	100 mcg

Note: Meperidine should not be used in patients with renal insufficiency, or for longer than 48 hours. The total 24-hour dose of meperidine should not exceed 600 mg in the average adult. Meperidine is not a first-line drug, but may have a role for patients who are allergic to or have excessive nausea with morphine-based products. Morphine metabolites accumulate with renal insufficiency. Remember that morphine is not dialyzable. Hydromorphone is generally considered to be safe for patients with poor renal function, as is fentanyl. However, metabolites may accumulate that cause central nervous system problems. Patients with concomitant hepatic dysfunction will have unpredictable responses to opioids because of prolonged metabolism.

23.3 for commonly used opioids and PCA settings. Not all patients are candidates for PCA.

The theory behind PCA is simple. When the patient experiences pain, he or she pushes the button, pain medication is delivered, and the patient experiences an increment of pain relief. If the increment of relief is inadequate, the patient pushes the button again and will receive an additional dose of medication, as long as the lockout interval, in this case 10 minutes, has elapsed since initially pushing the button. If less than 10 minutes has lapsed, the patient will not receive the additional dose. If the pain is inadequately controlled with the current settings, the provider can review the history of attempts and injections, which is electronically stored by the pump. A high ratio of attempts to injections can indicate an inadequate demand dose, a lockout interval that is too long, or an inadequate understanding by the patient of how to use the pump. For instance, a patient who does not understand that a few minutes are required from the time the button is pressed to the onset of pain relief may press the button multiple times in rapid succession.

The PCA has a built-in safety mechanism that safeguards the patient from unwanted respiratory depression. If the demand dose causes unwanted sedation, the patient falls asleep and is rendered incapable of pushing the button again until the sedation wears off.

It is important to note that sedation may herald the development of clinically significant respiratory depression. Dosing should be reduced to allow any sedative effects to wear off. Adequate oxygenation should be verified by pulse oximetry. Use of a sedation scale is suggested (0 = fully awake; 1 = mildly drowsy; 2 = frequently drowsy but easy to awaken; 3 = somnolent and difficult to arouse; S = sleeping). A score of 2 warrants turning off any basal infusion and reducing the demand dose, typi-

cally by 50%. A score of 3 requires further intervention, possibly including the use of a reversal agent such as naloxone (carefully titrated to vital signs, oxygen saturation, and respiratory function). The goal of PCA therapy is to provide adequate pain relief, with pain scores generally less than 4 of 10 and sedation scores less than 2.

The addition of the optional basal infusion renders the inherent safety mechanism of PCA less effective, because the background infusion, by definition, is not under the patient's control. This extra amount of analgesic may be sufficient to cause sedation and increases the risk of respiratory depression. Patients with basal infusions should be monitored more frequently for signs of sedation or respiratory depression. In our institution, we do not routinely add basal infusions, except on the first night following surgery, unless there is a demonstrated need to provide the basal infusion. Use with elderly patients is not recommended.

On occasion, well-intentioned family members, fearing that the patient is experiencing pain, will push the button for the patient. This also defeats the PCA concept and may increase the risk of respiratory depression. Family members must be made of aware of this danger and instructed not to administer analgesic doses for the patient.

Any opioid available in an intravenous formulation can be used with a PCA device. However, fentanyl and meperidine warrant special mention. Fentanyl is an opioid analgesic with potency 50 to 80 times greater than that of morphine. Because of its high potency, risk of diversion, rapid onset of effect, and the fact that most physicians are not familiar with fentanyl, its use on the general medical floors is discouraged, unless appropriate expertise with the drug is available.

On the other hand, fentanyl is commonly used in the operating rooms by experienced anesthesiologists and in

the intensive care units for patients on continuous monitors, and in some postoperative settings, fentanyl may be considered a drug of choice. Advantages of fentanyl include its rapid onset and lack of active metabolites that are excreted by the kidney. Provided that liver function is normal, fentanyl will not accumulate with renal insufficiency.

Meperidine has fallen out of favor in many hospitals because of potential toxicity associated with its metabolite, normeperidine, which is renally excreted and can accumulate in plasma, even with normal renal function. Normeperidine has been shown to lower seizure thresholds and cause myoclonus, even following therapeutic doses of meperidine. Nonetheless, meperidine usage remains widespread, despite its poor image. Although meperidine may be appropriate for patients who become nauseated with morphine derivatives (e.g., morphine, oxycodone, and hydromorphone), or for patients with true allergies to morphine derivatives, it can no longer be considered a first-line drug. In any case, meperidine should not be given in doses greater than 600 mg in a 24-hour period for the average adult and should not be administered for more than 48 hours, even with normal renal or central nervous system function (Max & Payne, 1999).

Providing patients with dosing independence, within programmed parameters, is one of the best features of PCA. When patients are placed on staff-dependent administration of pain medication, there may be a delay in response due to staffing levels and demands from other patients, often delaying pain relief. PCA has the advantage of allowing the patient to control the frequency of opioid administration without the time delay of having to ask the nursing staff or physician for another dose of analgesic. This efficiency leads to greater patient satisfaction as well as removing the burden of following a fixed dosing schedule by the nursing staff.

EPIDURAL INFUSIONS

An epidural catheter can be used to provide intraoperative regional anesthesia and postoperative analgesia (Liu, Allen, & Olsson, 1998; Narinder, 2000). Intraoperatively, the epidural is dosed with various concentrations of preservative free local anesthetics such as lidocaine, chlorprocaine, bupivacaine, or ropivacaine, which results in a dense sensory blockade and varying degrees of motor blockade, depending on the agent used. In some cases the epidural may be the sole modality of intraoperative anesthesia. However, in the postoperative period, the presence of motor blockade can be considered detrimental by delaying early ambulation and compromising respiratory function. Fortunately, dilute formulations of local anesthetics, combinations of local anesthetics and opioids, or opioid infusions alone can be safely infused, providing analgesia without delaying recovery time. Formulations and doses used for epidural infusions at University Hospitals of Cleveland are listed in Table 23.4 and Table 23.5.

The mechanisms of action of epidural local anesthetics and epidural opioids are different (Narinder, 2000). Epidural local anesthetics act primarily on the spinal nerve roots in closest proximity to the epidural catheter tip and lose effectiveness as the medication spreads. Local anesthetic epidural infusions produce segmental analgesia. Therefore, the catheter tip should be positioned at the spinal dermatome closest to the level of the incision to take full advantage of the technique, which allows the smallest infusion rate and reduces the risk of lower extremity weakness and hypotension.

On the other hand, epidural opioids act on receptor-mediated sites in the spinal cord dorsal horn and supraspinal brain sites. The degree of distal spread is determined by the opioid's hydrophilic or hydrophobic properties. Hydrophilic opioids such as morphine and hydromorphone tend to spread rostrally, whereas the lipophilic, hydrophobic opioid fentanyl tends to act locally at the dorsal horn of the spinal cord, closer to the site of injection. However, the high lipid solubility of fentanyl enhances its systemic absorption. Indeed, the analgesic effect of epidurally administered fentanyl is due in part to systemic action at supraspinal sites.

Epidural opioids are particularly effective in thoracic and upper abdominal surgeries where the infusions can provide excellent postoperative pain relief that is titratable to a patient's pain level. When combined, epidural local anesthetics and opioids can have additive effects.

Meta-analysis indicates that regardless of the choice of opioid or local anesthetic or whether the epidural catheter is placed in the thoracic or lumbar spine, epidural analgesia is superior to parenteral opioid administration (Block et al., 2003). Moreover, with appropriate monitoring, the technique is safely administered on hospitals wards.

TABLE 23.4
Standard Epidural Infusion Mixtures Used at University Hospitals of Cleveland

Name	Mixture
Bupivacaine/Hydromorphone	Bupivacaine (0.1%) Hydromorphone (0.01 mg/ml) 4–6 ml/hr
Morphine	Morphine (0.05 mg/ml) 4–8 ml/hr
Bupivacaine	Bupivacaine (0.1%) 4–6 ml/hr

Note: Hydromorphone is used more often than morphine. User preference or side effects, such as nausea, may suggest use of the alternate opioid.

TABLE 23.5
Examples of Epidural Infusions Used, Depending on the Surgery and Spinal Level of Epidural Catheter Insertion

Surgery	Epidural Catheter Insertion Level	Infusion Type
Thoracotomy	T5–T10	Bupivacaine/hydromorphone at 4–8 ml/hr
Upper abdominal procedure	T8–T12	Bupivacaine/hydromorphone at 4–8 ml/hr
Abdominal hysterectomy	T12–L1	Bupivacaine/hydromorphone at 4–8 ml/hr
Knee replacement	L3–L4	Bupivacaine at 4–8 ml/hr plus i.v. PCA

Note: See Table 23.4 for components of the infusions. These are approximate infusion rates, titrated to effect. In our institution, patients with total joint replacements have their epidural catheters removed the day after surgery, because all are started on coumadin the night of surgery; postoperative analgesia is continued with intravenous PCA.

A recent advance in epidural pain management is the use of patient controlled epidural analgesia (PCEA). As with intravenous PCA, patients have the ability to receive demand doses of epidural analgesics (opioids and/or local anesthetics) in addition to the normal basal rate. In one study, the use of PCEA with bupivacaine and fentanyl demonstrated better analgesia over standard epidural infusions and higher patient satisfaction, a lower incidence of side effects, and reduced overall costs (Liu & Benzon, 2000; Liu et al., 1998).

Epidural infusions are wonderful when they work. However, these too occasionally fail, but the failure rate is generally less than about 15%. Inadequate pain relief may be caused by improper catheter placement, migration of the epidural catheter out of the epidural space, or an extended delay between epidural dosing in the operating room and starting of the epidural infusion in the recovery area. Therefore, it is recommended that the epidural infusion be started as soon as the patient arrives in the recovery area. Generally, epidural catheters can be used safely up to 1 week, provided that catheter placement employed sterile technique and there is proper ongoing daily care of the catheter. Not all patients are appropriate candidates for epidural infusions. Specific factors to consider include patient preference, coagulation profile, and the presence of infection systemically or at the site of proposed catheter insertion.

COMMON CLINICAL SCENARIOS

THE POST ANESTHESIA CARE UNIT

The Post Anesthesia Care Unit (PACU), also known as the postsurgical recovery area, is by definition an intensive care unit. This unit is staffed by physicians and highly skilled nurses in ratios similar to those of an intensive care unit and is therefore able to deliver a level of care higher than what is available on the wards. Predetermined criteria such as hemodynamic stability and adequate pain control must be achieved prior to transfer to other patient care areas or discharge from the hospital. As all patients are monitored with blood pressure, telemetry, and pulse oximetry recording, the PACU is the safest place to initiate a pain treatment regimen. On the floors, review of the PACU records, including opioid requirements and response to treatment, can be a useful guide to determine which medications and dosages to use.

Upon the patient's arrival in the PACU, a systematic chart and operative course review should be performed with special attention to identifying patients with difficult airways and postextubation respiratory complications. The presence of these problems should warrant conservative dosing of opioids. Identification of preexisting pain syndromes and review of medication requirements may provide insight into future pain requirements. A focused physical exam should be performed and pre- and post-treatment pain scores documented. An example of opioid starting doses for an otherwise healthy adult patient could be morphine 2 to 5 mg i.v. every 15 minutes, hydromorphone 0.2 to 0.5 mg i.v. every 10 minutes, or fentanyl 25 to 50 μg i.v. every 5 minutes, and titrated until adequate pain control is achieved. Opioid naïve and elderly patients should receive smaller doses of intravenous opioids, allowing an appropriate interval for the onset of relief to take place before redosing. This approach will minimize the risk of unnecessary sedation and respiratory depression. In the absence of active bleeding, risk of bleeding, or renal disease, NSAIDs can reduce the requirements for opioids and the risk of sedation or respiratory depression.

THE HOSPITAL FLOOR

With the exception of the PACU, the floor will be the most common place where hospitalized patients may need acute pain management. Whether admitted for surgical recovery, from the emergency department, or directly from a phy-

sician's office, these patients require the same thorough assessment, detailed workup, and formulation of a course of action as previously described. For postoperative pain, where the source of pain is easily identified, simple titration of intravenous opioids through PRN orders and frequent assessments or, better yet, through PCA is usually a good course of action.

Patients admitted from the emergency department or directly from physicians' offices, where the etiology of pain is less certain, require a higher level of assessment and vigilance when starting a pain regimen. Patients who present for acute exacerbations of chronic diseases, such as a sickle cell crisis, pancreatitis, or cancer pain, may already be taking opioids chronically as outpatients. In such cases, the dose of opioids taken as an outpatient must be factored in to avoid starting an opioid at a dose too low to provide adequate analgesia. One may consider calculating the outpatient hourly dose-equivalent, and delivering an equianalgesic, parenteral dose via a PCA by basal infusion. In addition, an appropriate demand dose for breakthrough pain should be allowed. This approach requires extensive experience with PCA and in calculating conversion doses. Close monitoring is required, although the ICU setting may not be necessary.

Once the patient's analgesic requirement has been established or medical condition has stabilized, one must consider the possibility that the patient may require long-term pain therapy, such as for cancer-related pain. Unfortunately, logistical problems and lack of appropriate monitoring may make PCA impractical for general home use. On the other hand, home PCA commonly is used for patients with intractable pain due to cancer.

The conversion of intravenous to oral doses of opioids is mandatory and may be facilitated by using conversion tables or conversion calculators. However, these should only be used as guidelines, because marked variability with the final dose and dosing intervals is the rule rather than the exception.

The Outpatient Clinic

Most often, NSAIDs and acetaminophen prescribed in moderate doses are appropriate for outpatient pain management, given the low probability of life-threatening side effects. Fixed-combination opioids taken in conservative doses for short-term therapy can safely be prescribed. When starting a fixed-combination drug, such as hydrocodone and acetaminophen, the patient should be advised not to operate heavy machinery or drive until the response to the new medication is determined. Noncancer pain requiring larger dosages of opioids or cancer pain refractory to aggressive therapy should be reevaluated for other causes of pain and a referral to a pain management specialist for possible interventional therapy should be considered.

Acute or poorly controlled chronic pain may be a reason for consulting with the pain service. In the outpatient clinic, after initial evaluation, the provider must decide if the patient's medical condition and pain can be controlled on an outpatient-basis or if a higher level of care and monitoring is necessary, which would require admission to the hospital. If hospital admission is required, PCA is a convenient, efficient method of achieving rapid pain relief.

Patients with Cancer Pain

The diagnosis of advanced or metastatic cancer carries special significance to the pain practitioner due to its chronic nature and frequent poor prognosis. The psychological and emotional implications to the patient family can contribute to the modulation and perception of pain. It is common and expected that a patient with active cancer will eventually present with new pain complaints. Often these acute pain exacerbations are secondary to progression of the cancer to other areas of the body, pain from cancer treatments (surgical, chemotherapy), or the development of tolerance to the current pain regimen.

When the pain is severe and debilitating, inpatient admission and aggressive intravenous pain management is warranted while the cause of the exacerbation is determined. In the postoperative setting, if the patient with cancer has been on chronic opioids, standard postoperative doses may be inadequate to achieve pain control. As with all patients on chronic opioids, stool softeners and stimulant laxatives should be prescribed to avoid constipation, which is a common source of pain and discomfort.

Patients Who Abuse Opioids

When patients who abuse drugs present with acute pain, the practitioner's reflex is to call for a pain management consultation to avoid dealing with the patient and his or her abuse or addiction problem. The frustration involved with potential secondary gain issues, the fear of being unable to control the patient's pain without large doses of opioids, the fear of causing a patient to relapse into drug abuse behavior, and frank worries about deception and criminal activity may prompt physicians to label such patients as "difficult." The acute pain setting is probably not the ideal forum for preaching the virtues of drug rehabilitation. All patients suffering from acute pain arising from demonstrable injury deserve the same consideration and access to pain relief as patients who do not abuse drugs. Although avoiding the use of opioids might be ideal is this instance, certain situations, such as acute trauma or postoperative pain, may require the use of opioids. In the case of the recovered abuser, the alternative to the need for opioids may be as simple as placing an epidural catheter for postoperative pain control. For those

with ongoing abuse, opioid tolerance represents the main obstacle to achieving satisfactory pain control. Here, the question is not which drug to use, but how much. There is no place for the use of partial agonists or agonist/antagonists such as nalbuphine or pentazocine in this situation, as the antagonist properties of these drugs may induce withdrawal symptoms.

The initial evaluation of patients currently using illicit drugs involves obtaining an accurate history of prior and current drug use and the nature of the current pain. Identification of drugs used, frequency of use, and response should be documented. This requires a frank, honest discussion with the patient and description of consequences resulting from deception.

It may be impossible to accurately convert a street drug of unknown purity such as heroin to an equianalgesic dose of pharmaceutically pure opioid. However, analgesics tables provide a starting point for further dosage titration. Intravenous PRN or PCA dosing, while titrating the analgesic to patient comfort, may be used to rapidly establish the patient's opioid requirement. PCA dosing with a basal rate will help ensure against accidental underdosing and subsequent withdrawal symptoms.

The PCA pump with its opioid-filled syringe in close proximity to the patient may invite drug abusers to attempt to administer doses manually by manipulating the syringe or pump apparatus. It should be made clear that such behavior will result in the discontinuance of the PCA. Once the acute pain is under control, it is beneficial to seek the advice of Psychiatry or Addiction Medicine when formulating a long-term plan for possible drug rehabilitation.

PATIENTS TAKING CHRONIC OPIOIDS

The approach to treatment of acute pain in patients on long-term opioids is similar to that of patients who abuse opioids. However, the conversion calculation is more precise, because an accurate history of which opioid was used is readily available. Depending on the nature of the acute pain, whether surgical or traumatic, these patients will require their normal daily dose of opioid as well as an additional dose to cover the new acute pain.

The first step is to determine the outpatient dose of opioid and convert that to an equianalgesic hourly dose of parenteral opioid, to be delivered by hourly basal infusion with the PCA device. The demand dose may be calculated as approximately equal to the hourly basal infusion rate. The demand dose should be carefully titrated with the goal of relieving the new acute pain. Subsequently, the 24-hour total amount of opioid given can then be used to calculate a basal infusion that more closely matches the patient's ongoing needs and requires less reliance on the demand dose. Another approach would be to augment judicious opioid use with NSAIDs or acetaminophen, with the goal of minimizing the increase in total opioid requirement. In all cases, assessment and reassessment are keys to providing safe, effective dose conversions and satisfactory pain relief.

For patients on chronic, high-dose opioids (e.g., oral morphine of more than 90 mg per day), epidural analgesia with a local anesthetic and/or opioid for postoperative pain control must be augmented with supplemental oral or parenteral opioids to prevent withdrawal symptoms. Withdrawal can occur even with epidural opioids.

Withdrawal can be avoided by providing at least one third of the usual daily dose of opioid, in divided doses, given every 4 hours or so. Signs of withdrawal include restlessness, irritability, hypertension, and tachycardia, so the clinician must be prepared to adjust the opioid dose as needed to treat withdrawal symptoms.

PATIENTS WITH RENAL OR LIVER DISEASE

When choosing an analgesic, drug metabolism and excretion must be considered, given the prevalence of renal and hepatic disease in the general population. NSAIDs, as previously mentioned, can worsen renal disease and are contraindicated in patients with renal insufficiency. Acetaminophen may be contraindicated in patients with hepatic disease due to the formation of hepatotoxic metabolites. Opioids are metabolized in the liver, some to pharmacologically active compounds excreted via the kidneys.

Morphine is metabolized to morphine-6-glucuronide, which is more potent than morphine, but more hydrophilic and less able to cross the blood–brain barrier. Meperidine is metabolized to normeperidine, which can cause seizure activity, not reversible by naloxone. Both morphine-6-glucuronide and normeperidine are excreted by the kidneys and will accumulate with renal insufficiency. Therefore, both morphine and meperidine are contraindicated in renal insufficiency. In the presence of renal disease, hydromorphone and fentanyl are excellent choices given their lack of active metabolites. Note should be made that epidural catheter placement may seem to offer an advantage, but must be balanced against the potential risk of coagulopathy often seen in such patients.

GERIATRIC PATIENTS

In the last decade, much interest has grown in the field of geriatrics due to the ever-increasing size of the elderly population in Western countries. Physiologically, elderly patients differ from young adults by having less body water, lean muscle mass, and increased body fat. The cardiac, respiratory, and renal systems may begin to show signs of compromise. Elderly patients have a higher incidence of systemic diseases, which also tend to be at later stages of progression. On occasion, these systemic impairments may pose a barrier to effective pain relief. For example, cognitive impairment as with Alzheimer's dementia may eliminate the possibility of using a PCA.

Cognitive problems may make assessment of pain difficult, and the clinician must be patient and flexible. Use of faces-based pain scales may be helpful if the patient cannot comprehend a numerical pain scale.

Geriatric patients tend to metabolize pain medications less efficiently, which can lead to a greater incidence of side effects such as sedation, respiratory depression, and constipation. Opioid dosing should be decreased by at least 50% of the usual dose that would be given to a young adult; as with younger patients, titration to the desired analgesic effect is the best strategy to minimize the risk of injury, particularly in frail patients.

SUMMARY

The art and science of pain management need not be overly difficult, but they require attention to detail. With awareness that a patient is in pain and knowledge of methods that provide effective treatment, pain management often becomes a straightforward endeavor. However, the clinician must have a commitment to providing good medical care, possess a basic understanding of analgesic pharmacology, and be willing to utilize adequate analgesics to achieve satisfactory pain relief.

Untreated pain can have clinically significant consequences. However, patients have a right to effective pain management, and it is not necessary to invoke the risk of physiologic consequences to justify good pain management.

The key to successful pain management is assessment and reassessment. For most patients, pharmacologic methods are the mainstay for treating acute pain. NSAIDs are effective for mild to moderate pain, and can have significant opioid-sparing effects as well. For moderate to severe pain, oral or parenteral opioids or more specialized techniques, such as epidural infusions, may be indicated.

For hospitalized patients, more advanced techniques can provide excellent pain relief, even after major surgery. Although oral opioids may be effective if the patient can take medications by mouth, PCA is safe and effective and allows rapid titration of intravenous opioids for pain relief. Epidural infusions provide superior postsurgical pain relief, particularly when opioids are combined with local anesthetics and the catheter is positioned at a dermatomal level near the incision.

Certain patient populations warrant special consideration, particularly geriatric patients, patients with renal or hepatic insufficiency, patients on chronic opioids, and those with acute pain due to cancer. Patients who currently abuse opioids can be a particular challenge, but satisfactory pain control can be achieved with appropriate titration of opioids, and with epidural infusions in selected patients.

For all patients, the appropriate course of action is based on the history and physical examination, repeated pain assessments, proper patient education, and participation of the patient in the decision-making process. It is also important to remember that pain management is a team effort, particularly in the hospital setting and for patients with complicated medical problems.

Although occasionally labor intensive, the ability to provide good pain management remains one of the exemplary skills of modern medicine. Competent pain management also remains a rewarding professional experience for the clinician.

Neuropathic Pain

*David R. Longmire, MD, Gary W. Jay, MD, DAAPM, and
Mark V. Boswell, MD, PhD*

INTRODUCTION

In presenting this chapter the authors' original purpose was to offer a review of established *concepts* of neuropathic pain, supplemented by discussion of current practices related to its assessment and management. These goals notwithstanding, reports of more than a century of medical observation and research have demonstrated that neuropathic pain is much more than a concept or a single disorder. It is instead an evolving collection of established clinical and experimental conditions, all of which share the perpetuation of pain symptoms or pain-related behavior created by injury to neural tissue other than that involved with simple nociception (Bennett, 1994; Fields, 1987).

Although neuropathic pain has been operationally defined as an abnormal pain state that arises from a damaged peripheral nervous system (PNS) or central nervous system (CNS) (Merskey & Bogduk, 1994), there is evidence to suggest that several disease states within this category have active residual involvement of nociceptors at the site of the original injury, creating a mixed nociceptive–neuropathic pattern. As well, several painful disorders categorized as neuropathic are created or maintained by aberrant neural communication involving autonomic nervous system pathways that are not considered to be purely peripheral or central. These include complex regional pain syndromes (CRPS) Type I and II (reflex sympathetic dystrophy and causalgia, respectively) and sympathetically maintained pain (SMP) (Dworkin et al., 2003; Jay, 1996).

DIAGNOSTIC EVALUATION OF NEUROPATHIC PAIN

There exist two lines of thought relative to the clinical diagnosis of pain syndromes of this type. One suggests that because the symptom characteristics of neuropathic pain are not pathognomonic for the condition, their lack of specificity makes the diagnosis difficult to reach (Boswell et al., 2001). Another provides evidence to support certain symptom characteristics as strong indicators of neuropathic pain (Krause & Backonja, 2003). Regardless of which attitude is correct, the pain practitioner hoping to differentiate neuropathic from non-neuropathic disorders must begin, as always, with the clinical history.

MEDICAL PAIN HISTORY

The style of medical history which has been modified for the specific documentation of pain has been described in detail elsewhere (Longmire, 1991a, 1996). Within that system the clinician acquires patient information regarding at least eight aspects of the pain problem: A mnemonic often used to ensure that completeness of data collection regarding each characteristic is PQRST, in which P = provocative, palliative factors; Q = quality, R = region (of onset), radiation, and referred pain; S = severity, and T = timing. Of these characteristics, those that are most commonly considered in the diagnosis of neuropathic pain are quality (burning, shooting, tingling, sharp, or shock-like), timing (continuous or intermittent/paroxysmal), and pro-

vocative (stimulus-evoked or stimulus-independent) (Bennett, 1994). While verbal reports of the regional (spatial) distribution may be helpful in determining the relationship of pain to specific neurological syndromes, the use of a standardized Pain Drawing Instrument is preferred for documentation. One tragic error made by clinicians in the past is the dismissal of pain as being organic simply because it did not resemble an anatomic or dermatomal distribution. In fact, many neuropathic pains, which are maintained or mediated through autonomic pathways, may follow a pattern of sympathetic sclerotomes or blocks of pain referred from deep muscular or visceral afferent reflexes.

In recording pain severity or intensity, it is important to document the patient's subjective report using standardized scales such as a verbal Numeric Rating Scale (NRS-11) or nonverbal Visual Analogue Scale. Even more important is to avoid the cardinal sin of confusing results of a verbal and visual scale by reporting: "the patient stated that his/her Visual Analogue Score was 6 out of 10." For patients with multifocal neuropathic pain or mixed neuropathic/myofascial pain, a verbal scale is preferred, as it can be used easily to record intensity *for each region*, not just the peak or average pain. Finally, it has been suggested that this mnemonic should be changed to add the letter O, for *other* (associated) symptoms, such as loss of sensation or nonpainful paresthesias or dysesthesia occurring in the same general area as the pain.

PHYSICAL EXAMINATION OF PATIENTS WITH NEUROPATHIC PAIN

In general, all major parts of the physical examination are important for adequate determination of the presence of local disease, which may cause pain (Longmire, 1991b, 1996). Patients in whom the *symptom* characteristics suggest neurological origin may also demonstrate regional abnormalities of motor or reflex functions. However, the portions of the examination that are most relevant to the evaluation of neuropathic pain are those related to sensory dysfunction, such as hypoesthesia, hyperesthesia, hyperalgesia, and allodynia (Dworkin et al., 2003; Fields, 1987; Krause & Backonja, 2003; Longmire, 1991b).

There are three important aspects in performing the sensory examination in patients with neuropathic pain: (1) it must be remembered that the information obtained is still subjective, (2) stimulation with different modalities may create a mixed or uninterpretable response pattern, and (3) there may also be hypoesthesia or even areas of total anesthesia in the middle of areas that the patient describes as being so painful. The severity of a pain condition can be related to the size of a painful area, but the intensity is independent, no matter how large or small the territory.

INTEGRATION OF HISTORY/PHYSICAL DATA FOR NEUROPATHIC PAIN EVALUATION

It is evident from the preceding paragraphs that the duration and complexity of the clinical evaluation of human neuropathic pain is very dependent on the patient's ability to tolerate long and potentially uncomfortable procedures. For screening purposes, however, different methods have been developed to provide a combination of individual components of the history and physical examination. The simpler and more direct methods are exemplified by Galer and Jensen (1997) and Krause and Backonja (2003). A Neuropathic Pain Questionnaire has been developed: demonstrates burning pain, shooting pain, numbness, electric pain, tingling pain, squeezing pain, freezing pain, and significant sensitivity to touch. Analysis of the elements reveals that the three most valuable features are the symptoms of numbness, tingling pain, and the mixed response of symptoms/signs expressed as increased pain due to touch on physical examination.

LABORATORY, RADIOLOGIC, AND ELECTRODIAGNOSTIC ASSESSMENT

Once the history, physical findings, and neuropathic pain questionnaire have yielded sufficient evidence to support the potential presence of neuropathic pain, specific biochemical, structural, and neurophysiological tests may be applied to confirm or eliminate certain disorders from the differential diagnosis.

Laboratory evaluation is necessary to determine the presence of hematologic, chemical, or pathological processes with a high potential for causing or contributing to the pain (Kennedy, 1996; Kennedy & Longmire, 1992). Such tests are also used to monitor (1) systemic response to treatment because there are often effects on renal and hepatic function and (2) serum levels of primary analgesics and certain adjuvant medications such as anticonvulsants. DNA and other specific biochemical tests for neuropathic pain disorders that have a familial tendency or pattern of inheritance can be helpful for genetic counseling, but they are not often ordered in primary care pain practice. Similarly, direct and electron microscopic assessments of nerve tissue obtained at biopsy are only used selectively for the definitive pathological diagnosis of certain illnesses such as neuropathy.

Radiologic evaluation (Leak, 1992) provides valuable information about the presence or absence of structural lesions compressing or invading tissues of the brain, brainstem, spine, spinal cord, root, plexus, or nerve. Certain specialized tests are known to be helpful in the diagnostic assessment of specific conditions, e.g., triple-phase contrast bone scan as a tertiary way of testing for CRPS Type I/RSD.

Electroneurodiagnostic tests are helpful in localizing structural lesions or regional dysfunction in many disorders

of the nervous system, not just those related to neuropathic pain. However, common procedures such as electroencephalography and electromyography/nerve conduction studies to the medical assessment of painful conditions of brain and the spinal cord, root, and nerve, respectively, are known to be helpful in confirming and localizing many neurological illnesses presenting with pain (Longmire, 1993). For painful disorders such as CRPS types I and II and SMP, a wide range of electrophysiological tests of sympathetic sudomotor function can be found (Longmire et al., 1996) including selective tissue conductance assessment of the skin over painful and nonpainful regions (Longmire & Parris, 1991; Longmire & Woodley, 1993).

NEUROPATHIC PAIN SYNDROMES

In primary care as well as many types of specialty practice, the term *neuropathic pain* has been most often thought of as simply meaning painful peripheral neuropathy, as commonly occurs in severe diabetes mellitus. This association may have developed based on the high incidence of diabetes and the bilateral, distal distribution of other symptoms (sensory loss) and signs (reduced temperature, circulatory compromise) commonly seen in this illness. In general clinical practice, the pains of well-known neurological disorders such as those created by herpes zoster and inflammatory involvement of the trigeminal nerves are more likely to be thought of as focal neuralgias, rather than neuropathic pain. Similarly, the pain created by local compression of nerve roots is considered to represent just one aspect of a radiculopathy rather than being part of a neuropathic pain syndrome. Even when contralateral pain is created by unilateral thalamic or other deep hemispheric infarctions, the symptoms are first thought to represent a specific (central post-stroke) syndrome, rather than being part of a more general (neuropathic) pain category.

In addition to those syndromes mentioned in the preceding paragraph, there are several common conditions known to be associated with severe, persistent neuropathic pain (Scadding, 1992).

NEUROPATHIC PAIN DISORDERS BY ETIOLOGY

In theory, almost any of the pathological processes known to create damage or dysfunction to neural tissue can be considered as potential causes for neuropathic pain. Viral/bacterial, aseptic inflammation, pressure due to neoplasm or other structural lesions, degenerative, ischemia, autoimmune, toxic, traumatic, endocrine/metabolic mechanisms have all been implicated in the production of pain (Kennedy, 1996; Kennedy & Longmire, 1992; Longmire, 1996; Table 24.1).

TABLE 24.1
Common Causes of Neuropathic Pain

Polyneuropathy
    Diabetes (insulin-dependent and non-insulin-dependent)
    Alcoholism
    Human immunodeficiency virus
    Hypothyroidism
    Renal failure
    Chemotherapy (vincristine, cisplatinum, paclitaxel, metronidazole)
    Anti-HIV drugs
    B_{12} and folate deficiencies
Mononeuropathy
    Entrapment syndromes
    Traumatic injury
    Diabetes
    Vasculitis
Plexopathy
    Diabetes
    Avulsion
    Tumor
Root syndromes and radiculopathy
    Compressive lesions
    Inflammatory
    Diabetes
Post-herpetic neuralgia
Trigeminal neuralgia
Phantom limb pain
RSD/causalgia/CRPS

Note: Modified from B. S. Galer, *Neurology*, *45*(Suppl. 9), pp. S17–S25, 1995.

INITIAL SYMPTOM MANAGEMENT

There is some disagreement about which treatment approaches (pharmacologic or interventional) represent the best and worst chances for symptom control. Nevertheless, the mainstay of treatment of neuropathic pain is pharmacologic. Effective regimens often require multiple medications. Attempts at monotherapy with standard analgesics including opioids tend to be less effective because neuropathic pain is often resistant to medications of that type (Arner & Meyerson, 1988; Dellemijn, 1999; Portenoy, Foley, & Inturrisi, 1990).

Neuropathic pain may be treated with some success using adjuvant analgesics, i.e., medications not traditionally considered to be pain relievers (Hegarty & Portenoy, 1994). Adjuvant analgesics, such as tricyclic antidepressants and anticonvulsants, do not have strong antinociceptive analgesic properties in experimental or clinical studies, but have been shown to be helpful in neuropathic pain states (McQuay et al., 1996; Swerdlow, 1984). In addition, the possible effectiveness of opioids for neuropathic pain should not be overlooked, although doses may be considerably higher than typical antinociceptive doses.

The clinician should also keep in mind that successful management of chronic pain often requires treating neuropathic pain as well as pain associated with tissue injury, because both conditions may coexist and interact to maintain the painful condition. Chronic pain syndromes are often a product of integrated nociceptive and neuropathic mechanisms and, as such, require consideration of both types for any pain lasting greater than 3 to 6 months.

MECHANISTIC BASIS OF NEUROPATHIC PAIN MANAGEMENT

Management of neuropathic pain is a complicated endeavor and often is frustrating to patient and physician alike. This stems from our relatively poor understanding of mechanisms and the limited efficacy of currently available analgesics. Therapeutic approaches vary greatly among physicians reflecting the paucity of randomized clinical trials, particularly those comparing different drug regimens.

Given our current level of understanding of neuropathic pain mechanisms and the limitations of available drugs, nonpharmacological methods may be as effective as pharmacological approaches. Recalcitrant chronic pain syndromes warrant an interdisciplinary approach, which may include attempts to treat the underlying disease (e.g., causes of the peripheral neuropathy) as well as formulation of a rational approach to medications, interventions such as nerve blocks, and psychological and physical therapies.

It is often helpful to consider the various medications useful for neuropathic pain in terms of their traditional pharmacological indications (e.g., anticonvulsants and antidepressants). However, it is necessary to keep in mind that all these drugs have incompletely understood mechanisms of action, and the drug categories are more conventional than mechanistic.

From a practical standpoint, medications remain the pillar of pain management strategies, despite their limitations. From a conceptual standpoint, adjuvant analgesic drugs may be categorized into two broad classes, membrane-stabilizing agents and medications that enhance inhibitory mechanisms in the dorsal horn. This classification system may provide a simple framework with which to approach therapy; however, it should be kept in mind that most of these drugs have multiple mechanisms of action, and their effects may often overlap. Given the limitations of our current drugs, pain management often becomes an exercise in polypharmacy, where the clinician uses multiple medications to target different symptoms. This strategy may optimize the chances for success, but complicates management issues when side effects develop.

MECHANISMS OF ACTION

Membrane-stabilizing agents include local anesthetics such as lidocaine and some anticonvulsant drugs, including car-

bamazepine, phenytoin, and valproic acid (Tanelian & Victory, 1995). Their molecular mechanism of action involves blockade of frequency- and voltage-dependent sodium channels on damaged or regenerating neuronal membranes (Devor, 1994, 1995). It appears that minimal doses of suppressive drugs may inhibit ectopic discharges without interfering with normal neuronal function. It is also possible that the sodium channel targets are atypical and not involved in normal neuronal conduction. Although the evidence is less substantial, corticosteroids also appear to have effects on membrane conductance (Castillo et al., 1996; Devor, Govrin-Lippmann, & Raber, 1985). In addition, tricyclic antidepressants, such as amitriptyline, have effects on sodium channels (Pancrazio et al., 1998), an action that is distinct from their effects on the reuptake of serotonin and norepinephrine. The latter are traditionally thought to be responsible for their effects on depression and pain.

Conventional wisdom maintains that the adjuvant analgesics, particularly the tricyclic antidepressants and clonazepam and baclofen, modulate inhibitory mechanisms in the spinal cord and brain. Inhibitory pathways descend from the periaqueductal gray, reticular formation, and nucleus raphe magnus in the dorsolateral funiculus to the dorsal horn. These pathways mediate antinociception by adrenergic, serotonergic, GABAergic (γ-amino butyric acid), and opioid mechanisms (Yaksh, 1979). Although the putative mechanisms are complex and poorly understood, serotonergic effects are mediated in part by action on GABAergic interneurons (Alhaider, Lei, & Wilcox, 1991). For example, facilitory effects of large myelinated afferent fibers may be suppressed by tonic GABAergic activity, removal of which results in allodynia (Yaksh & Malmberg, 1994).

As noted earlier, tricyclic antidepressants alter monoamine transmitter activity at neuronal synapses by blocking presynaptic reuptake of norepinephrine and serotonin, thereby modulating descending inhibitory spinal pathways. However, additional mechanisms include effects on membranes, interaction with NMDA activity (Eisenach & Gebhart, 1995), and sodium channel blockade (Pancrazio et al., 1998).

It is crucial that psychosocial and emotional factors be explored because there is a high comorbidity of depression and anxiety disorders in patients with chronic pain. Moreover, given the similarities between the pharmacology of mood and depression and pain transmission (e.g., serotonin and norepinephrine), patients with concomitant systemic illness and stress may be at risk for depression and development of an abnormal chronic pain state. Pharmacological management of depression may improve neuropathic pain by addressing overlapping but distinct mechanisms.

ABLATIVE PROCEDURES

After multiple medication trials in which there has been minimal therapeutic benefit and perhaps significant drug-

related side effects, patients may believe that they have little recourse but to undergo invasive, ablative procedures in attempts to relieve their pain. Specific treatment modalities aimed at the underlying pathophysiology are usually not possible in most neuropathies, particularly with chronic sensory polyneuropathies. In general, ablative procedures are not warranted because of the high probability of long-term worsening of pain. Except for patients with advanced cancer-related pain, nerve ablation is likely to provide only temporary benefit, leaving the patient with sensory and perhaps motor deficits. Exceptions to this phenomenon appear to be ablation of sympathetic fibers, visceral plexi, and medial branch nerve blocks, which denervate painful facet joints in the spine. In cases of nerve entrapment, where ongoing nerve compression is likely to be responsible for pain, neurolysis or transposition of the nerve may provide benefit, as long as pain is not due to irreversible underlying nerve damage. In all cases of neuropathic pain, even when neuropathy is evident, it is appropriate from time to time to reevaluate the presumed etiology of the neurological problem.

When a medication trial proves to be ineffective, a multidimensional or interdisciplinary approach should be considered. Again, this includes an attempt to treat the underlying disease, as well as specific pharmacological, psychological, and physical therapy interventions. The outcome measure for successful treatment should include increased activity as well as decreased subjective pain ratings and improved patient satisfaction. The treatment goal in chronic neuropathic pain is different from that in acute pain. In the usual acute pain setting, the goal is nearly complete relief of pain, to allow recovery of normal function during the healing process. With chronic neuropathic pain, limitations of current analgesics usually make complete pain relief a very unrealistic goal. Therefore, attention to increasing function and comfort and treating associated problems, such as depression, become paramount. Reducing dependence on opioid medications may or may not be an important goal. The objectives to consider with chronic opioid therapy include determining whether nonopioid approaches have been tried, whether the pain syndrome is opioid responsive, and whether the patient demonstrates appropriate improvement in function, without undue side effects or evidence of abuse of medications.

Nonpharmacological approaches to treating neuropathic pain include the use of a TENS (transcutaneous electrical nerve stimulation) unit although relief may be poor when burning pain is a prominent complaint. This may be explained by the fact that burning pain is a C-fiber-mediated sensation, whereas TENS units probably modulate large fiber input into the dorsal horn.

Spinal cord stimulation may be efficacious for chronic pain, including neuropathic pain (North et al., 1993) and complex regional pain syndrome/reflex sympathetic dys-

trophy (Kemler et al., 2000). Mechanisms involved are poorly understood, which reflects current understanding of neuropathic pain states in general. However, central effects may include alteration in dorsal horn processing and transmission in the tract of Lissauer (Iacono, Guthkelch, & Boswell, 1992) and suppression of sympathetic outflow from the intermediolateral gray column of the spinal cord. The latter effect may explain improved peripheral blood flow in patients with chronic peripheral vascular insufficiency. The Craig PENS (percutaneous neural stimulation) technique, a novel application of electroacupuncture, has been shown effective in herpes zoster, diabetic peripheral neuropathy, and sciatica (Ahmed et al., 1998; Ghoname et al., 1999; Hamza et al., 2000).

Available evidence indicates that nonpharmacological approaches such as TENS and Craig PENS can provide an initial rational therapeutic strategy and may obviate the need for potentially toxic medications, improve the effectiveness of current analgesic regimens, or reduce the amount of medications required. Spinal cord stimulation still tends to be a treatment of last resort, although judicious use earlier in the course of treatment is probably warranted in carefully selected patients. Considering the current high cost of medication, alternative approaches, if efficacious, may prove to be cost effective.

A peculiar property of the nervous system is its plasticity. Damage to nerves often results in alteration or amplification of the signal encoded by the nerve. For example, peripheral nerve ablation, performed with good therapeutic intentions, may result in a pain syndrome that is worse than the one originally being treated. When dealing with the nervous system, "shooting the messenger" (the nerve) often intensifies and distorts the message. The new pain syndrome may be more severe and associated with allodynia, hyperalgesia, and spontaneous and paroxysmal pain, all in the presence of mild to moderate cutaneous numbness. This complex of signs and symptoms is paradoxical to the patient and confusing to the clinician, but quite typical of neuropathic pain.

MECHANISTIC APPROACH TO THE SELECTION OF TREATMENT

When standard therapies are found to be only partially effective in controlling symptoms, it is often helpful to select other medications or interventions based on the compatibility of the mechanisms of the illness and the treatment being considered (Goli, 2002). For example, it has become popular to contrast neuropathic pain with typical post-injury, nociceptive pain. Nociceptive pain, typically thought to indicate a properly functioning nervous system, is considered physiological because it results from activation of nociceptors, specialized nerve endings that respond to high-threshold noxious stimuli and gener-

ally serve a protective function. In contrast, neuropathic pain may be thought of as pathophysiological because it arises from a damaged PNS or CNS and provides no obvious protective benefit (Bennett, 1994; Tanelian & Victory, 1995).

On the other hand, pain associated with peripheral neuropathy may be maintained by sustained peripheral nociceptive input (Gracely, Lynch, & Bennett, 1992). Strong nociceptive input often produces central sensitization, an abnormal pain amplification process in the CNS. Therefore, the definitional borders of neuropathic pain are becoming more diffuse, not more distinct, as we gain a better understanding of the remarkable plasticity of the nervous system and its close association with the various tissues that it innervates.

Neuropathic pain may be classified as stimulus-evoked or stimulus-independent pain. Stimulus-evoked pain can result from stimulation of nervi nervorum present in connective tissue surrounding otherwise intact nerves. Painful stimuli that activate nociceptors around nerves include inflammation and tissue injury from tumor or trauma (Woolf & Mannion, 1999).

Stimulus-independent neuropathic pain may result from damage to afferent sensory fibers in the PNS or CNS. In this case, ongoing inflammation is usually absent. Days to months after peripheral nerve injury, persistent abnormal primary afferent activity from the periphery may arise from hypersensitive nerve terminals or nerves (Price, Mao, & Mayer, 1994).

PATHOPHYSIOLOGIC PROCESSES SUBSERVING NEUROPATHIC PAIN

As one might expect, there is substantial evidence that abnormal nerve activity is an important mechanism underlying the spontaneous pain typical of neuropathic pain states (Devor, 1994, 1995; Tanelian & Victory, 1995). It is hypothesized that sites of ectopic foci develop on injured or regenerating nerves in the periphery; at the level of the nociceptor, neuromas, or segments of injured nerves; at the dorsal root ganglion; and in the dorsal horn of the spinal cord. Indeed, after nerve transection, increased sensitivity occurs, followed in a few days by spontaneous activity. These abnormal ectopic foci may be thought of as spontaneous pain generators, resulting in paroxysmal and spontaneous pain.

Precise pathophysiology is unclear, but pharmacological evidence suggests that ectopic activity is due to an increased number of sodium channels or, more likely, to an abnormal subtype of sodium channel, resulting in unstable sodium channel activity (Chaplan, 2000). Pharmacological evidence supporting this hypothesis is the effectiveness of local anesthetics and some anticonvulsants (sodium channel-blocking drugs) in neuropathic

pain. These drugs presumably produce frequency- and voltage-dependent blockade of sodium channels on damaged neurons (Devor, 1995). The abnormal sodium channel involved in neuropathic pain states may be a tetrodotoxin-insensitive subtype, found only in neural tissue (Novakovic et al., 1998). Accumulation of atypical as well as tetrodotoxin-sensitive sodium channels (responsible for normal nerve conduction) may explain the often inadequate therapeutic benefit of current sodium channel-blocking drugs.

Work in animal models demonstrates that voltage-dependent calcium channels may also be important in modulating neuropathic transmission. Unfortunately, the currently available calcium channel blockers are cardioselective and are not particularly effective in neuropathic pain. There appear to be at least six calcium channel subtypes, and studies with novel N-type calcium channel blockers are promising in animals (Chaplan, 2000). Preliminary studies with conotoxin (SNX-111) are positive although the drug must be administered intrathecally.

Gabapentin, a novel anticonvulsant, appears to bind to the a2d subunit of a voltage-dependent calcium channel. Work by Chaplan (2000) and colleagues demonstrates that messenger RNA and protein for the a2d subunit are increased more than 10-fold in dorsal root ganglia following nerve injury, but are not changed after other forms of tissue injury. Blockade of a retrograde signal from the injury site (which may involve nerve growth factor) prevents upregulation of the a2d subunit. Chaplan points out that the a2d subunit does not seem to play a role in normal channel kinetics but may effect calcium channel assembly and insertion into the neuronal membrane. Thus, the subunit may act as a drug-binding site and secondarily modify channel kinetics.

COMPLEX REGIONAL PAIN SYNDROMES AS NEUROPATHIC PAIN

Following peripheral nerve injury, concomitant alternations may be evident in dorsal root ganglia, including transmitter changes and increased density of sympathetic nerve terminals (McLachlan et al., 1993). Tyrosine hydroxylase positive cell terminals that produce norepinephrine migrate from vessels supplying the dorsal root ganglion to nerve ganglion cells following sciatic nerve injury. The dorsal root ganglia then express a-adrenergic receptors. This may be a putative link between peripheral tissue injury, nerve injury, and sympathetically maintained pain states, such as reflex sympathetic dystrophy and causalgia (CRPS Type I and II, respectively). In the periphery, sprouting nerve terminals may exhibit sensitivity to prostaglandins, cytokines, and catecholamines. These kinds of changes further increase the complexity of the neuropathic

pain picture and blur the distinctions between nociceptive and neuropathic pain.

It should be noted that not all stimulus-independent pain is mediated by spontaneous activity in primary sensory neurons. Loss of normal inhibitory mechanisms, whether segmental, supraspinal, or both, may also cause neuropathic pain (Woolf & Mannion, 1999). After deafferentation injury, particularly following loss of C-fibers, arborization of Ab fibers into the substantia gelatinosa of the dorsal horn may result in central sensitization and allodynia (Woolf, Shortland, & Coggeshall, 1992). Available evidence supports the contention that tactile allodynia is mediated by large myelinated Ab afferents with input that is modulated at supraspinal sites in the dorsal columns (Ossipov et al., 2000).

This may explain why TENS and spinal cord stimulation, which produce a low-threshold, tingling sensation, characteristic of large fiber afferent activation, may be effective in chronic pain states, particularly neuropathic pain. Tactile allodynia should be differentiated from thermal allodynia, which appears to be mediated by nonmyelinated C-fibers and amplified by pathological spinal dynorphin.

STIMULUS-EVOKED NEUROPATHIC PAIN AND OPIOID ANALGESICS

Various studies suggest that stimulus-evoked neuropathic pain is more sensitive to opioids than stimulus-independent pain (Dellemijn, 1999). Opioid responsiveness may be maintained in some forms of stimulus-evoked pain because opioid receptors in the substantia gelatinosa are preserved. On the other hand, segmental loss of presynaptic central opioid receptors occurs following injury or loss of C-fibers, typically seen after deafferentation injury. However, the magnitude of receptor loss is minimal and largely segmental, and only partly explains the diminished opioid-responsiveness characteristic of neuropathic pain (Ossipov et al., 2000).

Supraspinal facilitative mechanisms may also be involved in maintenance of neuropathic pain and opioid resistance. Evidence suggests that sustained afferent drive induces facilitation of spinal cord pain transmission involving a descending pathway from the rostroventral medial medulla (RVM) (Ossipov et al., 2000). Tonic facilitation may involve supraspinal cholesystokinin (CCK), traditionally thought of as a visceral hormone that regulates emptying of the gallbladder. CCK antagonists injected into the RVM in animals reverse tactile and thermal allodynia produced by spinal nerve ligation (Kovelowski et al., 2000). Mechanistically, these antiopioid and pronociceptive actions may occur at spinal and supraspinal sites. Spinal CCK may antagonize opioid effects at the level of the primary afferent terminal in the spinal cord. Both CCK and opioids colocalize on primary nociceptive afferent neurons in the dorsal horn. In addition, CCK may act on supraspinal opioid-dependent pathways in the RVM to reduce opioid responsiveness and, thus, impair descending inhibition, an important mechanism involved in opioid pain relief. Ultimately, CCK antagonists may prove useful for treating neuropathic pain states.

The phenomenon of reduced opioid responsiveness in neuropathic pain has prompted extensive studies in animals, particularly the effects of intrathecal opioids on pain associated with thermal and tactile stimulation. The similarities between opioid tolerance and neuropathic pain are also an area of active study (Vanderah et al., 2000). It is well known that N-methyl-D-aspartate (NMDA) antagonists appear to minimize the development of opioid tolerance. Spinal dynorphin may be a common link between NMDA, central sensitization, and reduced opioid responsiveness. Following spinal nerve ligation, dynorphin levels in the spinal cord increase, suggesting that dynorphin may act as a pronociception mediator (Ossipov et al., 2000).

Although, under certain circumstances, dynorphin appears to have analgesic properties, it is becoming increasingly clear that dynorphin also has nonopioid, antianalgesic properties. Antiserum to dynorphin blocks thermal hyperalgesia after nerve injury in rats. Moreover, antiserum to dynorphin or MK801, an NMDA antagonist, restores normal spinal morphine analgesia following spinal nerve ligation. Furthermore, both agents restore morphine synergy between the brain and spinal cord (Ossipov et al., 2000), which is required for the full clinical analgesic effects of morphine. Therefore, current evidence suggests that the pain-promoting effect of dynorphin is mediated by the NMDA receptor. Although the full clinical ramifications of dynorphin are far from understood, it is clear that sustained nociceptive drive from the periphery maintains elevated levels of spinal dynorphin, which, in turn, may have toxic effects on the spinal cord. Thus, reducing sustained peripheral nociceptive input into the spinal (i.e., pain relief) may be an important way to reduce the incidence of neuropathic pain (Caudle & Mannes, 2000).

Currently, NMDA antagonists, such as ketamine, have only limited indications because of significant side effects. Ultimately, however, medications like NMDA antagonists may become available that can reduce the effects of pathological spinal dynorphin.

CENTRAL POST-STROKE PAIN

Central post-stoke pain (CPSP) was originally thought to be "thalamic" pain, as described by Dejerine and Roussy (1906), although it was described even earlier in 1883 (Greiff, 1883). Dejerine and Roussy (1906) characterized their eponymous thalamic pain syndrome as including hemiplegia; hemiataxia and hemiasterognosis; difficul-

ties with both superficial and deep sensation; persistent, paroxysmal, typically intolerable pain; and choreoathetoid movements.

The reported incidence of CPSP varies widely from 2% (Bowsher, 1993) to 8% (Anderson et al., 1995) of patients suffering and to 25% (MacGowan et al., 1997) in patients with lateral medullary infarctions (Wallenberg's syndrome).

The onset of the pain may be immediate or delayed for months to years (Bowsher, 1995; Holmgren et al., 1990; Leijon et al., 1989). The pain may encompass a large part of the contralateral body, but it may also involve only a small area. The pain attributes include dysesthesias, spontaneous or evoked, and burning.

Sensory abnormalities are also associated with CPSP. These may include altered sensory processing, whereby warm and cold stimulation applied to the skin may be perceived as paresthesias or dysesthesias rather than cold or warm (Anderson et al., 1995). Allodynia is found (Bowsher, 1996; Wessel et al., 1994) in 55 to 70% of patients. Hyperalgesia and dysesthesia are also frequently seen (Mersky, 1986).

Locations of the lesions inducing the CPSP are definitively referable to the spinothalamo-cortical tract/pathway, typically associated with abnormal evoked sensations in the peripherally affected area (Andersen et al., 1995; Boivie, 1994; Jensen & Lenz, 1995). There are at least three thalamic regions, which directly or indirectly, receive spinothalamic projections that appear to be involved in the development of CPSP: the ventroposterior thalamus, including the posteriorly and inferiorly located nuclei bordering on that region; the reticular nucleus; and the medial intralaminar region. It is the ventroposterior thalamic region that is proposed to be most significantly involved in central pain (Boivie, 1992; Jones, 1992; Lenz, 1992). It should also be noted that cerebrovascular lesions located above the diencephalon, i.e., in the parietal lobe, may also induce CPSP (Boivie, 1994; Sandy, 1985; Wessel et al., 1994).

Sympathetic dysfunction has also been felt to play a role in central pain secondary to signs of abnormal sympathetic activity: edema, hypohydrosis, trophic skin changes, changes in skin color, and decreased skin temperature (Bowsher, 1996; Riddoch, 1938). It is also noted that some or many of these changes may be secondary to "movement allodynia" (Bowsher, 1995), which makes the patient keep the affected limb motionless.

Reports of CPSP associated with abnormal "epileptiform" activities in thalamic cells may be involved with central pain (Gorecki et al., 1989; Hirato et al., 1994; Yamashiro et al., 1991). This would also indicate that some aspects of the problem may be secondary to cortical involvement, as epileptiform discharges typically are associated with that region.

Treatment of the CPSP is difficult and may include antidepressants, anticonvulsants, antiarrhythmics, analgesics, and nonmedication treatment including TENS, dorsal column stimulation, and deep brain stimulation (DBS).

One undesirable effect of repetitive DBS is the reduction of the seizure threshold, known as kindling. One of the authors (Longmire) is aware of a patient whose pain was only partially reduced with the original stimulus parameters of DBS. In an attempt to improve pain control, that individual used the external controller to increase the amount of stimulation above the amount by the attending neurosurgeon. After several days of this maneuver, the patient suffered a first-ever focal onset, secondarily generalized seizure. To the authors' knowledge, this patient may represent the first case of self-induced kindling of seizures in a human patient using DBS for pain control. Other treatments include sympathetic blockade, as well as surgical interventions, including cordotomy, dorsal root entry zone lesions, thalamotomy, or cortical and subcortical ablation (Awerbuch, 1990; Bowsher & Nurmikko,1996; Davidoff et al., 1987; Edgar et al., 1993; Ekbom, 1966; Kastrup et al., 1987; Leijon & Boivie 1989a, 1989b, 1989c; Loh et al., 1981; Nashold & Bullitt, 1981; Portenoy, Foley et al., 1990; Siegfried, 1983; Siegfried & Demierre, 1984; Swerdlow, 1986; Tasker, 1990; Tasker et al., 1991).

ANTICONVULSANTS

Anticonvulsants are useful for trigeminal neuralgia, postherpetic neuralgia, diabetic neuropathy, and central pain (Hegarty & Portenoy, 1994; Swerdlow, 1984). Although anticonvulsants have traditionally been thought of as most useful for lancinating pain, they may also relieve burning dysesthesias. Chemically, anticonvulsants are a diverse group of drugs, are typically highly protein bound, and undergo extensive hepatic metabolism. Carbamazepine has a long history of use for neuropathic pain, particularly trigeminal neuralgia. Trigeminal neuralgia is an U.S. Food and Drug Administration (FDA)-approved indication for the drug. Carbamazepine is chemically related to the tricyclic antidepressant imipramine, has a slow and erratic absorption, and may produce numerous side effects, including sedation, nausea, vomiting, and hepatic enzyme induction. In 10% of patients, transient leukopenia and thrombocytopenia may occur, and in 2% of patients, hematologic changes can be persistent, requiring stopping the drug (Hart & Easton, 1982; Sobotka, Alexander, & Cook, 1990; Tohen et al., 1995). Aplastic anemia is the most severe complication associated with carbamazepine, which may occur in 1:200,000 patients. Although requirements for hematologic monitoring remain debatable, a complete blood cell count, hepatic enzymes, blood urea nitrogen, and creatinine are recommended at baseline; and these are checked again at 2, 4, and 6 weeks, and every 6

months thereafter. Carbamazepine levels should be drawn every 6 months and after changing the dose to monitor for toxic levels and verify that the drug is within the therapeutic range (4 to 12 mg/cc).

Patients with low pretreatment white blood cell (WBC) counts are at increased risk of developing leukopenia (WBC < 3000/mm³). Because toxicity is entirely unpredictable, it is important to instruct patients to recognize clinical signs and symptoms of hematologic toxicity, such as infections, fatigue, ecchymosis, and abnormal bleeding, and to notify the physician if they develop. To improve compliance, carbamazepine should be started at a low dose (e.g., 50 mg twice daily) and increased over several weeks to a therapeutic level (200 to 300 mg four times a day). When a therapeutic dosage is achieved, a controlled-release preparation may provide more stable blood levels and enhance patient compliance.

Oxcarbazepine, a metabolite of carbamazepine, may be safer from the standpoint of potential hepatic toxicity and bone marrow depression. However, the potential for hyponatremia requires monitoring of serum sodium levels.

Phenytoin also has well-known sodium channel-blocking effects and is useful for neuropathic pain (Swerdlow, 1984). However, it is less effective than carbamazepine for trigeminal neuralgia (Blom, 1962). We have also noted that neuropathic pain caused by structural lesions causing nerve or root compression can paradoxically increase when phenytoin is administered. Phenytoin has a slow and variable oral absorption, some of which is dependent on gastrointestinal motility and transit time. Toxicity includes CNS effects and cardiac conduction abnormalities. Side effects are common and include hirsuitism, gastrointestinal and hematologic effects, and gingival hyperplasia (Brodie & Dichter, 1996). Allergies to phenytoin are common, and may involve skin, liver, and bone marrow. Phenytoin doses in the range of 100 mg two or three times a day may be helpful for neuropathic pain; therapeutic blood levels are in the range of 10 to 20 mg/ml. There are numerous potential drug interactions, including induction of cytochrome P450 enzymes, which may accelerate the metabolism of other drugs. Because of side effects and toxicity, phenytoin is not a first-line drug for neuropathic pain.

Valproic acid appears to interact with sodium channels but may also alter GABA metabolism. The principal FDA approved use of valproic acid is for the prophylaxis of migraine headache (Matthew et al., 1995). Potential toxicity includes hepatic injury and thrombocytopenia, particularly in children on multiple antiepileptic medications, although valproic acid is generally considered safe for adults.

Divalproex sodium is better tolerated than valproic acid. The recommended starting dose is 250 mg twice daily, although some patients may benefit from doses up to 1000 mg/day. As a prophylactic drug, valproic acid can reduce the frequency of migraine attacks by about 50% (Matthew et al., 1995). Although there is little published information on the efficacy of valproic acid for neuropathic pain syndromes, based on its mechanism of action it may be useful alone or in combination with other adjuvant drugs.

Clonazepam may be useful for radiculopathic pain and neuropathic pain of a lancinating character. Clonazepam enhances dorsal horn inhibition by a GABAergic mechanism. The drug has a long half-life (18 to 50 h), which reduces the risk of inducing an abstinence syndrome on abrupt withdrawal. The major side effects of clonazepam include sedation and cognitive dysfunction, especially in elderly people. Although the risk of organ toxicity is minimal, some clinicians recommend periodic complete blood count (CBC) and liver function tests for monitoring. Starting doses of 0.5 to 1.0 mg at bedtime are appropriate to reduce the incidence of daytime sedation.

Gabapentin is a popular anticonvulsant for neuropathic pain. Gabapentin was released for use in the United States in 1994, for the treatment of adults with partial epilepsy. Almost immediately after its release, physicians began to use gabapentin for various neuropathic pain disorders, such as diabetic peripheral neuropathy and postherpetic neuralgia. The structural similarity of gabapentin to GABA suggested that the drug might be useful for neuropathic pain. Although tricyclic antidepressants have been proved clinically effective for neuropathic pain for years, they often fail to provide adequate pain relief or they cause unacceptable side effects. Therefore, when gabapentin became available, its benign side-effect profile quickly made it very popular among physicians. Although initial enthusiasm for the drug was based largely on word of mouth, anecdotal published reports, and discussions at clinical meetings, animal studies have substantiated the efficacy of gabapentin in various types of neuropathic pain. Over time, a growing consensus concerning the usefulness of gabapentin has emerged.

It is clear that gabapentin is not a direct GABA agonist, although indirect effects on GABA metabolism or action may occur. A leading hypothesis suggests that gabapentin interacts with a novel receptor on a voltage-activated calcium channel (Chaplan, 2000; Taylor et al., 1998). Inhibition of voltage-gated sodium channel activity (such as occurs with classical anticonvulsants, e.g., phenytoin and carbamazepine) and amino acid transport, which alters neurotransmitter synthesis, may also occur. Although gabapentin is not an NMDA antagonist, there is evidence that gabapentin interacts with the glycine site on the NMDA receptor (Jun & Yaksh, 1998).

Ligation of rat spinal nerves L5 and L6 (the Chung model) produces characteristic pain behaviors, including allodynia, which are typical of neuropathic pain. Chapman et al. (1998) demonstrated that gabapentin reduces pain in the Chung model. Gabapentin appears to act primarily

in the CNS, in contrast to amitriptyline, which seems to act centrally and peripherally (Abdi, Lee, & Chung, 1998). Gabapentin also is effective in reducing pain behavior in the second phase of the formalin test, a model of central sensitization and neuropathic pain (Shimoyama et al., 1997a). Gabapentin reduces spinally mediated hyperalgesia seen after sustained nociceptive afferent input caused by peripheral tissue injury. Gabapentin also enhances spinal morphine analgesia in the rat tail-flick test, a laboratory model of nociceptive pain (Shimoyama et al., 1997b).

Gabapentin is effective in reducing painful dysesthesias and improving quality of life scores in patients with painful diabetic peripheral neuropathy (Backonja et al., 1998). Of patients randomized to receive gabapentin, 56% achieved a daily dosage of 3600 mg divided into three doses per day. The average magnitude of the analgesic response was modest, with a 24% reduction in intensity at the completion of the study compared with controls. Side effects were common. Dizziness and somnolence occurred in about 25% of patients, and confusion occurred in 8% of patients.

Morello et al. (1999) compared gabapentin with amitriptyline for diabetic neuropathy and found both equally effective. Although gabapentin probably has fewer contraindications than tricyclic antidepressants, it is considerably more expensive.

Post-herpetic neuralgia (PHN) is another difficult neuropathic syndrome. PHN affects approximately 10 to 15% of patients who develop herpes zoster and is a particularly painful syndrome associated with lancinating pain and burning dysesthesias. The incidence of PHN is age related, with up to 50% of patients older than 60 years of age developing persistent pain after a bout of herpes zoster. Pain relief usually requires pharmacological therapy. Unfortunately, most medications are not very effective. For example, only about one half of patients obtain adequate relief with antidepressants.

Rowbotham et al. (1998) evaluated the efficacy of gabapentin for the treatment of PHN. Of patients taking gabapentin, 65% achieved a daily dosage of 3600 mg. Although the average magnitude of pain reduction with gabapentin was modest, with approximately a 30% reduction in pain compared with controls, statistically pain reduction was highly significant. In addition, gabapentin improved sleep parameters and quality of life scores. Adverse effects that occurred more commonly in the gabapentin group included somnolence (27%), dizziness (24%), ataxia, peripheral edema, and infection (7 to 10%). Based on the data of Rowbotham and colleagues, it is reasonable to consider gabapentin as first-line therapy for post-herpetic neuralgia. Gabapentin probably is at least as effective as antidepressants, with fewer contraindications. Gabapentin may be used as monotherapy or add-on treatment.

Although gabapentin can theoretically be started at 300 mg three times a day with most patients, it has been the clinical experience of one of the authors (Longmire) that giving lower initial doses (100 mg) and gently escalating the drug to a schedule of four times a day (three times a day with meals and again at bedtime) has improved compliance. Use of the bedtime dose may assist with sleep and reduces nocturnal pain. In addition, this reduces the risk of patients stopping the drug because of side effects, before a therapeutic dose (i.e., 25 mg per kg per day) is achieved. In our experience the gentlest schedule involves starting with a bedtime dose of 100 mg for 2 days. The daily dose is then increased to 100 mg twice a day with breakfast and supper or breakfast and at bedtime, for 2 days. Thereafter, the dose can be increased to three times a day with meals and at bedtime. Further titration every 3 to 7 days can be continued until pain relief, side effects, or a maximum daily dose in the range of 2400 to 3600 mg/day is reached. An instruction sheet for the patients is helpful in clarifying the dosage schedule.

Gabapentin is generally well tolerated, even in the geriatric population, and has a safer side-effect profile than tricyclic antidepressants. In the PHN study, the majority of patients were titrated to 3600 mg/day, and the median patient age was 73 years. The kidneys excrete gabapentin, and the dosage must be reduced for patients with renal insufficiency (Beydoun et al., 1995). Table 24.2 presents various adjuvant analgesics for neuropathic pain.

ANTIDEPRESSANTS

Tricyclic antidepressants have been used for years for the management of neuropathic pain syndromes, including diabetic neuropathy, postherpetic neuralgia, and migraine headache (Max, 1994; McQuay et al., 1996; Onghena & van Houdenhove, 1992). However, pain relief is often modest and accompanied by side effects. Controlled studies indicate that approximately one third of patients will obtain more than 50% pain relief, one third will have minor adverse reactions, and 4% will discontinue the antidepressant because of major side effects (McQuay et al., 1996). Fortunately, some patients obtain excellent pain relief.

Because comparisons between tricyclic antidepressants have not shown great differences in efficacy (Max, 1994; McQuay et al., 1996), the choice of which antidepressant to use often depends on the side-effect profile of a given drug. For example, when a patient is having difficulty sleeping because of pain, a more sedating drug, such as amitriptyline, may be indicated. On the other hand, desipramine, which is less sedating, may be better tolerated in elderly patients.

The tricyclic antidepressants are generally highly protein bound with large volumes of distribution and long elimination half-lives. They undergo extensive hepatic first-pass metabolism and typically have active metabo-

TABLE 24.2
Adjuvant Analgesics for Neuropathic Pain

Drug Class	Mechanism of Drug Action
Anticonvulsants	
Carbamazepine	Sodium channel blockade
Carbatrol	
Trileptal	
Topiramate	
Lamotrigine	
Levotiracetam	
Phenytoin	Sodium channel blockade
Valproic acid	Sodium channel blockade
Gabapentin	Calcium channel binding
Clonazepam	GABAergic mechanism
Antidepressants	
Amitriptyline	As a group, norepinephrine and serotonin reuptake effects, possible NMDA effects, and sodium channel blockade
Nortriptyline	
Imipramine	
Desipramine	
Fluoxetine	Serotonin selective effects
Paroxetine	Serotonin selective effects
Venlafaxine	Mixed serotonin/norepinephrine uptake inhibitor (and opioid receptor binding effects)
Duloxetine	Mixed serotonin/norepinephrine uptake inhibitor
Antiarrhythmics	
Lidocaine	As a group sodium channel-blocking effects
Mexiletine	
EMLA cream	
Miscellaneous	
Corticosteroids	Anti-inflammatory and membrane stabilizing effects
Baclofen	GABA-B agonist
Capsaicin	Vanilloid agonist and C-fiber neurotoxin

lites. Although effective doses may be lower than typically used for depression, this is often not the case. Patients must be warned of potential side effects including sedation, cognitive changes, and orthostatic hypotension from a-adrenergic blockade. Anticholinergic side effects are common and include constipation, urinary retention, and exacerbation of glaucoma. Antihistaminic effects may cause sedation. Because of their long half-lives, these drugs may be given as a single bedtime dose. To minimize side effects, small doses (e.g., 10 to 25 mg) are used initially and increased over several weeks to a therapeutic dose, generally in the range of 50 to 150 mg/day. An electrocardiogram (ECG) is recommended if there is a history of cardiac disease. ECG changes such as QRS widening, PR and QT prolongation, and T wave flattening can be induced by these agents. Tricyclic antidepressants may have quinidine-like actions, consistent with their sodium channel-blocking effects, particularly in patients with underlying

ischemic cardiac disease or arrhythmias (Glassman et al., 1993). Because abrupt discontinuation of antidepressants may precipitate withdrawal symptoms, such as insomnia, restlessness, and vivid dreams, a gradual taper over 5 to 10 days is recommended. Occasional blood levels are recommended, as well as CBC and hepatic studies to monitor for organ toxicity.

Amitriptyline is a tertiary amine that inhibits norepinephrine and serotonin reuptake equally (American Medical Association, 1993). Amitriptyline is probably the most commonly used tricyclic agent for neuropathic pain. Amitriptyline also is the most sedating of the tricyclic antidepressants and has the most potent anticholinergic effects. A starting dose of 25 mg at bedtime is recommended.

Amitriptyline is metabolized into nortriptyline, a secondary amine with twice as much inhibition of norepinephrine reuptake, compared with serotonin. Nortriptyline is less sedating than amitriptyline with fewer anticholinergic side effects. A starting dose of 10 mg at bedtime is generally well tolerated.

Imipramine is a tertiary amine with equal inhibition of norepinephrine and serotonin uptake. This drug is moderately sedating and has average anticholinergic effects. The suggested starting dose is 25 mg at bedtime. Because of unpredictable metabolism, occasional blood levels are suggested. Imipramine is metabolized to a secondary amine, desipramine, which is a much more selective inhibitor of norepinephrine uptake. Desipramine is less sedating and has fewer anticholinergic effects than imipramine or amitriptyline, is at least as effective for pain control, and is better tolerated by elderly patients.

Compared with tricyclic agents, serotonin selective reuptake inhibitors (SSRIs) for neuropathic pain have been relatively disappointing. In addition, they are more expensive than the older generic agents. Nonetheless, at relatively high doses (e.g., 60 mg), paroxetine is effective for diabetic neuropathy (Sindrup et al., 1990). Fluoxetine may also be useful in the treatment of rheumatic pain conditions, many of which have neuropathic components (Rani et al., 1996). SSRIs are better tolerated than tricyclic antidepressants and should be considered as first-line drugs in patients with concomitant depression. In this group they may serve double duty.

Venlafaxine is a novel phentylethylamine antidepressant that is chemically distinct from the older tricyclic antidepressants and the serotonin selective uptake inhibitors. Although venlafaxine blocks serotonin and norepinephrine reuptake, its analgesic actions may be mediated by both an opioid mechanism and adrenergic effects (Shcreiber et al., 1999). The drug may be at least as well tolerated as tricyclic agents and more effective for pain than standard doses of serotonin-selective drugs. Indeed, an initial report suggests that venlafaxine is effective for neuropathic pain (Galer, 1995). Venlafaxine should be started at one half of a 37.5 mg tablet twice daily and

titrated weekly to a maximum of 75 mg, taken twice a day. Nausea appears to be the most common side effect.

Recently, clinical trials have demonstrated that several selective serotonin and norepinephrine reuptake inhibitors in the same class as venlafaxine, including milnacipran and duloxetine, are effective in relieving neuropathic pain. This class of antidepressants is as effective as the tricyclic antidepressants, and much better tolerated from a side-effect profile (Briley, 2004) Clinical trials comparing duloxetine at 60 mg per day against placebo, during 9-week randomized, double-blind trials, demonstrated that duloxetine-treated patients had significantly greater improvement in overall pain, back pain, and shoulder pain. About half of the improvements were independent of the benefit noted for depression (Fava et al., 2004). The most common side effects with duloxetine tend to be nausea, somnolence, dizziness, decreased appetite, and constipation.

The FDA recently approved duloxetine (Cymbalta®) for pain treatment of pain caused by diabetic peripheral neuropathy. Currently, this is the only FDA-approved treatment for this painful diabetic peripheral neuropathy. The magnitude of the response appears to be modest, with about 50% of patients noting 30% pain relief; approximately 30% of patients taking placebo obtained this amount of relief. However, this additional treatment option is welcome, given the fact that tricyclic antidepressants have significant side effects and SSRIs have not proven to be efficacious, except perhaps at high doses.

ANTIARRHYTHMICS

Antiarrhythmics block ectopic neuronal activity at central and peripheral sites (Chabal et al., 1992). Lidocaine, mexiletine, and phenytoin (type I antiarrhythmics) stabilize neural membranes by sodium channel blockade. Lidocaine suppresses spontaneous impulse generation on injured nerve segments, dorsal root ganglia, and dorsal horn wide-dynamic range neurons (Abram & Yaksh, 1994; Sotgiu et al., 1992). Lidocaine infusions have been used to predict the response of a given neuropathic pain disorder to antiarrhythmic therapy (Burchiel & Chabal, 1995). Lidocaine may be effective at subanesthetic doses, and following nerve blocks, analgesia may outlast conduction block for days or weeks (Burchiel & Chabal, 1995; Chaplan et al., 1995; Jaffe & Rowe, 1995). It has been reported that patients with PNS injury experience better pain relief than those with central pain syndromes (Galer et al., 1993). If a trial infusion of lidocaine is effective, a trial of oral mexiletine is worth considering.

Prior to starting mexiletine, a baseline electrocardiogram is recommended to determine if the patient has underlying ischemic heart disease. Dosages may be increased from 150 to 250 mg three times a day over several days. Taking the medication with food may minimize gastric side effects, which are common and a major

reason for discontinuing the drug. Other side effects of mexiletine are nervous system effects such as tremor and diplopia. Once on a stable dose, a serum level should be obtained (the therapeutic range is between 0.5 and 2.0 mg/ml).

TOPICAL PREPARATIONS OF LOCAL ANESTHETICS

Topical preparations of local anesthetics may be effective for neuropathic pain when there is localized allodynia or hypersensitivity. Topical blockade of small- and large-fiber nerve endings should reduce mechanical and thermal allodynia. A topical lidocaine patch (Lidoderm 5% lidocaine) has become available, which can be applied to painful areas in shingles (herpes zoster) and in more chronic forms of neuropathic pain such as diabetic neuropathy or the ischemic neuropathies created by prolonged peripheral vascular insufficiency. Up to three patches may be applied at one time to the painful area. The patches can be worn for up to 12 hours a day. However, the treating physician must ensure that the patient understands that chronic forms of neuropathic pain may require a longer therapeutic trial, e.g., 30 days, before optimal symptomatic control can be determined. In patients with diabetic neuropathy, the addition of topical lidocaine patches to exogenous GABAergic oral agents may provide further improvement of symptom control.

A topical cream, eutectic mixture of local anesthetic (EMLA cream), a mixture of lidocaine and prilocaine, may also be useful for cutaneous pain. The cream may be applied three or four times a day to the painful area.

CORTICOSTEROIDS

Corticosteroids are clearly useful for neuropathic pain, particularly in stimulus-evoked pain such as lumbar radiculopathy. The anti-inflammatory effects of corticosteroids are well known, which may partly explain their efficacy for pain. When administered epidurally for treatment of discogenic radiculopathy, corticosteroids inhibit phospholipase A_2 activity and suppress the perineural inflammatory response caused by leakage of disk material around the painful nerve root (Saal et al., 1990). However, corticosteroids also act as membrane stabilizers by suppressing ectopic neural discharges (Castillo et al., 1996; Devor et al., 1985). Therefore, some of the pain-relieving action of corticosteroids may be due to a lidocaine-like effect.

Depot forms of corticosteroids injected around injured nerves provide pain relief and reduce pain associated with entrapment syndromes. Corticosteroids are also effective if given orally or systemically. In cancer pain syndromes, steroids such as dexamethasone may be first-line therapy for neuropathic pain. The potential side effects of corti-

costeroids are well known and may be seen whether medication is given orally, systemically, or epidurally.

BACLOFEN

Baclofen is useful for trigeminal neuralgia and other types of neuropathic pain (Fromm et al., 1984), particularly as an add-on drug. Baclofen is a GABA-B agonist and is presumed to hyperpolarize inhibitory neurons in the spinal cord (Yaksh & Malmberg, 1994), thereby reducing pain. This GABA effect appears to be similar to benzodiazepines, such as clonazepam. Side effects of baclofen can be significant and include sedation, confusion, nausea, vomiting, and weakness, especially in elderly patients. A typical starting dose is 5 mg three times a day. Thereafter, the drug can be increased slowly to 20 mg four times a day. Abrupt cessation may precipitate withdrawal with hallucinations, anxiety, and tachycardia. The drug is excreted by the kidneys and the dosage must be reduced in renal insufficiency.

CAPSAICIN

Capsaicin is a C-fiber-specific neurotoxin and is one of the components of hot peppers that produces a burning sensation on contact with mucous membranes. Topical preparations are available over the counter and are widely used for chronic pain syndromes. Capsaicin is a vanilloid receptor agonist and activates ion channels on C-fibers that are thermotransducers of noxious heat (>43°C) (Caternia et al., 1997). With repeated application in sufficient quantities, capsaicin can inactivate primary afferent nociceptors. For patients with pain due to sensitized nociceptors, capsaicin may be effective if the patients can tolerate the pain induced by the medication. The drug causes intense burning, which may abate with repeated applications and gradual inactivation of the nociceptors. However, in patients with tactile allodynia, which is probably mediated by large fibers, capsaicin may not be as effective. Capsaicin extracts are available commercially as topical preparations, containing 0.025 and 0.075% and should be applied to the painful area three to five times a day. The preparation may be better tolerated if it is used after application of a topical local anesthetic cream.

SUMMARY AND RECOMMENDATIONS

Neuropathic pain is a common cause of chronic pain and tends to be resistant to usual doses of traditional analgesic medications. Three classic examples of neuropathic pain include trigeminal neuralgia, post-herpetic neuralgia, and diabetic neuropathy. Neuropathic pain is often described as lancinating or burning in nature. Both types

of pain may be present at the same time, often accompanied by allodynia.

Neuropathic pain may be manageable with one or more adjuvant analgesic drugs, often prescribed as part of a comprehensive treatment plan. From a theoretical point of view, it may be helpful to categorize adjuvant analgesics into two broad classes of drugs: those that act as membrane-stabilizing agents and those that enhance dorsal horn inhibition. Membrane-stabilizing drugs may act by blocking sodium and calcium channels on damaged neural membranes. Medications that enhance dorsal horn inhibition appear to act by augmenting spinal biogenic amine and GABAergic mechanisms. From a clinical standpoint, given the paucity of our understanding of neuropathic pain mechanisms and how the medications actually work, it is probably more useful to classify adjuvant drugs according to their traditional therapeutic indications (e.g., antidepressants and anticonvulsants). This point of view is strengthened by the fact that most drugs appear to have multiple mechanisms and sites of action, making further subclassification arbitrary and probably inaccurate.

Anticonvulsants, particularly carbamazepine (and more recently gabapentin), are useful for neuropathic pain. Although conventional wisdom suggests that anticonvulsants may be most effective for lancinating pain, anticonvulsants also are useful for burning dysesthesias. The mechanism of action of gabapentin is poorly understood, but the drug has been demonstrated to bind to a novel voltage-dependent calcium channel receptor. Gabapentin reduces the pain due to diabetic peripheral neuropathy and post-herpetic neuralgia. The overall safety record with gabapentin is good, making it an attractive alternative to carbamazepine and tricyclic antidepressants, particularly for elderly patients.

Clonazepam is another option and also poses minimal risk from the standpoint of organ toxicity. Clonazepam may be useful for radicular pain and pain associated with tumors, such as plexopathy. In addition, clonazepam may be used to supplement other adjuvant drugs. When given at bedtime, the mild sedating effect of clonazepam can be helpful for patients who have difficulty sleeping because of pain.

Antidepressants have been used effectively for years in the management of multiple pain syndromes, including diabetic neuropathy, post-herpetic neuralgia, rheumatoid arthritis, osteoarthritis, migraine headache, low back pain, and fibromyalgia. However, pain relief is often modest and accompanied by side effects. Studies indicate that only one third of patients obtain more than 50% pain reduction. However, some patients obtain dramatic pain relief.

The choice of which antidepressant to use for neuropathic pain often depends on the particular side effect profile of a given drug, as comparisons of individual tricyclic antidepressants have not shown great differences in efficacy. When a patient is having difficulty sleeping

because of pain, a more sedating drug, such as amitriptyline, is appropriate. On the other hand, desipramine, which is considerably less sedating and has fewer anticholinergic effects, may be much better tolerated in elderly patients.

SSRIs for neuropathic pain have been disappointing, although paroxetine at relatively high doses is useful for diabetic neuropathy. Fluoxetine may be useful in the treatment of rheumatic pain conditions, many of which have neuropathic components. As with the tricyclic agents, the SSRIs are probably interchangeable. However, SSRIs are better tolerated than tricyclics and may be extremely effective in treating patients with chronic pain and concomitant depression.

It remains unclear whether anticonvulsants or antidepressants should be first-line therapy for neuropathic pain. Similar results have been obtained with both, and current evidence concerning drug efficacy does not support the use of one drug over another. In many cases, selection of a particular drug may depend more on expected side effects (e.g., sedation) or the clinician's experience with the drug, than on theoretical considerations about mechanisms of drug action. It must be remembered that treatment of neuropathic pain remains largely empirical. In addition, for maximum analgesic benefit, more than one drug may be necessary. Until more effective medications become available, polypharmacy will remain the rule instead of the exception. This is probably understandable, given the multiple mechanisms involved in the pathophysiology of neuropathic pain.

In general, for neuropathic pain either gabapentin or amitriptyline (or a similar tricyclic antidepressant) should be first-line therapy. When considering issues such as time to effective analgesic action and toxicity, gabapentin is more attractive. Gabapentin often is our first choice, followed by a tricyclic antidepressant, such as nortriptyline. Both drugs must be started slowly and titrated to effect, perhaps to rather high levels, for full benefit. However, tricyclics have many potential side effects that must be considered, particularly anticholinergic and cardiac interactions and organ toxicity. Clearly, gabapentin is a safer drug, but may cause sedation or dysphoria in some patients. Occasionally, patients complain of weight gain and nonpitting edema. Until recently, other disadvantages of gabapentin included its cost (approximately 10 times the cost of a generic tricyclic antidepressant at usual starting doses) and the need to take the drug three or four times a day. Keep in mind that the dosage of gabapentin must be reduced appropriately for patients with renal insufficiency.

Recently, the FDA approved duloxetine, a selective serotonin norephinephrine reuptake inhibitor, for the treatment of painful peripheral diabetic neuropathy. Although clinical experience is not yet widespread with duloxetine for this indication, this is the only FDA-approved drug for painful diabetic peripheral neuropathy.

When an appropriate medication trial has been ineffective, an interdisciplinary approach should be considered. Reducing dependence on opioid medications may or may not be a primary goal, depending on whether the pain syndrome is opioid responsive, the patient is demonstrating appropriate improvements in function, and there are not undue side effects or evidence of drug abuse.

Current evidence indicates that nonpharmacological approaches may be reasonable, may obviate or reduce the need for potentially toxic medications, and may improve the effectiveness of analgesic regimens. Spinal cord stimulation may reduce pain in selected patients. Less invasive techniques, including TENS units and percutaneous nerve stimulation, are also beneficial.

The goals of providing medical care for patients with neuropathic pain are often directed by changes in the quality, intensity, timing, and regional distribution of the patients' symptoms, rather than objective signs or test results of the underlying etiology.

When considering those limitations it is helpful to target specific symptoms, for example, burning pain with tricyclic antidepressants and sharp, shooting pain with anticonvulsants. However, from a practical standpoint, pharmacological choices are often based on physician experience and comfort with the safety and efficacy profiles of a given drug. Moreover, the high cost of new drugs for which no generic yet exists may make older tricyclic antidepressants, such as amitriptyline, the only cost-effective alternative for some patients. Until more effective drugs become available, the pharmacological approach remains largely one of trial and error. In the meantime, nonpharmacological strategies may assume a larger role in clinical practice.

The authors agree that effective management of neuropathic pain requires patience and persistence on the part of the clinician and the patient. The ability of some patients to accept incomplete pain relief during many therapeutic trials, simply with the hope that an optimal treatment may be determined, provides an example of courage that should be emulated by all health care givers. When a patient's internal strengths flag due to protracted suffering, physicians should be prepared to treat, or arrange consultative treatment for, the anxiety and depression that often accompany prolonged pain illness.

R. Michael Gallagher, DO, FACOFP

INTRODUCTION

Headache disorders are an exceedingly common patient complaint and have been described throughout recorded medical history. Symptoms of head pain were noted as early as 7000 B.C. (Lyons & Petrucelli, 1978), and Neolithic trepanned skulls suggest the extreme measures once taken to relieve head pain that was attributed to evil spirits (Venzmer, 1972). Currently, the National Headache Foundation reports that more than 45 million Americans have chronic, recurring headaches. Each year, U.S. businesses lose billions of dollars to absenteeism and medical expenses caused by headache, and headache sufferers spend in excess of $4 billion on nonprescription analgesics (National Headache Foundation, 2000). Headache is responsible for approximately 10 million physician consultations per year (Linet & Stewart, 1987), and it is the fourth most common reason for emergency room visits in the United States (McCaig & Burt, 2003).

Although the last two decades of the 20th century produced significant advances in our understanding of headache, the precise pathophysiology of the primary headache disorders remains unknown. For many years, primary headaches were classified symptomatically, as either vascular headaches (migraine and cluster) or nonvascular headaches (tension-type). Technological advances in the 1980s allowed researchers to see for the first time that changes in cerebral blood flow during headache episodes, particularly in migraine, did not occur exclusively in areas defined by vascular boundaries.

In 1988, the International Headache Society (IHS) published a classification system for headache disorders (Headache Classification Committee of the International Headache Society [HCCIHS], 1988). Although the classification was designed to help diagnose patients for clinical trials, the IHS criteria reflect international expert consensus, and unlike earlier headache diagnostic criteria, they outline the specific characteristics necessary to confirm and to exclude a broad range of headache disorders (Friedman, Finley, & Graham, 1962). According to the IHS, most chronic or recurring head pain can be classified as one of the "primary headache disorders": tension-type, migraine, or cluster. Each of these headache types, as the descriptor suggests, can occur without the presence of a known underlying disorder. The IHS system classifies all other types of headache as "secondary headache disorders," as they can always be attributed to one of hundreds of indirect causes of head pain (e.g., fever, trauma, subarachnoid hemorrhage, medication). This chapter reviews the diagnosis and treatment of primary headache disorders and cervicogenic headache.

PRIMARY HEADACHE DISORDER MANAGEMENT — OVERALL APPROACH

The vast majority of patients with headache can be successfully treated. When therapy is successful, the management of headache can be extremely rewarding for the patient and for the physician. However, headache treatment sometimes is time-consuming and difficult. When it does not succeed, or if it succeeds only partially, the challenge can quickly become frustrating. Help for headache sufferers rests with the empathetic, knowledgeable medical professional who is willing to establish an honest partnership that aims at relieving symptoms, restoring function, and reducing disability, not toward "curing" the "problem." In many cases, a clinician's ability to educate

patients will be key; all headache patients should clearly understand the goals of their treatment plans. Unfortunately, many patients with headache seek medical attention during severe attacks, which demand immediate attention and prevent the complete evaluation necessary to make an accurate diagnosis. The most productive time for assessment is when the patient is headache-free or not so debilitated as to interfere with a complete history taking and examination. After the diagnosis is made, the clinician and patient can develop a realistic, achievable treatment plan.

There are two main elements of headache treatment. *Abortive treatment* aims at relief once a headache attack has begun, and *prophylactic treatment* is used to prevent or reduce the likelihood of headache episodes before they occur. Abortive treatment is used in patients whose headaches are infrequent and for those headaches that break through in spite of prophylactic therapy. When headaches are frequent or unresponsive to abortive medication, prophylactic measures should be taken. Many clinicians begin prophylaxis when a patient has more than three severe headache attacks per month, but this can vary from patient to patient.

Whether preventive or abortive therapy is indicated, management should follow a definite plan incorporating the clinician and the patient into a team that works actively to reduce the frequency and/or severity of headaches. All medicating and treatment modalities should be selected based on efficacy, patient tolerability, and adherence to recommended safety guidelines. Impressions and physical findings should be completely explained to the patient at whatever level and pace necessary to ensure complete understanding. The headache condition should also be explained, emphasizing the fact that the disorder is real, not imagined, and that it is controllable, not curable. Once a plan is developed, follow up and continuing care are important elements in a successful outcome.

TENSION-TYPE HEADACHE

In the 1988 IHS classification of headache, a headache type once known as "muscle contraction headache" was renamed "tension-type headache" (TTH) (HCCIHS, 1988). Traditionally, it was believed that TTH was caused by sustained muscle contraction of the neck, jaw, scalp, and facial muscles. It has since been learned, however, that the sustained contraction of pericranial muscles associated with TTH may occur as an epiphenomenon to possible central disturbances, not as a primary process. Alterations in the levels of serotonin (5-HT), substance P (SP), and neuropeptide Y in the serum or platelets have been shown in patients affected by TTH, leading to speculation that these neurotransmitters are involved in the genesis and modulation of pain in the condition (Ferrari, 1993; Gallai, Sarchielli, Trequattrini et al., 1994; Nakano, Shimomura, Takahashi, & Ikawa, 1993; Rolf, Wiele, &

Brune, 1981; Schoenen, 1990; Shukla et al., 1987; Takeshima, Shimomura, & Takahashi, 1987). Without definitive evidence of central activity, however, the cause of TTH remains unknown.

TTH is the most common type of headache and is considered to have episodic (ETTH) and chronic (CTTH) variations. One-year period prevalence estimates using the IHS criteria indicate that as large a percentage as 93% of the general population has at least one tension-type headache per year, although some investigators have found ETTH rates as low as 14.3% (Rasmussen et al., 1991; Lavados & Tenhamm, 1997). CTTH sufferers (more than 180 headache attacks per year) are far less common than ETTH sufferers; the highest 1-year period prevalence ever recorded for CTTH was 8.1% (Tekle et al., 1995).

Both ETTH and CTTH are characterized by intermittent or persisting bilateral pain, often described as a squeezing pressure or a tight band around the head. Some patients experience pain in the temporal or occipital regions, the forehead, or the vertex. The location of symptoms can vary from attack to attack, and associated tightness of the neck and shoulders is common. Unlike migraine, TTH is neither preceded by prodromal symptoms, nor are TTH episodes typically associated with nausea or vomiting. The intensity of pain in TTH varies widely, but it is not usually incapacitating. TTH can last from hours to days and, in some cases, persist for months. The IHS diagnostic criteria for ETTH and CTTH are listed in Table 25.1 (HCCIHS, 1988).

Precipitating Factors

TTH frequently occurs during periods of stress or emotional upset. Some patients with CTTH may display evidence of anxiousness as well as poor coping and adaptation skills. If headaches are frequent or near daily, depression may be involved and should be considered, even in the absence of obvious signs, such as mood changes, crying spells, or loss of appetite. Organic processes may also be involved in the precipitation of TTH. When the cause is organic rather than psychogenic, the pain may also be resistant to usual treatment modalities. Organic causes can be numerous, but the more commonly encountered in clinical practice include degenerative joint disease of the cervical spine, head or neck trauma, temporomandibular joint dysfunction, or ankylosing spondylitis (see Cervicogenic Headache, p. 325).

Treatment

ETTH can be resolved with nonpharmacologic measures, analgesics, muscle relaxants, or some combination of these modalities. Nonpharmacologic options for TTH include manipulation, massage, exercise, cold or warm packs, stress avoidance, and relaxation techniques (Table

TABLE 25.1
IHS Diagnostic Criteria for Episodic Tension-Type Headache

A. At least 10 previous headache episodes fulfilling criteria B to D listed below. Number of days with such headache <180/year (<15/month).

B. Headache lasting from 30 minutes to 7 days

C. At least two of the following pain characteristics:
   - Pressing/tightening (non-pulsating) quality
   - Mild or moderate intensity (may inhibit, but does not prohibit activities)
   - Bilateral location
   - No aggravation by walking stairs or similar routine physical activity

D. Both of the following:
   - No nausea or vomiting (anorexia may occur)
   - Photophobia and phonophobia are absent, or one but not the other is present

E. At least one of the following:
   - History, physical, and neurological examinations do not suggest one of the disorders listed in groups 5 to 11
   - History and/or physical and/or neurological examinations do suggest such disorder, but it is ruled out by appropriate investigations
   - Such disorder is present, but tension-type headache does not occur for the first time in close temporal relation to the disorder

Source: Data from Headache Classification Committee of the International Headache Society, *Cephalgia, 8*(7), 1–96, 1988.

25.2) (Stevens, 1993). When these approaches do not provide adequate relief, simple analgesics, such as acetaminophen (APAP), aspirin (ASA), or nonsteroidal anti-inflammatory drugs (NSAIDs), often will relieve the symptoms of ETTH. If simple analgesics fail, caffeinated combination analgesics often will provide effective relief. In TTH studies, it has been shown that it takes about 40% more of a simple analgesic to equal the analgesic potency

TABLE 25.2
Nonpharmacologic Management of Headache

- Topical heat or cold packs
- Topical analgesic balms
- Respite from stressors
- Stress-reduction education
- Relaxation techniques (including biofeedback, hypnotherapy, vacation)
- Regular exercise
- Physical therapy
- Massage therapy
- Manipulative therapy

Source: Data from Stevens, M. B., *American Family Physician, 47,* 799–805, 1993.

of the simple analgesic plus caffeine (Laska et al., 1984; Migliardi et al., 1994). If a prescription is required to provide adequate relief, some patients with ETTH will benefit from the combination of isometheptene, APAP, and dichloralphenazone. Other options include the alpha-agonist tizanidine, ASA combined with the muscle relaxants orphenadrine or carisoprodol, or APAP added to chlorzoxazone. In some patients, the symptoms of TTH can be extremely severe and require potentially addictive analgesic combination drugs containing butalbital or an opioid. These drugs provide analgesia and reduce the anxiety often associated with pain (Table 25.3). As with any potentially addicting drug, however, the amount prescribed should be limited and patients should understand that daily or near-daily use must be avoided.

Patients with CTTH require a different approach. Prescribing the stronger analgesics in this patient subset greatly enhances the risk of abuse. Prophylactic treatment may be needed for patients with CTTH or for those whose attacks are caused by organic abnormalities. Pharmacological treatment of CTTH can include the judicious use of sedatives or muscle relaxants, but most patients who respond do so only temporarily, and the risk of habituation is significant when these medications are used daily or near daily.

The NSAIDs and antidepressants appear to be the most useful in preventing TTH (Gallagher & Freitag, 1987b). Most patients with CTTH who improve with NSAID treatment will do so in 2 to 3 weeks. Side effects of the NSAIDs include fluid retention, nausea, diarrhea, dizziness, and gastric and duodenal irritation. Renal function monitoring should be done periodically to avoid renal injury in patients who take NSAIDs regularly. Bedtime tricylic antidepressants (TCA) or serotonin reuptake inhibitor antidepressants (SSRI) may also be effective in reducing the frequency of CTTH pain. Therapeutic response can take as long as 4 weeks. The TCA regimen should begin with a low dose and will be gradually titrated to the individual patient's needs. Side effects vary depending on the agent and the patient, but they most frequently include drowsiness, postural hypotension, weight gain, constipation, and dry mouth.

Nonpharmacologic options for CTTH include manual manipulation and soft tissue massage techniques to the scalp, cervical, or thoracic areas, stress management, and muscle tension–reducing biofeedback. Consider psychotherapeutic interventions for patients whose headaches are related to significant emotional conflict or are refractory to treatment. Choices can range from supportive to long term and may involve the family physician, psychiatrist, or psychologist.

MIGRAINE

An estimated 28 million Americans, about 18% of women and 6% of men, suffer from migraine (Stewart et al.,

TABLE 25.3
Selected Medications for Tension-Type Headache

Drug	Brand Name	Dose
Aspirin	Bayer/Bufferin/Ecotrin	650–1,000 mg
Acetaminophen	Tylenol	500–1,000 mg
Aspirin/acetaminophen/caffeine	Excedrin	2 tablets
Ibuprofen	Advil/Motrin	400 mg
Naproxen	Aleve/Naprosyn	225–550 mg
Carisoprodol/aspirin	Soma compound	2 tablets
Carisoprodol	SOMA	1 tablet
Chlorzoxazone	Parafon Forte	1 tablet
Butalbital/aspirin/caffeine	Fiorinal	1 tablet
Butalbital/acetaminophen/caffeine	Fioricet/Esgic/Repan	1 tablet
Flurbiprofen	Ansaid	50–100 mg
Isometheptene/dichloralphenazone/acetaminophen	Midrin/Duradrin	2 capsules at onset followed by 1 tablet hourly prn (up to 5)
Ketoprofen	Orudis	12.5–25 mg
Metaxalone	Skelaxin	2 tablets
Orphenadrine/aspirin/caffeine	Norgesic	2 tablets
	Norgesic Forte	1 tablet
Rofecoxib	Vioxx	25 mg
Tizanidine	Zanaflex	2–4 mg
Tramadol/acetaminophen	Ultrocet	1 tablet

2000). This chronic, neurologic disorder is characterized by periodically recurring attacks of head pain that are accompanied by gastrointestinal, visual, and auditory disturbances. Although the intensity and severity of attacks tend to vary throughout the migraine population, as well as within the same migraineur over a series of episodes, estimates suggest that pain and disability are mild in approximately 5 to 15% of attacks, moderate to severe in 60 to 70% of attacks, and incapacitating in 25 to 35% of attacks (Stewart, Schecter, & Lipton, 1994). The disorder occurs most frequently among persons aged 25 to 55, concentrating its burden on those who are typically in their most productive years (Stewart et al., 1992). Patients with migraine consistently report lower mental, physical, and social well-being than do unaffected controls (Lipton et al., 2000; Terwindt et al., 2000).

According to the IHS, migraine is "an idiopathic, recurring headache disorder manifesting in attacks lasting 4 to 72 hours. Typical characteristics of headache are unilateral location, pulsating quality, moderate to severe intensity, aggravation by routine physical activity, and association with nausea, photo-, and phonophobia" (HCCIHS, 1988). Migraine rarely occurs on a daily basis; typical frequency is one to four per month. In some patients, the migraine may occur once yearly or as often as 15 to 20 times per month.

Migraine pain typically affects one side of the head, can switch sides, or can become generalized. Many patients report that their pain localizes around or behind the eye, or in the frontotemporal area. The pain may radi-

ate toward the occiput or upper neck during an attack. The shoulder and lower portion of the neck also may be involved. In some cases, the pain radiates to the face.

A number of associated symptoms can accompany the pain of an acute attack. Nausea or vomiting, in addition to either photophobia or phonophobia, is required for the diagnosis of migraine. However, dizziness, lightheadedness, irritability, blurred or double vision, anorexia, constipation, diarrhea, chills, tremors, cold extremities, ataxia, dysarthria, and fluid retention may also be present. Some patients may experience lethargy and fatigue for several days following an attack. The occasional patient will report being especially mentally alert and agile during the early stages of the migraine attack.

A prodrome or aura often precedes migraine attacks. Aura symptoms are usually visual, typically start just before the acute headache, and continue for less than 1 hour. Aural symptoms include scotomata, teichopsia, fortification spectra, photopsia, paresthesias, visual and auditory hallucinations, hemianopsia, and metamorphopsia (Diamond, 1997). Despite the absence of visual and other prodromal characteristics, sufferers of migraine without aura have also described premonitions of impending migraine attacks. These symptoms are usually vague and can occur from 2 to 72 hours before an attack. The list of painless warnings includes hunger, anorexia, drowsiness, depression, food cravings, irritability, tension, restlessness, talkativeness, excess energy, and euphoria. Table 25.4 lists the complete IHS criteria for migraine with aura and migraine without aura.

TABLE 25.4

IHS Diagnostic Criteria for Migraine without Aura and Migraine with Aura

Migraine without Aura

A. At least five attacks fulfilling criteria B to D

B. Attack lasts 4 to 72 hours (untreated or unsuccessfully treated)

C. Attack has at least two of the following characteristics:
   - Unilateral location
   - Pulsating quality
   - Moderate or severe intensity (inhibits or prohibits daily activities)
   - Aggravation by walking stairs or similar routine physical activity

D. During attack at least one of the following:
   - Nausea and/or vomiting
   - Photophobia and phonophobia

E. At least one of the following:
   - History, physical. and neurological examinations do not suggest a secondary disorder
   - History and/or physical and/or neurological examinations do suggest such disorder, but it is ruled out by appropriate investigations
   - Such disorder is present, but migraine attacks do not occur for the first time in close temporal relation to the disorder

Migraine with Aura

A. At least two attacks fulfilling B

B. At least three of the following four characteristics:
   - One or more fully reversible aura symptoms indicating focal cerebral cortical and/or brainstem dysfunction
   - At least one aura symptom developing gradually over more than 4 minutes or two or more symptoms occur in succession
   - No aura symptom lasting more than 60 minutes; if more than one aura symptom present, accepted duration is proportionally increased
   - Headache following aura with a free interval of less than 60 minutes (it may also begin before or simultaneously with the aura)

C. At least one of the following:
   - History, physical, and neurological examinations do not suggest a secondary disorder
   - History and/or physical and/or neurological examinations do suggest such disorder, but it is ruled out by appropriate investigations
   - Such disorder is present, but migraine attacks do not occur for the first time in close temporal relation to the disorder

PRECIPITATING FACTORS

Certain factors, known as "triggers," can play a precipitating role in the onset of migraine attacks. Migraine triggers are categorized as physiological, psychological, or external stimuli. Although they are highly individualized, some of the most common migraine triggers appear in Table 25.5.

Foods long have been implicated in triggering migraine attacks. The more commonly reported by patients are fats, dairy products, various fruits and vegetables, artificial sweeteners, food additives, and salt. Many medications can precipitate headache as a side effect, but more often the headaches are described as pressure-like and not typical of migraine. These medications are voluminous and it should be kept in mind that individual sensitivities are highly variable (Table 25.6).

Physiological Factors

Migraine sufferers can be particularly sensitive to changes in eating and sleeping patterns. Fasting or missing a meal is a known headache trigger and patients with migraine should be encouraged to maintain a regular meal schedule. Sleep irregularities also precipitate a migraine and attacks that occur on weekends, holidays, or during vacations have been linked to oversleeping (Wilkinson, 1986). To avoid "weekend" or oversleep headaches, patients should be instructed to go to bed when they are tired and to arise at the same time each day. Lack of sleep and fatigue may also provoke an acute migraine attack.

A relationship between the menstrual cycle and migraine attacks is well documented and partially accounts for the higher prevalence of migraine in women. Among female migraineurs, 60 to 70% note a menstrual link to their migraine attacks, with severe attacks occurring immediately before, during, or after their menses (Diamond, 1997). Many sufferers will report a remission of migraine after the first trimester of pregnancy or see an improvement or complete remission of their headaches after menopause (Honkasalo et al., 1993). Oral contraceptives should be used judiciously in patients with migraine, as these drugs have long been known to increase the frequency, severity, duration, and complications of migraine (Whitty, Hockaday, & Whitty, 1966). Also, hormone replacement therapy (HRT) should be avoided in postmenopausal migraineurs, as these hormones can exacerbate or restart migraine attacks. However, side effects and headaches have been reduced in some with the patch delivery system or the use of continuous or low-dose estrogen.

The link between diet and migraine varies with the individual patient. The amines, including tyramine and phenylethylamine, nitrates, monosodium glutamate (MSG), and alcohol have all been implicated as triggers. Tyramine is found in aged cheese, pickled foods, fresh-baked yeast breads, and marinated foods. Another amine, phenylethylamine, is contained in chocolate, which is thought to precipitate attacks in many. The nitrates, which promote vasodilation, are found in cured meats. Many processed and Chinese foods contain MSG, which has been associated with headache. Alcohol has both central and direct vasodilating properties, and in some patients, migraine attacks can be precipitated, especially with red

TABLE 25.5
Recognized Migraine Triggers

Physiological	Psychological	External
Fasting, changes in eating patterns	Stress (external or unconsciously created)	Allergies
Over- or undersleeping	Post-stress "let down"	Loud noises
Exercise	Repressed hostility	Smoke
Cold/iced beverages	Depression	Strong odors
Ice cream	Fear	Bright or flickering lights
Food triggers (see Table 25.6)	Anger	Barometric pressure changes
Drugs (more common):		Sunglare
Danazol		Altitude changes
Diclofenac		Weather changes
Estrogen		Airline flights
H_2 receptor blockers		
Hydralazine		
Indomethacin		
Niacin		
Nicotinic acid		
Nifedipine		
Nitrates		
Nitrofurantoin		
Nitroglycerin		
Reserpine		

wine. Other possible triggers for migraine include caffeine, nicotine, ice cream, hypoglycemia, allergy, and monoamine oxidase inhibitors (MAOIs). Migraineurs who are sensitive to dietary triggers should be instructed to avoid the substances to which they are susceptible whenever possible.

Psychological Factors

Stress probably is the most readily identified psychological trigger of an acute migraine attack. However, many patients with migraine will remain headache-free during a severely stressful period only to experience a severe headache when the stress has resolved. Depression, fear, anger, anxiety, and repressed hostility may also be associated with migraine. Although avoiding stress is difficult, reducing stress is not, and instruction on coping methods may be beneficial for "psychologically overloaded" patients. Other psychological triggers may require additional counseling, treatment, or both.

External Stimuli

Some patients with migraine will describe a relationship between their headaches and weather. Rapid changes in barometric pressure as well as extreme variations in weather have been shown to provoke a migraine attack in certain patients (Diamond et al., 1989). During or subsequent to travel to an area with an altitude substantially different from the patient's norm (i.e., the mountains for

those who live at sea level, and vice versa), a patient may report an increase in headache frequency. A diuretic, such as acetazolamide, used on the day of a flight may help to prevent these headaches. Other external migraine triggers include bright or flashing lights, loud noises, and strong odors (such as smoke, perfume, or cleaning fluids).

TREATMENT

With a confirmed diagnosis of migraine, the clinician and patient should begin to devise a treatment plan that accounts for the practical realities of the patient's lifestyle. Migraine treatment plans usually involve some combination of behavioral change (avoiding triggers, increasing exercise, and relaxation) and pharmaceutical and non-pharmaceutical pain management approaches (prophylactic or abortive medications, manipulation and massage, cold compresses, warm baths). Determining the relative value of these strategies for each patient will shape the course of both acute and long-term therapy.

Behavioral changes and nonmedicinal treatments can be valuable, particularly in patients with frequent or severe migraine attacks. Most treatment plans incorporate behavioral modification in the form of avoiding foods, beverages, or situations that trigger attacks; each patient will be unique in this regard. Similarly, the use of cold compresses, warm baths, or massage for migraine should be governed by the nature of the individual's disorder.

If medication is a part of the treatment plan, the selection can be tailored to the patient's needs. Before

TABLE 25.6
Migraine Food Triggers

Beverages	Dairy
Alcoholic	Aged and processed cheese
Caffeine (limit to 2 cups/day)	Yogurt (limit to 1/2 cup/day)
Chocolate milk	
Buttermilk	**Baked Goods**
	Fresh baked breads
Meat/Fish	Sourdough
Pickled herring	
Chicken livers	**Vegetables**
Sausage	Fava beans
Salami	Lima beans
Pepperoni	Navy beans
Bologna	Peapods
Frankfurters	Sauerkraut
Marinated meats	Onions
Aged, canned, or cured meats	
	Desserts
Fruits	Chocolate
Canned figs	
Raisins	**Other**
Papaya	Soy sauce
Passion fruit	MSG
Avocado	Meat tenderizer
Bananas	Seasoning salt
Red plums	Canned soups
Citrus fruits (limit to 1/2 cup/day)	TV dinners
	Garlic
	Yeast extracts

Note: Extracted from the National Headache Foundation Headache Diet, Chicago, IL.

recommending or prescribing any medication for migraine, however, it is crucial to determine all remedies the patient may have already tried before consulting, as detailed information in this area may reveal important therapeutic limitations and opportunities. Familiarity with the wide range of options for migraine pharmacotherapy can increase the likelihood of meeting an individual patient's needs.

Standard Migraine Medications

Pharmacological therapy is most often the main component in migraine therapy. There are three broad categories of pharmacologic treatment of migraine: prophylactic, abortive, and symptomatic. If migraine attacks occur four or more times per month, or if attacks are incapacitating, many clinicians consider prophylactic therapy. If a patient has four or fewer migraine attacks per month, abortive treatment alone may be indicated. However, the clinician should determine the appropriateness of prophylaxis. When acute pain does not respond to abortive measures, symptomatic therapy can be employed as a backup.

Prophylactic Treatment

Preventive medications can be a part of a comprehensive plan, which may include behavior modification, diet counseling, exercise, stretching, or biofeedback. The goal of prophylaxis is to prevent the onset of migraine attacks, limit their frequency, or limit their severity. The decision about which medication or class of medications to use generally depends on comorbidities and interactions with concomitant medications. Beta-blockers, for example, could be used in patients with hypertension but are contraindicated in those with asthma; a patient with depression taking an SSRI should not take an MAOI for migraine because of dangerous interactions. Drugs currently approved for long-term use in migraine prophylaxis include propranolol, timolol, methysergide, divalproex sodium, and topiramate.

Propranolol, an adrenergic blocker, one of the most frequently used drugs in the prophylactic therapy of migraine, must be given carefully in patients with coronary heart disease and thyrotoxicosis. It may exacerbate coronary ischemia and can produce unstable angina or even myocardial infarction (Diamond, 1997). Propranolol is contraindicated in patients with asthma, chronic obstructive lung disease, congestive heart failure, or arterioventricular conduction disturbances. In some patients, administration may cause depression, nightmares, lethargy, fatigue, sexual dysfunction, and weight gain. Patients being treated with insulin or oral hypoglycemia drugs, or patients taking MAOIs, should avoid propranolol use. Propranolol is administered from 60 to 240 mg per day in a simple, long-acting dosage or in divided doses. Timolol is another beta-blocker that carries an FDA indication for migraine. It is an alternative to propranolol and can be taken in doses of 5 to 30 mg per day. Other beta-blockers, such as nadolol, atenolol, and metoprolol, have been used with varying degrees of success.

The alpha-agonist clonidine may be useful for migraineurs who are sensitive to cheeses and other foods containing tyramine (Diamond, 1997). Side effects are usually mild and include drowsiness, dry mouth, constipation, orthostatic hypertension, depression, and occasional disturbances of ejaculation.

Divalproex sodium is FDA approved for migraine prevention and is particularly useful in migraineurs with epileptic seizures, bipolar disorder, and possibly head trauma (Rapoport & Adelman, 1998). An extended-release formulation of divalproex, which produces less fluctuation in plasma concentrations than the standard therapy, is also available. The recommended starting dose for the extended-release formulation is 500 mg daily and can be increased to 1000 mg daily. Divalproex sodium should be avoided in any patient with a history of hepatitis or abnormal liver function; it is contraindicated in pregnancy, as it is associated with neural tube defects. Divalproex

sodium can be combined with tricyclic antidepressants or other medications in patients whose headaches are difficult to control (Gallagher, Mueller, & Freitag, 2002).

Methysergide is closely related to ergotamine and promotes serotonin inhibition and mild vasoconstriction. This agent is usually prescribed in doses of 2 mg three times daily and should not be used for more than 4 to 6 consecutive months, after which a 1-month hiatus is required before resuming therapy. Upon initiation of therapy, some patients experience transient mental confusion, nausea, vomiting, muscle cramps or aches, and insomnia. If the symptoms persist for more than 3 days or the patient develops evidence of peripheral vasoconstriction, claudication, or angina, the medication should be stopped. Methysergide is contraindicated in patients with peripheral vascular or cardiovascular disease, hypertension, active ulcer, cardiac vascular disease, hepatic or renal dysfunction, fibrotic conditions, or pregnancy. Approved by the FDA for migraine prophylaxis, the drug's sustained use is contraindicated because of the potential for cardiopulmonary and retroperitoneal fibrosis (Diamond, 1997). During the treatment period, the patient should be examined at regular intervals to detect the possible development of fibrotic conditions, murmurs, or pulse deficits. Some clinicians employ continuous methysergide therapy and monitor for fibrosis with computed tomographic (CT) scanning of the abdomen.

Topiramate, a polysaccharide anticonvulsant with several mechanisms of action, has also been assessed in various clinical studies for prevention of migraine. The average daily dose varies from 50 to 200 mg per day and its effectiveness has been demonstrated (Biandes et al., 2004; Gallagher et al., 2002; Kruzs & Scott, 1999; Silberstein, Neto, Schmitt et al., 2004). Transient paresthesias are common, and an unusual side effect of topiramate is that it may cause some patients to lose weight during a course of therapy. With a positive efficacy and tolerability profile, topiramate appears to be a promising option for patients with frequent migraine.

Abortive Treatment

Abortive medications indicated in the treatment of migraine include both over-the-counter (OTC) and prescription agents. These include ibuprofen and APAP/aspirin/caffeine as well as a range of prescription-only medications, including ismotheptane, ergotamine preparations, naproxen sodium, rofecoxib, dihydroergotamine (DHE), and the 5HT1b-1d receptor agonists (triptans). Selected abortive agents are reviewed below.

Over the counter: Multiple studies of ibuprofen and the combination APAP/aspirin/caffeine have demonstrated efficacy superior to placebo in treating migraine and its symptoms (Codispoti et al., 2001; Lipton et al., 1998). The OTC medications are well tolerated, effective (espe-cially when taken early in the attack), and rarely cause serious side effects.

Ergotamine preparations: The utility of these medications in arresting migraine attacks is due to their ability to counteract the dilation of small cerebral arteries and arterioles, primarily the branches of the external carotid artery. Nausea and lethargy are common side effects of the ergotamine preparations. Ergotamine tartrate use should be limited and not repeated for at least 4 days to avoid the possibility of ergotamine rebound headache, characterized by a self-sustaining cycle of daily or near daily migraine headaches coupled with the urge to take ergotamine to relieve symptonms (Gallagher, 1983). Ergotamine and its derivatives should be avoided in elderly and in pregnant patients. Dihydroergotamine, which was developed as an improvement over ergotamine tartrate, is highly effective and has a better safety profile. It is available in parenteral and nasal formulations. The nasal spray is more convenient and tolerable, has a low recurrence rate, and resolves migraine attacks in up to 70% of patients (Gallagher, 1996).

Nonsteroidal anti-inflammatory drugs: NSAIDs have been shown to be superior to placebo and equivalent to other reference drugs in the abortive treatment of migraine (Pradalier, Clapin, & Dry, 1988). Nonprescription formulations of ibuprofen have also been approved for the treatment of acute migraine. Although fewer side effects are reported with NSAIDs than with ergotamine and triptans, gastrointestinal, renal, and hepatic risks linked with NSAIDs are possible (Rapoport & Adelman, 1998). The COX-2 rofecoxib (unavailable in the U.S. market) has demonstrated effectiveness and causes fewer GI side effects than other fast-acting NSAIDs (Silberstein et al., 2004).

Isometheptene: This sympathomimetic with vasoconstrictive effects is found in combination with acetaminophen 325 mg and dichloralphenazone 100 mg. The combination can be effective in migraine without aura. It is taken orally, two capsules at onset headache and one each hour thereafter, to a maximum of five capsules in 1 day. Side effects include drowsiness and nausea, and it is contraindicated in patients with uncontrolled hypertension, with renal disease, or those taking MAO inhibitors.

5-HT (5-hydroxytryptamine) agonists: The serotonin agonists triptans became a mainstay of acute migraine headache treatment in the 1990s and now are the treatment of choice of most clinicians. Their therapeutic effects are thought to be the result of activation of the $5HT_{1B-1D}$ receptors. Three mechanisms of action have been proposed: cranial vasoconstriction, peripheral neuronal inhibition, and an inhibition of transmission through second-order neurons of the trigeminocervical complex, all of which inhibit the effects of activated nociceptive trigeminal afferents (Goadsby, 2000; Goadsby, Lipton, & Ferreri, 2002; Humphrey et al., 1990; Moskowitz & Cutrer, 1993). The

TABLE 25.7
Triptans

Medication	Brand Name	Form	Dosage	Half-Life	Recurrence Range
Sumatriptan	Imitrex	Oral tab	50, 100 mg	2 h	35–47%
		Nasal spray	5, 20 mg		
		Subcutaneous injection	6 mg		
Zolmitriptan	Zomig	Oral tab	2.5, 5 mg	2.5–3 h	22–37%
		Melt tab	2.5, 5 mg		
		Nasal spray	5 mg		
Naratriptan	Amerge	Oral tab	1, 2.5 mg	6 h	17–28%
Rizatriptan	Maxalt	Oral tab	5, 10 mg	2 h	35–47%
		Melt tab	5, 10 mg		
Almotriptan	Axert	Oral tab	6.25, 12.5 mg	3.5 h	18–30%
Frovatriptan	Frova	Oral tab	2.5 mg	25 h	7–25%
Eletriptan	Relpax	Oral tab	20, 40, 80[a] mg	5 h	6–34%

[a] 80 mg not available in United States.

migraine drugs marketed as "next generation" agents are similar to sumatriptan. As of this writing, there are seven additional triptans: zolmitriptan, naratriptan, rizatriptan, almotriptan, elitriptan, frovatriptan, and eletriptan.

The onset of action, duration of action, recurrence of headache, and tolerability vary with the triptan. Side effects tend to be a little greater with the more rapidly absorbed triptans, and the recurrence rate of headache tends to be less with the longer-acting triptans. Individual tolerability and efficacy can vary with the patient and a trial with different triptans may be necessary in some sufferers.

Reports of clinical experience with the approved triptans suggest that while they all are effective, response is highly individualized. Various attempts have been made to analyze and compare the triptans. Frietag and co-workers (2000), in a retrospective study of clinical experiences with naratriptan, rizatriptan, and zolmitriptan, concluded that all were highly effective, and they observed that no clear differences between them would distinguish one agent as "the best." A study by Ferrari et al. (2001) using a meta-analysis of 53 clinical trials comparing efficacy, recurrence, and duration of action was completed in 2001. Efforts were made to adjust for differences in protocols and placebo response, but there was not a clear agreement by specialists on its validity and usefulness. A limited number of clinical trials compared zolmitriptan with sumatriptan, rizatriptan with zolmitriptan, eletriptan with sumatriptan, almotriptan with sumatriptan, and so on (Diener, Pascual, & Vega, 2000; Gallagher, Dennish, Spierings, & Chitra, 2000; Sandrinia et al., 2002; Spierings et al., 2001) (Table 25.7).

The triptans initially were recommended for the treatment of moderate to severe migraine attacks. Clinical trials were conducted with traditional protocols and patients were instructed to treat only when migraine symptoms were well established. However, efficacy rates on average

remained well under 70%. Consequently, the later view of specialists changed to treat sufferers at the onset of attacks. Recent studies have shown that early treatment results in more rapid efficacy rates, often within 2 hours of treatment (Carpay et al., 2004; Matthew, 2003).

As a class of drugs, the triptans are contraindicated in patients with ischemic heart disease, uncontrolled hypertension, and cerebrovascular disease. Triptans exert physiologic activity primarily in the cranial circulation, but can affect the coronary circulation to a much lesser degree. To date, there has been substantial human exposure to triptans and clinically significant myocardial ischemia or infarctions are rare (Goadsby et al., 2002; Mueller, Gallagher, & Ciervo, 1996; Ottevanger et al., 1994; Welsch et al., 2001). Chest pain following triptan use is a troubling side effect that occurs in a small percentage of patients.

Recurrence of headache within 24 hours, following initial relief, is a concern with migraineurs being treated with abortive medications. The recurrent headache results in the patient's needing to take additional medication and in some cases results in medication overuse. Recurrence appears to be influenced by pharmokinetics and pharmacological properties of the triptans. The triptans with the longer half-life and 5HT1-b receptor potency, such as frovatriptan, naratriptan, and eletriptan, tend to have the lower recurrence rates (Geraud, Keywood, & Senard, 2003). Some sufferers who experience longer migraine attacks or women who experience menstrual migraine frequently benefit from the longer-half-life triptans.

Sumatriptan was the first triptan to be widely used for the acute treatment of migraine headache. Because its availability predated other triptans, sumatriptan often is used as the comparator drug in head-to-head trials for the later-released triptans. Absorption is rapid and its elimination half-life is 2 hours. It is available in multiple forms

including subcutaneous injection (6 mg), a rapid release oral table (50 mg, 100 mg), and nasal spray (5 and 20 mg). The subcutaneous injection tends to produce a rapid and effective response, but duration of action can be brief and a repeat dose is frequently required. The oral and nasal forms are effective, more convenient, and generally better tolerated.

Zolmitriptan was the second triptan to become available. It has a relatively rapid onset of action and an elimination half-life of 2.5 to 3 hours. Zolmitriptan demonstrates a favorable consistency rate among patients, especially when a second dose is used (Tepper et al., 1999). It is available in oral tablets (2.5 mg, 5 mg), melt tab (2.5, 5 mg), and nasal spray (5 mg).

Naratriptan was the first of the longer-acting triptans and is available in 1 and 2.5 mg tablets. Its elimination half-life is 6 hours and its onset of action is gradual. Patient tolerability is good and it often is used in sufferers with slow-onset and longer-duration migraine attacks. Natatriptan frequently is used in menstrually related migraine and can be helpful in "mini-prophylaxis" during the vulnerable period of time (Newman et al., 2001).

Rizatriptan has a rapid onset of action and an elimination half-life of 2 hours. It has a favorable one dose, 2-hour pain-free response without recurrence (Pascual et al., 2000). Rizatriptan is available in oral tablets (5, 10 mg) and melt tablet (5, 10 mg) with 10 mg being the usual starting dose. Patients who are concomitantly taking propranolol should be advised to take a lesser dose, 5 mg, because of increased rizatriptan plasma levels with propranolol use.

Almotriptan is an oral triptan with a broad T_{max} range of 1.4 to 3.8 hours. It has an elimination half-life of 3.5 hours, and its efficacy, tolerability, and recurrence profiles are favorable. Almotriptan is available in oral tablets (6.25, 12.5 mg) with 12.5 mg being the recommended dose. Unusual for this triptan is its incidence of chest pain side effects that are similar to placebo (Dahlof et al., 2001).

Frovatriptan is a relatively new triptan with a long duration of action. It has a 25-hour elimination half-life and a favorable headache recurrence rate (Ryan et al., 2002). Frovatriptan is well tolerated and is available in 2.5 mg oral tablets. Because of its long duration of action, it is frequently used in menstrual migraine and in patients who suffer with prolonged attacks.

Eletriptan is the most recent triptan to be released. It has a rapid onset of action with a relatively longer duration of action. Its elimination half-life is 5 hours. Eletriptan is available in oral tablets (20, 40 mg in the U.S., and an additional 80 mg elsewhere). It has been shown to be well tolerated and frequently effective in patients who have not responded to other treatment (Farkkila et al., 2003).

Approximately two thirds of patients report neck symptoms during migraine attacks (Blau & MacGregor, 1993). Stiffness and pain of muscles of the neck can be a part of premonitory symptoms or part of the headache phase of migraine (Waelkens, 1985). Physiotherapy, massage, or soft tissue osteopathic or chiropractic manipulative treatment can be of help in aborting or reducing symptoms of the attack in these patients, especially when used with medication (Astin & Ernst, 2002). Local anesthetic or saline infiltration injections into painful neck muscles can relieve migraine in some patients (Tfelt-Hansen, Louis, & Olesen, 1981).

Symptomatic Treatment

Symptomatic treatment for pain is indicated for patients with migraine whose abortive medications have failed or in patients who experience severe pain early in the migraine attack. Symptomatic agents are sometimes referred to as "rescue medications." Transnasal butorphanol, a nasal preparation, is one of the more useful drugs in patients with infrequent attacks. Pain relief has been demonstrated as early as within 15 minutes (Goldstein, Marek, & Winner, 1998), and the nasal formulation is particularly convenient for patients who are suffering from nausea or vomiting. Other options for rescue therapy include injectable NSAIDs, butalbital combinations, opioids, opioid-like agents, and other combination compounds. Because of their overuse potential and the possibility of rebound headache (overuse headache), proper prescribing precautions must be observed when using symptomatic medications (Limmroth et al., 2002).

INTRACTABLE MIGRAINE

Episodic migraine may become incessant and refractory to standard care (Matthew, Reuveni, & Perez, 1987). For many of these patients, drug dependence is a factor; for others, disabling headaches continue, unabated, seemingly indefinitely. For such patients, clinicians should be aware of several approaches to the management of intractable migraine. DHE, administered in a protocol developed by Raskin (1986), can produce a headache-free state in 90% of patients with intractable migraine within 2 days. Metoclopramide or antinauseants are used adjunctively with DHE to suppress accompanying symptoms (Ramaswamy & Bapna, 1987). Alternative treatments for intractable migraine include parenteral steroids such as dexamethasone, ketorolac (30 to 60 mg intramuscularly or intravenously), chlorpromazine (0.1 mg/kg intravenously every 6 to 8 hours), or naratriptan (2.5 mg twice daily for a limited period of time) (Gallagher, 1986; Gallager & Mueller, 2003; Newman, 2000).

CLUSTER HEADACHE

Cluster headache is a devastatingly severe type of recurrent vascular headache. It sometimes is referred to as histaminic cephalalgia, histaminic headache, Horton's

cephalalgia, Horton's headache, Horton's syndrome, or migrainous neuralgia. Its clinical constellation of symptoms with the characteristic patient behavioral tendencies during attacks should make it easy to recognize and distinguish from migraine or tension-type headache. Of the recurrent headache syndromes, it is probably the most distressing and brutal to the afflicted.

A cluster attack is characterized by severe unilateral pain, often described as a burning, boring, or stabbing sensation in the area of the eye, temple, or forehead with radiation to the jaw, ear, or neck. During attacks, sufferers often pace or become extremely active, similar to patients experiencing renal colic. Frequently associated with the pain are ipsilateral lacrimation, eye injection, rhinorrhea, congestion, facial droop, or sweating of the face. The pain usually builds quickly over several minutes and lasts approximately 30 to 90 minutes in most sufferers.

Cluster headache attacks can occur numerous times daily, sometimes at the same hour each day. Early morning awakening with headache two to three hours after retiring is common. In its typical form, episodic cluster, the headaches cluster or group for periods of weeks to months and mysteriously disappear for months to years, thus the name "cluster headache." In its chronic form, which affects approximately 10 to 15% of sufferers, the headaches continue to occur indefinitely, affording the patients few headache-free days (Ekbom & Olivarius, 1971). The IHS criteria for cluster headache are shown in Table 25.8.

The typical onset of cluster headache is in the third or fourth decade of life, although cluster attacks have been reported from childhood to the late 60s (Heyck, 1981). Unlike migraine, cluster headache is more prevalent in men; its gender ratio favors men by 5:1. The etiology remains poorly understood. However, it has been proposed that vasomotor, hypothalamic, or neurohormonal disturbances may be involved (Kudrow, 1983; Moskowitz, 1984; Saper, 1983).

Unlike migraine, diet does not seem to precipitate cluster, although an occasional patient will report that chocolate can be a factor. The one exception, however, is the consumption of alcohol during cluster periods. Many cluster patients are heavy smokers, former smokers, and alcohol drinkers. During remission periods when patients are not on preventive medications, alcohol appears to have no provoking effect.

TREATMENT

The preferred approach to the treatment of cluster headache patients is prophylactic. The tremendous pain and relatively short but frequent attacks makes symptomatic treatment less practical and often ineffective. Appropriate pharmacological prophylactic regimens can reduce the frequency and severity of attacks in most patients. When treating patients with cluster headache, the benefits of

TABLE 25.8
IHS Diagnostic Criteria for Cluster Headache

A. At least five attacks fulfilling B to D
B. Severe unilateral orbital, supraorbital, and/or temporal pain lasting 15 to 180 minutes untreated
C. Headache is associated with at least one of the following signs that have to be present on the pain-side:
    1. Conjunctival injection
    2. Lacrimation
    3. Nasal congestion
    4. Rhinorrhea
    5. Forehead and facial sweating
    6. Miosis
    7. Ptosis
    8. Eyelid edema
D. Frequency of attacks: from one every other day to eight per day
E. At least one of the following:
    • History, physical, and neurological examinations do not suggest a secondary disorder
    • History and/or physical and/or neurological examinations do suggest such disorder, but it is ruled out by appropriate investigations
    • Such disorder is present, but cluster headache does not occur for the first time in close temporal relation to the disorder

Source: Data from Headache Classification Committee of the International Headache Society, *Cephalgia, 8*(7), 1–96, 1988.

therapy should be weighed against the hazards of taking medication. Patients should be monitored closely, as some of the medications prescribed in treatment can potentially cause problems. Ergotamine and DHE preparations, methysergide, calcium channel blockers, corticosteroids, and lithium are commonly used. Other agents, such as cyproheptadine, indomethacin, chlorpromazine, antidepressants, doxepin, and ergonovine, have been used with limited success.

For patients with cluster headache, ergotamine tartrate is administered orally in divided doses throughout the day and will often limit the severity and frequency of cluster attacks. The daily dose should be kept as low as possible (1 to 2 mg daily), and additional ergotamine for breakthrough headaches should not be permitted. Individual tolerance and sensitivity vary greatly, and patients should be followed closely for untoward reactions and complications.

Methysergide, an ergotamine derivative, also may be used to treat patients with cluster headache. It is administered orally in divided doses not to exceed 8 mg per day. If being used in patients with the chronic form, a drug holiday after 4 to 6 months of use is recommended (see Migraine Prophylactic Treatment).

Corticosteroids, alone or in combination with methysergide, are frequently effective for difficult patients. Their mechanism of action is not completely understood, but it is thought to involve suppression of hormonal mecha-

nisms. This treatment is more suited for patients with episodic cluster headache, as its long-term use could be hazardous. However, because of the extreme distress and suffering of some patients with chronic cluster headache, corticosteroids can provide temporary relief while other prophylactic drugs are being introduced.

Prednisone or triamcinolone is commonly prescribed, although others are effective. The steroids are given in divided doses that must be titrated to the individual. The average daily starting dose is 60 mg of prednisone or 16 mg of triamcinolone. The medication is then tapered over 2 to 4 weeks with adherence to usual steroid precautions. Side effects include fluid retention, weight gain, gastrointestinal disturbances, lethargy, and Cushing's syndrome. Contraindications are hypertension, diabetes, peptic ulcer disease, infection, active immunization, or pregnancy.

Calcium channel blocking drugs have been helpful to many patients, especially those with the chronic form of cluster. It is believed that they alter smooth muscle tone of cerebral arteries by interfering with calcium ion function (Gallagher & Freitag, 1987a). Verapamil generally is well tolerated and more frequently used. It has been suggested as a first-line pharmacologic treatment for the prevention of cluster headache, although weeks of therapy may be required before control of the condition is established (Saper, 2000). It is given in divided doses with an average daily dosage of 360 to 480 mg per day. The most frequent side effects with verapamil are constipation and fluid retention. Verapamil is contraindicated in hypotension, cardiac conduction disease, and significant renal or hepatic disease. Other calcium channel blockers sometimes used are nifedipine (40 to 280 mg per day) and nimodipine (30 to 60 mg per day).

Lithium carbonate is reported to be effective in reducing frequency and severity of attacks in the treatment of patients suffering with the chronic form of cluster headache. Its mechanism of action has been debated, but it may involve its effect on cyclic changes in serotonin and histamine or electrical conductivity in the central nervous system (Diamond & Dalessio, 1980; Gallagher & Freitag, 1987a). It is administered orally in divided doses with a daily dosage of 600 to 1200 mg. Serum lithium level monitoring is necessary to avoid toxicity. Effective therapeutic ranges vary greatly, but generally should not exceed 1.2 meq/liter. NSAIDs and thiazide derivatives should be used with caution; when used concomitantly, these agents will raise the potential risks of toxicity. Side effects include fatigue, tremor, sleep disturbances, diarrhea, decreased thyroid function, goiter, and fluid retention. Lithium is contraindicated in the presence of significant renal or cardiovascular disease.

Abortive therapy for cluster patients is of limited effectiveness because of the relatively brief headaches and the time necessary for medication absorption. Few non-pharmacologic measures are helpful to patients with cluster headache. However, the complete abstinence from alcohol during cluster periods is imperative. Drinking alcohol, without question, will interfere with prophylactic therapy. Reducing cigarette smoking and caffeine consumption, as well as avoiding of daytime napping, may benefit some patients (Diamond & Dalessio, 1980; Gallagher & Freitag, 1987a). The inhalation of oxygen during a cluster attack is a relatively safe and effective treatment and, in the majority of sufferers, will abort attacks within 12 minutes (Kudrow, 1981). Oxygen is administered at a rate of 7 liters per minute by facial mask at the onset of attack and continued for up to 15 minutes. The main drawback to the use of oxygen is the cumbersome equipment, which makes it difficult to transport for patients whose attacks are unpredictable.

For patients who experience longer headaches and those who are not sufficiently controlled by preventive medication, abortive medication may be needed. This generally is limited to a triptan, ergotamine, or analgesics. The injectable, nasal, or faster-acting triptans, sublingual or injectable ergotamine, and nasal or injectable DHE can be administered early in the attack. This may give relief to some, while simply delaying the completion of the headache attack in others. The usual triptan, ergotamine, and DHE precautions must be observed, which limit the amount that can be taken and the number of headaches that can be treated. Analgesics and sedatives are of limited help, but they aid certain patients psychologically and reduce the anxiety associated with cluster attacks. Unmonitored use of these medications should be avoided, as potential habituation or toxicity can develop.

MIXED HEADACHE SYNDROME AND CHRONIC DAILY HEADACHE

Many patients with headache experience more than one distinct headache type, with pain-free periods between attacks. However, there is a group of patients who experience intermittent migraine attacks superimposed on a daily or near daily, less-intense headache similar to that of TTH. This pattern is characteristic of the mixed vascular headache syndrome. The patient with mixed headache syndrome is one of the more difficult to manage.

The patient with daily headache will, in many cases, have a long history of evaluations and failed therapeutic attempts. Such patients' constant fear of the daily or near-daily headaches worsening will sometimes lead to self-treatment and excessive medication use. The frequent use of any immediate-relief medication for head pain can cause rebound headache, which perpetuates the problem and often renders other treatments ineffective until the immediate-relief medications are discontinued (Kudrow, 1982). Psychogenic factors, such as chronic stress, anxiety, burnout, or depression, are often present and further contribute to the ongoing problem.

The patient–doctor relationship is critical in the management of patients with mixed headache. A definite, comprehensive treatment plan that addresses each element of the patient's problem must be developed and supervised by a single physician. The patient must be educated as to the nature of his or her headaches and how each aspect of treatment is expected to contribute to the control of the headaches. Once a plan is begun, continuity of care with regular follow-up visits is vital.

The treatment of the chronic daily or mixed headache syndrome usually will require prophylactic medications in addition to "tailored" nonpharmacologic measures such as diet, exercise, stretching, stress reduction, biofeedback, social adjustments, and counseling. Patients experiencing only a chronic daily dull headache usually will do best with a single nightly dose of a tricyclic antidepressant such as amitriptyline or nortriptyline. Other patients who experience coexisting tension-type and migraine headaches will require that each individual component be treated with its own appropriate therapy. The management of tension-type and migraine headache has been described earlier in this chapter. Patients who do not respond to outpatient therapy or who are unable to withdraw from frequent analgesic or ergotamine use may benefit from hospitalization at dedicated in-patient, tertiary care facilities (Diamond, Freitag, & Maliszewski, 1986).

CERVICOGENIC HEADACHE

Physicians and patients anecdotally have associated neck symptoms with headaches for a long period of time. Identifying the specific association among neck pathology, neck symptoms, and specific headache types has presented more of a challenge. In fact, some experts believe that more questions on this topic have been raised than the availability of acceptable and reliable answers. Adding to the complexity of this issue is the relatively high percentage of atypical headache that specialists encounter (i.e., atypical migraine, cluster, or tension-type headache.) Regardless, it is clear that the neck–headache association does exist and should become a part of the evaluation and treatment of headache sufferers.

DIAGNOSIS

The definition of "cervicogenic headache" or "headache associated with neck disorders" has varied with specialty group, society, or association. In general, it can be defined as headache originating from muscular, articular, osseous, neurologic, or vascular structures of the neck. The headache frequently is unilateral, starting in the neck and becoming protracted. Some sufferers experience restricted ranges of motion of the neck, ipsalateral shoulder and arm pain, and on occasion, photo/phonophobia similar to migraine. Different areas of the cervical spine can be involved and many causes can be attributed to its symptoms (Sjaastad, 1997). Most specialists consider cervicogenic headache to be a syndrome and not a disease.

The IHS includes radiological evidence of movement abnormalities, abnormal posture, congenital abnormalities, bone fractures, tumors, rheumatoid arthritis, or distinct cervical pathology. However, the sensitivity of radiological studies in determining headache cause has been questioned (Fredriksen et al., 1989; Pfaffenrah et al., 1988). The Cervicogenic Headache International Study group of 1998 includes diagnostic anesthetic blockade as confirmatory evidence, but again, the confirmation of a diagnosis by therapeutic procedure can be questioned (Sjaastad, Fredriksen, & Pfaffenrath, 1998). Nerve blocks relieve pain locally or along the distribution of the anesthetized nerve and may not identify the origin of pain.

The varied criteria used to differentiate cervicogenic headache as a distinct entity rather than a precipitant of migraine or other types of headache account for a widely variable prevalence. Complicating the matter further is the reporting of cervicogenic headache in patients who suffer with concomitant migraine without aura and/or other distinct headache disorders. The reported prevalence varies greatly from 0.4% to as high as 42% in a population of headache sufferers older than age 50 (Leone, D'Amico et al., 1995; Olesen, 1990; Pearce, 1995; Pfaffneath & Kaube, 1990). Regardless, cervicogenic headache is an entity that deserves adequate attention of those clinicians evaluating and treating patients with headache.

Cervicogenic headache can occur after whiplash and neck or head injury, and has been reported or mentioned in various manuscripts. In one study of 222 patients with whiplash headache treated in an emergency department, 8% were diagnosed with cervicogenic headache (Drottning, Staff, & Sjaastad, 2002). Even minor trauma can be enough to unmask an underlying neck problem, which results in neck pain or cervicogenic headache (Wilson, 1991). Falling outside the cervicogenic headache criteria are those patients whose cervical pathology exacerbates primary headache disorders (Mueller, 2003).

Unilateral migraine without aura and cervicogenic headache share similar symptoms that can pose a diagnostic challenge for the clinician. This may account for varying outcomes when patients with similar symptoms are treated with the same regimen. In addition, as migraine sufferers age, attacks precipitated by the neck tend to increase. For this reason, a carefully made diagnosis is critical for the patient to receive optimum treatment and relief.

PATHOPHYSIOLOGY

The neck is replete with pain-sensitive structures, which include muscles, bony attachments, nerve roots, arteries, dural matter, joints, intervertebral ligaments, and perios-

teum of vertebral bodies. Although little is known about the nerve supply of the atlanto-occipital (C0, C1) articulation, the upper cervical segments (C1 to C3) converge with trigeminal sensory fibers in the trigeminocervical nucleus in the upper cervical spinal cord (Bogduk, 1992; Edmeads, 1988; Wilson, 1991). Many clinicians believe that cervicogenic headaches originate from this area. However, other areas of the neck can be involved and the lower cervical segments also may cause radiating pain to the neck, shoulder, or arm.

Direct stimulation of the dura can occur by way of a dura–muscular band that connects the posterior spinal dura matter to the rectus capitus posterior minor muscle at the atlanto-occipital (C0, C1) junction (Hack et al., 1995). Consequently, it is presumed that torsion strain injuries or repetitive muscle contraction of the upper neck can more directly precipitate pain and headache.

Neck strain, injury, or chronic muscle spasm of the scalp, neck, or shoulders may result in heightened muscle sensitivity similar to the allodynia proposed in migraine (Bendtsen, 2000; Burstein, Cutrer, & Yarnitsky, 2000). Consequently, a lowered pain threshold may contribute to greater headache and associated symptoms.

TREATMENT

Patients who suffer with cervicogenic headache may have experienced pain for an extended period of time and frequently present a significant challenge to the clinician. The most successful treatment usually is comprehensive and can involve medication, physical therapy, manipulation, exercise, behavior modification, counseling, nerve blocks, nerve stimulation, radiofrequency, and in some cases, surgical intervention. The correct diagnosis, an individualized treatment plan, and a motivated patient afford the best chance of relief.

In many cases, the patient suffering with cervicogenic headache has taken a multitude of medications or has been subjected to various interventional procedures. This, of itself, adds another complexity for the clinician. These patients frequently are frustrated and, because they may have taken a particular medication in the past, may challenge the clinician on the selection of a pharmacologic regimen. This is when it is an absolute necessity to achieve "buy-in" and an understanding of the patient for the comprehensive treatment plan. The medication or medications in combination with other physical interventions or psychosocial therapies often are the difference between success and failure.

In some cases, the clinician may discover that the patient is taking excessive analgesics (prescription and OTC) and/or tranquilizers to relieve symptoms. As with other headache treatment, previously described, the daily or near daily use of analgesics, especially those containing caffeine can cause rebounding (Limmroth et al.,

2002). Successful treatment rarely is achieved until the offending medications are withdrawn.

PHARMACOLOGIC TREATMENT

Pharmacologic treatment of cervicogenic headache can include medications used in other headache disorders, such as anti-inflammatory drugs, muscle relaxants, analgesics, antinauseants, antiepileptics, and antidepressants. It is unusual that one medication alone will be adequate to effectively control cervicogenic headache. Combinations of medications in patients, who are appropriately screened, often are most useful, e.g., NSAIDs with muscle relaxants. Also, the clinician should be cognizant that the perception of pain differs from patient to patient. The patient's state of mind and expectation as well as pain modulation activity of the brain can influence treatment outcome (Naider, Ramesh, Anuradha et al., 1991).

The NSAIDs can be of significant value in a treatment regimen. From aspirin to the COX-2 inhibitors, there is a wide array and selection, which can be individualized for the patient, taking into account tolerability, onset, and duration of action. Regardless of the medication used, all NSAIDs are not equally effective in every patient and an alternative may be necessary. In some situations when there is severe inflammation, the temporary and judicious use of steroids can be considered.

The central-acting muscle relaxants can be helpful, especially when there is spasm or disruption of normal muscle tone. These agents have effects on higher brain centers and have analgesic as well as anxiolytic effects (Gallagher, 2002).

Baclofen, chlorphenesin, carbamate, chlorzoxazone, metaxalone, methocarbamol, orphenadrine, or tizanidine can be used in the usual doses. Diazepam is a benzodiazepine with significant anxiolytic, hyponotic, and sedative effects as well as muscle relaxation. Although other benzodiazepines are used, diazepam tends to be preferred because of its rapid primary and secondary peak levels, 1 hour and 6 to 12 hours, respectively. However, caution should be used because of tolerance and dependency possibilities with a benzodiazepine. Cyclobenzaprine is similar to the tricyclic antidepressants with like actions and adverse effects. It is preferred by some specialists because of its long duration of action and its psychotherapeutic and antidepressant effects. Evening doses can minimize its sedative effects.

The tricyclic antidepressants (TCA) and like drugs historically have been used for a multitude of pain and headache disorders. Relief has been reported in migraine and TTH, neuritic conditions, chronic pain, myofascial syndrome, fibromyalgia, and "unexplained physical symptoms and symptom" syndromes (Cormeck, Ziegler, & Hassanein, 1976; Diamond & Baltes, 1971; Gallagher, 2002; O'Malley, Jacson, Santoro et al., 1999). The TCAs

were derived from neuroleptics and their psychotherapeutic effects seem to enhance improvement in patients with emotional and depression overlay.

Amitriptyline is considered the basic TCA, but others can be substituted with equal benefit. Side effects can be numerous, especially its anticholinergic and sedative effects. Imipramine, nortriptyline, maprotiline, desipramine, or doxepin also can be prescribed. In general, starting with a low dose in the evening and titrating to tolerability and efficacy is recommended. Protriptyline is nonsedating and is rarely given at night because of its strong anticholinergic effects.

In numerous studies, the anticonvulsants have demonstrated effectiveness in various types of headache and neck pain (Gallagher, 2002). An understanding of their exact mode of action is unclear. However, similar neurophysiologic mechanisms have been suggested for both pain and epilepsy and the anticonvulsants have shown usefulness in the treatment of head pain (Naider et al., 1991). Divalproex sodium and topiramate are more commonly used and frequently in combination with NSAIDs or muscle relaxants. Other anticonvulsants such as gabapentin, carbamazepine, felbamate, and phenytoin are utilized to a lesser degree. Divalproex sodium is indicated by the FDA for the treatment of migraine headache and various studies have demonstrated the effectiveness of topiramate. These medications have been discussed earlier in the chapter.

Physical Management

The muscles of the neck are prone to spasm from a multitude of causes. The necessary muscle tone of the neck is maintained by complex neurological mechanisms. Biologic disturbances, injuries, or physical abnormalities can interfere and cause sustained spasm of the neck, scalp, and shoulder muscles, which contributes to the headache.

The restoration of normal physiologic function and tone of the muscles of the neck and scalp is important in treating sufferers with head pain of neck origin. Appropriate physical therapeutic modalities such as heat, cold, ultrasound, or massage, tailored to the patient as part of a comprehensive program, can be of value (Vernon, McDermaid, & Hagino, 1999). In some patients, immobilization of the neck may be necessary, but should be limited in duration and followed by stretching and muscle strengthening exercises. In all cases, however, care should be given to the physical evaluation to ensure that discomfort to the patient does not aggravate the pain and symptoms.

Acupressure, acupuncture, transcutaneous nerve stimulation (TENS), and local muscle or facet join injections are sometimes utilized with varying degrees of success. Cervical epidural steroid injections are not commonly used, but can be considered in selected patients, with clear pathology within the vertebral canal, which is accessible to an epidural injection (Wilson, 1991).

Manipulative treatment properly administered by an osteopathic physician or chiropractor can be of help. Slow-paced progression of manipulation beginning with gentle stretching of muscle and manual cervical traction, later followed by muscle energy and strain/counterstrain techniques when appropriate, is more effective. Too aggressive or improperly administered manual treatments can result in more pain for the patient (Biondi, 2000). Therefore, frequent evaluations with appropriate modifications to the physical program are necessary.

Radiofrequency lesioning to decrease the nociceptive input from various areas of the cervical spine has been reported to be of help. However, the number of cases reported is few, and recurrence of symptoms can be common. Also, the degree of headache and the diagnosis of cervicogenic headache are not always clear. However, it appears that radiofrequency treatment shows promise for the future if standardization of trials and/or treated patients can be established (Mehta & Sluijter, 1995; Vankleef et al., 1993).

Surgical intervention is considered only when patients are nonresponsive to medical and physical modalities. Risks and benefit should be balanced and the patient should completely understand all aspects of a surgical alternative; only the rare patient may present with grossly apparent physical pathology of the neck requiring surgery. The majority of patients will be less clear.

Surgical procedures more commonly include ganglionectomy, ventral decompression, and dorsal laminectomy and laminoplasty. A review of 102 carefully selected patients who were surgically treated showed an 80% improvement of pain (Jensen, 2000).

Post-Traumatic Headache: Diagnosis, Pathophysiology, and Treatment

Gary W. Jay, MD, DAAPM

INTRODUCTION

Post-traumatic headache (PTHA) is a poorly understood disorder. There are 2 million traumatic brain injuries (TBI) each year, 500,000 of which are serious enough to need hospitalization (Brown, Fann, & Grant, 1994). Another study indicates that PTHA affects more than 2 million Americans each year (Cady & Farmer, 1998).

Patients with PTHA range from 30 to 80% of patients who have had a mild head injury (Elkind, 1992). Chronic PTHA (see below) is associated with increased headache frequency and disability compared with nontraumatic headache (Marcus, 2003).

The International Classification of Diseases (ICD-10) classification system is based on criteria that primarily concern the temporal relationship as well as pathogenicity between the relationship of PTHA and trauma, and ignore the clinical features of the PTHA (World Health Organization, 1997). These criteria state that the headache onset must occur within 2 weeks of the traumatic event or the patient's return to consciousness. However, post-traumatic cluster headache, for example, typically does not fit this time course. Furthermore, the ICD-10 criteria for acute or chronic PTHA require one of the following: loss of consciousness, a period of antrograde amnesia of at least 10 minutes, or abnormal neurological examination/neurodiagnostic testing. The ICD-10 criteria find that acute PTHA resolves in 8 weeks, while chronic PTHA lasts longer than 8 weeks. This is in counterdistinction to the International Headache Society (IHS) criteria (Headache Classification Committee of the International Headache Society [HCCIHS], 1988).

These criteria are contrary to the most commonly accepted criteria, those of the Brain Injury Special Interest Group of the American Congress of Rehabilitation Medicine (Kay, Harrington et al., 1993), which states that minor traumatic brain injury (MTBI) is a "traumatically induced physiological disruption of brain function" (p. 86) associated with at least one of the following: any period of loss of consciousness; any memory loss for events just before or after the accident; any alteration in mental state at the time of the accident, such as feeling dazed, disoriented, or confused; and focal neurological deficits, which may or may not be transient. Most importantly, there is no necessity of direct head trauma to meet the diagnosis.

Nosological problems abound, such as the synonymous use of various terminology — concussion, minor traumatic brain injury, postconcussion syndrome/disorder, and post-trauma syndrome. For a number of specific reasons, it is felt that the postconcussion syndrome, which affects multiple organ systems, should be differentiated from MTBI (Jay, 2000). Patients with PTHA do not, by definition as well as clinically, have to have a coexisting MTBI.

PTHA may occur alone or as part of the postconcussion syndrome. Post-traumatic headache has been classified by the IHS as associated with head trauma and as acute (resolving within 8 weeks after injury) or chronic (lasting longer than 8 weeks). The IHS divides PTHAs into disorders associated with (1) significant head trauma and/or confirmatory signs or (2) minor head trauma with no confirmatory signs. It states that significant head trauma is defined by loss of consciousness, post-traumatic

amnesia lasting longer than 10 minutes, or abnormalities in at least two of the following: neurologic evaluations, skull radiograph, neuroimaging, evoked potentials, spinal fluid evaluation, vestibular functioning, or neuropsychological testing. The IHS has determined that headache must occur less than 14 days after injury or after a patient regains consciousness (HCCIHS, 1988).

There is an inverse relationship between the occurrence of PTHA and the degree of traumatic brain injury. One study found chronic daily PTHA in 80% of patients ($N = 54$) with a MTBI and 11% had no headache. In patients with moderate to severe TBI ($N = 23$), 27% had chronic daily PTHA, 68% had no headache (Couch & Bearss, 2001). A number of other authors also found that PTHA was the most common symptom after MTBI as well as the most common part of the postconcussion syndrome (Martelli, Grayson, & Zasler, 1999; Packard & Ham, 1994; Uomoto & Esselman, 1993).

By some definitions, headache after head trauma can be "postconcussive," if the patient has had a period of unconsciousness, or "post-traumatic," if there was no associated loss of consciousness (LOC). Furthermore, studies note that patients with MTBI who had no LOC developed headaches that were more intractable to treatment (Yagamuchi, 1992).

The trauma inducing PTHA has been noted in one study to be less than half (45%) secondary to motor vehicle accidents, 30% from falls, 20% from accidents at work or play (Jennet & Frankowski, 1990). Typically, the neurological examination is negative, so these patients' complaints are considered inconsequential, unless the patients are in litigation, when other possibly incorrect assumptions about the patients' PTHA may be made.

Post MTBI or "whiplash" headaches are one of neurotraumatology's most prominent problems. One study found of 112 patients who experienced whiplash or an acceleration/deceleration injury, 42 (37%) had post-traumatic tension-type headaches, 30 patients (27%) had post-traumatic migraine headache, 20 patients (18%) had cervicogenic headache, and 20 patients (18%) had headaches that do not fit specific primary headache criterion; 93% of 104 patients had neck pain with their headaches (Radanov, Di Stefano, & Augustiny, 2001).

Another study (Keidel & Diener, 1997) found that whiplash injury and minor head trauma are followed by PTHA in about 90% of patients. PTHA secondary to whiplash injury was noted to be located occipitally in 67% of patients, with dull, pressing, or dragging characteristics in 77%. Post-traumatic tension-type headache was most common and was found in 85% of patients. Of patients with PTHA after minor head trauma or whiplash injury, 80% had remission of their headaches within 6 months. Chronic PTHA lasting at least 4 years was found in 20% of patients.

PTHA has been found to have great variation in both nature and severity. In another study, 78% of 297 patients had either continuous or intermittent headache secondary to MTBI (Jacobsen, 1963).

A German study found that 80% of patients who had a whiplash injury recovered within a few months, while 15 to 20% developed "late whiplash injury syndrome" with many complaints of the cervico-cephalic syndrome, including PTHA, vertigo, instability, nausea, tinnitus, and hearing loss (Claussen & Claussen, 1995).

As previously noted, many clinicians view PTHA, by definition, as persisting 2 months or longer; this includes the IHS criteria. This may be considered an arbitrary time-frame as the definition of chronic pain is different, being pain persisting for 3 to 6 months. Some studies indicate PTHA patients improve or change over 6 months and then plateau. One felt that 6 months was a better time period for chronicity, as it was more consistent with the chronic pain literature (Packard & Ham, 1993b). Other estimates of persistence for 6 months or more are as high as 44% (Martelli et al., 1999).

PTHAs can be classified as part of the PTHA syndrome, part of the postconcussive syndrome, or by themselves, as an independent medical problem, which may be secondary to an MTBI or whiplash injury or a part of the postconcussive syndrome (Packard, Weaver, & Ham, 1993). If the latter, it may be associated with depression, irritability, decreased memory, fatigue, dizziness, decreased concentration, and tinnitus (Alberti, Sarchielli, Mazzotta, & Gallai, 2001). The postconcussive syndrome is associated with decreased cognitive functioning, impairment of rapid processing of information, decreased attention and short term memory (Elkind, 1992; Jay, 2000).

The pathophysiology of chronic PTHA (CPTHA) has biological, psychological, and sociological aspects. Post-traumatic tension-type headache is the most common form of PTHA, but exacerbation of migraine-like headaches also occurs (Jay, 2000; Solomon, 2001).

It is important to note two aspects of CPTHA with respect to its association with the postconcussive syndrome. First, it is very important to treat the headache problem prior to beginning to treat the cognitive deficits associated with an MTBI. Second, these patients react differently to treatment (Jay, 2000). MTBI patients with PTHA or pain frequently also have attentional deficits as well as psychological distress, both of which can coexist with chronic headache/pain alone. It is therefore important to determine all coexisting diagnoses early on and to factor these problems into the design of treatment for headache and/or pain (Jay, 2000; Uomoto & Esselman, 1993).

It is also important to note that after a structural lesion has been ruled out, treatment of PTHA is very similar to treatment of the primary headaches, vascular and tension-type (Solomon, 2001).

A closed-head injury with brain concussion or contusion is the most frequent type of head injury in children. Headache is a major complaint of early and late postinjury

periods. Of 100 children (3 to 14 years of age), 83% had headache after cerebral concussion/contusion: 56% had acute PTHA; 27% had CPTHA, tension-type; 3% had post-traumatic migraine; 21% had headache lasting the entire year of observation (Lemka, 1999).

In another study of children 3.3 to 14.9 years of age (mean 11.2) who were followed for 5 to 29 months (average 12.5), 5 patients had post-traumatic migraine, 13 patients had post-traumatic tension-type headache, and 3 children had mixed headache. Tension-type headache was more common in children with chronic PTHA than those with no history of head injury (Callaghan & Abu Arafeh, 2001).

Sakas, Whittaker, Whitwell, & Singounas (1997) felt that children who experience neurological deterioration after trivial head injury without focal structural abnormalities (i.e., headache, confusion, vomiting, hemiparesis, cortical blindness, and seizures) may have an "unstable trigeminovascular reflex" that is activated by craniofacial trauma. They note that head trauma may be associated with noncongestive cerebral hyperemia. They further propose that head trauma activates the trigeminal nerve endings in the face, scalp, dura, or cortex and, via a reflex, causes vasodilatation and cerebral hyperemia.

Briefly, the basic pathophysiological elements found in an MTBI may include axonal shearing; marked increases in the excitotoxic neurotransmitters including acetylcholine and glutamate; a lack of the cohesiveness of the blood–brain-barrier, which becomes "porous" for 8 to 24 hours or more; and possible changes in the hemodynamics of the brain (Jay, 2000).

The most important aspect to keep in mind is that the "type" of PTHA must be accurately diagnosed so that appropriate treatment can be prescribed.

Typically, PTHA is noted after acceleration/deceleration injuries (whiplash) in up to 90% of patients who experience MTBI (Keidel & Diener, 1997). These headaches can be determined to be post-traumatic tension-type, migraine, cluster, or possibly, cervicogenic. Aside from motor vehicle injuries, PTHAs may be secondary to work related injuries, slip and fall injuries, and violent altercations. These headaches are frequently part of the postconcussive syndrome, which refers to the above noted signs and symptoms that may follow a blow to the head or an acceleration/deceleration injury, but which may or may not induce an MTBI.

Acute post-traumatic tension-type headache, the most frequently diagnosed PTHA (defined as 15 headache days or fewer a month), may last up to 3 to 6 months; after that it becomes "chronic." The IHS has determined that 15 headache days or more a month defines chronic headache (HCCIHS, 1988). General pain management principles place pain as chronic after 3 to 6 months, after physiological healing has occurred. Up to 80% of patients with PTHA will have their pain remit within 6 months, leaving an estimated 20% of patients with chronic PTHA, which may last years in many cases.

A simple concussion may also be associated with PTHA, as well as, in the extremes, vegetative and even psychotic difficulties (Kojadinovic, Momcilovic, Popovic et al.,1998; Muller, 1974).

PTHA may also be associated with dizziness, irritability, and decreased concentration, even without the additional finding of a minor traumatic brain injury. Patients with chronic PTHA frequently present significant difficulties for the typical general practitioner, as well as the neurological specialist. This may be especially true if there is evidence of *de novo* migraine or cluster headache.

Because of the emotional/affective aspects that most frequently accompany PTHA, including depression and anxiety disorders as well as problems with anger, the affective component of PTHA may contribute to the patients' perception of the degree to which their PTHAs are disabling (Duckro, Chibnall, & Tomazic, 1995; Fordyce, Roueche, & Prigatano, 1982). Patients with PTHA may also meet the diagnostic criteria from the DMS-IV for post-traumatic stress disorder and, thus, require additional appropriate treatment (Hickling, Blanchard, Schwartz et al., 1992).

Clinically, it has been noted that patients with PTHA who also have a MTBI may have additional treatment-related problems. It may be difficult to establish the presence of an MTBI via neuropsychological testing as long as the PTHAs persist, as the headache pain generally makes such evaluations more difficult for the patient and may have a true negative effect on the testing itself, making the differential diagnosis more difficult (Duckro et al., 1995; Jay, 2000). Other reports indicate that there is little if any problem with a patient with MTBI performing a neuropsychological evaluation while he or she is having significant PTHA (Lake, Branca, Lutz, & Saper, 1999), but clinically this appears to be quite unrealistic.

Medicolegally, PTHA is a common problem, as the patient does not "look" ill and may have few if any abnormalities on examination. In depositions, or in court, a physician is frequently asked to explain why such a significant problem was found after a relatively minor "rear-end" automobile accident or slip and fall. Why, it is asked, do professional football players, for example, not have a high incidence of PTHA and/or MTBI? The answer is simple, and based on two things — physical conditioning and the fact that when they play, these people are always very prepared and always anticipate the possibility of physical contact or trauma. This differentiates them from the vast majority of people who are not even close to being in optimal physical condition and who are injured unexpectedly, before they are even aware of the impending trauma, and are therefore unable to physically prepare themselves for a trauma by, for example,

bracing themselves against the headrest before their car is struck from behind.

A great deal of research has shown that when the head is free, rather than confined, it is more susceptible to the effects of an acceleration/deceleration injury. Six decades ago, it was shown in cats that less force was required to produce concussion when the head was free to move, as compared with when it was fixed or confined in place (Denny-Brown & Russell, 1941). The concept of "whiplash," essentially a legal term, medically known as acceleration/deceleration, is very important, as it involves a multitude of medical aspects. When an acceleration/deceleration injury occurs (most frequently from a rear-end automobile accident), the physical or gravitational forces of a massive object such as a car striking another automobile are passed onto the most fragile and movable object not firmly secured in the automobile that was struck: the passenger. Even when the passenger is wearing a seat belt, the head — the ball at the end of a tether (the neck) — is first thrown forward and then backwards, when the tether can reach no farther and snaps back. If the head is turned at the moment of impact, the rotational forces are also very important, particularly in the etiology of a traumatic brain injury.

PTHA encompasses a number of different diagnostic entities. Specific diagnosis is needed for appropriate treatment. These diagnoses include

Post-traumatic migraine headache
Post-traumatic cluster headache
Post-traumatic tension-type headache
Temperomandibular joint (TMJ) related headache
Neuropathic pain syndromes
Cervicogenic headache

POST-TRAUMATIC MIGRAINE

Trauma may be one of the triggers of migraine, and in some cases it may be the predominant or even the sole precipitating event in the onset of migraine (Solomon, 1998). Trauma may trigger the first attack of migraine in a susceptible patient; biochemical along with epidemiological studies/factors have implicated trauma as the main etiological factor in the onset of new migraine (Solomon, 1998).

Whiplash, with or without MTBI, may decrease an individual's migraine threshold as well as exacerbate an episodic migraine pattern, which was previously under good control (Jennet & Frankowski, 1990).

Post-traumatic migraine, which may begin *de novo*, without a previous personal or family history of migraine, may have neurochemical similarities with MTBI, although they are not always found together. These may include increased extracellular potassium and intracellular sodium, calcium, and chloride; serotonergic changes;

decreases in magnesium; excessive release of excitatory amino acids; changes in catecholamine and endogenous opioid tonus; decreased glucose utilization; changes in neuropeptides and abnormalities in nitric oxide formation and function (Jay, 1999; Packard & Ham, 1997). Packard & Ham (1997) hypothesized that the presence of similar changes suggested PTHA associated with MTBI and migraine may share a common headache pathway.

Migraine, including post-traumatic migraine, may be associated with a number of neurological symptoms or phenomena. These may include transient global amnesia, vestibular dysfunction, visual and auditory changes, and possibly, an increased incidence of seizures (Buchholz & Reich, 1996; Jay, 1999; Leisman, 1990).

The trigeminovascular system is of great import in migraine (Jay, 1999). In some children who develop post-traumatic neurological deterioration without focal lesions after minor head trauma, there may be an association with an "unstable trigeminovascular reflex," which induces the release of perivascular vasodilatory peptides that can contribute to cerebral hyperemia (Sakas et al., 1997).

Transient global amnesia (TGA) was initially attributed to bilateral temporal lobe seizure phenomena, but more recently it has been attributed to migraine by some (Jay, 1999), and thought to be a totally separate disorder by others, possibly due to a different form of paroxysmal disorder in the brainstem (Schmidtke & Ehmsen, 1998). TGA in the pediatric population is still felt to be secondary to ischemia of the temporobasal structures induced by an MTBI and associated with a migrainous diathesis (Vohanka & Zouhar, 1988).

PTHA, including migraine, is commonly associated with children, adolescents, and teens who play football and frequently goes unreported (Sallis & Jones, 2000). Any degree of postconcussion headache in high school athletes a week postinjury is likely associated with an incomplete recovery postconcussion (Collins, Field, Iverson et al., 2003).

Caution is needed when returning high school athletes to the playing field after a concussion. On-field mental status changes appear to have some prognostic utility and should be taken into account when making return-to-play decisions after concussion. Athletes who show on-field mental status changes for more than 5 minutes have longer-lasting postconcussion symptoms and memory decline (Lovell, Collins, Iverson et al., 2003).

"Roller coaster" migraine is also seen, following many short but fairly significant brain insults delivered during a roller coaster ride, and may be an important factor in triggering a patient's post-traumatic migraine headache (McBeath & Nanda, 2000).

Migraine equivalents, transient neurological symptomatology not associated with headache, are not uncommon; proper diagnosis is more difficult to the generalist, as well as the neurologist. In some, possibly more susceptible indi-

viduals, minor, even trivial, head trauma can induce a migraine equivalent known as "footballer's migraine" as well as "post-traumatic cortical blindness." This particular migraine equivalent is certainly rare, but transient total blindness may certainly be cause to call for a total, "full court press" workup (Harrison & Walls, 1990).

Other, more common forms of transient neurological disturbances associated with migraine are brainstem symptoms including vestibular difficulties, such as dizziness, disequilibrium, vertigo, and motion intolerance. These symptoms may also present as a migraine equivalent, between migraine headache episodes or instead of the cephalic pain. Vertigo as a migraine equivalent may occur in about 25% of patients with migraine, with the diagnosis made, typically, by history of familial migraine, as all testing is usually negative. Migraine can also mimic Meniere's disease, with "vestibular Meniere's disease" more frequently, but still not commonly, associated with migraine (Baloh, 1997; Harker & Rassekh, 1988). Also, one should not forget the cervical causes of vertigo and dizziness, secondary to post-traumatic cervical and/or myofascial pathophysiology.

There is also a question of the possible relationship between post-traumatic migraine and post-traumatic benign encephalopathy. The latter, in children, may be associated with cortical blindness, brainstem disturbances, and seizure, lasting from 5 minutes to 48 hours (Vohanka & Zouhar, 1990).

A significant question then arises. Post-traumatic vertigo or dizziness is a very frequent accompaniment to MTBI. It may be secondary to peripheral, labyrinthine disturbance, brainstem disturbance secondary to trauma, or it may be a migraine equivalent. The importance of this differential is most significant, possibly, when treatment is attempted.

As noted, trauma may induce the first migraine attack in a possibly susceptible patient or increase the frequency and possibly the severity of preexisting migraine. The etiology of these changes may be secondary to neuronal and/or axonal abnormalities secondary to trauma as well as post-traumatic involvement of the trigeminovascular system.

Prophylactic treatment is typically with valproic acid, an anticonvulsant medication. The use of beta-blockers such as propranolol may also be useful, but this may have significant side effects. The same is true for verapamil. The use of a triptan for abortive care is well tolerated if used appropriately.

Cluster headache has also been seen secondary to head trauma, again possibly secondary to neuronal and/or axonal injury. The incidence ranges from 6 to 10% (Duckro, Greenberg, Schultz et al., 1992; Packard & Ham, 1997). Many times, this is seen as a primary chronic, rather than episodic, form of cluster or cluster-like headache. Clinically, this is one of the rarest forms of PTHA seen.

Treatment, abortive or prophylactic, has been dealt with elsewhere (Jay, 1999).

POST-TRAUMATIC TENSION-TYPE HEADACHE

Post-traumatic tension-type headache (PTTHA; with or without secondary analgesic rebound headache) is probably the most common primary headache disorder found after trauma. Diagnostically, and clinically, this entity appears to be almost if not totally identical to acute and chronic tension-type headache without a traumatic etiology.

The diagnostic criteria of tension-type headache, according to the IHS (HCCIHS, 1988) describes episodic tension-type headache as being recurrent headache occurring fewer than 15 days a month, lasting from 30 minutes to 7 days. The pain characteristics include two of four of the following: pain with a pressing/tightening (nonpulsating) quality; pain that is mild to moderate in intensity and may inhibit, but not prohibit, activities; pain that is always bilateral; and pain that is not aggravated by walking stairs or doing other routine physical activity. These criteria also state that both of the following are true: no nausea or vomiting, but anorexia may occur, and photophobia and phonophobia are absent, or one but not the other is present. All other organic diagnoses must be ruled out first, as well as other primary headache diagnoses, including migraine and cluster headache.

In PTTHA, like non-post-traumatic tension-type headache, the pain is typically described as aching or pressure like, "like there's a vice around my head." The pain has also been described as feeling like a tight band around the head. The pain is typically bilateral, although it may be unilateral. It may include various areas, some or all of the following: occipito-nuchal, bifrontal, bitemporal, suboccipital, at the vertex (crown) of the head; the pain may also extend into the neck and shoulders.

The pain intensity may wax and wane depending on a number of factors including movement, activity level, stress, and others. Even in PTTHA, emotional/psychological aspects may increase pain. There is a female preponderance.

Unlike patients with migraine headache, patients with PTTHA may carry on with their activities. Most take some form of analgesic, frequently on a daily basis. Without question, patients with PTTHA may also have migraine, post-traumatic or otherwise.

The patient with chronic PTTHA has headache 15 or more days a month. This is also a diagnostic exercise, as most frequently, nosologically, PTTHA may be one of several headache diagnoses all of which are part of a chronic daily headache differential, which would include analgesic rebound headache, at a minimum.

The patient with PTTHA frequently has headache daily or every other day. The headache is typically there when patients awaken and remains until they go to sleep.

The intensity of the pain varies, decreasing for several hours after analgesics are taken.

The majority of patients with PTTHA, if seen early on, will have associated pericranial muscle spasm or pain, while others will not, yet still complain of pain.

Patients with PTTHA will also endure elements of depression and anxiety. There is a "chicken and egg" aspect to this, in terms of which problem comes first. In many cases, central neurochemical changes begin concurrently with the injury and manifest as both pain and affective disturbances (see below).

Nosologically, post-traumatic headache is incident to trauma. Some problems may be noted in making this diagnosis: the patient may not experience direct trauma to the head, but have an acceleration/deceleration injury (whiplash); there may not be significant physical findings on examination (conversely, there may be physical findings that are missed unless a good musculoskeletal examination is done); secondary to the lack of profound physical findings, the patient may be labeled with a psychogenic diagnosis, or worse, with the term *malingering*.

When one understands the pathophysiology of the problem, specifically PTTHA, it should be understood that the history and physical examination must be done quite specifically, not with "one size fits all diagnoses." Knowing what questions to ask and what, on occasion, can be fairly subtle physical findings to look for on examination are obviously important.

PATHOPHYSIOLOGY OF PTTHA

The typical PTTHA begins post-acceleration/deceleration injury, which most frequently occurs during a motor vehicle accident. A slip and fall accident as well as a sports-related injury or a violent altercation can be the initiating event.

As described above, the head and the neck, likened to a ball on a chain, is flung forward and backward from acceleration/deceleration forces, frequently without direct trauma to the head, or following direct trauma to the head. However it occurs, the physical forces involved will cause the cervical and shoulder musculature, at a minimum, to be suddenly stretched and sustain both microtears and strain/trauma as well as endure a reflex muscle contraction after the sudden stretching. It is obviously important to understand the myofascial pain syndrome.

Pathological changes in the musculoskeletal system may initiate, modulate, or perpetuate PTTHA. Episodic and chronic PTTHA are, at least at first, secondary to a muscle-induced pain syndrome that is typically associated with the aforementioned myofascial pain syndrome (MPS).

The central nervous system controls muscle tone via systems that influence the gamma efferent neurons in the anterior horn cells of the spinal cord, which act on the alpha motor neurons supplying muscle spindles. The Ren-

shaw cells, apparently via the inhibitory neurotransmitter gamma aminobutyric acid (GABA), will influence this synaptic system. There is also supraspinal control from cortical, subcortical, and limbic afferent and efferent systems. Physiological and emotional inputs interact in the maintenance or flux of muscle tone. Adverse influences from both localized or regional myofascial nociception, with or without limbic (affective) stimulation, may produce significant muscle spasm, which, if prolonged, will become tonic with the additional aspects of increased anxiety or a maintained muscle contraction-pain cycle (Diamond & Dalessio, 1980; Speed, 1983). This helps to differentiate acute versus chronic PTTHA, to a degree.

Tonic or continued post-traumatic muscle contraction may induce hypoxia via compression of small blood vessels. Ischemia, the accumulation of pain-producing metabolites (bradykinin, lactic acid, serotonin, prostaglandins, etc.), may increase and potentiate muscle pain and reactive spasm. These nociception-enhancing or algetic chemicals may stimulate central mechanisms that through continued stimulation, may induce continued reactive muscle spasm/contraction and maintenance of the myogenic nociceptive cycle (Dorpat & Holmes, 1955; Hong, Kniffki, & Schmidt, 1978; Perl, Markle, & Katz, 1934).

Changes in peripheral blood flow in muscle seen in patients with chronic tension-type headache appear to be secondary to disturbances in the regulation of peripheral mechanisms due to central sensitization. Muscle pain in tension-type headache may be secondary to microtrauma of muscle fibers and tendonous insertions, accentuated by the accumulation of algetic metabolites: serotonin, bradykinin, and potassium ions effectively stimulate skeletal muscle nociceptors (Mense, 1993). When combinations of endogenous substances (serotonin, bradykinin, prostaglandin E_2, histamine) were slowly infused into the trapezius muscles of patients with episodic tension-type headache, they developed significantly more pain and muscle tenderness than healthy controls (Mork, Ashina, Bendtsen et al., 2003).

Although PTHA may include migraine, some of Moskowitz and Cutrer's work (1993) may be pertinent here. They have shown that when stimulated antidromically, the trigeminal nerve can release vasoactive/algetic peptides such as substance P, neurokinin A, bradykinin, neuropeptides Y, vasoactive intestinal peptide, and calcitonin-gene-related peptide from its afferent nerves, which innervate vascular structures. This can initiate a sterile inflammation that will lower the pain threshold, causing exacerbations in pain from typically benign behavior such as movement of the head. (This is *not* allodynia.) It is conceivable that such a disruption of the trigeminal system may possibly help determine neurogenic pain in some patients who may be susceptible to migraine and who develop PTHA.

As discussed below, the myofascial aspects of tension-type headache are clinically identical to those of PTTHA, with the significant difference in diagnoses being the etiology — post-traumatic or otherwise.

The MPS was, for a long while, ignored in the pathophysiology of headache of any type. Some researchers found a causal relationship between muscle spasm and headache (Martin & Mathews, 1978; Rodbard, 1970; Sakuta, 1990), while others have felt that muscle spasm associated with headache is an epiphenomenona, not the etiology of headache (Haynes, Cuevas, & Gannon, 1982; Philips, 1978; Philips & Hunter, 1982; Riley, 1983; Robinson, 1980; Simons, Day, Goodell, & Wolff, 1943), but a reflexive response. Other authors have indicated that muscle activity/spasm or increased tone may be more pronounced in migraine than in tension-type headaches (Bakal & Kaganov, 1977; Cohen, 1978).

Unfortunately, this research, which was obtained via electromyographic (EMG) studies, appears to be problematic, as the various authors evaluated different groups of muscles in different types of patients, many of whom had poorly defined diagnoses (Anderson & Franks, 1981; Bakal & Kaganov, 1977; Martin & Mathews, 1978; Pozniak-Patewicz, 1976). Other authors defined chronic tension-type headache as an entity with or without associated pericranial muscle disorder. The concept of muscle fatigue was not taken into consideration; metabolically spent muscles may become relatively flaccid, losing aspects of increased tonus or spasm.

Also of interest is the fact that the vast majority of research deals with tension-type headache, not PTTHA; in spite of identical physical/clinical findings as well as historical findings, all are essentially the same, except for the presence of initiating trauma.

One study found a positive correlation between pericranial muscle tenderness and headache intensity, with the former felt to be a source of nociception (Langemark & Olesen, 1987; Shoenen, Pasqua, & Sianard-Gainko, 1991). Another study (Langemark, Jensen, Jensen, & Olesen, 1989) found that pressure pain thresholds in patients with chronic tension-type headache were highly dependent on myofascial factors. This study indicated that the generally lower pain thresholds in patients with chronic tension-type headache suggested a dysmodulation of central nociception. A lower pain threshold in patients with chronic tension-type headache, when compared with normal volunteers, was also noted (Bendtsen, Jensen, & Olesen, 1996a; Borgeat, Hade, Elie, & Larouche, 1984). Findings of decreased pressure pain and tolerance thresholds indicate the presence of allodynia (pain elicited by non-painful stimuli) and hyperalgesia (increased sensitivity to painful stimuli), in patients with chronic tension-type headache. That patients with chronic tension-type headache are hypersensitive to different types of stimuli applied at both cephalic and extracephalic regions would indicate that the pain sensitivity in the central nervous system is increased in the supraspinal regions.

Scalp muscle tenderness and sensitivity to pain in both patients with migraine and patients with tension-type headache were measured in another study, and the author indicated that the pathophysiology of tension-type headache may involve a diffuse disruption of central pain-modulating mechanism (Drummond, 1987). Lower pain thresholds were also found in patients diagnosed with myofascial pain syndromes, including lower back pain (Malow, Grimm, & Olsen, 1980; Yang, Richlin, Brand, Wagner, & Clark, 1985).

It should be noted that the diagnoses in the majority of research papers include tension-type headache (TTHA), but whether they were associated with trauma is typically not indicated.

Both patients with PTTHA and with chronic tension-type headache frequently have a stereotypic posture, with their shoulders raised and their heads flexed forward. This tightly held posture, or muscular splinting, is effective in preventing unconscious head movement that may induce pain. The continued splinting, by maintaining tonic muscle contraction, also works to increase myogenic nociception and perpetuate this cycle.

The pericranial muscles are innervated by sensory fibers in nerves from the second or third cervical roots and in the trigeminal nerve (Langemark & Jensen, 1988). The functions of these muscles contribute to the maintenance of posture and the stabilization of the head, as well as withdrawal and protection of the head. These factors contribute to the myofascial aspects of both TTHA and PTTHA.

Muscle fatigue occurs, both metabolic and neurochemical in nature, and typically follows prolonged or tonic muscle spasm. It may be secondary to "sympatheticopenia" or the depletion of epinephrine and norepinephrine (NEP), the peripheral sympathetic transmitters (Cailliet, 1993). The muscle spindle is directly affected by the sympathetic nervous system via these neurotransmitters, particularly NEP. Prolonged and sustained peripheral sympathetic activity may lead to depletion of NEP at the synaptic receptors. Continued afferent sympathetic input from myogenic nociception, at least in part from buildup through ischemia of nociceptive metabolites, may result in sympatheticopenia (Cailliet, 1993; Jay, 1996). There are also significant sympathetic aspects of myofascial pain (Jay, 1995b).

The sympathetic nervous system also interacts with the trigeminal system and may act as an activating entity. Sympathetic fibers from the stellate ganglia innervate the cranial and cervical structures. These fibers extend rostrally and form a large nerve plexus behind the origin of the vertebral artery and superiorly, with the cervical ganglia lying on the capitus longus muscle behind the carotid sheath at the base of the skull. Sympathetic fibers supply the carotid, basilar, and cerebellar circulatory vessels. Sympathetic fibers in the carotid sheath interconnect with

the caudate nucleus of the trigeminal nerve, providing interactions between the two systems (Shealy, 1995). Autonomic fibers surrounding the carotid do appear to be involved in the induction of significant pain in patients with cluster headache (Jay, 2001).

Tenderness of the cervical, thoracic, and lumbar paravertebral muscles is also positively correlated with pericranial muscle tenderness (Langemark, Olesen, Poulsen, & Bech, 1988). It has also been noted that the contraction of shoulder and cervical muscles as well as emotional arousal contributes to tension-type headache (Murphy & Lehrer, 1990). These issues are significant factors in PTTHA.

Three mechanisms of muscle pain are thought to be relevant to acute, but more often chronic, tension-type headache, which has the same physiological stigmata of PTTHA, in that myogenic nociception may be induced by (1) low-grade inflammation associated with the release of algetic, or pain-inducing substances, rather than signs of acute inflammation; (2) short- or long-lasting relative ischemia; and (3) tearing of ligaments and tendons secondary to abnormal sustained muscle tension (Langemark & Jensen, 1988). These factors do not take into consideration the possibly more significant initial trauma from acceleration/deceleration injuries, slip and fall accidents, and other reasons for direct or indirect head trauma that induces muscle trauma, primarily or secondarily.

Increased myofascial pain sensitivity in tension-type headache may be secondary to activation or sensitization of peripheral nociceptors, most probably from a combination of mechanisms.

MYOFASCIAL PAIN SYNDROME

Travell and Rinzler (1952) identified the contribution of musculoskeletal factors in the etiology of acute and chronic tension-type headache. They demonstrated that there are consistent patterns of referred pain from trigger points within specific muscle and defined perpetuating factors that convert acute myofascial pain into a chronic pain syndrome (Travell & Simons, 1983).

The myofascial pain syndrome is a localized or regional pain problem associated with small zones of hypersensitivity within skeletal muscle called trigger points. With palpation of these points, pain is referred to adjacent or even distant sites. Trigger points in the head, neck, and upper back may elicit headache, as well as tinnitus, vertigo, and lacrimation, all features noted in patients with PTTHA as well as chronic tension-type headache (Jay, 1995a; see Figure 26.1 through Figure 26.8).

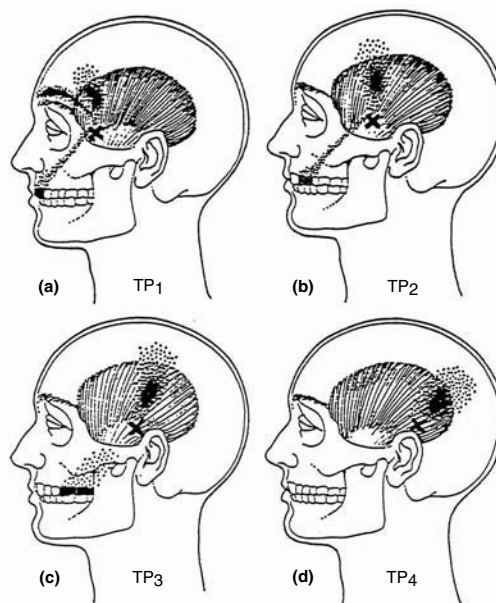
Trigger points may be active, with consistently reproducible pain on palpation, or latent, with no clinically associated complaints of pain, but with associated muscle dysfunction. Trigger points may shift between active and latent states. Clinically, continuous myogenic nociception from active trigger points appears to be a prime instigator of the central


FIGURE 26.1 Referred pain patterns from trigger points in the left temporalis muscle. Dark areas show essential zones; spillover zones are stippled. (a) Anterior "spokes" of pain arising form the anterior fibers, trigger point 1 region. (b) and (c) Middle spokes, trigger point 2 and 3 regions. neurochemical nociceptive dysmodulation found in patients with chronic tension-type headache as well as PTTHA.

Increased stiffness, weakness, and fatigue as well as a decreased range of motion are typically found in muscles in which trigger points are identified. These muscles may be shortened, with increased pain perceived on stretching. Patients may protect these muscles by adapting poor posture with sustained contraction, as noted above (Fricton, 1990; Langemark & Jesnen, 1988). The resulting muscular restrictions may perpetuate existing trigger points and aid in the development of others.

Other authors (Fricton, Kroening, Haley, & Siegart, 1985) found that a large percentage of patients suffering from an MPS of the head and neck were found to have significant postural problems, with forward head tilt and rounded shoulders, as well as poor standing and sitting postures, all findings frequently seen in both patients with chronic tension-type headache as well as those with PTTHA.

MPS of the head and neck, via myofascial trigger point referred pain, may mimic other conditions, including migraine headache, TMJ dysfunction, sinusitis, and cervical neuralgias, as well as various otological problems including tinnitus, ear pain, and dizziness (Fricton, 1990).

The onset of an acute, single-muscle MPS may be associated with trauma, such as an acceleration/deceleration injury, a slip and fall, or even a direct blow. It may also come on insidiously, for example, in patients who work multiple hours typing or at the computer.

The MPS may show a spontaneous regression to a latent status, with continued muscular dysfunction, but with significant diminution of the initial pain complaints. In other patients, the MPS may "metastasize" and involve associated musculature, becoming regional, or even involving multiple muscular regions.

OTHER CLINICAL ASPECTS

After the onset of chronic PTTHA (CPTTHA), emotional/psychological factors including stress, anxiety, and depression may become important in the maintenance or perpetuation of the headache. This is frequently seen in the patients with the postconcussive syndrome. Patients with MTBI have other significant emotional stigmas that contribute to this headache diathesis.

A major difficulty in the literature is that determinations of depression, anxiety, and other affective components to the PTTHA are found to occur in patients with CPTTHA. Without premorbid psychological analyses, it is very difficult to state with any certainty whether these patients were depressed or anxious prior to the onset of their headache problems. It is therefore possible that the neurochemical changes associated with CPTTHA, such as probable central serotonergic dysfunction, initiate depression as a response to these pain-induced neurochemical changes (see below).

Some authors have noted that the "conversion V" found in the hypochondriasis, depression, and hysteria scales of the Minnesota Multiphasic Personality Inventory is a marker for chronic TTHA as well as PTTHA; however, similar responses are found in patients with chronic non-headache pain (Jay, Grove, & Grove, 1987; Kudrow, 1986; Martin & Rome, 1967).

ASSOCIATED SLEEP DISORDERS

There appears to be an important relationship among sleep, headache, and the muscle-pain syndromes. Central biogenic amines, particularly serotonin and norepinephrine, are important to sleep physiology as well as to the central pain-modulating systems. Both human and animal research indicates that central serotonin metabolism plays a role in pain modulation, affective states, and the regulation of non-REM (rapid eye movement) sleep (Goldenberg, 1990).

A high incidence of sleep difficulties has been found in patients with chronic tension-type headache (Mathew, Glaze, & Frost, 1985). Different sleep disorders appear to be associated with different headache entities. CTTHA and CPTTHA appear to be similar if not identical. Migraine has been found to occur in association with REM sleep, as well as have an association with excessive stage 3, 4, and REM sleep (Shahota & Dexter, 1990). Chronic TTHA has been found to be associated with frequent awakenings and decreased slow wave sleep, as well as an alpha-wave intrusion into stage 4 sleep (Drake, Pakalnis, Andrews, & Bogner, 1990).

Moldofsky, Scariabrick, England et al. (1975) noted a disturbance in stage 4 sleep to be the first laboratory-based abnormality found in fibromyalgia. They induced a similar alpha non-REM pattern of alpha-wave intrusion in delta (stage 4) sleep in normal subjects by stage 4 sleep deprivation. These subjects developed musculoskeletal pain and affective changes comparable with those seen in patients with fibromyalgia. Small doses of serotonergic tricyclic antidepressant medications, which reduced the

alpha intrusions into stage 4 sleep, were used to ameliorate the symptoms.

Alpha-wave intrusions into deep sleep have also been found in patients with other chronic pain syndromes, including rheumatoid arthritis (Goldenberg, 1989). The alpha non-REM disturbance has also been seen in asymptomatic people as well as in those who experience severe emotional stress, such as combat veterans (Goldenberg, 1990). In the latter group, the veterans with this sleep disorder also complained of chronic headaches, diffuse pain, and emotional distress.

Sleep disturbance is also associated with increased pain severity. As noted above, patients with chronic headache seem to have a higher incidence of sleep abnormalities than do normal, pain-free subjects. Etiological aspects of chronic headache may be linked to sleep abnormalities as an initiating event or as the result of the underlying pathologically dysmodulated neurochemical factors inducing a sleep disorder.

OTHER POSSIBLE ASSOCIATED FACTORS

There are several possible mechanical etiologies of chronic PTTHA. First is cervical spondylosis, which is defined as a degenerative disease affecting intervertebral discs and apophyseal joints of the cervical spine. While several authors indicate a possible correlation between cervical spondylosis and TTHA and PTTHA (Harrison & Walls, 1990; Jay, 1999; Packard & Ham, 1997), others conclude the contrary (Iansek, Heywood, Karnaghan, & Nalla, 1987), suggesting that the basis of existing headache is secondary to muscle contraction and/or central neurochemical dysmodulation.

Cervicogenic headache, from referred pain perceived in any region of the head that was referred by a primary source in the musculoskeletal tissues innervated by cervical nerves, is a second suggestive diagnosis. It is discussed in detail below.

Last, the dental literature has been most active in reporting a possible correlation between TMJ dysfunction and tension-type headache, including PTTHA (Forsell, 1985; Mikail & Rosen, 1980). The relationship appears to be dependent mainly on tenderness of the masticatory muscles, which may have other etiologies and induce TMJ dysfunction, when it exists, on a secondary basis (Magnusson & Carlsson, 1978a, 1978b; Philips & Hunter, 1982). Clinically, in the presence of direct trauma to the TMJ, the incidence of anatomical dysfunction is increased.

NEUROPHYSIOLOGICAL CHANGES

Fewer than 50% of patients with PTTHA complain of mild associated autonomic symptoms such as lack of appetite, hyperirritability, dizziness, and increased light sensitivity (photophobia) (Olesen, 1988). Notably, some of these symptoms may be secondary to autonomic changes associated with active myofascial trigger points located in the head and neck.

While muscle contraction and tenderness may be interpreted as primary symptoms of PTTHA, EMG activity, and muscle tenderness increase, in some studies more often during migraine than tension-type headache (Cohen, 1978; Olesen, 1978; Tfelt-Hansen, Lous, & Olesen, 1981).

In research comparing patients with TTHA with patients with common migraine exposed to auditory stimulation, patients with TTHA showed a lower heart-rate reactivity than patients with migraine (Ellertsen, Norby, & Sjaastad, 1987). It was shown that patients with TTHA exhibited the greatest cardiovascular arousal during headache (Haynes, 1981). In another study (Bakal and Kaganov, 1977), both patients with migraine and patients with TTHA had decreased pulse velocity. In a psychophysiological comparison of migraine and tension-type headache, it was found that patients with migraine are vasodilated and patients with TTHA are vasoconstricted both during and between headache episodes (Cohen, 1978). During another study, administration of ergotamine tartrate, a vasoconstrictor, increased the pain of tension-type headache, while amyl nitrate, a vasodilator, yielded only transient pain relief (Tunis & Wolff, 1954).

Greater sympathetic arousal was found in patients with tension-type headache as compared with controls (Murphy & Lehrer, 1990). Another study reported both patients with TTHA and patients with migraine demonstrated cardiovascular sympathetic hypofunction, indicated by low basal levels of NEP, as well as orthostatic hypotension (Mikamo, Takeshima, & Takahashi, 1989). It has been suggested that patients with TTHA have phasic hypersympathetic activity, while migraineurs do not differ from controls during psychogalvanic response testing (Covelli & Ferrannini, 1987).

Evidence of pupillary sympathetic hypofunction and subtle anisocoria has been found in both patients with tension-type headache and patients with migraine (Takeshima, Takao, & Takahaishi, 1987). It was suggested that this may have reflected a central bioaminergic system dysfunction. Another study suggested a pupillary sympathetic system imbalance in patients with CTTHA, who showed asymmetric mydriasis after tyramine instillation and in the physiologic pupillary tests (Shimomura & Takahashi, 1986). Oculomotor dysfunction in the amplitude and number of corrective saccades during testing of patients with TTHA has also been found (Rosenhall, Johansson, & Orndahl, 1987).

The oculocephalic sympathetic functions were evaluated in five patients with PTHA (Khurana, 1995). Thermoregulatory sweat testing and biochemical papillary responses were evaluated. Four patients who had experienced a "whiplash" injury were found to have bilateral sympathetic dysfunction, while one patient who had

trauma to the forehead had unilateral sympathetic dysfunction. The biochemical papillary responses were diagnostic soon after the initial post-traumatic injury, while the thermoregulatory sweat test was found to be abnormal up to 56 months postinjury. The author also noted that the oculocephalic sympathetic dysfunction may induce head pain by an effect on cephalic pain via its effects on the trigeminovascular system.

Drummond (1986) has reported increased photophobia in patients with TTHA as compared with controls. He hypothesized that changes in central neurotransmitter modulation may induce increased sensitivity or hyperexcitability-induced photophobia.

Episodic platelet abnormalities with associated serotonergic dysfunction have been well documented in migraine (D'Andrea, Toldeo, Cortelazzo, & Milone, 1982; Hanington, Jones, Amess, & Wachowicz, 1981). Nonepisodic decreased platelet serotonin in patients with chronic tension-type headache has also been documented (Rolf, Wiele, & Brune, 1981).

Patients with PTHA have been found to have decreased regional cerebral blood flow, with regional and hemispheric asymmetries, which supports an organic etiology for chronic PTHA (Gilkey, Ramadan, Aurora, & Welch, 1997).

The P300 event-related potential was found to be useful in evaluating cognitive problems in patients with the postconcussive syndrome with associated PTHA. Abnormal P300 latency was found to be associated with decrements in cognition, in spite of the lack of detectable lesions found on neuroimaging, indicating that functional impairment of specific cerebral areas can occur in patients with associated PTHA, cognitive deficits, and abnormal P300 latencies only (Alberti et al., 2001).

Another group looked at the changes in auditory evoked potentials in patients with postconcussive syndrome that included PTHA. Consistent abnormalities were noted which could reflect post-traumatic disturbances in the presumed subcortical middle latency auditory evoked potential generators, or in the frontal or temporal cortical structures that would modulate them (Drake, Weate, & Newell, 1996).

Brainstem-mediated antinociceptive inhibitory reflexes of the temporalis muscles, using the latencies and durations of the early and late exteroceptive suppression (ES1 and ES2), were evaluated. Abnormalities of the trigeminal inhibitory temporalis reflex was felt to be based on a transient dysfunction of the brainstem-mediated reflex circuit specifically of the late polysynaptic pathways, with the reflex abnormalities considered to be correlates of the post-traumatic cervico-cephalic pain syndrome, which pointed to alterations in central pain control in patients with acute PTHA secondary to whiplash injury (Keidel, Rieschke, Juptner, & Diener, 1994; Keidel, Rieschke, Stude et al., 2001).

Again, it must be reiterated that the single differentiating aspect between chronic TTHA and chronic PTTHA is the historical factor of some form of trauma. Findings on examination and treatment techniques and methodology are the same, with the same outcomes in both entities, if done appropriately. The research noted above does not differentiate patients with TTHA from those with PTTHA. Clinically and diagnostically there are few, if any, differences.

NEUROANATOMY AND NEUROCHEMISTRY

The central modulation of pain appears to originate in the brainstem and involves at least two systems. The "descending" inhibitory analgesia system appears to regulate the "gating" mechanisms of the spinal cord. This system includes the midbrain periaquaductal gray region, the medial medullary raphe nuclei, and the adjacent reticular formation, as well as dorsal horn neurons in the spinal cord (Basbaum & Fields, 1984). The "ascending" pain modulation system originates in the midbrain and is projected to the thalamus (Andersen & Dafny, 1983). Both systems utilize biogenic amines, opioid peptides, and nonopioid peptides (Andersen & Dafny, 1983; Basbaum & Fields, 1984; Raskin, 1988b).

The ascending system appears to show more relevance to headache disorders. This system has projections from the brainstem to the medial thalamus, which include large numbers of serotonergic and opiate receptors. The midbrain dorsal raphe nucleus, a serotonergic nucleus, projects to the medial thalamus and is associated with pain perception. Serotonergic projections to the forebrain are implicated in the regulation of the sleep cycle, mood changes, pain perception, and the hypothalamic regulation of hormone release (Raskin, 1988).

The endogenous opiate system (EOS) within the central nervous system may act as a nociceptive "rheostat" or "algostat," setting pain modulation to a specific level. As this level changes, an individual's pain tolerance may also change. Fluctuations in pain intensity may be interpreted as secondary to fluctuations in the function of antinociceptive pathways (Fields, 1988; Wall, 1988). Headache, along with other "non-organic" central pain problems, is thought to be the most common expression of impairment of the antinociceptive systems (Sicuteri, 1982).

The EOS modulates the neurovegetative triad of pain, depression, and autonomic disturbances that are found in only two conditions: chronic tension-type headache (post-traumatic or otherwise) and acute morphine abstinence (Sicuteri, 1982). The EOS is also implicated as primary protagonist in idiopathic headadche (Sicuteri, 1982; Sicuteri, Spillantini, & Fanciullacci, 1985). Reduced plasma concentrations of beta-endorphin have been found in patients with idiopathic headache, including those with chronic (and post-traumatic) tension-type headache

(Facchinetti & Genazzani, 1988; Genazzani, Nappi, Gacchinetti et al., 1984; Mosnaim, Diamond, Wolf et al., 1989; Nappi, Gacchinetti, Legnante et al., 1982).

A primary relationship also exists between the EOS and the biogenic amine systems that are intrinsic to both the pathophysiology of pain modulation and its treatment. Clinical and neuropharmacological information indicates that dysmodulated serotonergic neurotransmission probably generates chronic headache and head pain. It has also been noted that the ordinary, acute, or periodic headache may be the "noise" of serotonergic neurotransmission (Raskin, 1988).

Decreased levels of serotonin (Giacovazzo, Bernoni, Di Sabato, & Martelletti, 1990; Rolf et al., 1981; Shimomura & Takahashi, 1990) (with good indications of an impairment of serotonergic metabolism in patients with chronic tension-type headache), substance P, an excitatory neuropeptide (Almay, Johansson, von Knorring et al., 1988; Pernow, 1983), and plasma norepinephrine (Takeshima, Takao, Urakami et al., 1989) are found in patients with chronic tension-type headache. The last is also indicative of peripheral sympathetic hypofunction, which may participate in the etiology or maintenance of central opioid dysfunction (Nappi et al., 1982). Platelet GABA levels are significantly increased in patients with chronic tension-type headache. This may also act as a balance mechanism to deal with neuronal hyperexcitability and be associated with depression (Kowa, Shimomura, & Takahashi, 1992).

The opioid receptor mechanisms appear to be very susceptible to desensitization, or the development of tolerance. In patients with chronic tension-type headache, opioid receptor hypersensitivity is marked, secondary to the chronically diminished secretion of neurotransmitters. This "empty neuron syndrome" may involve both autonomic and nociceptive afferent systems, as well as being latent, subpathological, or pathological with spontaneous manifestations (Sicuteri, Nicolodi, & Fusco, 1988).

The EOS modulates the activity of monoaminergic neurons. A chronic EOS deficiency can provoke transmitter leakage, of both opioid and bioaminergic neurotransmitters, and lead to neuronal exhaustion and "emptying," as well as compensatory effector cell hypersensitivity. The poor release of neurotransmitter along with cell/receptor hypersensitivity appears to be the most important phenomenon of the hypoendorphin syndromes. It has also been concluded that chronic tension-type headache, and clinically PTTHA, may result from dysmodulation of nociceptive impulses, with associated sensitized receptors (Langemark et al., 1989).

Central factors may also be responsible for increased myofascial pain and sensitivity in patients with PTTHA. These central factors may include sensitization of second-order neurons in the spinal cord dorsal horn and trigeminal nucleus along with sensitization of supraspinal neurons and decreased descending antinociceptive activity from supraspinal neuronal systems (Bendtsen, 2000).

Chronic tension-type headache, including the chronic post-traumatic tension-type headache, may be, along with other chronic idiopathic headache, a "pain disease" directly linked to central dysmodulation of the nociceptive and antinociceptive systems, either latent or pathological in nature. Research indicates that at least two arms of the main endogenous antinociceptive systems, the EOS and the serotonergic systems, are involved in the pathogenesis of chronic tension-type headache. Clinical diagnosis and treatment of PTTHA demonstrate identical findings. This problem appears to be progressive, and the dysfunctions may result from neuronal exhaustion secondary to continuous activation of these systems (Facchinetti & Genazzani, 1988; Sicuteri et al., 1988).

PATHOPHYSIOLOGY

Looking at the upper portion of Figure 26.1, most of the basics have been mentioned: Continuous peripheral stimulation from myofascial nociceptive input from an MPS, with or without trigger points, may effectively trigger a change in the central pain "rheostat" associated with nociceptive input, secondary to the continuous need for pain-modulating antinociceptive neurotransmitters. This increased myofascial pain sensitivity may be secondary to activation or sensitization of peripheral nociceptors. The affective aspects of pain, including depression, anxiety, and fear, are secondary to changes in neurotransmitters such as serotonin and norepinephrine and directly influence myofascial nociception, as well as further reinforce central neurochemical changes.

After between 4 to 6 and 12 weeks or so, changes in the central nervous system's central modulation of nociception can occur. Secondary to continuous peripheral nociceptive stimulation, in association with affective changes, the central modulating mechanisms will assume a primary rather than a secondary or reactive role in pain perception, as well as antinociception, shifting the initiating aspects of pain perception from the peripheral regions to the central nervous system.

As noted earlier, patients with chronic tension-type headache show lower pressure pain tolerance than normal controls which indicates that the central nervous system is sensitized at the level of the spinal cord dorsal horn and trigeminal nucleus (Bendtsen, 2000; Bendtsen, Jensen, & Olesen, 1996b). Sensitivity in muscle (Bendtsen, 2003) as well as the skin is also noted, and the latter may indicate an expansion of receptive fields and convergence secondary to central sensitization.

This intrinsic shift may make innocuous stimuli more aggravating to the pain-modulating systems, the "irritable everything syndrome." The already dysmodulated internal feedback mechanisms may react until central neurochem-

ical mechanisms dominate, secondary to neurotransmitter exhaustion, and receptor hypersensitivity and abnormal biogenic amine metabolism/exhaustion occur. These neurochemical changes may induce and/or exacerbate a sleep disorder (serotonergic in nature, from the nucleus raphe magnus), which by itself can perpetuate the central neurochemical dysmodulation, which is primarily responsible for chronic tension-type headache.

Chronic post-traumatic tension-type headache, whether or not it is associated with an MTBI, has the same pathophysiological mechanisms. In the presence of an MTBI, other significant pathophysiological changes occur, which can potentiate or exacerbate the mechanisms described above.

In the face of dysmodulated neurochemical systems found in chronic tension-type headache, add direct myofascial trauma as an initiating event. The effects of diffuse axonal injury from MTBI, which also affects the neurochemistry of the brain as neuronal degeneration and death occurs, can exacerbate the neurotransmitter pathophysiology. This may also explain the initiation of *de novo* migraine, as brainstem trigeminovascular mechanisms may obviously be affected. Finally, excitotoxic injury, which leads to cell death from the over-exuberant production of acetylcholine and glutamate, also may induce significant neuropathological "holes" in the primary neurotransmitter systems and exacerbate the headache pathophysiology.

Affective changes follow, with the additional problem of possible cognitive changes resulting from MTBI. The cognitive changes may make treatment of PTTHA more difficult.

PTTHA is the most common sequela of an MTBI. It may also be associated with iatrogenic analgesic abuse. Before treatment or even diagnosis of cognitive deficits is attempted, inappropriate medications must be stopped and the headache ameliorated. Most commonly, for this to be done, the patient must be treated using an interdisciplinary headache treatment protocol. Please see the *Headache Handbook: Diagnosis and Treatment* for the details of this protocol (Jay, 1999).

The neurochemical factors leading to the perpetuation of PTTHA appear to be further and more complexly involved than in chronic tension-type headache without associated MTBI. Treatment is most appropriately and cost-effectively performed in an interdisciplinary headache rehabilitation program. Tricyclic medications, GABAnergic medications, and nonsteroidal anti-inflammatory drugs (NSAIDs) are appropriate, while narcotics, Dilantin, barbiturates, and early-generation benzodiazepines are not.

It is worth noting that patients with MTBI who complain of headache do not appear to perceive their headache pain the same way as patients with headache without MTBI. These patients know that they have headaches. On a scale of 0 (no pain) to 10 (worst pain imaginable),

individual patients, when first seen, will give high numbers, e.g., 7 to 10, which is correlated to pathophysiological myofascial findings, including decreased cervical range of motion, muscle spasm, active trigger points, and more. As they go through treatment, they will regain appropriate physical functioning: normal cervical range of motion, amelioration of spasm and trigger points, etc, with a marked associated improvement of function. The patients' affect will be brighter, they will smile, have fewer if any pain behaviors, and resume doing the physical things they enjoy.

Yet, when asked, they will continue to state that their headache pain is at the same level of 7 to 10 as when they were first seen. Whether they are perseverating or are just unable to give an accurate subjective pain level (probable frontal lobe involvement), their stated pain levels may not change very much at all. Therefore, they must be evaluated on improvements in function, not by self-reported subjective decrements in headache pain levels.

EVALUATION AND TREATMENT OF PTTHA

As Olesen (1991) also noted, the expression of headache is the sum of the input into the trigeminal system, with vascular, sympathetic, myofascial, and central factors all possibly contributing to the clinical picture of headache. It is up to the clinician to try to determine how much each aspect contributes to the clinical picture — only then can an appropriate treatment paradigm be determined.

In attempting to acquire this information, the medical evaluation includes a very detailed history, which must include the facts, as the patient remembers them, of the initiating trauma; preexisting headache; a very detailed headache history including the location, intensity, frequency, duration of the headache; the pain attributes (very important); associated symptoms such as nausea and vomiting; and factors that increase or decrease the headache pain. A thorough medication history is necessary, typically asking specifically about over-the-counter analgesic medications, which can also produce analgesic rebound headache.

At least the mini-mental status evaluation should be performed, with testing of the patient's short- and long-term memory, mental acuity, and the presence of behavioral changes. It may be necessary to speak with the patient's family to determine some of these changes, as pain may cause the patient to focus on things other than a possible loss of cognitive functioning.

An evaluation of the patient's psychological status should be done, including screens for depression (and all three neurovegetative aspects: sleep, appetite, and libido), as well as personality changes, motivational changes, and ability to continue working. Again, it may be necessary to speak with family members or even co-workers to determine what is happening. Laboratory tests are typically not

helpful. Neuroimaging will most frequently have been done after the injury. The general physical examination, neurological examination, and musculoskeletal examinations follow.

The neurological examination of patients with migraine is, in the absence of complicated aura, negative. The examination of the patient with cluster headache may yield signs of a partial Horner's syndrome. The examination of the patient with PTTHA may yield a great deal of information.

Typically, the neurological examination is negative. It's the musculoskeletal evaluation that will provide the facts. Begin by observing the patient's shoulders. In the vast majority of cases, there is an asymmetry of the acromioclavicular joints, with one higher than the other secondary to greater ipsilateral muscle spasm. The large muscles should be carefully palpated for both general tenderness and the presence of trigger points. These include the trapezius muscles, the deltoids, the scalenes, the rhomboids, the levaeter scapulae, and all associated muscles, including the pericranial musculature. Pay careful attention to the sternocleidomastoid muscles, particularly in patients complaining of dizziness and tinnitus. Palpate the bioccipital and bitemporal insertions. Look for true pericranial muscle tenderness, as well as masseter pain or tenderness. Observe the patient open the mouth: look for the amount of space between the teeth and see if the jaw deviates. Perform the passive as well as active cervical range of motion. Observe the patient's head: is it flexed forward? Is it tilted to one side? What about the shoulders: are they rounded? Rolled forward? Evaluate the presence and degree of muscle spasm found in the paravertebral muscles over the entire length of the spine. If the patient is a chronic tension-type headache sufferer, post-traumatic or otherwise, or if there is a complaint of upper extremity or hand numbness, perform an axillary stretch maneuver as well as the Adson's maneuver to evaluate for a myogenic thoracic outlet syndrome. And these are just the basics.

Until you know what you are dealing with physiologically, it is impossible to determine an appropriate treatment plan. Once you know, and are positive about your diagnosis reached by the history and physical/neurological examination, you can begin to formulate a treatment plan.

Treatment of Acute PTTHA

The medical management of acute or episodic PTTHA is relatively simple. Remember that the older nomenclature titled these headaches as "acute muscle contraction headache" or "tension headache." This form of headache is the most common, as previously indicated, accounting for up to 80% of all non-organic types of headache. It has been estimated that greater than 90% of Americans experience an acute tension-type headache, with or without predis-

posing trauma, at some time. The majority of these headaches are self-treated with over-the-counter medications and therefore never come to the attention of a physician. This indicates that the statistics are probably low, in that a fairly large number go unnoticed by physicians.

The greatest problem in the treatment of acute PTTHA is the avoidance of the development of analgesic rebound headache, which can easily occur if a patient is overmedicated. This is one step into the development of chronic or daily PTTHA.

Physicians should be particularly familiar with the various types of medications that can be used for patients complaining of acute PTTHA. The old adage that less is better certainly applies here. Many patients deal with the pain and discomfort by taking two aspirin and relaxing. Exercise is useful, as is a simple glass of wine, on an occasional basis. Any type of relaxation that distracts patients from their headache is useful.

Dealing with the medication management, physicians have a more than ample supply from which to choose. It may therefore be tempting to overtreat a minor headache with medications that have a significant risk of dependency. The simple analgesics are easily chosen by the patient, if not the physician. They are inexpensive and easy to get. They include aspirin and acetaminophen. Like the other NSAIDs, aspirin appears to work by inhibiting the synthesis of prostaglandin by blocking the action of cyclooxygenase, an enzyme that enables the conversion of arachidonic acid to prostaglandin to occur. Remember that prostaglandins are synthesized from cellular membrane phospholipids after activation or injury and sensitize pain receptors.

Aspirin, the prototypical NSAID, has anti-inflammatory and antipyretic properties, along with its pain-relieving properties. The recommended adult dose for treatment of acute PTTHA is 650 mg every 6 hours. Taking the aspirin with milk or food may decrease gastric irritation. Aspirin can also double bleeding time for 4 to 7 days after taking 650 mg. Peak blood levels are found after 45 minutes. The plasma half-life is 2 to 3 hours.

Acetaminophen usage is common. It provides about the same amount of analgesia as aspirin, but does not have the gastrointestinal side effects. That acetaminophen may work by inhibition of prostaglandin synthesis in the central nervous system has been suggested. It has much weaker anti-inflammatory activity than aspirin. Peak plasma levels occur between 30 and 60 minutes. Its plasma half-life is 2 to 4 hours.

Ibuprofen, an NSAID, is also available over the counter in doses of 200 mg per tablet. It can cause significant gastrointestinal distress. It has a half-life of 2 to 4 hours, with peak plasma levels attained in 1 to 2 hours. The adult dosage is 200 to 400 mg every 4 to 6 hours, with a maximum of 1200 mg per day.

These medications are frequently sold in combination with other drugs such as caffeine, which exerts no specific

analgesic effects, but may potentiate the analgesic effects of aspirin and acetaminophen. There are aspirin–caffeine combination drugs (Anacin®) and aspirin, acetaminophen, and caffeine combinations (Excedrin Extra-Strength®, Excedrin Migraine®, and Vanquish®). The recommended dosage is two tablets every 6 hours as needed.

The biggest problem is that taking aspirin, acetaminophen, or combination tablets daily or even every other day for a week or more (possibly less) can induce the problem of analgesic rebound headache (which is discussed below).

As with birth control pills, when you ask patients what medications they are taking, they may forget that the birth control pill or aspirin or acetaminophen are medications, and forget to tell you, or even be too embarrassed to tell you because they are taking a large number of pills each day, so you must be certain to ask specifically.

There are a number of NSAIDs that are prescribed. Because of the variability in their efficacy, pharmacokinetics, and side effects, patients may need to be tried on more than one, sequentially, not in combination, to determine the best one for them.

The NSAIDs work, as noted before, by interfering with the action of cyclooxygenase in the synthesis of prostaglandins. Gastrointestinal side effects are common in up to 15 to 20% of patients and may include epigastric pain, nausea, heartburn, and abdominal discomfort. A history of gastrointestinal bleeding or ulcerations should indicate that great caution must be used if these medications are used at all. The most frequently prescribed NSAIDs include

Naproxen sodium (Anaprox®), which reaches peak plasma levels in 1 to 2 hours and has a mean half-life of 13 hours. It can be taken at 275 or 550 mg every 6 to 8 hours, with a top dosage of 1375 mg per day. Remember that this NSAID is useful in treating hormonally related migraine.

Ibuprofen (Motrin®) is prescribed in dosages of 100 and 800 mg per tablet. The suggested dosage for mild to moderate pain is 400 mg every 4 to 6 hours as needed.

Ketoprofen (Orudis®) is a cyclooxygenase inhibitor, but also stabilizes lysosomal membranes and possibly antagonizes the actions of bradykinin. Its peak plasma level is reached in 1 to 2 hours, and it has a 2-hour plasma half live. It is now over the counter (12.5 mg tablets), but is best used at 50 to 75 mg capsules. The recommended daily dosage is 150 to 300 mg a day in three or four divided doses. Gastrointestinal side effects are generally mild. Care should be taken when given to a patient with impaired renal function.

Keterolac tromethamine (Toradol®) can be given orally or parentally for moderate to severe acute headache pain. Peak plasma levels occur after intramuscular injection in about 50 minutes. Its analgesic effect is considered to be roughly equivalent to a 10 mg dose of intramuscular (IM) morphine. The typical injectable dose is 60 mg. Because of its potentially significant hepatic/renal side effects, the FDA has stated that Toradol should be given orally, after an IM injection of 60 mg, at 10 mg, every 8 hours, for a maximum of 5 days.

The COX-2 inhibitors (celecoxib and rofecoxib) are nonsteroidal anti-inflammatory agents that also have analgesic properties without, for most patients, the typical gastrointestinal problems associated with NSAIDs. They appear to work by inhibiting prostaglandin synthesis, via inhibition of cyclooxygenase-2, which corresponds to its improved gastrointestinal side-effect profile, while not affecting the cyclooxygenase-1 isozyme responsible for its anti-inflammatory functions. Celecoxib may be taken twice a day, 100 to 200 mg, while rofecoxib is taken once a day, at dosages ranging from 12.5 to 50 mg. The third Cox-2 inhibitor, valdecoxib, is utilized at dosages of 10 to 20 mg a day. Rofecoxib was withdrawn from use at the end of 2004 secondary to apparent cardiovascular problems. The fate of valdecoxib and celecoxib remains to be seen.

Muscle relaxants are given for acute tension-type headache by some clinicians. They are probably best utilized during the first 3 weeks postinjury-related headache. They are useful in patients with significant muscle spasm and pain, which may be seen in acute PTTHA, but which is not usually seen with an episodic tension-type headache. They are used appropriately after the development of muscle spasm after injury such as a slip and fall, motor vehicle accident, work and athletic injuries, or overstretching.

These medications work via the development of a therapeutic plasma level. Their exact mechanism of action is unknown, but they do not directly affect striated muscle, the myoneural junction, or motor nerves. They produce relaxation by depressing the central nerve pathways, possibly through their effects on higher central nervous system centers, which modifies the central perception of pain without affecting the peripheral pain reflexes or motor activity.

Carisoprodol (Soma®) is a central nervous system depressant that metabolizes into a barbiturate, which makes it both addictive and particularly inappropriate to use for patients with pain from muscle spasm in addition to MTBI. It acts as a sedative and it is thought to depress polysynaptic transmission in interneuronal pools at the supraspinal level in the brainstem reticular formation. It is short lived, with peak plasma levels in 1 to 2 hours and

a 4 to 6 hour half-life. Dosage is 350 mg every 6 to 8 hours. It should not be mixed with other central nervous system depressants. It is also marketed in two other combined forms (with aspirin as Soma Compound) and with codeine, for additional analgesic effects.

Chlorzoxazone (Parafon Forte DSC®) is a centrally acting muscle relaxant with fewer sedative properties. It inhibits the reflex arcs involved in producing and maintaining muscle spasm at the level of the spinal cord and subcortical areas of the brain. It reaches it peak plasma level in 3 to 4 hours, and its duration of action is 3 to 4 hours. It is well tolerated, and side effects are uncommon. Dosage is 500 mg three times a day.

Metaxalone (Skelaxin®) is a centrally acting skeletal muscle relaxant that is chemically related to mephenaxalone, a mild tranquilizer. It is thought to induce muscle relaxation via central nervous system depression. Onset of action is about 1 hour, with peak blood levels in 2 hours, and duration of action is 4 to 6 hours. The recommended dose is 2,400 to 3,200 mg a day in divided doses (tablets are 400 mg each). It should be used carefully in patients with impaired liver function and should not be used at all in patients with significant renal or liver disease as well as those with a history of drug-induced anemias. Side effects include nausea, vomiting, gastrointestinal upset, drowsiness, dizziness, headache, nervousness, and irritability, as well as rash or pruritis. Jaundice and hemolytic anemia are rare.

Methocarbamol (Robaxin®) is a centrally acting skeletal muscle relaxant. It may inhibit nerve transmission in the internuncial neurons of the spinal cord. It has a 30-minute onset of action. Peak levels are found in about 2 hours, and its duration of action is 4 to 6 hours. It comes as 500 and 750 mg tablets. Tablets containing methocarbamol and aspirin (Robaxisal) are also available. The recommended dose of Robaxin is 750 mg three times a day. As with all of these medications, it should be taken for 7 to 10 days. It is well tolerated, with initial side effects, which resolve over time, including lightheadedness, dizziness, vertigo, headache, rash, gastrointestinal upset, nasal congestion, fever, blurred vision, urticaria, and mild muscular incoordination. In situations of severe, seemingly intractable muscle spasm, Robaxin may be given intravenously in doses of about 1 g every 8 to 12 hours.

Orphenedrine citrate (Norflex®, Norgesic®) is a centrally acting skeletal muscle relaxant with anticholinergic properties thought to work by blocking neuronal circuits, the hyperactivity of which may be implicated in hypertonia and spasm. It is available in injectable and oral formulations. The IM dose of Norflex is 2 mg, while the intravenous dosage is 60 mg in aqueous solution. The oral formulation (Norflex) is given in 100 mg tablets, 1 tablet every 12 hours. Norgesic is a combination form, including caffeine and aspirin, and should be given 1 or 2 tablets every 6 to 8 hours. Norgesic Forte, a stronger combination,

is given 1/2 to 1 tablet every 6 to 8 hours. Because of its anticholinergic effects, it should be contraindicated in patients with glaucoma, prostatic enlargement, or bladder outlet obstruction. Its major side effects are also secondary to its anticholinergic properties and include tachycardia, palpitations, urinary retention, nausea, vomiting, dizziness, constipation, and drowsiness. It may also cause confusion, excitation, hallucinations, and syncope.

Many of these medications are given in combination with other drugs, including barbiturates (butalbital and meprobamate) and narcotics (codeine, oxycodone, propoxyphene, etc.). This is probably not a good idea, as the barbiturates and narcotics can easily help develop patient dependence.

A good combination used by the author is methocarbamol 750 mg three times a day for 10 days in patients with significant spasm, accompanied by ketoprofen, 75 mg, every 6 to 8 hours as needed, with food as needed. For the acute PTTHA, 1 tablet of each taken together every 6 to 8 hours for two to three doses works very well.

For patients with extreme pain on an acute basis, the use of tramadol hydrochloride (50 to 100 mg every 4 to 6 hours) may be helpful. This medication appears to bind to the opioid receptors as well as inhibit reuptake of serotonin and norepinephrine. Other patients may need an opioid such as codeine or hydrocodone. These medications should be given for up to 7 to 10 days, if necessary. One published rule of thumb notes that immediate-relief analgesic medication of any kind should be taken no more than 2 days a week.

Again, narcotic medications should not be used, if they can be avoided, for the patient with acute TTHA, as the risk of dependence, as well as analgesic rebound headache, is too great.

It may be appropriate to include a short course of physical therapy for patients with significant myofascial findings on an acute basis.

Remember, too, that simple acute PTTHA is a problem that the headache specialists are rarely called in to see. It is the patient's family physician or chiropractor who most frequently sees this problem.

One of the most important treatments is most often forgotten — simply educating the patient regarding what exactly is going on. Patients need explanations of what is causing their pain and what is being done to help them as well as how a particular medication or treatment helps their particular problem. This is even more important for patients with chronic PTHA.

Medication Management of Chronic PTTHA

The medication treatment of choice is the tricyclic antidepressants (TCAs) or the specific serotonergic reuptake inhibitors (SSRIs).

The TCA medication of choice is amitriptyline, a sedating tricyclic antidepressant. As all of the tricyclics, it works in the synapse to decrease reuptake of serotonin and (depending on the individual medication) NEP. Amitriptyline, unlike the other TCAs, also works to repair the damage in stage 4 sleep architecture. It is the most sedating tricyclic. The typical dosage is between 10 and 50 mg at night. The author has found it rare to need more than 20 or 30 mg at night.

Amitriptyline appears to have prophylactic treatment ability secondary to its blockade of serotonin and noradrenergic reuptake in the central nervous system. It has been noted that amitriptyline may also act as an *N*-methyl-D-aspartate (NMDA) receptor antagonist (Watanabe, Saito, & Abe, 1993). The analgesic effects of amitriptyline may result from this ability (Eisenach & Gebhart, 1995). NMDA receptor activation is prominently involved in the development of sensitization of the spinal cord dorsal horn, which appears to be found in chronic tension-type headache patients, particularly if the hypothesis of central sensitization in these patients is correct, as this clinical fact could indicate.

Treatment with amitriptyline may also be associated with a reduction of myofascial tenderness, probably secondary to segmental reduction of central sensitization along with peripheral antinociceptive activity (Bendtsen & Jensen, 2000).

Doxepin® is also a very good tricyclic. Anticholinergic side effects such as sedation are reduced (but not by much) when compared with amitriptyline. It does *not* work on the sleep architecture. It is used at the same dosage levels of amitriptyline. Notice that the tricyclics are not used in their antidepressant dosages, anywhere from 100 to 350 mg a day. Even though the doses are low, their effectiveness in the treatment of chronic PTTHA is present.

The SSRIs include Prozac®, Paxil®, and Zoloft®. These medications are not typically sedating (although for some patients they may be), and with the exclusion of those patients, they are energizing. They should be given in the morning. Prozac and Paxil should start at 10 to 20 mg a day, and they can be increased to 60 to 80 mg. Zoloft should be given at 25 to 50 mg in the morning, up to 150 mg in divided doses. The doses should be divided, giving one when the patient arises in the morning (around 7:00 A.M.) and one at noon. Explain to the patients that taking these medications later than noon can, in many cases, give them problems sleeping.

One can also safely combine 10 to 40 mg of Prozac or Paxil, or 50 mg of Zoloft, with a small dose of amitriptyline or doxepin (10 to 30 mg) at night. Inappropriate dosages of these two forms of medications can, rarely, induce the serotonin syndrome. There are other excellent antidepressants such as Wellbutrin®, Serzone®, and Effexor®. These should be considered as needed. Do not combine these medications with the MAO inhibitors.

Another excellent medication is Clonazepam®, a fifth-generation form of benzodiazepine. It is GABAnergic in effect. It works at the level of the internuncial neurons of the spinal cord to enhance muscle relaxation. It helps, a bit, with anxiolysis. It has a side effect of sedation. In doses of 4 to 12 mg a day, it works as an anticonvulsant. At smaller doses, 0.5 to 1 mg given at night, it is very useful in the treatment of patients with chronic tension-type headache. The sedation lasts for a shorter time than the sedation from tricyclics, and this in itself is useful.

If the acute use of muscle relaxant medications is not enough to end the problem, Tizanidine® is a good choice of medication after the first 3 weeks or so have elapsed and the patient is still exhibiting painful neuromuscular spasm. Tizanidine is an alpha₂ noradrenergic agonist (Coward, Davies, Herrling, & Rudeberg, 1984; Sayers, Burki, & Eichenberger, 1980). It has supraspinal effects by inhibiting the facilitation of spinal reflex transmission by the descending noradrenergic pathways, as it decreases firing of the noradrenergic locus ceruleus (Palmeri & Wiesendanger, 1990). It acts presynaptically in the spinal cord inducing a polysynaptic reduction in released excitatory transmitters (Davies, Johnson, & Lovering, 1983). It also decreases hyperexcitability of the muscle without acting on the neuromuscular junctions or muscle fibers (Wagstaff, Koch, Hirst, Bryson, & von Wartburg, 1989). Short acting, its maximum plasma concentrations are reached within 1 to 2 hours (Wagstaff & Bryson, 1997. It has a large first-pass metabolism, with a half-life of 2.1 to 4.2 hours (*Professional's handbook of drug therapy for pain*, 2001). Dosages should be slowly increased, starting at 1 to 2 mg at night and slowly increasing to 20 to 24 mg. Maximum dosage is 36 mg in divided dosages, typically found in patients who need an antimyotonic. Interestingly, this medication appears to decrease muscle pain while providing its antimyotonic effects.

In the opinion of this author, treating patients with chronic PTTHA with tricyclics, physical therapy, psychotherapy, etc. will not work if the patient is taking daily or four times a week analgesic medications of any type! In the presence of analgesic rebound headache, nothing will show long-lasting effectiveness until the chronic analgesics are stopped. More information regarding appropriate use of medications can be obtained from any clinical pharmacology text (*Professional's handbook of drug therapy for pain,* 2001). Nonmedication treatments may include biofeedback-assisted relaxation (Ham & Packard, 1996), as well as a trial of percutaneous electrical nerve stimulation (Ahmed, White, Craig et al., 2000).

Cost-Effective Treatment of Chronic PTTHA

Treatment of CPTTHA is best accomplished via an interdisciplinary rehabilitation approach, the main purpose of which is *not* to "teach the patient to live with the head-

ache," but to properly diagnose and effectively ameliorate or stop the patient's headache.

Drug detoxification is the necessary first step, whether the patient is overutilizing simple, over-the-counter analgesics or narcotics or barbiturates. Chronic daily analgesics appear to prevent appropriate functioning of the EOS (via negative neurochemical feedback loops) and other associated antinociceptive systems, inducing analgesic rebound headaches, which are secondary problems from the medications that induce headache secondary to purely neurochemical/neurophysiological changes. Vascular rebound headaches from overutilization of vasoconstrictors may also occur and must be stopped before other treatment is applied. Clinically, an effective way to detoxify patients with CTTHA is with the repetitive DHE-45 protocol described by Raskin (1988b). Concurrently, prophylactic medications should be started. The use of prophylactic medications, as well as physical therapy and other treatments given while a patient is enduring analgesic rebound headaches, is an ineffectual waste of time and money.

One study of 34 patients with PTHA and the postconcussion syndrome found that the repetitive use of DHE-45 and metaclopramide induced improvement in headache in 85% of patients, improved memory in 94%, improved sleep in 94%, and decreased dizziness in 88% (McBeath & Nanda, 1994). Many of the postconcussive syndrome improvements may have been secondary to the diminution of headache pain.

Another small study found the use of subcutaneous sumatritptan (6 mg) to be useful when treating PTHA that is refractory to other medication treatment (Gawel, Rothbart, & Jacobs, 1993).

The use of divalproex sodium was found to be a safe, effective treatment for patients with persistent chronic daily PTHA in a study that did not differentiate migraine from nonmigrainous PTHA (Packard, 2000). Sodium valproate is a good anticonvulsant choice for the patient with TBI as it does not produce any further cognitive decline, unlike Dilantin®, Phenobarbital®, or Neurontin® (Jay, 2000).

After detoxification, an outpatient interdisciplinary headache rehabilitation program using neuropharmacological therapy (to restore neurochemical homeostasis), physical therapy (Jay, Brunson, & Branson, 1989), psychotherapy, and stress management (including biofeedback-enhanced neuromuscular re-education and muscle relaxation) is the most time- and cost-effective treatment. Optimal psychotherapy or physical therapy regimens by themselves will not resolve myofascial difficulties or depression if the affective, sleep, and central nervous system neurochemical dysmodulation affecting them is not concurrently and appropriately treated. The interdisciplinary treatment paradigm also enables fine-tuning of diagnosis and possible determination of a secondary or "hidden" etiology for a patient's headaches.

In patients with recalcitrant soft tissue pain problems the use of botulinum toxin A or B to decrease muscle spasm and pain has increased significantly (Argoff, 2002; Gobel, Heinze, Heinze-Kuhnk, & Jost, 2001). However, several randomized, placebo-controlled studies do not support the effectiveness of botulinum toxin in the treatment of headache (Gobel, Lindner, Krack et al., 1999; Smuts, Baker, Smuts et al., 1999). In one randomized study (Rollnik, Tanneberger, Schubert et al., 2000) no improvement of primary or secondary pain end points was found after 6 weeks. Similar findings were reported in a study of episodic tension-type headache (Eros & Doric, 2002). More recent abstracts presented at the American Headache Society meeting in 2002 touted more successful results; however, few patients were noted to have CPTHA (Ashina, Lassen, Bendtsen et al., 1999; Miller, 2002; Troost, 2002).

Future use of nitric oxide synthase inhibitors may also promise to bring headache relief (Basbaum & Fields, 1984; Keidel et al., 2001). These studies indicate that the locus for nociception for CPHTA is found in the brainstem, not the peripheral nervous system.

Nitric oxide (NO) is found in the nociceptive neurons in the trigeminal nucleus caudalis and possibly higher in the central nervous system (Ashima, Lassen, et al., 1999). Inhibition of nitric oxide synthase (NOS), which enables the generation of NO, decreases central sensitization in animal models of continuous pain. In a clinical investigation of an NOS inhibitor, both headache and pericranial myofascial tenderness and hardness in patients with chronic tension-type headache were diminished (Ashina, Bendtsen, Jensen et al., 1999; Ashima, Lassen et al., 1999). This study supports the theory that central sensitization is involved in the pathophysiology of chronic tension-type headache.

The use of the interdisciplinary pain management paradigm to treat these patients also enables early goal-setting and continued education throughout the evaluation and treatment process.

Failure to treat the patient with chronic PTTHA with an interdisciplinary, whole-person approach (Figure 26.9) is responsible for multiple treatment failures as well as monetary waste, as long-term response — headache remediation — is most often not achieved.

OTHER ASPECTS OF POST-TRAUMATIC HEADACHE

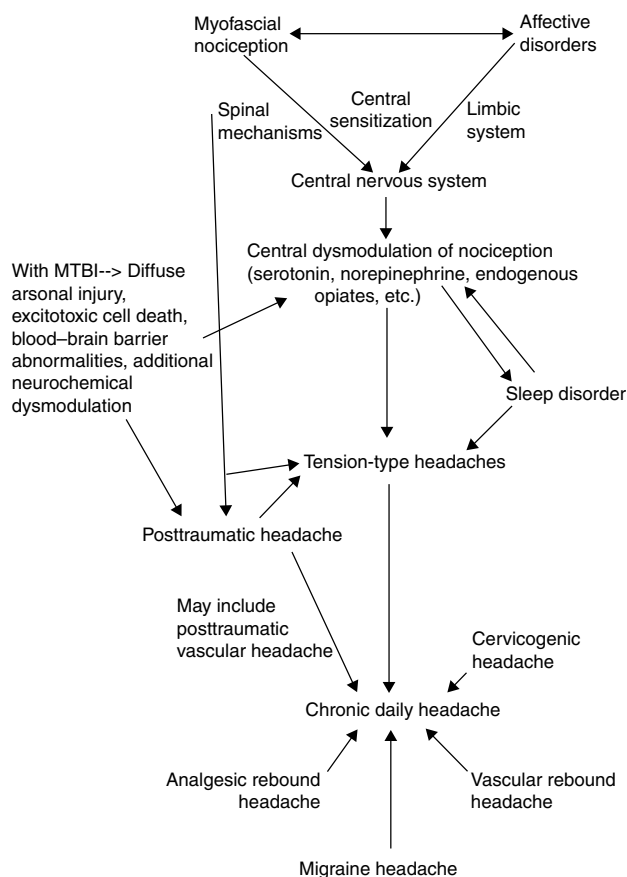
An initial trauma may involve soft tissue injury to the scalp or face, which may be followed by an entrapment of a sensory nerve, or the sensory nerve may have been cut via laceration during the trauma. The entrapment may


FIGURE 26.9 Headache diatheses found in posttraumatic headache patients.

also occur during suturing of a laceration. Such entrapments may induce nerve, or neuropathic, pain. This is easily differentiated from other primary headache types. The pain is constant, burning, and relegated to the sensory distribution of the affected nerve. Anticonvulsant medications such as carbamazepine are best for the first-line treatment. Neurontin has been used, but it has different, possibly more significant, side effects in some patients, particularly in those with a concurrent MTBI. In some cases, neurolytic procedures such as radiofrequency coagulation or cryo-ablation may be necessary. Both are good procedures, but have varying durations of benefit, most typically between 6 to 12 months.

Without question, injuries to the cervical spine and the superficial and deep structures of the neck (muscles, ligaments, bone, discs, or nerve roots) may occur. Cervical pain from trigger points in spasmed musculature as well as from cervical joint dysfunction may be referred to the head.

If the post-traumatic pain is suboccipital with lancinating, electrical-like shooting pain attributes, secondary to involvement of the occipital neurovascular bundle (the occipital nerve, artery, and vein), or secondary to prolonged muscle spasm/contraction or excessive vascular

dilatation impinging on the greater occipital nerve of Arnold, this pain is known as occipital neuralgia. It is always in the C_2 distribution at the back of the head. Indomethacin may be an effective treatment for this problem. Steroidal injections may also be utilized. Neuroablative procedures should be performed only when all other treatment has failed.

Preexisting arthritis or discogenic disease may also be exacerbated by the initial trauma. An appropriate neurological evaluation will help with these entities.

The dysautonomic cephalalgia of Vijayan (1977) is associated with injury to the anterior aspect of the carotid sheath. The headache is severe and unilateral, in the frontotemporal area, and associated with ipsilateral hyperhidrosis and dilatation of the ipsilateral pupil. The role of sympathetic nervous system dysfunction, while it may remain controversial, is shown in many studies, as noted above. Also, the signs and symptoms are, of course, similar to cluster headache.

Zasler (1999) also published an interesting case demonstrating late or delayed PTHA secondary to post-traumatic tension pneumocephalus.

CERVICOGENIC HEADACHE

Just as the community of headache specialty physicians was rather hesitant to accept that the musculature played any role in tension-type headache, post-traumatic or otherwise, the idea that headache can arise from the structures of the neck still has many detractors.

Dwyer, Aprill, and Bogduk (1990) utilized fluoroscopic control to stimulate joints at segments C_{2-3} to C_{6-7} by distending the joint capsule with injections of contrast medium. They were able to show that each joint produced a clinically distinguishable, characteristic pattern of referred pain that enabled the construction of pain charts to be used in determining the segmental location of symptomatic joints in patients presenting with cervical zygapophyseal pain.

The diagnostic criteria for cervicogenic headache (CGHA) have been noted by several authors to differ a bit. Bogduk, Corrigan, Kelley et al. (1985) defined them as referred pain perceived in any region of the head, which was referred by a primary nociceptive source in the musculoskeletal tissues innervated by cervical nerves. Clinical features include pain that is not lancinating, and is dull or aching but could be throbbing, located in the occipital, parietal, temporal, frontal, or orbital regions, unilaterally or bilaterally. There is some indication of cervical spine abnormality such as neck pain, tenderness, impaired cervical motion, aggravation of the headache by neck movements, or a history of cervical trauma.

Bogduk and co-authors' (1985) diagnostic criteria included identification by clinical examination or by imaging of the cervical sources of pain found, by valid

antecedent studies, to be reliably associated with the head pain. Their criteria also include complete relief of the head pain seen after controlled local anesthetic blockade of one or more cervical nerves or structures innervated by cervical nerves.

The North American Cervicogenic Headache Society determined that CGHA is essentially referred pain noted in any region of the head, caused by primary nociceptive sources in the musculoskeletal tissues that are innervated by the cervical nerves (Sjaastad, Fredriksen, Pfaffenrath, 1990). The pain of CGHA begins in the occipitonuchal region and is typically secondary to an abnormality within the region of the occiput to C_3 that results from trauma or prolonged postural/functional strain (Sjasstad et al., 1990).

Sjaastad et al. (1990) also weighed in with specific criteria. They noted that CGHA are one sided, but could also be bilateral, "unilaterally on two sides." The duration of a headache or exacerbation ranges from several hours to several weeks. Initially, the headache may be episodic, but can later become chronic-fluctuating. Symptoms and signs are referrable to the neck, and include decreased range of cervical motion and mechanical precipitation of attacks, and autonomic symptoms such as nausea and photophobia are not marked, if present. A positive response to appropriate anesthetic blockade is considered essential.

Sjaastad et al. (1990) noted several major criteria:

1. Symptoms and signs of cervical involvement:
   a. Provocation of an irradiating head pain similar to the spontaneously occurring one:
      i. By neck movement and/or sustained awkward head positioning, and/or
      ii. By external pressure over the upper neck or head on the side ipsilateral to the pain
   b. Restriction of cervical range of motion
   c. Ipsilateral neck, shoulder, or arm pain of a vague, nonradicular nature or, on occasion, sharp arm pain in a radicular region

Symptoms and signs 1a to 1c are listed in "order of importance." One or more of these must be present for the term cervicogenic headache to be used. Point 1a is itself a sufficient criterion, but 1b and 1c are not. Point 2 is a necessary additional point.

2. Confirmation by diagnostic anesthetic blocks
3. Unilateral pain which does not shift from side to side
4. Pain characteristics:
   a. Nonthrobbing pain, usually beginning in the neck
   b. Episodes of varying duration
   c. Fluctuating, continuous pain

5. Other characteristics of some importance:
   a. Marginal or no effect from treatment with indomethacin
   b. Marginal or no effect from treatment with triptans or ergots
   c. Female preponderance
   d. History of head or neck trauma

None of the single points under 4 or 5 is essential.

6. Other descriptions of less importance — various headache-related phenomena that are rarely present, and of only mild to moderate severity when present:
   a. Nausea
   b. Photo- and phonophobia
   c. Dizziness
   d. Blurred vision ipsilateral to the pain
   e. Difficulty with swallowing
   f. Fluid around the eye epsilateral to the pain

The anatomical basis of CGHA is thought to be secondary to convergence in the trigeminocervical nucleus between nociceptive afferents from the field of the trigeminal nerve and the receptive fields of the first three cervical nerves. Headache appears to be secondary to structural problems in regions innervated by C_1 to C_3. These regions include the muscles, joints, and ligaments of the upper three cervical segments, as well as the dura mater of the spinal cord and the posterior cranial fossa and the vertebral artery (Bogduk, 1992).

Other anatomical causation has been identified and includes

1. Disrupted and/or ruptured cervical discs with irritation of the sympathetic sinu-vertebral nerves (in the disc) and nerve roots by mechanical and chemical means at single or multiple levels
2. Irritation of the articular branches to the cervical zygapophyseal joints derived from the medial branches of the cervical dorsal rami
3. Irritation of the peripheral branches and unmyelinated nerve structures to the muscle attachments at the spinous process of C_2 supplied by the C_2 and C_3 nerve roots; this includes the rectus capitis posterior, major obliquus capitis inferior major, semispinalis cervicis multifidus, semispinalis capitis major, and rectus capitis posterior minor, and interspinal muscles at C_{1-2} and C_{2-3}
4. Pain from the end fibers of the greater tertiary occipital and sympathetic nerve structures with its C-fibers including the periosteum and suboccipital musculature (semispinalis capitis, rec-

tus capitis posterior minor and major, trapezius, and occipitalis) (Blume, 1997)

The treatment of CGHA begins with diagnostic anesthetic blocks that are typically mixed with long-acting steroids such as hydrocortisone. This should temporarily relieve the CGHA for hours to days. If pain relief lasts for weeks to months, blocks should be repeated.

Once a specific targeted joint or disc is identified, the latter with discography if needed, a number of procedures have been used for treatment of CGHA:

1. Neurolysis of the C_2 nerve root via decompressive surgery (Poletti, 1983) as well as partial denervation of the suboccipital and paraspinal musculature (Pikus & Phillips, 1995)
2. Radiofrequency lesions to the muscle attachments of the spinous process at C_2 (Blume, Kakolewski, Richardson, & Rojas, 1982; Rogal, 1995)
3. Radiofrequency neurotomy of the sinu-vertebral nerves to the upper cervical disc, as well as to the outer layer of the C_3 or C_4 nerve root (Sluijter, 1990)
4. Radiofrequency denaturation of the occipital nerve (Blume, 1976; Blume et al., 1981; Blume & Ungar-Sargon, 1986)
5. Radiofrequency denaturation of the C_2 medial rami (Rogal, 1986)
6. Cervical discectomy and fusion
7. C_2 ganglionectomy (Jansen & Spoerri, 1985)

The last procedure is not often performed, while there remain proponents of radiofrequency lesioning versus the "old" cervical discectomy and fusion.

It is imperative to differentiate CGHA from both migraine headache and PTTHA, as the treatments are completely different. Unfortunately, the literature in general argues the question of cervicogenic headache, although not the idea that headache may be associated with cervical pathology. It should be noted that the International Association for the Study of Pain has recognized cervicogenic headache as a pain syndrome (Zwart, 1997). The criteria use neck mobility as the major indicator of this diagnosis, but both tension-type headache and migraine have associated decrements in cervical mobility.

The different criteria for the diagnosis of CGHA make other previously recognized primary headache sufferers fall into a diagnostic hole. There appears to be too much overlap in the varying diagnoses. Likewise, patients with the diagnosis of CGHA may also fall into other diagnostic categories or even multiple diagnostic categories (Leone, D'Amico, Grazzi et al., 1998; Pfaffenrath & Kaube, 1990; Sjaastad, Bovim, & Stovner, 1992; Treleaven, Jull, & Atkinson, 1994).

Not to be forgotten is the fact that the diagnosis specifically may follow an acceleration/deceleration injury or other cervical trauma (Obelieniene, Bovim, Schrader et al., 1998; Treleaven et al., 1994). This makes it imperative to consider the diagnosis of CGHA in patients with PTHA who do not show improvement following appropriate treatment for other diagnosed headache diatheses. On the other hand, clinically, CGHA appears to be found in less than 3 to 5% of the PTTHA population. If a patient with PTHA also has an MTBI, the level of difficulty in making the diagnosis and treating that patient increases dramatically.

Psychological factors exist; the neurochemical aspects of depression and anxiety, for instance, are well known. In the presence of an MTBI, they become more difficult to tease out and deal with, as the patients may be dealing with pain as well as changes in cognition and behavior, including frontal lobe difficulties such as increased irritability and labile emotionality.

LEGAL ASPECTS

It appears, to this author, seems a sad commentary that a section dealing with "legal aspects" is even needed in a medical textbook chapter. But it is.

There is no set, established method used in determining an impairment rating for PTHA. The *AMA Guides to the Evaluation of Permanent Impairment*, 5th edition (Cocciarella & Andersson, 2001) now allows a "pain" impairment, but it is not particularly specific to PTHA and behavioral aspects are important. Packard and Ham (1993a) developed a mnemonic to do this: IMPAIRMENT: for Intensity, Medication use, Physical signs/symptoms, Adjustment, Incapacitation, Recreation, Miscellaneous activity of daily living, Employment, Number (frequency), and Time (duration of attacks). Each is scored from 0 to 2 points, with three physician modifiers, including motivation for treatment, overexaggeration, or overconcern and degree of legal interest. Unfortunately, their methodology has not been taken into wide use.

Another major problem facing patients and their treating physicians is the question of medicolegal disability secondary to the PTHA syndrome, with or without the question of MTBI. Patients whose injuries involved a skull fracture, subdural hematoma, or severe lacerations and whose gray matter is leaking out of their ears *may* not have a problem in regard to disability. Unfortunately, for patients and their physicians, insurance problems do exist, beginning with obtaining approval to treat a PTHA syndrome.

Some insurance companies deny that there is such a thing as an MTBI or PTHAs. They have a number of paid consultants to assure the legal system that this is so. They will try to prevent clinicians from even becoming involved with treating these patients by refusing to pay them for treatment. *It does not matter* how devastating a patient's

symptoms are; the patient will still face a difficult and totally unjustified legal battle just to get treatment approved, never mind the question of disability compensation.

It is interesting (but medically expected) that the vast majority of patients with PTHA, particularly those with headaches as part of a postconcussion syndrome, present the same way. This is pertinent, as the legal concern is typically that the patient complaining of significant PTHA is either lying or malingering. They are for real and are expressing the same symptomatology from the same causation (head trauma or acceleration/deceleration injuries). This is just like patients with chicken pox who initially present, clinically, in the same way.

Then there is the *M* word — malingering. This is associated with the idea that settlement of litigation is all that is needed to put a stop to the PTHA syndrome. This is also a favorite theme of the insurance companies. True malingering is almost as rare as hens' teeth. There are published studies that demonstrate that legal settlement has nothing to do with the patients' symptoms ending or encouraging them to return to work (Cicerone, 1992; Elkind, 1989; Evans, 1992; Merskey & Woodford, 1972).

Chronic PTHAs, with or without the other aspects of the postconcussion syndrome, are extremely common after head trauma as well as after an acceleration/deceleration injury. These patients are very consistent in their presentations as well as in their descriptions of their symptoms and sequelae. This consistency is strong evidence that their problems are organic in nature and produced by the trauma.

Most patients with PTHA will have their headache resolve if they are given appropriate medical treatment. About 15 to 20% will have prolonged difficulties. Correct diagnosis and treatment in the majority of cases should decrease this percentage.

Temporomandibular Joint Dysfunction

Christopher R. Brown, DDS, MPS

INTRODUCTION

The art and science of the diagnosis and management of temporomandibular joint (TMJ) dysfunction has come a long way since its humble beginnings in the 1920s. Since then, many treatment philosophies have come and gone. Often patients have been bounced from one treatment discipline to another, leaving them feeling rejected, ignored, and depressed, with little effective resolution of their pain. There have been many attempts to find the "solution" to this baffling problem in both dentistry and medicine. The truth of the matter is there is not a single solution to TMJ dysfunction because it is not a single entity; rather, it is a group of problems from different etiologies lumped under one broad and often generic diagnosis. The most effective way to help patients suffering from head, neck, and facial pain, collectively called TMJ dysfunction, is for all practitioners of the arts to work together to achieve an accurate diagnosis and resulting management. The technology, knowledge, and training exist to bring all professions together to assist in the alleviation of head, neck, and facial pain.

The abbreviation TMJ is a very misused term. It is commonly used descriptively both as human anatomy and also erroneously as a diagnostic entity. The term TMJ used correctly describes only the temporomandibular joints, which are diarthroidal joints connecting the mandible to the skull. When delineating a dysfunction of the TMJs, the term TMD is the more accepted term, "D" referring to the dysfunction of the TMJs. The term TMD is in and of itself a very vague diagnosis. In fact, TMD does not indicate a single diagnostic entity but rather a collection of symptoms affecting or arising from the TMJs, the muscles of mastication, and/or contiguous soft and hard tissue

entities. This accounts for much confusion within the professional community of all disciplines that diagnose and treat facial pain. TMD is often used to describe collectively anything from sore muscles of the face from cheering too hard at a ballgame all the way to advanced degenerative joint disease. As a result, many patients, clinicians, and third-party payers have found themselves in a virtual no man's land of confusion.

The occurrence of TMD symptoms will vary according to epidemiological studies (Kaplan & Assael, 1991). Symptomatically, it has been conservatively estimated that more than 10 million people in the United States suffer from symptoms attributed to TMD. Up to 75% of nonpatient populations have at least one sign of TMJ dysfunction. Approximately 33% of these have at least one painful symptom in the face or TMJs. While reports may differ somewhat among epidemiological estimations, TMD sufferers are most commonly females (a ratio of 5 to 1) between the ages of 15 and 45 years (Cady & Fox, 1995). It is a real problem that costs the United States billions of dollars in health care and lost days of productivity.

Historically, Costen in 1934 first addressed this entity by hypothesizing that lost vertical dimension in the facial structures was the main source of symptomatology (Bell, 1982). As a result, the idea of "opening the bite" through various forms of dental reconstruction became the chief pathway to problem solving; hence, the field of TMJ fell into dentistry and the role of occlusion as the dominant etiological factor was conceptualized. Dentistry, as a leader in TMD treatment, began a strict focus in the role of occlusion and alterations of mandibular position to reduce or eliminate facial pain. Unfortunately, the treatment approach for TMD has often been as if it was a single disease entity. The search has been for an answer to a very

complex problem that often requires multiple treatment modalities and interdisciplinary approaches. Although there have been concerted efforts to discover the cure for TMD, logic would dictate that the first approach, as in any disease entity, should be to achieve an accurate working differential diagnosis. Through the decades following Costen's initial approach, scientific constructs have begun to emerge. Dentistry along with a multidisciplinary approach has begun to find workable solutions for TMJ/facial pain resolution.

ANATOMY

Functionally, the TMJs involve the articulation of the mandibular condyles in the temporal bones. The fossae are the concavities hosting the mandibular condyles and the eminentiae are the bony convexities anterior to the fossae. The articulating surfaces of the temporal bones consist of concave, thin bony surfaces or fossae, and convex, thick bony surfaces or eminentiae. In addition, the TMJs include soft tissue structures including the articulating discs (menisci), retrodistal tissues, joint capsules, and synovium. The discs medially and laterally insert at the medial and lateral poles of the condyles. Anteriorly, the discs are continuous with the superior belly of the lateral pterygoid muscles. The temporomandibular capsule is a dense fibrous tissue sheet enclosing each joint in a 360° fashion with its insertion lines at the neck of the condyle below and at the temporal bone above. The upper and lower compartments of the TMJs have a synovial lining, which appears to have a highly active immunologic ability to produce antibodies, and collagenase type materials, which help to protect and ensure the continuity of the synovial fluid. The TMJs, while considered synovial joints, actually have a number of attributes that distinguish themselves from other synovial joints in the human body. The TM joints' articulating surfaces are covered by fibrocartilage rather than hyaline. They are actually divided into upper and lower compartments by a fibrous meniscus (disc), the purpose of which is to help facilitate the motions of both rotation and translation. TMJs are the only joints in the human body that must work in harmony with another joint during function and dysfunction. A dysfunctional joint often will create an equal and opposite force on the contralateral joint (e.g., hypomovement on the left can produce hyperfunction on the right). The function of the TMJs can be influenced by masticatory muscles, supportive structures of the joints, teeth, and parafunctional activities.

The anatomy of TMJs provides both rotational and translational movement. The TMJs are actually formed by the mandibular condyles fitting into the glenoid fossae of the temporal bones. The condyle and glenoid fossae are separated by a fibrous cartilage disc (meniscus), which divides the joint into the upper and lower chambers. The articular portion of the disc, which is composed of connective tissue, is devoid of any nerves or vessels. The posterior attachment of the disc, however, is richly vascularized and innervated. The disc itself is attached to the condyle both medially and laterally by collateral ligaments that permit both rotational and translational movement of the disc/condyle complex during opening and closing of the mouth. Rotational movement occurs between the condyle and the surface of the disc during early opening, while translation takes place in the space between the superior surface of the disc and the glenoid fossa. Synovial fluid provides lubrication to the joint and acts as a medium for transporting nutrients and waste products to and from the articular surfaces. The joint surface cartilage and the attached structures allow for an almost frictionless articulation while transmitting compressive forces uniformly to the subchondral bone (Bumann & Lotzmann, 2002).

SUPPORTING MUSCULATURE

Mandibular movement and stability are assisted by a series of skeletal muscles. The primary masticatory muscles include the masseter, medial pterygoid, temporalis, digastric, and lateral pterygoid muscles, which are further divided into the inferior and superior belly. All muscles collectively account for mandibular motion and provide stabilization for the condyle/disc during function. Musculoskeletal disturbances of the entire body are the leading cause of disability in people in their working years (Mense & Simons, 2001). A majority of collective symptomatic orofacial pain complaints are musculoskeletal in nature which may lead to TMJ articular dysfunction. Muscle pain complaints often include myofascial trigger points and resulting skeletal unit restriction.

INNERVATION AND VASCULAR SUPPLY

The innervation of the TMJs and supporting structures is primarily supplied by the trigeminal and facial nerves. The trigeminal nerve (cranial nerve V) provides both sensory and motor innervation and, hence, is the primary nerve that supplies the TMJs themselves. Sensory fibers of the trigeminal nerve extend to synapses in the trigeminal spinal nucleus of the brainstem. The trigeminal nerve is divided into three branches: the ophthalmic, maxillary, and mandibular. The mandibular nerve provides sensory and/or motor branches to the medial and lateral pterygoid muscles, temporalis, masseter, and TMJs via the auriculotemporal nerve, which while passing behind the TMJs, emerges distal to the condyle, then traverses into the temporal area. It also supplies sensory perception to the tongue and the lower teeth. The TMJs primary nerve supplies arise from the auriculotemporal nerve posteriorly, the masseteric nerve medially, and the posterior deep temporal nerve laterally. While the facial nerve (cranial nerve

VII) does not directly supply the TMJs per se, it does provide motor and sensory functions to associated musculature and supporting structures including the orbicularis oculi and the anterior two thirds of the tongue. Afferent information from sensory receptors produces stimuli causing both concurrent muscular contraction and inhibition resulting in antagonistic inhibition. This myotatic reflex helps protect the masticatory from sudden stretching of the muscles. Golgi tendon organs protect against muscle overcontraction by inhibition stimulation directly to the affected muscles (Okeson, 1989). The result is a complex control system allowing for both protection and function. The arterial supply to the TMJs originates from the superficial temporal artery (posterior to the joint), the posterior auricular artery, the deep auricular artery, the lateral-pterygoid pedicle, and the masseteric artery; the last three are branches of the maxillary artery.

CLASSIFICATION OF TM DISORDERS

A classification system for TM disorders, as originally presented by Bell (1989), is presented in Table 27.1. This system is more accurately a categorization of orofacial pain etiologies, rather than TMD alone, and suggests correctly that TMD is actually a continuum of disorders rather than a single clinical entity.

SYMPTOMOLOGY

The symptoms involved with TMD are often varied and at first may seem unrelated. An old catchphrase for TMD was "the great imposter." This moniker was given because of the diversity of symptoms that may be attributed to other conditions as well. Any or all of the following may be as a result of TMD: (1) TMJ noise (popping, clicking, grinding, crepitation), (2) mandibular trismus or the inability to open the mouth uniformly (can be measured in lack of opening or deviation of the mandible from the midline), (3) pain in or approximating the TMJs, (4) headaches (bilateral, unilateral, occipital, frontal, that may be exacerbated by chewing or stress), (5) neck aches, (6) inability to properly fit the maxillary and mandibular teeth together (this may be perceived by the patient as "not a normal bite"), (7) facial pain on chewing (located around the TMJs or perceived by the patient as a headache, earache), (8) tinnitus, (9) earache (bilateral, unilateral, in the absence of ear pathology), (10) excessive ear wax (usually found in conjunction with chronic retrodistal inflammation and posterior displacement of the condyle), (11) photosensitivity, (12) dysphagia, (13) palpable masticatory muscle trigger points, and (14) myalgia (generalized in the head and neck or focalized in the masticatory muscles).

The severity of these symptoms may range from annoying to debilitating. They also may fluctuate with

TABLE 27.1
Classification of TM Disorders

I. Physical (non-neurogenic) Origins of Pain

III. Psychogenic Origins of Pain
  A. Chronic facial pain
  B. Psychoneurotic pain
    1. Conversion hysteria
    2. Delusional pain

time. It is not unusual for patients to go through a period of quiescence. As in any nonmalignant pain entity, fluctuations of intensity and duration are to be expected.

WHY DO THE TMJs MAKE NOISE?

The TMJs "pop," "click," and/or "crunch" for a variety of reasons. The most common clinical situation is a displacement of the disc(s) to the anterior/medial with a resulting distalization of the condylar head(s) within the glenoid fossae. These conditions result in the classic "popping" of the TMJ(s). A chronic displacement of the disc(s), espe-

cially in women, may lead to degeneration of the condylar head(s), distortion of the disc(s), and total dysfunction of the TMJ(s) resulting in pain. As this degeneration progresses, the noises emitted by the TMJs may change to crepitation as a result of a roughening of the articulating surfaces or soft tissue articular breakdown. Along with this degeneration often comes restriction of mandibular range of motion, loss of function, and an increase in pain. In certain individuals, ischemic necrosis of the condylar heads may exacerbate the situation.

Anatomical variations, such as aberrations of the condylar heads, discs, capsular lining, retrodistal tissues, and articulating surfaces, that are nonpathological, may cause the TMJs to make noise. Various types of arthritic conditions that lead to articular surface degeneration can also contribute as in any synovial joint. Growths or foreign bodies present within the TMJs, although rare, must be ruled out in the presence of TMJ noise. A careful analysis of the individual patient must be accomplished to determine if the joint noises are pathologic, contributory to pain, or circumstantial. A cursory examination can be accomplished by fingertip palpation, auscultation by stethoscope, or Doppler. Achieving a definitive diagnosis may require the use of computer-aided diagnostics including joint vibrational analysis, EMGs, MRIs, and a combination of radiographs.

ETIOLOGIES OF TMD PAIN

The most common origin of TMD-type pain is musculoskeletal and its various subsets. Other etiologies can include neurological, vascular, cartilage, bone, and dental. Aside from anatomically specific functional disorders, the TMJs are subject to the same pathology that affects other synovial joints such as various kinds of arthritis, synovitis, hyperuricemia, neoplasia, and fibrosis (Bell, 1982). Patients may have pain from multiple sources producing similar symptoms all of which may need to be addressed for effective pain management (Raj, 2003).

TMD and orofacial pain cannot be approached as a unique entity from the rest of the body in which the laws of human physiology and physics do not apply. Although there are several factors that make the TMJs anatomically and functionally unique, their form, function, and physiology are very similar to other synovial joints. When making clinical assessments of TMJ dysfunction and resulting orofacial pain, keep in mind the principles of treating other joints. This concept will help guide an accurate differential diagnosis. There are no other joints in the body for which there has been such a zealous search for a solution for pain and dysfunction. The answer is actually simple, in a roundabout way. There is not a single answer to the entity known as TMD. It is without a doubt multifactorial in nature, both symptomatically and etiologically. For suc-

cessful resolution, clinicians from various disciplines must work together.

Any malady with multiple etiologies and various precipitating factors does not accommodate the scientific model desired for clinical study. Close scrutiny of clinical studies to measure and delineate pain involving humans and their idiosyncrasies results in scientific flaws when compared with laboratory controlled tests. The best that can be accomplished is a blend of academia, clinical study, and common sense. While trends can be followed and measured, epidemiological studies must be estimated and weighed in conjunction with unique individual factors to achieve a full understanding of the pain entity.

THE ROLE OF OCCLUSION

The importance of occlusion in the etiology of TMD is controversial. Occlusion, from an epidemiology standpoint, does not as a whole play a dominant role in TMD. Occlusal factors should be considered, although as possible contributing factors, when developing a differential diagnosis on an individual basis (McNeill, 1993). Occlusal factors may place the patient at a higher risk for dysfunctions and parafunctional activities, which may result in orofacial pain. Occlusion may play a major role in a given individual and his or her painful state. Another person suffering from similar symptoms may not have occlusion as an etiology. The treating doctor, however, must have a thorough understanding of occlusion to help provide a differential diagnosis. Malocclusion, like all other variables, may be a subset of pain etiologies that needs to be understood and analyzed. The kinematics of the stomatognathic system requires harmony of all components for normal pain-free function. Any aspect of the system at any give time may dominate causing dysfunction with resulting pain. Therefore, a multidisciplinary approach usually yields the best clinical results.

TRAUMA

Trauma is one of the most common etiologies of TMD. In fact, it has been estimated that trauma accounts for the majority of TMDs (McNeill, 1993). According to Shankland, 1998), it is estimated that 44 to 99% of all TMJ problems are a result of trauma.

Direct trauma to the mandible, depending on the pulse duration and force vectors, is capable of injuring the TMJs. This can be in the form of soft tissue damage or bony involvement. There is no such thing as a pure direct blow except under strict laboratory conditions. Resulting injuries may depend on the position of the head on an *X/Y* axis, the position of the mandible at the time of impact, the angle of the blow, the amount of soft tissue to absorb the blow, the modulus of elasticity of the individual's tissue under those particular circumstances, etc. Even

under the banner of "direct trauma," all these factors lead to other forces often thought of as indirect such as shear, torsion, compression, and tension. While injury categories are certainly evident and can be theoretically delineated, each person's physical response to trauma is unique. Keep in mind the term *direct* is descriptive as to the point of impact only and to the tissue precisely affected and not to the total injury component. Every *direct* injury has a facet of *indirect* as well.

Soft tissue injuries to the TMJs can be the result of direct blows to the mandible. The categories of these injuries are considered the result of "crush" type forces. Because of the nature of the anatomy, there are various soft tissue components (menisci, cartilage, blood vessels, etc.) juxtapositioned between bony surfaces, the condylar head, the superior articulating surface of the bony socket, and the distal and medial aspects of the socket. When a condyle is forced beyond its physiological range either anteriorly or posteriorly, especially in rapid motion, the chance of a crush-type injury exists. The result is a disruption of the joint surfaces and supporting tissues on both a cellular and macrolevel. Hemarthrosis may result, leading not only to an acute situation, but also to a synovitis that contributes to inflammation of the affected surfaced resulting in long-term articular degeneration and possible degenerative joint disease.

Direct blows to the mandible or TMJs causing immediate soft tissue damage usually result in a rapid onset of symptoms. This is a generalization and must be ascertained with each patient's unique situation. It is not uncommon for the victim to feel a change in occlusion, noticing their teeth do not match together normally, soon after the traumatic event. If the meniscus/menisci are anteriorly displaced but within the physiologic range of motion of the condylar head, the injury may be accompanied by popping or clicking of the TMJs due to displacement of the menisci. This may be unilateral or bilateral. If unilateral, this noise may be accompanied by trismus or deviation of the mandible to the side of the disc displacement. This is in essence a hypomobility/subluxation of the affected TMJ. By nature, the contralateral side results in hypermobility with a deviation of the mandible away from the joint. Another possibility as a result of a direct blow, if there is an influx of fluid into the affected joint, the void left by a displaced disc may be filled by fluid volume resulting in no noticeable joint noise. This lack of joint noise can often lead to a misdiagnosing of TMJ injuries and to a lag time or what is commonly referred to as "latency period" before effective treatment can be initiated.

In some cases, the force and pulse duration is such that the disc is displaced beyond the physiologic range of motion of the condylar head resulting in a disc displacement that is not "recaptured" during motion. The result is a severely injured TMJ that does not make noise, unaffected mandibular range of motion, and little if any devi-

ation of the mandible. This is a particularly difficult injury to diagnose initially due to the lack of overt clinical symptoms. The clinician must be astute and soft tissue injuries must be considered as a result of direct blows to the mandible. A one-time examination may not be sufficient to develop a true diagnosis. The patient should be seen on a 2-week, 6-week, and up to 6-month follow-up to determine if function is altered and a micro/cellular level injury has led to an alteration in system function.

A form of direct impact to the face that is becoming more prevalent is air bag inflations. While there is no question that air bags save lives, it has also been indicated that passengers who do not wear their seat belts and those who sit so close to the air bags that they receive the full force of inflation may actually have a greater chance of injury in low-speed collisions (Hollowell & Stucki, 1974). Careful review of crash test films indicates that often the dummies contacting the air bags lead with their chins. Because of the dummies' construction, the forces to the TMJs have not been measured, but dentists across the nation are reporting patients with broken teeth, facial abrasions, facial bone fractures, and TMJ disc displacements as a result of impacts with air bags. As a rule of thumb, when you have a patient who has been involved in a motor vehicle accident with sufficient force to inflate an air bag, suspect a TMJ injury.

INDIRECT TRAUMA

Think of the head, neck, and mandible in the form of a free body diagram, each a separate entity held together by various soft tissue components. In a direct blow to the mandible, for instance, there is a point of impact at which blunt trauma (crush) can occur. If there is enough force, the mandible is moved along a vector line until it contacts another bony component (the skull). The force transmitted moves the skull along the same vector that will ultimately cause movement of the neck as well. Along and between the bony interfaces and interconnections lie various soft tissues, which absorb the shock and are subjected to these forces.

In an indirect injury to the TMJs from acceleration injury (whiplash) in a rear-end motor vehicle accident (REMVA), the dynamics and chain of events change, but the results are similar. In a REMVA, the auto actually moves out from under the occupant. The first movement is the relative forward motion of the torso followed by movement of the neck occurring within 0.1 to 0.2 seconds. There is a lag time of skull movement during this motion. The skull moves both translationally for a brief period of time and in an arch around the movement of the neck (rotational). Considering the component of a free body diagram, there is also a lag time regarding mandibular movement when comparing the mandible to the skull and the cervical column. This movement is also both transla-

tional and rotational by nature of the anatomy. This lag time forces the soft tissues to absorb the energy involved while going from standing still (zero acceleration) to multidirectional movement. If the soft tissues did not absorb this movement the skull and mandible would disarticulate. The time period of energy transfer is so short that there is often movement of the head, neck, and TMJs before the Golgi tendon organs have time to fire the muscle bundles for resistance, resulting in muscular damage on either a microlevel, macrolevel, or both (Foust et al, 1974; Schneider et al., 1975). Once this absorption has been completed and the various body components are in motion, yet at different vectors, the movement is interrupted by the neck and torso contacting the seat or head rest. There comes a brief moment when all rearward movement is stopped with multidirectional compressive forces on the "shock absorbers," which are the soft tissues. The whole process is begun again in reverse with the skull leading the way arching around the neck and mandible, producing large compressive and shear forces on the supporting soft tissues as the body goes through the rebound stage of deceleration.

There are aspects of indirect trauma in acceleration injuries in which the victim did not hit his or her head that warrant attention. The first is *contact among the mandible, skull, and cervical spine*. The only thing that actually stops bone striking bone is the soft tissue components. The amount of forces involved is influenced greatly by the acceleration of the various body parts both in unison and relatively with each other. $F = M \times A$ (F = force, M = mass, A = acceleration). The second is *the neck and skull striking the head rest.* It has been indicated that head rests are often not designed properly to stop cervical injuries (Anonymous, 1995). The resulting forces in some instances may in fact be magnified, resulting in added forces to the neck. The third is *the chin hitting the chest during the ride down or deceleration phase*. It has been suggested that striking the chin on the chest reduces the forces on the cervical spine (Mertz & Patrick, 1967). The law of conservation of energy, however, dictates that the forces must go somewhere. They are not dissipated. The resulting stresses on the mandible and, therefore, the TMJs may increase as a result. Last, due to the shortness of the force duration and confusion and disorientation of the occupants, the patient's history regarding this brief period is not always reliable. The actual time of impact is very short, averaging between .1 and .2 seconds. The victim's recollection may or may not be accurate. The actual resulting injuries to the body are a more significant indication of trauma.

Many chronic TMJ disorders may not be readily apparent at the initial injury and may be temporally removed from the development of symptoms (Raj, 1996). It is not uncommon for a latency period to exist between the traumatic event and the dysfunction and pain in the TMJs and soft tissue supporting structures. This relatively asymptomatic period of time can extend from 3 to 6 months. Because acceleration-induced TMD, by nature of human anatomy and REMVAs, are commonly associated with cervical injuries (Talley & Ousley, 1994), the focus on the cervical injuries, as well as the pain, often takes precedence over injuries to the TMJs. Cervical soft tissue injuries produce such similar symptoms that the two are often confused early in treatment. There is a direct connection between the trigeminal nerves that help mediate noxious stimuli and the motor movements of various structures of the TMJs, and the occipital nerves originating in the cervical spine. Anatomical dissections indicate direct anastomization of these two supposedly separate nervous components (Baburr, 1989; Cox & Cocks, 1979). A change in function of the musculature of the masticatory system via the occipital nerves and the trigeminal system may result, leading to a delayed onset of TMD symptoms without initial direct damage to the TMJs. Damage to the TMJs and their supporting structures can also occur on a cellular level and may take time to cause systemic changes that are perceived by the patient as pain. Microdamage in the human body may lead to macrodamage that leads to dysfunction. This process may take months to complete depending on which level damage has occurred and whether healing has taken place.

Resulting injuries can initiate a repetitive strain syndrome. As a result of trauma, the occlusal surfaces of the teeth may be the only component of the masticatory system that has not been altered. The unchanged occlusion takes over the masticatory system's dominant role causing a tug of war among edematous soft tissues of the TMJs themselves, dysfunctional muscles, damaged ligaments, strained capsules, and the teeth. This discrepancy may surface clinically as bruxism, exacerbating an already compromised functional ability. The result is a scenario not unlike other repetitive strain syndromes that result from biochemical insults, cellular breakdown, and eventually system breakdown as a function of repetitive dysfunction and time. Misdiagnosis is probably one of the leading causes of delay of treatment onset. People are often advised that the pain will go away and to wait. NSAIDs, muscle relaxants, and rest, while appropriate initially, may not be efficacious for a given patient. If pain and dysfunction persists then further evaluation and treatment is in order. The development of a good working relationship with dentists specifically trained in the diagnosis and treatment of TMD in a multidisciplinary team approach is extremely important for successful diagnosis and treatment.

PSYCHOGENIC ORIGINS

The exact role of emotional problems such as stress, anxiety, and depression in patients with TMD is uncertain. Diamond and Delessio (1980) report a phenomenon of

"depression headache," which is a somatic characterization of depression. It has been suggested that almost any psychiatric disorder predisposes patients to tension-type headaches. Too often patients with clearly discernible signs of TMD have been diagnosed as having somatization of emotional disorders resulting in pain. The variability of pain complaints associated with frequent maladaptive behavioral psychosocial sequelae often leads clinicians to diagnose TMD problems as purely psychogenic. Having a good working relationship with a skilled dentist can prove vital in achieving an accurate diagnosis from which to initiate treatment. In many cases, chronic muscle spasm of the masticatory and cervical muscles results in a vague diagnosis of "tension" type headaches. After months of pain, the patient's serotonin level can become depleted resulting in clinical depression. This is sometimes coupled with many visits to multiple doctors all with no diagnosis, direction, or hope of recovery. Before a patient is relegated to the category of psychosomatic disorders or somatization, clinically demonstrable signs of TMD should be pursued by a dentist specifically trained in the diagnosis and management of TMD.

Sleep Disturbances

Sleep deprivation often accompanies chronic pain. The patient's situation can become a "chicken or egg" dilemma. It is known that the interruption of stage IV — deep restorative sleep — is common in patients with chronic pain (Cady & Fox, 1995). There are times sleep disturbances are initiated by an acute episode such as trauma or surgery and, when perpetuated, result in chronic sleep deprivation (Cady & Fox, 1995). On the front line of defense in treating TMD is to make sure the patient is sleeping well. There should be a differentiation between a lack of sleep due to pain and a true sleeping disorder, which may require the attention of a physician concentrating in the area of sleep disorders and deprivation.

TREATMENT OPTIONS

Traditionally, TMD treatment is divided into two phases. Phase I is the segment of treatment that includes all techniques designed for pain reduction, tissue healing, and restoring the TMJs to a state of quiescence. Phase II is the segment of treatment that corrects any discrepancies between the mandibular position, the teeth, and the supporting structures that is often thought of as the dental aspect of TMD treatment.

Phase I

There is, of course, not one sole treatment mode that will help alleviate dysfunction of TMJs or the resulting pain. As in any problem, there are multiple ways to address

issues and achieve clinical success. As a rule of thumb, a conservative approach should be used initially. Physical modalities such as moist heat, ice massage, rest, and a soft food diet should be attempted as a first line of defense. A mild exercise regimen may augment healing and reduction of symptoms. NSAIDs, muscle relaxants, and analgesics should be used as adjuncts for a limited period of time. Narcotics should be prescribed with caution due to the potential for both physical and/or emotional attenuation. As in any chronic pain condition, tricyclic antidepressants have been found efficacious both for the inhibition of serotonin uptake and as an adjunct for sleep.

If symptoms do not resolve rapidly, then an intraoral orthotic designed to relax the musculature and reduce intra- and extra-capsular inflammation should be employed. Pharmacological support as previously mentioned can help in pain reduction. Physical therapy modalities in conjunction with a guided rehabilitation program will help restore the patient to proper form and function. Other supportive care can be furnished by speech pathologists, occupational therapists, dietitians, massage therapists, and biofeedback programs.

Surgical intervention should be used with caution. Often arthrocentesis or arthroscopy is preferred over a full open joint procedure. There are times, due to severe degenerative joint disease, that more complex surgeries or variations of joint reconstruction may be needed. These, however, are rare, and careful case selection is tantamount to assuring success. Physical therapy rehabilitation is a must following any type of surgical intervention. The regimen must be carefully designed to restore the affected areas to proper physiologic function allowing for maximum medical improvement.

Phase II

There are times restoring TMJs to proper form and function requires alterations in the dentition. Several methods can be used in combination for this purpose. These methods almost never should be attempted when the patient is in an active state of pain but rather should be used as a finishing technique only after Phase I has been successful (Shankland, 2001). In most instances pain is a soft tissue phenomenon. Hard tissue landmarks, as indicated by x-rays, do not dictate a "pain-free" position for the patient. Categorically you cannot look at x-rays, casts of the teeth, or other hard tissue diagnostics alone and predict within the realm of human physiologic function where a pain-free stomatognathic position should be. Drawing these conclusions is often erroneous and indicates a possible misunderstanding of pain etiology. Not everyone needs perfect occlusion or aesthetically pleasing teeth to live a pain-free life. The object of TMD treatment should be the resolution of the patient's pain, not the restoration of the dentition to as perfect a position as possible unless dictated

TABLE 27.2
Common Methods of Phase II Finishing Techniques

1. *Equilibration.* This is a technique in which the enamel surfaces of the teeth are altered by the use of dental handpiece to restore proper occlusal alignment with the TMJs and their supporting structures.
2. *Crown and Bridge: Prosthetics.* Missing or broken teeth often need to be restored to provide maximum stomatognathic support during function. There are a variety of devices that fall into this category all of which aim for the same result. The required prosthesis is dictated by patient's need and desire.
3. *Orthodontics.* This technique is best used when there is a resulting discrepancy between the maxillary and mandibular position or the patient's teeth have had limited restorative work. This finishing technique can be quite effective when properly utilized.
4. *Use of an appliance/orthotic on an as-needed basis.* There are times when this is the most conservative and logical approach to a chronic problem. The use of this technique should be infrequent, however, and after all other physical means are exhausted. Long-term use of an orthotic can cause problems with the teeth and periodontium. There is also the chance of dental compensation with the orthotic yielding an acquired malocclusion or mandibular reposturing.
5. *Orthognathic surgery.* Surgical techniques should be used judiciously. Great care must be taken to guide the patient to as pain free a state as possible before any reconstructive surgery should be attempted. Rarely is surgery an initial treatment.

by the patient's specific needs. A lot of people are in chronic pain with perfect occlusion, and many with terrible occlusion and compromised stomatognathic function are pain-free. A proper diagnosis and clinical stabilization will help determine the need for Phase II treatment. Methods for Phase II finishing techniques are shown in Table 27.2.

THE TWO-MINUTE TMJ EXAM

Initial screening for TMD does not have to be complicated. Table 27.3 delineates some simple procedures that will help provide an indication if there is a need for a dental consultation to rule out TMD as a contributing factor to the patient's pain complaints.

MULTIDISCIPLINARY PAIN TREATMENT

Because TMD is often a manifestation of multiple precipitating factors, management requires cooperation between many health care professionals. A review of the signs and symptoms often associated with TMD brings to mind many clinical possibilities that need to be considered when determining a proper diagnosis. No one profession can dominate all care when it comes to chronic pain. The artificial delineation of practice parameters as dictated by licensure and custom is artificial indeed when it comes to the management of pain.

TABLE 27.3
The Two-Minute TMJ Exam

1. *Maximum mouth opening.* Look for limitations or deviations
   a. Normal is approximately the width of three fingers without pain
   b. Mandibular opening should be relatively straight without deviation
2. *Joint noise.* Healthy TMJs should be virtually silent both to you the clinician and the patient
   a. Popping, clicking, or grinding in one or both of the TMJs in the presence of facial pain, headaches, or neck aches
   b. This can be by patient report, manual palpation of the TMJs, or using a stethoscope
3. *Pain upon muscle palpation.* Facial muscles in healthy conditions are not tender to touch
   a. Masseters
   b. Temporalis
   c. Intraoral muscles
4. Otological exam
   a. Excessive earwax bilaterally or unilaterally in the absence of obvious pathology
   b. Pain in the external auditory canals distal to the TMJs upon insertion of the otoscope in the absence of obvious pathology

The key to success in the management of the patients with facial pain is to understand the limitations of one's own abilities and to appreciate the talents and skills of other professions. While one profession may be the primary provider in any given situation, the manifestation of the various symptoms of the patients with TMD in all probability will require a true team effort. Although many patients can present a challenge for treatment, one of the benefits to the practitioner is the opportunity to communicate with fellow professionals outside his or her chosen discipline. Discussion with others can produce exciting opportunities for learning and sharpening each other's diagnostic skills. Unfortunately, without these opportunities various disciplines of the healing arts go without communication resulting in a misunderstanding of each other's abilities. The modern age of information availability and transfer are converging the once rigid walls between professions, resulting in a better, more rounded approach to management of the patient with TMD/chronic head, neck, and facial pain.

COMMON CONCERNS ABOUT TMD

Determining if a patient's headache complaints are related to a dysfunction of the TMJs: Obvious indications may include popping noises, inability to open his or her mouth, pain in the TMJs upon chewing, etc. There are frequently more insidious indications as well. Remember the TMJs and their supporting structures may produce symptoms anywhere along the trigeminal nerve tract, making the diagnosis difficult at times.

TMJ problems and mouthpiece use: While an orthotic (appliance) is necessary in many situations, localized inflammation sometimes may be handled conservatively by NSAIDs, muscle relaxants, exercise, and physical therapy. As with any other functional orthotic, the design is dictated by the patient's needs. Often they are used to keep the mandibular condyles from pressing into the edematous retro-discal lamina, which is richly innervated. Decompressing of the joint mechanism is often necessary to help break the spasm–pain–spasm cycle reducing pain and dysfunction. In addition, orthotics can also be used strictly for myositis, myalgia, muscular imbalance, or repositioning the mandible on a temporary or permanent basis.

TMJs that pop and click: A proper diagnosis is necessary to determine if TMJ noises are contributing to the patient's pain. TMJ noises are one of many symptoms that indicate pathology but are not pathognomotic for pathology that needs to be treated.

TMJ patients and headaches: Many times the temporalis, masseters, lateral pterygoids, and various neck muscles are all under tension. A TMJ headache is often a skeletal muscle contraction headache. Across the board, 80% of all headaches are of the muscle contraction variety. A chronic dysfunction of the TMJs may result in chronic muscle tension.

TMJ therapy: The length of time needed will vary greatly according to the type of problem as well as its chronicity. Obviously, a muscle sprain will respond more quickly than a joint with rheumatoid arthritis. Unfortunately, all conditions of this nature are erroneously placed under the label of *TMJ* and should be more accurately differentially diagnosed.

Prevalence of TMJ: Women outnumber men about eight to one except for victims of automobile accidents, where the ratios tend to be more equal. Women also suffer about the same ratio for every other joint injury. They seek care more often than men in about those same numbers for other afflictions. The reasons are thought to be structural, hormonal, and societal.

TMJ pain caused by depression: Depression may play a major role in some cases of facial pain but does not lead to a true dysfunction of the TMJs. Chronic pain from any source often leads to depression due to depletion of serotonin and other neurotransmitters. Remember, many TMJ sufferers have been labeled as malingering due to improper or misdiagnoses and have been suffering for years. Chronic pain may take on a familial setting exacerbating feelings of guilt, inadequacy, and depression.

Curing TMJ: As in any condition, without proper diagnosis, there can be no cure. Many acute injuries to the TMJs, if caught early, will respond rapidly to conservative care, often within days or weeks. Even patients with chronic conditions can be successfully managed with proper treatment. Conservative care of chronic degenerative TMJ often yields a positive response using procedures from physical medicine such as those previously mentioned.

Proper time for a dental consultation: A properly trained dentist should be thought of as a partner in the management of head, neck, and facial pain. Dentistry and other disciplines do not compete with each other. The more each profession understands the other, the more comfortable each will feel in asking for opinions. As a rule of thumb, if a patients with headache/facial pain does not respond to a medicinal treatment regimen, then a consultation with a dentist should be in order. All fields of pain management working together often yield a synergism resulting in good clinical results and satisfied patients.

Dental referrals for TMJ: Many dentists, due to the complexity and time needed to treat these types of patients, choose not to treat patients with TMD. On the other hand, some dentists choose to concentrate their practices in this field and have spent much time in continuing education and specialized training. Typically, a well-trained dentist should look at teeth as a component in the pain cycle and not always as the sole entity. The way the bite fits together may or may not be an issue in the patient's head, neck, or facial pain, and the dentist should have the proper training to be able to differentiate. A treating dentist should also have the mind-set of a "team" approach so that proper treatment reciprocation is present.

Abdominal Pain

Sean R. Lacey, MD

INTRODUCTION

Pain originating from the abdominal region can challenge even the best clinician. As with any patient symptom, it is of utmost importance to obtain a detailed history. Unlike other regions of the body, many different organ systems can give rise to abdominal symptoms. Pain originating from the gastrointestinal tract and its solid organ constituents is the focus of this chapter. Other potential causes of abdominal pain including vascular, gynecological, and renal sources should be considered although they are not the subjects of this chapter.

When first evaluating a patient with abdominal pain, it is extremely important to establish a timeline of events. In doing so, the clinician will separate acute from chronic pain and constant from intermittent pain. It will allow the physician to focus on the pain for which the patient is seeking consultation. Extracting the location or locations of pain and whether the pain has changed in location over time can elucidate the physician and allow for a more focused exam. If the pain seems to radiate to other regions, this can also give helpful information. Also, the association of new symptoms other than pain can narrow the differential diagnosis for the origin of pain. Such symptoms may include, but not be limited to, nausea, vomiting, diarrhea, constipation, bloating, intestinal bleeding, weight loss, early satiety, dysuria, dysparunia, and fever. The association of symptoms with eating, fasting, or how they change with flatus or bowel movements can also assist in providing additional information to arrive at a correct diagnosis.

The physical examination is an extremely valuable tool to use in cases where abdominal pain is present. Usually, the sequence of events used during the exam includes inspection first; followed by auscultation, palpation, and percussion. Inspection and palpation are the most useful, however. Many of the organs of the abdominal cavity are palpable even under normal circumstances, and therefore, knowing and appreciating the normal abdomen are essential. When the normal abdominal structures are well known, it will be much easier to recognize the "abnormal" abdomen. When palpating the abdomen, first identify where the painful region or regions are located by asking the patient, then examine that area *last*. This will allow for a more through exam by keeping the patient comfortable and preventing involuntary contractions of the abdominal musculature.

It may be easiest to separate the contents of the abdomen into solid and viscous structures. Solid structures are often appreciated during the physical exam and include the liver, spleen, pancreas, kidneys, uterus, and ovaries. Hollow organs such as stomach, intestines, urinary bladder, and gallbladder are generally not well appreciated, but may be palpable and appreciated if involved in a neoplastic process or if they are distended by air/gas.

In the performance of the physical exam it is important to follow a general routine so that a thorough exam is employed. However, depending on the clinical circumstance, an astute diagnostician will occasionally employ other techniques to confirm/refute suspicions. The most common way of examining the abdomen is to have the patient lie in a supine position. Flexing the knees will often take tension from rectus muscles of the anterior abdominal wall and allow for a more successful experience during palpation. In conveying and recording the exam findings, it is important to identify the location or topography of the abdomen. This is illustrated in Figure 28.1. The most commonly used system divides
FIGURE 28.1 Topographical regions of the abdomen. A = right upper quadrant; B = left upper quadrant; C = right lower quadrant; D = left lower quadrant; E = epigastric; F = suprapubic.
FIGURE 28.2 Locations of visceral pain and organs often associated with each region. A = epigastrium: stomach, duodenum, liver, biliary tree pancreas; B = periumbilical: small intestine, appendix, right colon; C = suprapubic: transverse/left colon, rectum, gynecological.

the abdomen into four quadrants with their intersection through the umbilicus. More specific regions have been described as either periumbilical or epigastric in location. Making the distinction about location is important in following the clinical course of the patient and conveying the findings to other colleagues. A simple diagram such as that illustrated in the figure with the area of pain shaded can be very helpful in following such patients with chronic symptoms.

Throughout the years, many physical exam maneuvers and findings have been associated with clinical conditions. Although many of the signs and symptoms elicited during the physical exam are lacking specificity and sensitivity and have not undergone rigorous scientific testing, it is important to mention them. In modern-day medicine, the clinical suspicion of a condition has been augmented by confirmatory testing, including serology and diagnostic imaging (i.e., magnetic resonance imaging, computed tomography, and ultrasound). Included in Table 28.1 are common signs elicited during the physical examination and the clinical condition(s) often associated with each.

Pain can be visceral, somatic, or referred. Visceral nociceptors are most sensitive to stretch and these stretch receptors are located in the muscular layers of the hollow viscera between the muscularis mucosa and submucosa and in the serosa of solid organs (Leek, 1972). This type of pain is generally not well localized and patients will often give a very vague description of their discomfort. Nerves that transmit these signals originate from multiple segments and can be mechanoreceptors or nocireceptors, among others. These nerves are nonmyelinated and give rise to symptoms that are diffuse and poorly localized, typically described as achy, gnawing, burning, or cramping. Somatic pain tends to be much better localized and may be easier for patients to describe. Nerves are often myelinated. Irritated areas that may give rise to somatic pain include the abdominal wall, parietal peritoneum, or diaphragm. Referred pain is located in the same dermatome as the source for the pain, but is perceived in a distant location. Pain is often well localized and therefore does resemble somatic pain in its characteristics (Figure 28.2).

TABLE 28.1
Common Physical Exam Signs and Associated Conditions

Physical Signs	Examination Findings	Clinical Condition(S)
Caput medusa	Engorged veins extending out from the umbilicus	Portal vein thrombosis, vena cava obstruction
Cullen's sign	Blue discoloration around the umbilicus	Hemoperitoneum
Grey Turner's sign	Discoloration of skin of lower abdomen and/or flanks; color may vary red/blue/purple	Hemorrhagic pancreatitis, bowel infarction
Borborygmus	Intestinal sounds heard without the assistance of a stethoscope associated with abdominal pain and visible peristalsis	Partial or complete intestinal obstruction
Rebound tenderness	Pain resulting from rapid withdrawal of depressed fingertips	Peritoneal inflammation; perforated viscous
Murphy's sign	Cessation of inspiration in mid-breath secondary to pain when gallbladder comes in contact with examining fingers in RUQ	Cholecystitis

TABLE 28.2
Causes of Acute Abdomen Pain According to Pain Quality and Onset

Pain Type	Possible Condition
Excruciating, acute onset over seconds	Heart attack, perforated ulcer, ruptured aneurysm, biliary or renal colic
Rapid, severe and constant over minutes	Acute pancreatitis, mesenteric ischemia/infarction, complete bowel obstruction
Gradual onset/steady over hours	Acute cholecystitis, diverticulitis, appendicitis
Intermittent/colicky pain over hours	Early pancreatitis/bowel obstruction

The evaluation of the acute abdomen must take into consideration many factors, but most important is that of whether surgery is needed. Generally, acute abdominal pain is described as sudden in onset and present for less than 24 hours. In the setting of a perforated viscous, the emergent need for surgery may be a lifesaving measure. Careful attention should be paid to the characteristics of abdominal pain and the progression of current symptoms. Although this detailed history does not always allow the correct diagnosis to be made, certainly some conditions are associated with common symptoms and the clinical suspicion will be higher for that particular entity.

Table 28.2 depicts common causes of the acute abdomen and the typical characteristics associated with each.

PAIN FROM FLUID

Collections of fluid outside the intestinal lumen are generally considered abnormal. However, a small accumulation of fluid in the cul-de-sac in female patients can be a nonspecific finding. Ascites is never normal. Fluid in the peritoneal cavity usually does not cause pain unless there is a significant amount of fluid, called "tense ascites." In this circumstance, the abdomen is distended and pressure is exerted on the abdominal wall as well as on the intra-abdominal contents. Relief can be achieved by decompressing the distended abdomen with paracentesis or diuretic therapy. If the fluid is infected, the peritoneum can become inflamed leading to pain. Spontaneous bacterial peritonitis (SBP) should always be suspected in patients with ascites, but only 50% of patients with SBP will complain of abdominal pain (O'Grady, Lake, & Howdle, 2000). SBP is a condition where the ascitic fluid is infected, but a source cannot be identified. A significant proportion of hospitalized patients with ascites, 10 to 30%, may have or develop SBP (Yu & Hu, 2001; Jaffe, Chung, & Friedman, 1996). Patients with a low ascitic protein content are at higher risk for the development of SBP and those with a prior history of SBP have a 70% chance of

TABLE 28.3
Causes of Ascites Based on SAAG Measurement

SAAG ≥ 1.1 g/dl	SAAG < 1.1 g/dl
Cardiac ascites	Chylous acities
Cirrhosis	Peritoneal carcinomatosis
Hepatic failure	Infection, tuberculosis, chlymydia
Alcoholic hepatitis	Biliary ascites
Massive liver involvement with tumor	Pancreatic ascites
Budd-Chiari syndrome	Bowel perforation
Hepatocellular carcinoma	Peritonitis from connective tissues diseases
Portal vein thrombosis	
Myxedema	
Acute fatty liver of pregnancy	
VOD (venoocclusive disease)	

a recurrent episode (Garcia-Tsao, 2001). Mortality rates have dropped significantly given the prompt recognition of the infection and appropriate therapy; however, inpatient mortality still approaches 20% and the 2-year survival rate is 30% after a documented case of SBP (Garcia-Tsao, 2001).

The diagnosis of SBP is made by examination of the ascitic fluid. If the leukocyte count exceeds 250 cells/mm^3 or ascitic fluid culture is positive, SBP is confirmed (Guarner & Runyon, 1995). Solely relying on a positive culture is not sufficient, as many patients, up to 40%, will exhibit culture negative SBP (Yu & Hu, 2001). In the past, ascites was evaluated using the terms *transudative* or *exudative*. This terminology has been largely replaced by the determination of the serum-ascites albumin gradient (SAAG). The determination of the SAAG can be accomplished by measuring the serum and ascites albumin concentrations at the same time and subtracting the ascitic fluid albumin concentration from the serum albumin concentration. This is highly accurate in predicting ascites from portal hypertension (Runyon, 1998). The differential diagnosis of ascites based on SAAG is listed in Table 28.3 (Runyon, 1998).

LIVER AND BILIARY PAIN

Conditions that affect the liver often will go unnoticed by the patient. It is only when the liver capsule expands that pain is generally perceived. Therefore, most any condition that causes liver enlargement will produce pain. Pain will also generally be more intense if the capsule expands at a rapid rate. The number of conditions that can lead to liver enlargement is quite extensive and is beyond the scope of this chapter. Common conditions that are recognized to cause rapid liver enlargement are acute hepatitis, alcoholic hepatitis, and space-occupying lesions such as metastatic and primary liver neoplasms.

Pain originating from the gallbladder classically presents as a positive Murphy's sign, but this is generally only appreciated in acute cholecystitis, a condition that occurs when the cystic duct becomes blocked. Pain is usually in the right upper quadrant and radiates to the right scapula and is associated with nausea and vomiting. Fever is usually also present along with leukocytosis. Symptoms of biliary colic are also very similar to those of cholecystitis; however; the pain symptoms generally subside after several hours, whereas pain from cholecystitis can persist longer until more definite therapy is begun (i.e., antibiotics, cholecystectomy, etc.). Last, cholangitis, an infection of the bile ducts, can have similar presenting signs/symptoms. This infection generally produces significantly high fevers, chills, rigors, and abnormal liver enzyme values. Jaundice will often accompany this infection. The cornerstone of therapy involves systemic antibiotics and prompt decompression of the biliary tree. This is usually accomplished via endoscopic retrograde cholagiopancreatography or percutaneous transhepatic catheter drainage.

IRRITABLE BOWEL SYNDROME

Irritable bowel syndrome (IBS) is an extremely common condition and has been prevalent for many years. Physicians and other health care professionals historically have thought that it was a condition brought on by psychiatric problems and that it was "in the patient's head." Although there has been no definite connection between psychological disorders and IBS, there does seem to be a higher incidence of comorbid psychiatric conditions (Olden, 2002). Referral centers have reported that patients seeking consultation have a high percentage (54 to 94%) of already recognized coexisting psychiatric disorders such as anxiety or depression (Olden, 2002; Thompson, 2002). Sexual abuse has also been seen more commonly in patients suffering from IBS (Michell & Drossman, 1987). It is not clear if there is a cause–effect relationship between psychiatric disorders and IBS, but it does seem to influence which patients are more apt to seek medical attention for IBS symptoms and it may also influence symptom severity and outcome (Michell & Drossman, 1987).

In more recent years, IBS has finally received much-needed attention. Significant research into the cause of this disorder has led to new discoveries to explain symptoms and subsequently to new therapies. The impact that IBS has on North America is astounding. Approximately, 15% of the adult population is affected by the symptoms of IBS, two thirds of which are female (American College of Gastroenterology, 2002; Brandt et al., 2002). In one study of 1,597 patients with IBS, 57% reported daily symptoms, 25% reported weekly symptoms, and 50% of respondents had experienced symptoms for longer than 10 years (Schmulson & Chang, 1999). Additionally, symptoms interfered with work where 12% stopped work-

TABLE 28.4
Diagnosing Irritable Bowel Syndrome; ROME II Criteria

1. Patient has had abdominal pain or discomfort for at least 12 weeks over the past 12 months. Pain does not need to occur in consecutive weeks.
2. Abdominal pain or discomfort has two of the following three features:
   a. Relief with defecation
   b. Onset associated with an alteration in bowel movement frequency
   c. Onset associated with an alteration in stool appearance/form
3. Nine symptoms supporting the diagnosis of IBS
   a. Fewer than three bowel movements per week
   b. More than three bowel movements per day
   c. Hard or lumpy stools
   d. Loose or watery stools
   e. Straining during bowel movements
   f. Urgency
   g. Feeling of incomplete evacuation
   h. Passing mucus during bowel movement
   i. Abdominal fullness, bloating, or swelling

ing and 47% had missed days at work secondary to their symptoms (Schmulson & Chang, 1999). IBS symptoms also can interfere with leisure activities, diet, and social relationships in a negative way, thus leading to impaired quality of life (Schmulson & Chang, 1999; Whitehead, Palsson, & Jones, 2002). The financial impact is also significant. Because there are no objective biochemical markers, anatomical defects, or physical exam findings that are clearly linked to IBS, the diagnosis is made by the constellation of symptoms and the presenting characteristics a patient possesses (Brandt et al., 2002: Hungin et al., 2002).

IBS is a multisymptom complex that is manifested by alteration in bowel habit frequency, stool consistency, and associated abdominal discomfort (pain, cramping, bloating, etc.). In an effort to help define the characteristics for IBS and ultimately to establish a "common ground" to study this disorder, specific diagnostic criteria have been developed by the Multinational Working Teams to Develop Diagnostic Criteria for Functional Gastrointestinal Disorders (International Foundation for Functional Gastrointestinal Disorders, 2002). The resultant ROME II criteria are very helpful in arriving at an accurate diagnosis of IBS (Table 28.4).

Patients who present other signs or symptoms, sometime called "red flags," which may represent diseases mimicking IBS, may require additional testing. Red flags may include, but not be limited to, occult positive stool, overt gastrointestinal bleeding, weight loss, vomiting, anemia, fever, family history of celiac disease, intestinal cancers, or inflammatory bowel disease.

The treatments of IBS are generally focused around alleviating the predominant symptoms. In other words, if

TABLE 28.5
Commonly Used Treatments/Medications for the Management of IBS

Drug Class	Dosage	Side Effects	Intended Use
Antispasmodics			
Dicyclomine	10–40 mg qid	Sedation, dry eyes and mouth, urinary retention, constipation	Improve abdominal pain/bloating
Hyoscyamine	0.125–0.25 mg tid–qid	Same as dicyclomine	Improve abdominal pain/bloating
Bulking Agents			
Fiber	20–35 g/day	Bloating/gas	Improve constipation
Antidiarrheals			
Loperamide	2–4 mg qid, max of 16 mg/24 hrs	Nausea/constipation, dry mouth/abdominal pain	Improve diarrhea
Diphenoxylate	5 mg tid–qid	Constipation, abdominal pain	Improve diarrhea
Atropine	—	Nausea, anorexia	—
Cholestyramine	4 g qd-q12h	Gas, may affect absorption of other drugs	Bile resin binder
Opiates	Variable	Sedation/constipation, addiction potential	—
Laxatives			
Lactulose	10–20 g qd–bid	Bloating/gas/cramping	Improve constipation
Polyethylene glycol	17 g/day	Bloating/gas/diarrhea	Improve constipation
Tricyclic Antidepressants			
Amitriptyline	10–100 mg qhs	Dry mouth/eyes, sedation, constipation	Improve diarrhea/pain
Imipramine	10–100 mg qhs	Same as amitriptyline	Improve diarrhea/pain
SSRIs			
Sertraline	Variable	Sexual dysfunction	Improve pain
Fluoxetine	—	Sedation, fatigue, weight gain	—
5-HT$_3$ Antagonist			
Alosetron	1 mg qd × 4 wks, if tolerated 1 mg bid	Ischemic colitis, constipation	Improve diarrhea, pain, and bloating
5-HT$_4$ Agonist			
Tegaserod	6 mg bid × 12 wks	Diarrhea, headache, ischemic colitis	Improve constipation, pain, bloating

a patient is constipated with hard/lumpy stools, then the treatment would be to soften the bowel movement and increase frequency of bowel habits. Traditional therapies have been the use of antispasmatics, laxatives, antidiarrheal agents, and fiber. Table 28.5 presents a list of drugs that are commonly used, including doses and potential side effects.

Only recently have new therapeutic agents been developed and FDA-approved for the treatment of IBS. It is known that serotonin receptors are very plentiful in the intestinal tract. Binding to these receptors is important in the regulation of motility and secretion of the bowel. Cortisol, acetylcholine, histamine, and serotonin are some of the more important hormones currently under investigation for the understanding of IBS.

Serotonin has become a focus of interest because of the rich concentration of this substance in the intestinal tract; in fact, nearly 95% of this hormone is found within the enterochormafin cells of the intestine. Of note are the drugs alosetron HCl (Lotronex™; Glaxo-SmithKline) and tergasarod (Zelnorm®; Novartis). Alosetron, a 5-HT$_3$ receptor antagonist, gained FDA approval for the treatment of diarrhea-predominant IBS (IBS-D); however, it was voluntarily removed from the market secondary to potential adverse events thought to possibly be caused by the drug in November 2000. Some of the adverse events include ischemic colitis and constipation. After additional consideration, the FDA approved the use of alosetron in June 2002 under a restricted prescribing program. As of this writing, only women with severe IBS-D who have failed other traditional therapies are eligible for treatment. Patients and physicians are required to sign an agreement form and special stickers are required to prescribe the medicine. Initial dosage of alosetron is 1 mg daily for 4 weeks which can be increased to a maximum of 1 mg twice daily if it is tolerated. If no symptom improvement is achieved after 4 weeks of treatment at the maximum dose, it is then advised to discontinue alosetron and seek

alternative management options. Alosetron has not only been shown to decrease the number of bowel movements, but perhaps just as important, it has also been demonstrated that it has some efficacy in relieving global symptoms of IBS and therefore improving quality of life (Lievre, 2002). For more information regarding the educational materials for Lotronex or to enroll in the prescribing program, call 888-825-5249 or visit www.lotronex.com.

Tegaserod was released in July 2002 and is FDA-approved for the treatment of constipation-predominant IBS (IBS-C). Tegaserod is a 5-HT$_4$ receptor agonist, which is involved in the peristaltic action of the gut (Lacy, 2002). Large randomized controlled studies have been done using tegaserod and have demonstrated significant global symptom improvement (pain, bloating) in addition to relieving constipation problems. Nearly two thirds of women studied had improvement or resolution of IBS-C related symptoms (Brandt et al., 2002; Lacy, 2002; Muller-Lissner et al., 2001; Prather et al., 2000). At the current time, tegaserod is approved only for use in women, but studies showing efficacy in men with IBS-C are currently in progress. In April 2004, Novartis, makers of Zelnorm, released a statement warning physicians of the dangers of diarrhea that can be induced by the medication and rare case reports of ischemic colitis. All potential serious adverse events are to be reported to the FDA MEDWATCH program.

INFLAMMATORY BOWEL DISEASE

Crohn's disease (CD) and ulcerative colitis (UC) are idiopathic intestinal inflammatory disorders that are lifelong. Both diseases are associated with abdominal pain, among other symptoms, including gastrointestinal bleeding, diarrhea, fistula, abscess, weight loss, anemia, and increased prevalence of intestinal cancer, especially of the colon when it is involved. Both diseases are associated with relapses resulting in high morbidity and have a negative impact on quality of life (Cohen, 2002). The goal of treatment of these chronic illnesses is to control symptoms effectively, to prevent complications as a result of the disease, and to avoid adverse reactions related to available treatment. Although the etiology is not completely understood, several mechanisms are important in the development and manifestation of inflammatory bowel disease (IBD) and include genetic as well as environmental factors. The therapies available continue to evolve and currently involve conventional therapy in addition to biologic and anti-tumor necrosis factor-alpha (TNF-alpha) agents. It is hoped that a cure will be discovered, but for the 1 to 2 million plus patients with IBD in North America (Crohn's & Colitis Foundation of America, Inc., 2004), symptomatic control offers the best opportunity for improved quality of living.

CD is a lifelong illness that can be diagnosed at any time; however, it is most often diagnosed in the second to

---

TABLE 28.6
Side Effects Associated with Corticosteroid Use in the Treatment of Crohn's Disease

Dermatological	Acne, hirsutism, striae, telengiectasia
Endocrine	Adrenal suppression, diabetes
Ophthalmologic	Cataracts, glaucoma, retinal hemorrhage
Musculoskeletal	Weakness, osteoporosis
Metabolic	Hyperlipidemia, fluid retention, electrolyte abnormality
Infectious	Increased risk of infection
Psychiatric	Insomnia, anxiety, psychosis, depression

---

third decades. CD can affect any part of the digestive tract with the ileum and cecum the most commonly affected. Symptoms that often accompany active CD include abdominal pain, fever, and diarrhea. Intestinal bleeding is also seen, but less often. One cardinal feature that distinguishes CD from UC is transmural inflammation of the intestinal lumen. This inflammatory process makes patients with CD more prone to fistula, abscess, and perforation. In fact, nearly 35% of patients with CD will develop fistulae (Schwartz et al., 2002). Other systemic manifestations of CD include malnutrition, osteoporosis, arthritis, uveitis, and nephrolithiasis. Once diagnosed and appropriately managed, remission is often achieved. Unfortunately, 47% of individuals will experience a relapse within the first year (Moum et al., 1997) and nearly 50% of patients with CD will undergo surgery within a decade of being diagnosed with the illness (Mekhijan et al., 1979).

The management of CD is composed of conventional agents (i.e., corticosteroids, aminosalicylates, and antibiotics) and newer therapies to be discussed. Corticosteroids are very good at inducing remission rapidly with success rates of 60 to 92% (Malchow et al, 1984; Modigliani et al., 1990; Summers et al., 1979). Clinical symptoms may also be improved with steroid use, but there remains endoscopic evidence of active inflammation despite the use of steroids (Yang & Lichtenstein, 2002). The chronic long-term use of steroids is not very effective in maintaining remission and has a high likelihood of causing side effects. Table 28.6 lists the common side effects seen with chronic corticosteroid usage.

In an effort to reduce the side effects of corticosteroids, a newer second-generation steroid agent was developed, budesonide. It has low systemic bioavailability due to its high first-pass hepatic metabolism. It is able to induce remission relative effectively at a rate of 52 to 69% (Campieri et al., 1997; Greenber et al., 1996; Retgeerts et al., 1994; Thomsen et al., 1998). Unfortunately, it also is not able to achieve long-term maintenance of remission, and relapse rates are similar in those patients using placebo compared with budesonide 6 mg daily (Ferguson et al., 1998; Greenberg et al., 1994; Lofberg et al, 1996).

Immune system–modulating agents have also been implemented to help maintain remission, but are not efficacious in inducing remission. 6-Mercaptopurine (6-MP) and azathioprine (AZ) have been used for many years as a way to diminish the need to use steroids and have therefore been called steroid-sparing agents. Although they are generally thought to be safer for chronic use than corticosteroids, the use of 6-MP and AZ requires continuous monitoring. One of the biggest limitations of their use is the slow onset of action. In patients who do respond favorably to these medications, the effect may not occur for 3 to 6 months after initiation of the medication. Also there are known side effects of 6-MP and AZ that include nausea, abnormal liver enzymes, pancreatitis, and allergic reactions. Bone marrow suppression can also occur and may be more profound in patients with diminished/absent thiopurine methyltransferase (TPMT) enzyme activity, a problem seen in 11% of the general population. As a consequence, it has been suggested to measure complete blood counts weekly upon initiation of therapy for the first month, biweekly for the next month, and then monthly to every 3 months thereafter. As a way to reduce potential toxicities related to their use, some have proposed the measurement of TPMT activity prior to commencing therapy; however, a consensus has not been reached regarding this routine practice. Approximately 45% of patients maintained on AZ were able to sustain remission compared with 7% tapered to placebo (Candy et al., 1995). The accepted doses for 6-MP and AZ are 1.5 and 2.5 mg/kg/day, respectively.

Methotrexates (MTX), cyclosporine A, mycophenolate mofetil, and tacrolimus have also been used as immunomodulators. The most data exist for the use of MTX for the induction/maintenance of remission; however, all of these agents are generally reserved for those who have failed other more conventional therapies.

Aminosalicylates have also been long used to help intestinal inflammation related to UC and CD. The exact mechanism of action for these drugs is not known, but several theories have been proposed. It is thought that this class of drugs may influence and downregulate the production of proinflammatory cytokines (TNF-alpha, interleukin-1, and nuclear factor kappa B). They may also affect oxygen free radical production and lymphocyte/monocyte activity (Lichtenstein, 2003). Several different aminosalicylate agents have been developed (Table 28.7) and are generally well tolerated, but all can have a paradoxical effect of making IBD symptoms worse. Should this happen, the medication should be discontinued. Formulations of the 5-aminosalicylate (5-ASA), the active portion of the medicine, are designed to be released in the lumenal intestinal tract at different locations. Most of the formulations are meant to release 5-ASA in the distal ileum/colon, but Pentasa® (mesalamine; Proctor and Gamble) can be delivered to the proximal small bowel

TABLE 28.7
5-ASA Agents Available and Recommended Doses

Sulfasalazine	500 mg tablets	2–6 g/day
Mesalamine		
Pentasa	250 mg capsules	2–4g/day
Asacol	400 mg tablets	2–4.8 g/day
Suppository	500 mg	0.5–1 g/day
Enema	4 g	2–4 g/day
Olsalazine	250 mg capsules	1.5–3 g/day
Balsalazide	750 mg capsule	2–6 g/day

also. Topical mesalamine in the form of suppositories and enemas is also available to treat the rectum and distal colon, respectively.

The presence of bacteria in the bowel may be partially responsible for the inflammation seen in IBD. Clinical and experimental data have shown a delay in recurrence of CD follow surgery if the fecal stream is diverted. Also, bacteria have been shown in the wall of the intestine and within mesenteric lymph nodes. Although the exact mechanism by which bacteria exert their effect is not well understood, the use of antibiotics to alter the bacterial makeup/concentration has been part of the treatment of active IBD (Stein & Lichtenstein, 2001). Metronidazole and ciprofloxacin have been used most extensively for the treatment of active IBD, especially when the colon is involved. The accepted dose of metronidazole is 10 to 20 mg/kg/day and for ciprofloxacin is 1 g/day.

Ciprofloxacin is better tolerated, with up to 90% of patients reporting a metallic taste with the use of metronidazole. Antibiotics have also been particularly helpful in management of perianal CD. Information regarding the long-term efficacy in the management of remission as maintenance therapy using antibiotics is lacking.

Tremendous enthusiasm has emerged with the discovery and use of newer biological agents in controlling inflammation of the bowel, in particular the use of infliximab for the treatment of CD. Infliximab is a chimeric IgG monoclonal antibody directed against TNF-alpha. In binding to TNF-alpha, it can make the biological activity of this proinflammatory cytokine inactive. Infliximab has been used to treat CD with modest success rates. The use of infliximab at a dose of 5 mg/kg has been shown to allow complete response of fistulizing disease in 33% of patients and partial response in an additional 30.8%. Those with inflammatory and fistulizing disease had a 69% complete response and 15.5% partial response (Ricart et al., 2001). Infliximab for the treatment of UC is currently under investigation.

It remains hopeful that other biological agents will be helpful in managing IBD. Modulators of cytokine production, cellular adhesion, and bacterial activity may be the

best agents to offer long-term control of inflammatory activity. As these agents and others are tested, the future treatments may be much different than what are currently offered, which by many standards, is suboptimal in the management of this difficult disease.

Fundamental Concepts in the Diagnosis of Low Back Pain

Bruce A. Piszel, MD

EPIDEMIOLOGY AND RISK FACTORS FOR LOW BACK PAIN

It has been estimated that episodic low back pain is frequent or persistent in 15% of the U.S. population, with a lifetime prevalence of 65 to 80% (Manchikanti, Singh, & Saini, 2002). In addition, approximately 8% of the entire working population will become disabled in any given year, contributing to 40% of all lost workdays. Regarding cost estimates in relation to morbidity and mortality of occupational injury or illness, direct costs total $65 billion, with indirect costs approaching $106 billion.

Low back pain is the most common cause of chronic illness irrespective of gender in adults younger than 65 years of age, and the second most common in adults older than 65 years of age (Nachemson, Waddell, & Norlund, 2000). Low back pain–associated disability continues to rise with approximately 10 million lost workdays per year in 1955 and 105 million in 1995 (a 10.5-fold increase). The annual incidence of low back pain from all causes is about 60% (Lawrence, Helmick, & Arnelt, 1998). Frequent or persistent low back pain occurs in about 15% of the population during the course of a year. Herniated discs are associated with radicular symptoms in about 2% of patients. In contrast, only about 25% of episodes of low back pain are associated with sciatica (Borenstein, Wiesel, & Boden, 2004). Other causes of low back pain include osteoarthritis (15%) and fibromyalgia (2%).

There has been much debate about the correlation between potential risk factors and the actual development of low back pain (Manchikanti & Fellows, 2002). These

risk factors are listed in Table 29.1. Low back pain continues to be an important clinical, social, economic, and public health problem affecting the United States and the world. Risk factors are many, but none is convincingly causal.

The specific causes of low back pain are diverse and vary with age. Common causes of low back pain are listed in Table 29.2. Radiculopathy due to herniated disc may be more common in younger patients, whereas radiculopathy in patients older than 50 years of age may be associated with degenerative changes of the spine, which reflects the age-related incidence of disk herniation. Indeed, disc herniation may be uncommon in patients younger than 25 years or older than 60 years of age (McCormick, 2000). The majority of patients are male, often with a history of trauma.

It is important to note that back pain may result from nonspinal causes, such as pancreatitis and aortic aneurysms that refer pain to the back. Common causes of pain referred to the low back are shown in Table 29.3. Metastatic tumors involving the spine become more common with advancing age, particularly tumors of lung, breast, and prostate (Table 29.4). Although relatively uncommon, infections of the spine account for about 1:20,000 hospital admissions per year (Miller & Jubelt, 2000).

The more common causes of low back pain are discussed in this chapter:

- Erector spinae muscular strain
- Radiculopathy
- Central canal stenosis

TABLE 29.1
Potential Risk Factors of Low Back Pain

Physical Factors	Individual Factors	Habits	Psychosocial Factors
Occupational	Genetic make up	Smoking	Marital
Heavy physical work	Age	Exercise	Social
Static work postures	Gender	Posture	Psychological
Bending, twisting, and lifting	Height	Physical activity	History of back pain
Vibration	Weight	Alcohol consumption	Family history
	Kyphosis		Work environment
	Scoliosis		Job dissatisfaction
	Leg length discrepancy		

TABLE 29.2
Causes of Low Back Pain

- Facet (zygapophyseal) joint
- Sacroiliac joint
- Trochanteric bursitis
- Fibromyalgia and other muscular causes
- Ligamentous injury
- Spondylolisthesis
- Herniated nucleus pulposis
- Discogenic (from a degenerated disc not causing radicular symptoms)
- Osteoarthritis and/or spondylosis (degenerative spine disease)
- Spinal stenosis (associated with neurogenic claudication or radiculopathy)
- Osteoporosis/fracture producing axial back pain and/or radiculopathy
- Rheumatoid diseases, particularly involving the cervical spine
- Osteomyelitis/discitis (bacterial and fungal infections)

TABLE 29.3
Common Nonspinal Causes of Low Back Pain

- Pancreatitis
- Pancreatic cancer
- Kidney stones
- Aortic aneurysm
- Retroperitoneal processes (e.g., psoas abscess)

TABLE 29.4
Common Malignancies Causing Low Back Pain

- Metastatic tumors
  - Lung cancer
  - Breast cancer
  - Prostate cancer
- Multiple myeloma (primary spinal tumor)

Note: Malignancies due to metastatic tumor involving the spine are a common cause of back pain in older patients, particularly those with a previous history of cancer.

- Arthritic changes of the facet (zygapophyseal) joint
- Piriformis syndrome
- Metastatic lesions of the vertebrae from a primary cancer
- Sacroiliac joint pain
- Arachnoiditis
- Secondary gain and/or drug-seeking behavior

ERECTOR SPINAE MUSCULAR STRAIN

The erector spinae muscle group is named anatomically from lateral to medial: iliocostalis, longissimus, and spinalis. Muscle strain is a common presenting problem when dealing with low back pain. (Remember, muscles strain; ligaments sprain.) It often occurs with overexertion by the patient involved in sports, incorrect posture the patient assumes when lifting heavy objects, or through repetitive movements either with extension alone or through a combination of extension and rotation as is involved in snow shoveling.

Muscular strains are categorized as first-degree, second-degree, and third-degree strains. First-degree strains are minor and indicate muscular injury at the microscopic level. Second-degree strains (moderate strain) involve a partial tear of the muscle(s) involved, and a third-degree strain is a complete tear of the muscle.

Low back pain from a strain is usually localized to the muscles involved and does not radiate down the thigh or leg as would be seen with a radiculopathy. There tends to be localized tenderness to palpation due to the development of trigger points, possibly in conjunction with muscular spasm. Symptoms can be reproduced with extension of the erector spinae group along with truncal rotation.

RADICULOPATHY

Radiculopathy may be defined as an abnormality of the spinal nerve root that may result in numbness or weakness, depending on whether afferent or efferent nerve fibers are

involved. Causes of radiculopathy include mechanical compression and vascular compromise of the root. Radiculopathy per se does not imply that the injured nerve root is painful. On the other hand, radicular pain implies irritation of a spinal nerve root, rather than root compression. Possible causes of root irritation include leakage of inflammatory material from a damaged disc onto the nerve root. Patients may present with radicular pain radiating in a dermatomal pattern, without obvious nerve root compression on magnetic resonance imaging (MRI) or neurologic deficit. Some patients will have both radiculopathy and radicular pain.

The spinal nerve root injury usually begins proximal to the dorsal root ganglion, due to compression of the involved nerve root or inflammatory changes caused by the herniated disc. The proximal location of the abnormality decreases the sensitivity of electromyographic (EMG) studies because muscles of the lower extremity are supplied by more than one spinal nerve level. Therefore, a negative EMG, in and of itself, does not rule out a radiculopathy.

The structural causes of radiculopathy include protrusion or frank rupture of an intervertebral disc, inflammation due to material derived from the herniated disc, intervertebral foraminal stenosis, osteophytes, and rarely, infection. Narrowing of the intervertebral foramen may be due to trauma and degeneration. Slippage of one vertebral body on another may result in nerve root entrapment and radicular symptoms. Spondylolisthesis occurs when one vertebra moves either anteriorly or posteriorly (anterolisthesis or retrolisthesis, respectively) and may be congenital, associated with spondylolysis (fracture of the pars interarticularis), or acquired, related to degenerative changes.

The symptoms of lumbar radiculopathy and radicular pain are common and fairly characteristic. The patient may have low back pain with numbness or paresthesias that radiate in a dermatomal pattern, characteristically below the knee. The L5 or S1 nerve roots are most often involved.

Upon examination, decreased sensation, motor weakness, changes in reflexes, and muscle spasms may be present. In an acutely ruptured disk, having the patient perform a Valsalva maneuver may reproduce the patient's symptoms.

An L4 radiculopathy may specifically depress the patellar reflex, cause weakness of the leg extensors or ankle muscle dorsiflexors, and radiate to the medial aspect of the foot. An L5 radiculopathy may present with weakness of the extensor hallicus longus and with pain referred to the dorsum of the foot. An S1 radiculopathy may present with gastrocnemius weakness, Achilles tendon reflex abnormalities, and pain that radiates to the lateral aspect of the foot.

Keep in mind the differential diagnosis of anterior and posterior tarsal tunnel syndrome (anterior represents compression of the deep peroneal nerve, and posterior the compression of the posterior tibial nerve at the ankle) that

may mimic radicular pain and radiculopathy. In addition, just because a patient presents with pain in the back and leg does not in and of itself secure the diagnosis of a radiculopathy. If the patient has a history of coronary artery disease, cerebrovascular disease, or any other vasculopathy, it is appropriate to assess the popliteal, dorsalis pedis, and posterior tibial pulses as part of the physical examination. Pain that involves the lower extremities, with ambulation, suggests ischemia (vascular claudication) of the muscles of the legs. Absent pulses on examination warrant Doppler studies to evaluate adequacy of blood flow to the legs. On the other hand, back pain that occurs with the patient standing, but not walking, suggests a spinal etiology.

Given the fact that the differential diagnosis of low back pain includes arthritides and infection, depending on the patient's presentation, appropriate laboratory studies may include a complete blood count, erythrocyte sedimentation rate, C-reactive protein, antinuclear antibody, and HLA-B27.

CENTRAL CANAL STENOSIS

Central canal stenosis may be due to a bulging or herniated disc, spondylolisthesis, arthropathy of the zygopophyseal (facet) joints, and pathology of the interlaminar ligaments. This process classically presents with neurogenic claudication; however, in the early stage of the disease, the patient may be asymptomatic. The patient will present with leg or calf pain while standing or walking that does not improve with rest (differentiating this from vascular claudication, which does improve with rest) but will improve with forward flexion of the lumbar spine, even while standing. For example, a patient may experience relief of symptoms while leaning over a shopping cart at the grocery store or walking up stairs, both involving forward flexion of the lumbar spine. Pain may worsen when walking down stairs, which requires extension of the lumbar spine. Additional findings may include altered reflexes, motor weakness, and the presence of numbness or paresthesias. However, the neurologic exam may be normal when the patient is seated and asymptomatic. Also, the clinician should inquire about the presence of urinary or fecal incontinence and saddle anesthesia (frank numbness of the perineum), as these, in addition to motor weakness, could indicate the presence of a cauda equina syndrome, which is an indication for surgical decompression of the spine.

FACET (ZYGAPOPHYSEAL) SYNDROME

The facet (zygapophyseal) joint is a synovial diarthrodial joint that receives its innervation from the medial branches of the posterior primary division. Facet joint pain may be

caused by arthritic changes to the joint itself, due to osteoarthritis or rheumatoid arthritis; however, in many instances, the etiology is unknown. Degeneration of the facet joints may be worsened with loss of intervertebral disc height, resulting in the facets becoming weight-bearing joints.

The patient typically presents with low back pain reproducible with palpation lateral to the spinous processes, along with extension of the spine or truncal rotation. The patient's pain typically does not radiate inferiorly and does not involve paresthesias. The incidence of facet-mediated pain is quite common, accounting for symptoms in at least a third of patients with low back pain (Manchikanti, Singh, & Saini, 2001).

PIRIFORMIS SYNDROME

Piriformis syndrome should be considered when formulating a differential diagnosis for lumbar radiculopathy. The underlying mechanism presumably involves an entrapment neuropathy of the sciatic nerve (which divides distally into the tibial and common peroneal nerves) between the piriformis muscle superiorly and the inferior gemellus inferiorly. In some patients, the symptoms may be more severe because the sciatic nerve pierces the piriformis muscle (may occur in 12% of the population). Patients may present with weakness, numbness or paresthesias, and pain in a sciatic nerve distribution. An effective way to differentiate sciatic nerve entrapment from lumbosacral radiculopathy is to palpate the piriformis (located between the sacrum and greater trochanter of the femur) to assess if point tenderness is present. Piriformis syndrome may demonstrate point tenderness, whereas radiculopathy does not present with such focal signs on examination. Also, internal rotation of the femur, which stretches the piriformis muscle, may aggravate pain.

METASTATIC CANCER INVOLVING THE SPINE

Low back pain due to metastasis needs to be considered in patients with unremitting back pain, particularly in patients with a history of cancer. Bone pain can involve both nociceptive and neuropathic elements. The nociceptive mechanisms involve bone destruction from osteoblastic and osteolytic lesions. Neuropathic pain may result from tumor invasion of the spinal nerve, which may also involve a nociceptive process. Tumors that commonly metastasize to the spine are listed in Table 29.3.

In older men, prostate cancer needs to considered, because of the relatively high lifetime prevalence of prostate cancer. As previously mentioned, metastatic spread occurs from the prostate to the lumbar vertebrae via Batson's venous plexus. On examination, there may be point tenderness over the spinous processes and lamina. Also, there may be pain to percussion with a reflex hammer.

SACROILIAC JOINT PAIN

Sacroiliac joint pain can be caused by osteoarthritis, rheumatoid arthritis, ligamentous strain due to poor posture while lifting, and collagen vascular diseases. The patient typically presents with pain around the sacroiliac joint with radiation to the buttock, groin, and possibly the posterior thigh, generally without radiation below the knee. Also, those with reproducible symptoms on palpation over the sacroiliac joint should have a plain radiograph taken to exclude overt pathology, such as tumor. Again, when collagen vascular diseases are suspected (the patient may present with systemic complaints), a rheumatologic panel is necessary.

ARACHNOIDITIS

Pain from arachnoiditis occurs as a result of inflammation of the arachnoid membrane surrounding the spinal rootlets. Although the exact etiology of arachnoiditis is still unclear, a number of possible causes have been implicated. These include infection, intrathecal administration of medications, disc herniation, and as a complication of thickening and scarring of roots following myelography.

The patient with arachnoiditis may present with burning, radiating pain (the pattern of symptoms depending on the nerve root affected), altered reflexes, numbness or paresthesias, frank motor weakness, or bowel and bladder abnormalities.

FEIGNING OF SYMPTOMS

The clinician will at some point encounter a patient suspected of exaggerating symptoms due to drug-seeking behavior or for acquiring disability payments. In 1980, Waddell (Waddell, McCulloch, Kummel, & Venner, 1980) presented a list of signs that may help distinguish patients with non-organic back pain from those with pain more likely to be associated with structural causes. Known as Waddell's signs, these criteria remain in common use:

- Pain in lumbar region with superficial palpation
- Nonpainful palpation of a previously painful area with distraction
- Non-anatomic pain distribution; for example, pain that radiates from the lumbar spine inferiorly and superiorly to the ear
- Overreaction to provocative tests
- Reproducibility of low back pain symptoms when rotating the trunk with the center of rotation below the lumbar spine; the area of the body that is rotating is the hips, knees, and ankles

Each item present is given one point. A score of 0 to 2 is considered to be within normal limits. A score greater than 2 should alert the physician to the possibility of non-organic pain that requires further investigation.

If a patient presents with hip flexor weakness that the clinician believes is due to poor effort on the part of the patient, the physician can lay the patient supine and perform a Hoover's maneuver. The physician lifts the patient's lower extremities by cupping the calcaneus with the palmar aspect of the hand. Then, the patient is asked to lift the symptomatic leg first, and then the other leg. If the patient is not giving a full effort, the physician will not feel the patient pushing down with the opposite lower extremity.

There are patients who present with histories or symptoms that should alert the physician to the possibility of drug-seeking behavior. These include

- History of multiple physician visits for pain without any clear diagnosis
- History of opioid prescriptions without any clear diagnosis or specific workup
- Multiple opioid allergies except "the one" that relieves the patient's pain
- Pain complaints in non-anatomic distributions as indicated on the dermatome drawing
- Admission by the patient of acquiring opioids without a physician's prescription because none of the other physicians understands or can diagnose his or her pain, requiring the patient to self-medicate

It is the responsibility of the doctor to bring up the subject of drug abuse and addiction, and if the patient admits to having a problem, an addiction medicine consult is indicated. Long-term opioid therapy may be appropriate for the management of low back pain, but the risks and potential benefits are a matter of increasing controversy.

LOW BACK PAIN HISTORY

The clinician should have the patient complete a specific pain history:

- The patient should complete a pain drawing indicating areas of pain with a red pencil and areas of numbness or paresthesias with a blue-colored pencil. Figure 29.1 is a dermatomal drawing used by the pain clinic at University Hospitals of Cleveland.
- On a scale of 1–10, the patient should quantify the pain (when interviewing the patient, it is helpful to give an example of "ten out of ten" pain).
- Where is the pain localized?

- Does the pain radiate, and to what part of the body?
- Is the pain accompanied by numbness?
- What exacerbates the pain and what improves it?
- Pain characterization (is it sharp, dull, electric-like)?
- Does the pain interfere with the patient's sleep (initiation or maintenance)?
- Does the pain affect the patient's mood?
- Does the pain interfere with the patient's activities of daily living?
- Is there a periodicity to the pain (worse in the morning, afternoon, or evening)?
- Was there an inciting event?
- Is the pain work related?
- Is the patient currently involved in litigation?
- Is the pain worsening?
- Is there a history of a psychiatric illness?
- Previous workup for pain?
- Medication allergies and all current medications
- Past medical history
- Past surgical history
- Social history
- Family history

RADIOGRAPHIC STUDIES

Plain radiography is frequently the first imaging study ordered because it is the most widely available and the least expensive modality to image the lumbar spine. Plain films can provide information on acute and chronic changes. In the acute setting, a radiograph is the most expedient tool to demonstrate a fracture. Chronic changes such as bone spurs, intervertebral disc height collapse, vacuum disc phenomenon, and endplate remodeling can also be seen. Malalignment of bony structures such as vertebral bodies, pedicles, and zygopophyseal joints provides evidence of spondylolysis, spondylolisthesis, scoliosis, and kyphosis.

Assessing the integrity of the osseous structures can identify bony destruction and erosive changes from malignancy, infection, spondyloarthropathies, and metabolic diseases. It is widely believed that routine radiographs of the lumbar spine are of limited value in the workup and treatment of acute nontraumatic low back pain. This may be true for low back pain without radicular symptoms, in the acute nontraumatic setting. However, there are specific factors that necessitate the ordering of plain films:

- Age over 50
- Neuromotor deficits
- Unexplained weight loss
- Suspicion of ankylosing spondylitis
- Drug or alcohol abuse

Use BLUE to indicate areas of numbness
Use RED to indicate areas of pain
FIGURE 29.1 Pain drawing. Patient uses colored pencils to indicate painful areas and numbness.

- Cancer history
- Corticosteroid use
- Fever
- Impending litigation
- Low back pain and neurologic compromise of unclear etiology

Although the majority of patients have resolution of low back pain over 4 to 6 weeks, as many as 10% will continue to have back pain longer than 6 weeks, despite conservative management. In this group of patients with subacute low back pain, radiographs are recommended. It is worth remembering that plain radiographs can assess the spine dynamically rather that statically and identify degenerative changes, fractures, and tumors.

COMPUTED TOMOGRAPHY

Computed tomography (CT) provides the most detailed osseous images. In the lumbar spine, CT is used primarily to evaluate bony anatomy, particularly the spinal canal and cortical bone integrity. CT can be performed more quickly than an MRI, making it an ideal test to assess the spinal column following major trauma. Other indications include patients unable to undergo an MRI because of weight, claustrophobia, and the presence of ferromagnetic shrapnel, aneurismal clips, or some implantable devices. CT scans are relatively contraindicated in pregnancy and surgical fusion with instrumentation (the metal hardware creates scatter resulting in artifact often severely limiting the usefulness of the images).

MAGNETIC RESONANCE IMAGING

This imaging modality is used clinically to provide superior and detailed soft tissue images. The soft tissue imagery evaluates water density within different types of tissues. Intra- and extrathecal neural elements, epidural space, spinal ligaments, paraspinal soft tissues, disc morphology, and alignment can be evaluated. When used with

gadolinium contrast, MRI provides unparalleled visualization of intramedullary diseases such as myelomalacia, syrinx, neoplasms, demyelination, intradural, and extradural tumors and spinal infections. Furthermore, it can differentiate between recurrent and retained disc herniation and scar tissue.

About 30% of asymptomatic people have MRI evidence of a disc protrusion (asymmetric disc bulge extending beyond the interspace (Jenson, Brant-Zawadski, & Obuchowski, 1994). For those over 50 years of age, two thirds of individuals show disc abnormalities, compared with about one third of individuals younger than 30 years. Although a large proportion of asymptomatic patients may have abnormalities on MRI, the study is useful when evaluating patients with focal neurologic findings accompanying radicular symptoms, in addition to back pain.

The physics of image generation during an MRI is complicated and beyond the scope of this chapter. Essentially, an external magnet polarizes the hydrogen protons in water molecules and a specific radiofrequency is pulsed into the body. Depending on the number of mobile hydrogen ions intrinsic in the tissue, different images will be generated. The three primary spins sequences are longitudinal relaxation time (T1), transverse relaxation time (T2), and proton density. T1-weighted images are best to evaluate fat-rich tissues such as bone marrow. An evolving hemorrhage and other high-protein fluid collections can also be evaluated. T2-weighted images emphasize extracellular water, such as cerebrospinal fluid, fluid collections, cysts, and abscesses.

Necrotic tissue, neoplasm, and the intervertebral disc are examples of tissues that have high signal intensity on T2-weighted images. Proton density–weighted images are best used to evaluate spinal ligaments and zygapophyseal joint morphology.

When compared with CT, MRI is more sensitive for providing radiologic evidence of lumbar discogenic disease because it provides better information on the soft tissues before disc contours change. These alterations include annular tears and disc desiccation.

Both CT and MRI are adept at identifying a disc herniation. A focal protrusion is a disc herniation where there is an annular contour abnormality. But the displaced nuclear material is still contained within the outer wall of the annulus. In contrast, a disc extrusion is present when nuclear material is found beyond the outer wall of the annulus, suggesting a tear of the annulus. It can be contained by the posterior longitudinal ligament (known as a subligamentous extrusion). CT is not as sensitive as MRI in differentiating this type of abnormality. Also, an MRI is the best means to identify disc degeneration associated with stenosis.

MRI is the imaging modality of choice in patients who have undergone prior disc surgery. MRI has difficulty discriminating posterior disc margins from postop-

erative changes. After 6 months of surgery, MRI with gadolinium is recommended. In this case, the MRI is useful in evaluating the degree of neural encroachment from soft tissues, such as the ligamentum flavum, disc, and facet joint capsule.

MRI is superior to plain films and CT scans for imaging tumors of the lumbar spine. If tumor or infection is suspected, gadolinium is used because it enhances neovascularized proliferating tissue, inflammatory processes, and necrotic tissue.

The imaging study ordered should be based on the patient's history and clinical examination, with due consideration of the structures that need to be visualized. Although MRI and CT can identify abnormalities, no imaging study can ascertain whether an abnormality is painful.

ELECTRODIAGNOSIS

If a patient presents with a radiculopathy that includes muscle weakness and sensory changes, EMG may be a helpful tool to determine if the lesion exists centrally or peripheral to the spinal nerve root. This is especially true after a diagnostic block fails to improve a patient's symptoms. EMG interpretations are complex and are usually performed by an experienced rehabilitation physician or neurologist. However, a physician treating pain should be familiar with some of the muscles and nerves that are tested during a routine radiculopathy screen.

Although an EMG usually includes nerve conduction velocity (NCV) testing, the overall test is typically referred to as an EMG. The motor portion of the NCV typically evaluates the following nerves (Preston & Shapiro, 1998):

- Peroneal nerve: extensor digitorum brevis, and tibialis anterior
- Tibial nerve: abductor hallicus brevis and abductor digiti quinti pedis

The sensory portion of the NCV will include sural and superficial nerves and, occasionally, the saphenous and the lateral and medial plantar nerves

Suggested muscles to be sampled in the EMG proper for a suspected lumbosacral radiculopathy include:

- Tibialis anterior (L4–L5)
- Medial gastrocnemius (S1–S2)
- Flexor digitorum longus (L5–S1)
- Extensor digitorum brevis (L5–S1)
- Vastus lateralis (L2–L4)
- Gluteus medius (L5–S1)
- Mid and low lumbar paraspinals (L4–S1)

The EMG results will help guide the treatment options with regard to location of the lesion (peripheral vs. centrally located) and whether a surgical consultation is warranted.

BASICS OF THE PHYSICAL EXAMINATION FOR LOW BACK PAIN

The initial examination should be comprehensive, in that low back provocative tests should be used, in addition to tests that examine the hip and pelvis. This is especially true if the lumbar tests fail to reproduce symptoms. A good place to start is to ask the patient to demonstrate active range of motion of the lumbar spine in the following planes: extension, flexion, right and left lateral flexion, and finally, right and left rotation. It is a good idea to demonstrate these maneuvers first and stand close to the patient during the movements, in case the patient loses balance. Also, instruct the patient to stop the maneuver whenever pain is experienced.

While the patient is standing, ask the patient to walk on the heels and toes, while nearby or holding the patient's hands to accurately assess the strength of the plantar flexors and dorsiflexors.

The primary plantar flexors of the ankle include the following:

- Peroneus longus and brevis: innervated by the superficial peroneal nerve (S1)
- Gastrocnemius and soleus: innervated by the tibial nerve (S1 and S2)
- Flexor hallicus longus: innervated by the tibial nerve (L5)
- Flexor digitorum longus: innervated by the tibial nerve (L5)
- Tibialis posterior: innervated by the tibial nerve (L5)

The primary dorsiflexors of the ankle include

- Tibialis anterior: innervated by the deep peroneal nerve (L4 and L5)
- Extensor hallicus longus: innervated by the deep peroneal nerve (L5)
- Extensor digitorum longus: innervated by the deep peroneal nerve (L5)

If these muscles (ankle dorsiflexors and plantar flexors) are tested while the patient is seated or supine, the physician will not get an accurate assessment of the muscle strength because these muscles are quite powerful, as they carry the weight of the entire body.

Muscle strength is classified using the following scale:

5/5   Normal muscle strength
4/5   Muscle strength slightly decreased from normal
3/5   Muscle strength greater than gravity (antigravity that gives way quite easily to the slightest pressure)

2/5   Muscle strength not able to overcome gravity, but movement of the joint takes place with gravity eliminated; e.g., if bicep flexion strength is less than a grade of three, lift the elbow up and see if the joint moves in the horizontal plane
1/5   The examiner is able to see the muscle contracting; however, there is no joint movement
0/5   No muscle contraction seen (flaccid paralysis)

With the patient seated on the examination table, assess muscular strength of the hip flexors and knee flexion strength. The muscles involved in these movements and their innervations are as follows:

- Hip flexors: Iliopsoas: innervated by the femoral nerve (L1,2,3). Note that the rectus femoris is also involved in flexion of the hip.
- Hip adduction: Adductor longus: innervated by the obturator nerve (L2,3,4). Note that the adductor magnus, brevis, pectineus, and gracilis are also involved in adduction.
- Hip abduction: Gluteus medius: innervated by the superior gluteal nerve (L5). Note the gluteus minimus also plays a role in this movement.
- Knee extension: Quadriceps: innervated by the femoral nerve (L2,3,4).
- Knee flexion: Hamstrings (made up of the semimembranosis, semitendinosis, and biceps femoris): innervated by the tibial nerve (L5–S1).

With the patient seated, test the deep tendon reflexes of the lower and upper extremities. These include the following:

- Biceps reflex: (C5)
- Triceps reflex: (C7)
- Patellar reflex: (L4)
- Hamstring reflex: (L5)
- Achilles tendon reflex: (S1)

In the seated position, the paraspinal musculature can be palpated, looking for spasm and trigger points. Finally, tapping the reflex hammer over the spinous processes to evaluate for the presence of bony pain or tenderness.

There are extensive formally named clinical maneuvers to assess the low back, many overlapping. The straight leg raise (SLR) test is used to assess for the presence of nerve root irritation, which would support the diagnosis of radiculopathy. The examiner raises the leg on the symptomatic side until the patient complains of pain, noting the approximate point when the pain begins as well as whether the pain is localized to the back or radiates into the extremity. If radiating pain is elicited, the examiner lowers the leg slightly and, while dorsiflexing the foot (Braggard's test), determines whether the radiating pain is replicated. The

examiner can also extend the great toe (Sicard's test), both maneuvers indicative of positive root tension signs. If the initial test is negative, the examiner can increase the tension on the sciatic nerve by performing the same maneuvers. Many examiners should note the approximate angle of hip flexion assuming 0° to 35° typically causes pain due to extradural involvement, 30° to 70° from disc pathology, and 70° to 90° indicates lumbar joint pain. Alternatively, the examiner places one hand under the patient while palpating the lumbosacral spine, so as to help better differentiate the location of the pain (Goldwaith's test). In the case of unilateral pain, the asymptomatic side is then tested. If the patient experiences pain on the symptomatic side while raising the asymptomatic lower extremity, it could indicate a disc protrusion medial to the nerve root on the symptomatic side (Fajersztajn's test, also called a contralateral or well leg SLR test). Elevating the patient's legs together, and asking the patient to hold the legs up or having the patient raise both legs together several inches above the table (leg-lowering or Milgram's test) are both signs of increasing intrathecal pressure, often associated with nerve root compression, such as a disc herniation. The prudent examiner will often alter the examination based on the examination findings to even better help differentiate or confirm the suspected cause of the patient's pain.

With the patient remaining in the supine position, the passive range of motion of both hips is assessed by flexing the hips to the end range of motion and then moving the hips in an arc laterally and returning the lower extremity to the original position onto the examining table.

Now, the examiner asks the patient to roll over into the prone position. The examiner can assess the hip extensor strength, sacroiliac joint, and tender zygopophyseal joints. The examiner can locate the sacroiliac joint by starting at the superior aspect of the gluteal crease and palpating at an angle up to the point where the superior articular process contacts the inferior articular process of the fifth lumbar vertebrae. A provocative test that can be performed to reproduce pain from the sacroiliac joint is the Yeoman's test. This is performed by flexing the leg and grasping the ankle with both hands and lifting the leg and thigh, which puts maximal stress on the joint. Palpate the facet joints that lie on either side of the spinous processes.

The piriformis muscle should be examined with the asymptomatic side down and the hip and knee flexed. This stretches the muscle and makes palpation more likely to reproduce symptoms. The piriformis is located between the sacrum and greater trochanter. If point tenderness is elicited over the piriformis with or without radiation of pain distally, the piriformis may be the pain generator.

SUMMARY

The diagnosis of low back pain can be difficult due to large number of possible etiologies involved. It is incumbent on the clinician to obtain a complete and thorough history, addressing questions specific to the patient's complaints and mitigating factors.

The hallmark of a thorough examination includes the reproducibility of symptoms, as there may be poor correlation between radiographic abnormalities and symptoms. Of equal importance is making sure that the patient's complaints are not due to a potentially life-threatening condition, such as prostate cancer that has metastasized to the lumbar spine. Also, it is important to address the issue of the patient who may be feigning symptoms for secondary gain or the patient who demonstrates drug-seeking behavior.

Although the list of potential diagnoses is long, muscular strain, degenerative changes in the spine producing facet-mediated and discogenic pain, and radiculopathy are commonly seen in the clinic. The most important service a physician can do for the patient is to clearly delineate a differential diagnosis. This will help narrow the list of possible causes to a more specific diagnosis, upon which definitive treatment can be planned. It is also important to remember that there are common nonspinal causes of pain that must be considered when evaluating patients with back pain.

Diagnostic studies may help identify pain generators in the spine that are amenable to specific therapeutic interventions. The role of interventional pain management is considered in detail in Section VII of this textbook.

Chronic Pelvic Pain

Andrea J. Rapkin, MD, and Candace Howe, MD

INTRODUCTION

Chronic pelvic pain is, by definition, pain that persists for more than 6 months. In its various forms, chronic pelvic pain affects an estimated 12 to 15% of women in the United States, accounting for more than $881 million spent each year on outpatient visits (Mathias et al., 1996). It is one of the most common but taxing problems in gynecologic practice. Even after a thorough workup, the etiology may remain obscure, and the relationship between certain types of pathology and the pain response may be inconsistent and often inexplicable. In the patient who has no obvious pathology, it may be tempting to remove pelvic structures for their physiological variations. Approximately 12% of all hysterectomies are performed for pelvic pain and 30% of patients who present to pain clinics have already had a hysterectomy (Chamberlain & La Ferla, 1987; Reiter, 1990b).

The purpose of this chapter is to outline the anatomy and physiology of pelvic pain and to explore the differential diagnosis and management of chronic pelvic pain, including the role of medication, surgery, psychotherapy, and the multidisciplinary pain management.

NEUROANATOMY AND NEUROPHYSIOLOGY OF PELVIC PAIN

The pelvic viscera receive afferent innervation by way of the autonomic nerve trunks (Kumazawa, 1986). The major neural pathways for visceral pain from the female pelvic organs travel with the sympathetic nerve bundles and have cell bodies in a thoracolumbar distribution. Sensory afferents that travel with the parasympathetic (sacral) fibers are probably of secondary importance for pain

transmission from the pelvic organs. These latter nerves have their cell bodies in the sacral dorsal root ganglia (Kumazawa, 1986). The innervation of the female pelvic viscera and somatic structures is depicted in Figure 30.1 and Table 30.1. The transmission of painful stimuli from the pelvic organs relies on an intact lumbosacral autonomic nervous system (Cervero & Tattersall, 1986). However, the sacral autonomics are crucial for urination, defecation, and reflex regulation of the reproductive organs (Kumazawa, 1986). The role of the sacral autonomics in the genesis of pelvic pain is likely but remains to be delineated. A large proportion of the sacral afferents from the colon and urinary bladder are usually silent. Only 5% of colon afferents and 2.5% of bladder afferents can be activated by mechanical distension. A proportion of the nonmechanosensitive unmyelinated sacral afferents are chemosensitive and can develop *de nouveau* mechano-sensitivity (Janig et al., 1993). These usually "silent" fibers may be activated by and sensitized by inflammation or unusually strong mechanical stimulation and may play a role in pelvic pain of urinary tract or gastrointestinal etiology and theoretically from the internal reproductive organs as well.

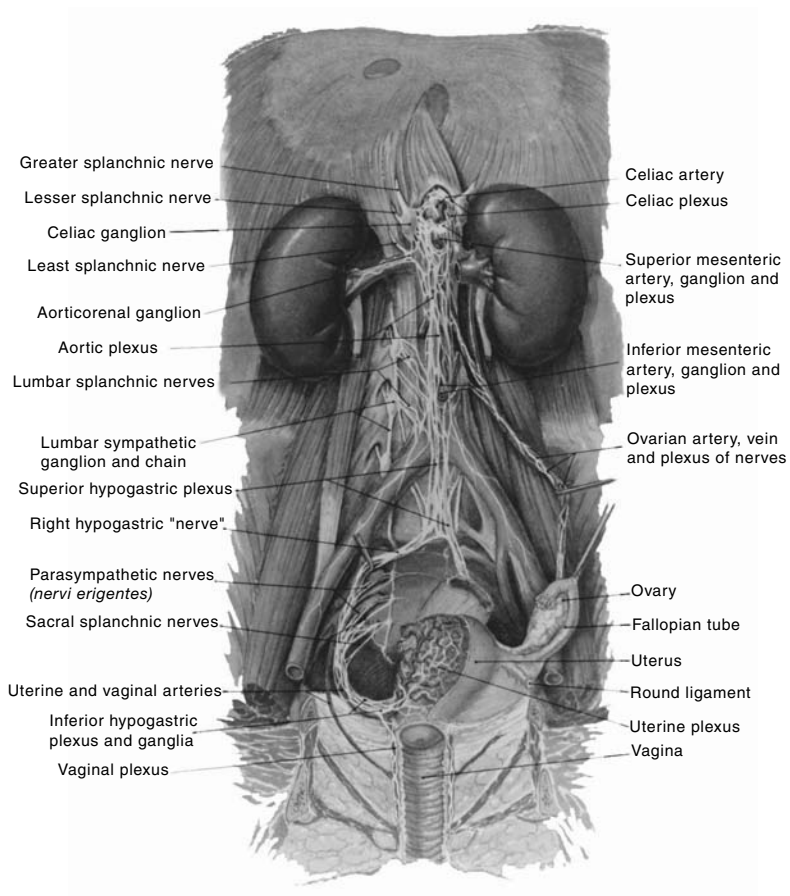
The cell bodies of the afferent axons from the pelvic organs are located in the dorsal (sensory) ganglia of the spinal nerves (Fields, 1987). Before entering the spinal gray matter of the dorsal horn, branches of these afferent axons may extend for two or more segments beyond the level at which the original axons entered the cord. Much of neuronal modulation occurs in the dorsal horn. Evidence from animal studies indicates that supraspinal factors interact at the level of the dorsal horn to modulate the sensory perception of pain from the pelvic viscera (Berkley & Hubscher, 1995; De Groat, 1994).


FIGURE 30.1 The innervation of the female pelvic viscera.

TABLE 30.1
Innervation of the Female Pelvis

Organ	Spinal Segments	Nerves
Abdominal wall	T12–L1	Iliohypogastric, ilioinguinal, genitofemoral
Lower abdominal wall, anterior vulva, urethra, and clitoris	L1–L2	Ilioinguinal, genitofemoral
Lower back	L1–L2	
Pelvic floor, anus, perineum, and lower vagina	S2–S4	Pudendal, inguinal, genitofemoral, posterofemoral cutaneous
Upper vagina, cervix, uterine corpus, inner third of fallopian tube, broad ligament, upper bladder, terminal ileum, and terminal large bowel	T11–L2 S2–S4	Thoracolumbar autonomics (sympathetics) via hypogastric plexus; sacral autonomics (parasympathetics) via pelvic nerve
Ovaries, outer two thirds of fallopian tubes, and upper ureter	T9–T10	Thoracic autonomics (sympathetics) via renal and aortic plexus and celiac and mesenteric ganglia, aortic and superior mesenteric plexuses

The dorsal horn is an important site of modulation of afferent input (Cervero & Tattersall, 1986). The second-order neurons are subjected to excitatory and/or inhibitory interactions. For example, if a visceral structure and a cutaneous (somatic) structure transmitting to the same second-order neuron in the dorsal horn are stimulated simultaneously, the second-order neuron response may be greater than either the cutaneous or the visceral stimulus would evoke on its own. These viscero-somatic neurons tend to have larger receptive fields than the somatic neurons. There are also many more somatic second-order neurons than there are viscero-somatic neurons (Cervero & Tattersall, 1986). Both of these facts may account for the vague, poorly localizable quality of visceral pelvic pain.

The concept of neuromodulation has proved promising as a partial explanation for the persistence of chronic pelvic pain. Prolonged severe acute pain unrelieved for more than 24 hours induces neuroplastic changes via excessive and prolonged stimulation of N-methyl-D-aspartate (NMDA) receptors and increase nerve irritability, among other mechanisms. This irritability creates an allodynia and hyperalgesia (Doggweiler-Wiygul, 2001). In addition to afferent conduction due to noxious stimuli there is damage to local tissue by antidromic conduction. Neurogenic inflammation can become pathogenic such as in disorders like asthma, migraines, endometriosis, and arthritis (Wesselmann, 2001). This may prove important in the development of new medical treatment for chronic pelvic pain, which could be directed at prolonged neurogenic inflammation, visceral, and referred hyperalgesia.

The neurophysiology of pain transmission from the viscera (internal organs such as bowel, bladder, rectum, uterus, ovaries, and fallopian tubes) differs from that of somatic structures (cutaneous elements, fascia, muscles, parietal peritoneum, mesentery, external genitalia, anus, urethra). Nociceptors receive pain evoked at somatic nerves, whereas a plentitude of nonspecific receptors receive pain induced in the viscera (Berkley, 1994; Cervero, 1994). Visceral pain, in contrast to somatic pain, is usually deep, difficult to localize, and frequently associated with various autonomic reflexes such as restlessness, nausea, vomiting, and diaphoresis (Procacci et al., 1986). Early surgical studies performed under local anesthesia have shown that cutting, crushing, or burning the bowel, for example, evokes no pain, whereas distension of muscular organs or hollow viscera, stretching of the capsule of solid organs, hypoxia or necrosis of viscera, production of algesic (pain producing) substances, rapid compression of ligaments or vessels, and inflammation may cause severe pain. In contrast, cutting or crushing a somatic structure produces exquisite pain that is well localized (Procacci et al., 1986). Well-localized abdominal wall or pelvic floor pain in patients with chronic pelvic pain is likely secondary to referred hyperalgesia, myofascial pain/trigger points, or nerve entrapment. Familiarity with the anatomy of somatic structures delineating the pelvis is therefore important (McDonald & Rapkin, 2001).

PERIPHERAL CAUSES OF CHRONIC PELVIC PAIN

ADHESIONS

The differential diagnosis of the peripheral component of pelvic pain is listed in Table 30.2. Laparoscopic studies for the evaluation of chronic pelvic pain would suggest that adhesions play a prominent role. However, when these studies were performed, nongynecologic sources of pelvic pain such as abdominal wall or pelvic floor myofascial pain or neuropathy, irritable bowel syndrome, and interstitial cystitis were often not excluded prior to laparoscopy. Adhesions were present in 16 to 44% of the patients undergoing laparoscopy for chronic pelvic pain (depending on the series) (Kresch et al., 1984; Liston et al., 1972; Lundberg et al., 1973; Rapkin, 1986; Renaer, 1981). Do adhesions actually cause pelvic pain? Of 100 patients Kresch laparoscoped for chronic pelvic pain, 38% had adhesions and 10% had bowel adhesions. However, of 50 asymptomatic patients undergoing laparoscopy for sterilization, only 12% had adhesions and only 2% exhibited adhesions involving the bowel. These differences were highly significant (Kresch et al., 1984). Keltz et al. (1995) in a combined retrospective/prospective study found colon to side-wall adhesions in a higher proportion of patients (93 vs. 13%) with pelvic pain than the control group (sterilization).

In comparison, Rapkin (1986) noted that many infertility patients with severe adhesions had no pain and compared the results of laparoscopies performed on two groups of patients—the first group complained of chronic pelvic pain and the second group had infertility, without complaints of pain. When evaluating both the site and density of adhesions, it was notable that there were no significant differences between the group with chronic pelvic pain and asymptomatic patients in the infertility group. The results of this study question the role of pelvic adhesions as a common cause of chronic pelvic pain.

If adhesions cause pain, then lysis of adhesions should relieve pain. A prospective noncontrolled, nonrandomized study of lysis of adhesions did not show significantly lower postoperative pain ratings (Steege & Scott, 1991). However, *post hoc* analysis consisting of separation of the subjects into those with and without psychosocial dysfunction revealed a significant improvement in pain scores in the group without psychosocial dysfunction. An early prospective randomized study of adhesiolysis revealed no differences in the pain scores between the groups (adhesiolysis vs. no adhesiolysis). Again, *post hoc* analysis of the data suggested there was a significant improvement (although only on two of the three methods of pain assess-

ment) in pain scores in the subgroup of patients with dense vascular adhesions involving small bowel (Peters et al., 1991). A more recent prospective randomized controlled multicenter trial concluded that although laparoscopic adhesiolysis relieves chronic abdominal pain, it is not more beneficial than diagnostic laparoscopy alone (Swank et al., 2003). In addition, they remind the reader of the 10 to 25% of bowel injuries that occur during laparoscopic adhesiolysis for pain (Chapron et al., 1999; Swank et al., 2002) and the risk of bleeding or bladder and ureteral injury. As many as 20 to 90% of adhesions reform or form *de nouveau* after an adhesiolysis procedure. A review from the Cochrane database concluded that the outcome was no different in women who had had adhesiolysis of minor to moderate adhesions than in women who had not undergone surgery (Stones & Mountfield, 2004). The authors did, however, comment that there may be a possible benefit for patients with severe adhesions based on a small subgroup with significant benefits seen after adhesiolysis.

Advances using a 3-mm laparoscope have enabled development of "conscious pain mapping" whereby patients under local anesthesia and conscious sedation guide in determining which adhesions are those associated with pain (Palter, 1999). An observational pain mapping study of 50 women under local anesthesia demonstrated that 62% of the patients had pelvic adhesions found at the time of laparoscopy, but only 25 of these cases reported adhesions that exhibited tenderness to manipulation (Almeida & Val-Gallas, 1997). In a series by Howard (2003a), 7 of 21 patients with adhesions had focal dramatic tenderness upon manipulation of their adhesions. Although adhesions may be prevalent in patients with chronic pelvic pain, these adhesions may or may not be the cause of pain. Tenderness elicited by

probing or traction during pain mapping may very well be simply a hyperalgesic central response to a mechanical stimulus. It is this truth that makes it difficult to ascertain whether the source of pain identified is in fact responsible for the patients' pain and makes the value of directed pain mapping questionable. No studies to date have noted improved outcome with pain mapping and guided laparoscopic management.

Investigators have proposed the routine use of barrier agents for the prevention of adhesion formation to reduce the chances of pelvic pain and infertility in the future. A Cochrane review of evidence-based studies found that the absorbable adhesion barrier Interceed reduces the incidence of adhesion formation, both new formation and reformation, at laparoscopy and laparotomy, but there are insufficient data to support its use to improve pregnancy rates (Farquhar et al., 2003). In addition, Gore-Tex may be superior to Interceed in preventing adhesions, but its usefulness is limited by the need for suturing and later removal (Farquhar et al., 2003). These barriers, of course, would not prevent adhesions due to causes such as pelvic inflammatory disease and endometriosis.

ENDOMETRIOSIS

Another "peripheral" cause of chronic pelvic pain is endometriosis. The actual incidence of endometriosis is unknown because many individuals undoubtedly have endometriosis without sufficient symptomatology to warrant surgical intervention. It seems that the incidence of endometriosis is increasing. However, this apparent increase in prevalence may be a reflection of the more liberal use of laparoscopy and of the recognition of atypical forms of endometriosis. Endometriosis is noted in patients undergoing laparoscopy for chronic pelvic pain in anywhere from 5 to 37% of the cases (Kresch et al., 1984; Liston et al., 1972; Lundberg, Wall, & Mathers, 1973).

The diagnosis of endometriosis is usually made in the thirties or forties; however, it has been noted to be a prominent diagnosis in adolescents and women in their twenties who are evaluated for chronic pelvic pain (Chatman & Ward, 1982). In fact, endometriosis has been suggested by one study to be the etiology in up to 70% of adolescents with chronic pelvic pain unresponsive to medical treatment (Probst & Laufer, 1999).

The most common symptoms of endometriosis are dysmenorrhea, dyspareunia, infertility, and abnormal uterine bleeding, usually from a secretory endometrium (Kitchen, 1985). Three criteria have been proposed to indicate endometriosis as the cause of pelvic pain (Hurd, 1998). These criteria are that the pain should be cyclic, worsening before and during menses; that endometriosis must be diagnosed surgically, and finally that appropriate medical or surgical treatment should result in prolonged pain relief. The first requirement, that the pain be cyclic,

exacerbated before and during menses, is thought to occur as a result of endometrial implants in the pelvis that are hormonally responsive. Dysmenorrhea may be so prolonged that the patient may complain of what seems like acyclic, continuous pain; beginning 7 to 10 days before the onset of the menstrual period and persisting until 1 week or so after the bleeding has ceased. The patient often describes pressure-like pain and aching in the lower abdomen, back, and rectum. There may be radiation of pain into the vagina, thighs, or perineum.

Dyspareunia is common when the disease involves the cul-de-sac (pouch of Douglas), uterosacral ligaments, or rectovaginal septum directly, or may also be related to referred hyperalgesia to the vagina. Pain with defecation (dyschezia) may also be present even in patients without direct bowel wall involvement. These symptoms may be due to endometrial implants near the rectum. Urinary urgency, frequency, and bladder pain may also be associated with urinary tract involvement. If these urinary symptoms are present, the physician should also be aware that interstitial cystitis may be the cause and this should be ruled out as described later.

Because endometriosis may be present in unusual locations, the manifestations of endometriosis are protean (Kitchen, 1985). Usually the previously noted common symptoms and signs are present, but, rarely, patients may complain of rectal bleeding, symptoms similar to bowel obstruction, suprapubic pain, and/or urinary symptoms (such as frequency, dysuria, or hematuria). If ureteral involvement is present, there may be flank pain, backache, or hypertension. Signs and symptoms of an acute abdomen occur infrequently and are usually related to rupture of an endometrioma or bowel obstruction.

Examination of patients with endometriosis may reveal tenderness and nodularity on the rectovaginal examination of the uterosacral ligaments and posterior cul-de-sac (Kitchen, 1985). Progressive disease results in findings of obliteration and fibrosis of the cul-de-sac, and fixed retroversion of the uterus. Enlarged ovaries (endometriomas) with decreased mobility may be noted.

The second criterion is that endometriosis be diagnosed surgically (Hurd, 1998). Laparoscopy is necessary for definitive diagnosis of endometriosis although the diagnosis may be suggested by history and pelvic examination. Evidence of powder burns, red or blue spots, and nearby puckering of the peritoneal surface is almost 100% specific for endometriosis, although laparoscopically directed biopsy is optimal (Vercellini et al., 1991). Ultrasound is not diagnostic and cannot differentiate an endometrioma from a benign or malignant ovarian neoplasm, and scattered small implants are not detectable by ultrasound. Magnetic resonance imaging (MRI) has been suggested as being useful for the detection of endometriotic lesions and endometriomas, especially when using a fat-saturated MRI, which can pick up lesions that are less

than 5 mm 50% of the time (Takahashi et al., 1996). Laboratory studies are usually not specific. CA-125 and erythrocyte sedimentation rate (ESR) can be elevated in women with endometriosis.

Currently research is being more and more focused on possible markers for endometriosis. The difficulty with encountering a reliable marker is lack of specificity. Initially CA-125 and ESR, as above, were looked at but were found to be elevated in multiple processes that could be occurring besides endometriosis. A current marker of interest is aromatase P450 (the enzyme that converts androstenedione and testosterone to estrone), which is expressed in eutopic endometrium of women with endometriosis, but not in disease-free controls (Kitawaki et al., 1997; Nobel et al., 1996). Expression of aromatase P450 is independent of the timing of the menstrual cycle and has a sensitivity of 91% and a specificity of 100% according to Kitawaki et al. (1999). Other authors have found that the sensitivity and specificity is closer to 82% and 59%, respectively, and therefore it is not a viable marker for clinical use (Dheenadayalu et al., 2002). In addition other serum markers such as soluble intercellular adhesions molecules-1, placental protein-14 (glycodelin), and antiendometrial and anticarbonic anhydrase antibodies yield the same poor specificity (Brosens et al., 2003; Somigliana, 2002). Finally, new possibilities on the horizon are leptin levels and interleukin-6 because their proinflammatory and neoangiogenic actions may promote endometriosis and therefore be useful markers (Vigano et al., 2002).

The final criterion is that appropriate medical or surgical treatment of endometriosis should result in prolonged pain relief (Hurd, 1998). Endometriosis can be treated with nonsteroidal anti-inflammatory drugs (NSAIDs) for pain control along with hormonal agents such as androgenic hormones (Danocrine®), progestins (oral or injectable), estrogen–progestin combinations, or gonadotropin-releasing hormone agonists (GnRH-a) to create pseudomenopause and to atrophy ectopic endometrial implants (Rice, 2002). An expert consensus panel recently published recommendations for therapy in *Fertility and Sterility* (Gambone et al., 2002). According to these experts the first-line medical treatment should begin with a trial of NSAIDs with or without combined estrogen–progestin formulations (Gambone et al., 2002; Rice, 2002; Rouff & Lema, 2003). Estrogen–progestin combinations have been established as first-line agents for many years and recently many new forms in addition to oral contraceptives such as the combined estrogen–progestin contraceptive patch and ring are available. A new generation of NSAIDs, which inhibit cyclooxygenase-2 (COX-2), are as effective at treating dysmenorrhea as ibuprofen or naproxen and they have a much lower risk of causing gastric ulceration and inhibiting platelet function (Katz, 2002; Morrison et al., 1999; Ormrod et al., 2002; Rouff

& Lema, 2003; Scott & Lamb, 1999; Weaver, 2001). The disadvantage of COX-2 over COX-1 inhibitors is a much higher cost. If this therapy fails, then second-line therapy consists of either a 3-month trial of full-dose danazol, GnRH-a or a progestin such as medroxyprogesterone acetate (MPA).

Progestins induce decidualization and decrease the proliferation of endometriotic tissues. Medroxyprogesterone acetate in a 50 mg oral daily dose has been found to be just as effective at reducing pelvic pain as danazol, as danazol and an oral contraceptive, and as compared with a GnRH-a in randomized trials, although the effects regress after 6 to 12 months (Fedele et al., 1989; Vercellini et al., 1993; Walton & Batra, 1992). A *Cochrane Review* article recently concluded that both continuous progestins and antiprogestins (mifepristone, RU-486) are effective in the treatment of painful symptoms of endometriosis. Progestins given in the luteal phase have not been shown to be effective (Prentice et al., 2003). Mifepristone, 50 to 100 mg/day, was shown to decrease pain scores and induce amenorrhea without hypoestrogenism in small, open-label, cohort studies (Kettel et al., 1996). Progestin side effects include weight gain, breast atrophy, hot flushes, and hirsutism (Rice, 2002).

Danazol is a synthetic androgen that inhibits endometrial stimulation and growth resulting in atrophy by inhibiting pituitary gonadotropin release and ovarian steroid synthesis. Many randomized controlled studies (RCTs) have shown that it is more effective at relieving pain over placebo in laparoscopically diagnosed endometriosis (Kauppila et al., 1988; Telimaa et al., 1987, 1990; Telimaa et al., 1987). Danazol, although effective, has many intolerable side effects such as hirsutism, acne, and voice deepening.

GnRH-a are also very commonly used and effective in the treatment of endometriotic pain. There are many formulations available such as buserelin and nafarelin, which are given via an intranasal route; leuprolide depot, which is given intramuscularly; and leuprolide and goserelin, which are given subcutaneously (Rice, 2002). GnRH-a reduce proliferation by inhibiting pituitary pulsatile release of GnRH and therefore the positive drive for ovaries to produce endometrial growth-enhancing estrogen. GnRH has been extensively studied alone and in comparison with other agents. Depot leuprolide acetate (3.75 mg/month) was shown in one RCT of 100 women to cause a significant decrease in dysmenorrhea, pelvic pain, and tenderness as compared with a control group (Ling & Pelvic Pain Study Group, 1999). This study also reported the benefit, efficacy, and safety of medical treatment with depot leuprolide before laparoscopy based on empirical, clinical diagnosis. GnRH-a re-treatment for recurrent endometriotic symptoms after effective 3 to 6 months prior GnRH-a use has been found to positively affect symptom severity (Hornstein et al., 1997a).

If a GnRH-a is used, a hormonal add-back therapy, such as norethindrone acetate with or without estrogen, prevents long-term hypoestrogenic side effects such as bone loss and vasomotor symptoms (Hornstein et al., 1998). Surrey and Judd (1992) showed in a study containing 19 patients receiving GnRH-a with either norethindrone (10 mg/day orally) or norethindrone (2.5 mg/day) along with a cyclic bisphosphonate (etidronate, 400 mg/day orally) for 48 weeks that pain symptoms, extent of disease, and vasomotor symptoms were all suppressed, but that bone density was unchanged (no significant difference).

If side effects or risks prevent medical therapy or if there is a finding of an adnexal mass or infertility, then surgical evaluation should be considered. Laparoscopic electrosurgery, laser surgery, or laparotomy with resection or ablation of disease often is reserved for treatment of severe endometriosis. A prospective cohort study on patients with stage III to IV endometriosis found that 87.7% of the patients were satisfied or very satisfied with the results of their ablative laparoscopic surgery at 12 months postoperatively and that no surgical complications had occurred (Jones & Sutton, 2003). Laparoscopic surgical resection may have a place in patients with minimal to moderate endometriosis. In a prospective randomized double-blinded study of 63 women with minimal to moderate endometriosis subjected to laser laparoscopy 62% of the women noted improvement in pain after 6 months and, at the time of the 1-year follow-up, there was continued improvement in 90% of the initial responders (Sutton et al., 1997). After review of the literature one can conclude that in comparison with expectant treatment, there is a significant amount of pain relief at 6 months after surgery with laser laparoscopic surgery for minimal, mild, and moderate endometriosis (Jacobson et al., 2003).

Of note, laparoscopic pain mapping of endometriotic lesions and directed obliteration have been attempted. In a study by Howard (2003a), patients who underwent directed destruction of their endometriotic lesions had no better outcomes of pain relief than a historical control group undergoing laparoscopy prior to the introduction of laparoscopic pain mapping.

Very commonly, after conservative surgical therapy, adjunctive medical therapy is given. This, however, is controversial and in a study by Bianchi et al. (1999) danazol was given for 3 months in 77 women with moderate-to-severe disease and they reported that it did not significantly improve pelvic pain or short-term reproductive outcomes. On the other hand, G. Morgante (1999) found that 6 months of 100 mg/day of Danazol resulted in significantly ($P < 0.01$) lower pain scores than in the control group and that there were no significant differences between the two groups' estrogen concentrations, bone mineral density, or side effects. Another study compared patients who received ablative therapy and 6 months of postoperative GnRH-a with patients who were treated with

excision alone and found that at the end of 2 years 60% of the GnRH-a group was pain free and only 23% of the untreated group was still pain free (Winkel, 1999). The conclusion one can draw on review of the available studies is that short courses of treatment (3 months) do not delay recurrence of endometriosis-associated pain but longer courses of 6 months do, lasting up to 12 months post-treatment (Bianchi et al., 1999; Busacca et al., 2001; Hornstein et al., 1997b, 1998; Parazzini et al., 1994; Telimaa et al., 1987; Vercellini et al., 1999).

Patients who do not desire fertility may opt for radical surgery for endometriosis, which consists of a total abdominal hysterectomy with bilateral salpingo-oophorectomy as well as removal of any residual gastrointestinal (GI), genitourinary (GU), or peritoneal disease. It should be noted that patients with endometriosis, who have failed hormonal or conservative surgical therapy, may still benefit from the pain management approach (Rapkin & Kames, 1987). At least 30% of patients with recurrent pain after treatment of endometriosis did not have residual disease at the time of repeat laparoscopy.

There are many new treatments on the horizon, most of which are based on altering the factors that stimulate the immune system, cytokine secretion, and growth factors involved in the pathology of endometriosis. Tumor necrosis factor alpha, an activator of macrophages, has been found to be an important modulator of immune system responses, endometrial cell turnover, and cell adhesion (Sidell et al., 2003). Studies of pentoxifylline, an anti-tumor necrosis factor agent, in animals have shown regression of implants and reversal of surgically induced endometriosis-associated infertility (D'Hooghe, 2003; Nothnick, Curry, & Vernon, 1994; Steinleitner et al., 1991). In addition, a small pilot study in humans recently showed a benefit in the treatment of infertility with the use of pentoxifylline (Balasch et al., 1997). Aromatase (as described earlier), another factor in the growth of endometriosis, converts steroids such as testosterone and androstenedione to estrogens such as estradiol and estrone (Bulun, 1999; Fang et al., 2002). Normal endometrium does not express aromatase, but endometriotic implants do (Fang et al., 2002). Animal model studies have shown near total resolution of endometriotic nodules with the use of aromatase inhibitors and these inhibitors are felt to be the preferred treatment for the rare postmenopausal women with recurrent endometriosis (D'Hooghe, 2003; Fang et al., 2002; Somigliana et al., 2003; Takayama et al., 1998; Vigano et al., 2003). GnRH antagonists (e.g., cetrorelix) are now being studied. One author reported that 15 of 15 patients receiving 3 mg of cetrorelix subcutaneously once a week over 8 weeks remained symptom free (including mood changes, hot flushes, loss of libido, vaginal dryness, and other symptoms) and 9 of 15 patients who showed a mean stage III disease on diagnostic laparotomy pretreatment had a 60% regression to a stage II after treatment

(Kupker et al., 2002). Finally, estrogen antagonists (selective estrogen receptor modulators) such as raloxifene are showing promising results at controlling endometriotic lesion growth in recent studies (Somigliana et al., 2003; Vigano et al., 2003).

Endometriosis is a common finding in reproductive-age women, but it is clear in many women with chronic pelvic pain and endometriosis that the latter may not be the cause of the pain and may be only a contributing or associated factor. A response to medical management may also suggest a different underlying pathology since gastrointestinal, urological, and other gynecological processes can improve with therapies used to treat endometriosis. There is no significant correlation between the amount of disease and pain severity although higher-stage disease tends to be associated with a greater prevalence and increased intensity of pain. Additionally, there is no correlation between location of pain and site of endometriotic lesions and as many as 30 to 50% of patients regardless of stage have no pain (Fukaya et al., 1993). However, deeply infiltrating lesions, particularly of the uterosacral ligaments, are strongly associated with pain (Cornillie et al., 1990). Vaginal and uterosacral endometriosis has been associated with complaints of deep dyspareunia probably due to neural invasion in the region of the uterine nerve and the inferior hypogastric nerve (Vercellini et al., 1996).

Clinically, it is possible to determine whether there is a relationship between pain and endometriosis in a specific patient because of the hormonal sensitivity of the disease and the potential to surgically cure disease. Clearly, pain that does not respond to adequate surgical and medical management of endometriosis should be reevaluated for another source of pain as the cause or for the possibility of central sensitization as a major contributory factor. As discussed earlier, neuroplastic changes induced by persistent inflammation and nociceptive input from endometriotic tissue implants may lead to central sensitization. This could account for persistence of pain after medical or surgical ablation. A recent psychophysiological study demonstrated central sensitization in the responses to an experimental pain stimulus in women with endometriosis (Bajaj et al., 2003).

PELVIC CONGESTION

The concept of autonomic nervous system dysfunction leading to a vascular disorder affecting the uterine and ovarian veins was proposed in 1954 and has been resurrected over the last decade (Hobbs, 1976; Perry, 2001; Taylor, 1954). Patients in Taylor's work typically complained of secondary dysmenorrhea, low back pain, dyspareunia, infertility, and menorrhagia. Their pain was usually bilateral, lower pelvic in distribution, and exacerbated with the menstrual period. Two thirds of the patients also complained of nervous tension, chronic fatigue, breast tenderness, and spastic colon, as well as symptoms similar to the premenstrual syndrome. On exam, patients manifested tenderness over the uterus. The cervix and the fundus of the uterus were often bulky and the ovaries often enlarged with multiple functional cysts. The parametria, especially the uterosacral ligaments, were noted to be tender and indurated.

Beard and co-authors (1984) performed the only blinded study of venograms in patients with chronic pelvic pain. Larger mean ovarian vein diameters, delayed disappearance of contrast medium, and ovarian plexus congestion were present in a significantly greater proportion of women with chronic pelvic pain without pathology than those with pathology or controls. In support of pelvic congestion as a true entity in the spectrum of causes of pelvic pain, Foong et al. (2002) in a prospective, controlled longitudinal study using Beard's criteria for diagnosis of pelvic congestion found systemic microvascular dysfunction due to neutrophil-mediated increases in postcapillary resistance measurements. Diagnostic means other than venograms include transvaginal ultrasound, which may reveal uterine enlargement, thickened endometrium, cystic ovaries, and dilated pelvic veins, or more recently for more detailed visualization of structures, MRI (Adams et al., 1990; Gupta & McCarthy, 1994; Stones et al., 1990).

It was noted that nearly all patients with pelvic congestion were of reproductive age, and therefore hormonal suppression consisting of a hypoestrogenic environment was considered as a mode of treatment. Medroxyprogesterone acetate (MPA) given in doses of 30 mg daily for 3 months was administered in a randomized, placebo-controlled treatment trial for women with chronic pelvic pain with pelvic congestion (abnormal venograms) (Farquhar et al., 1989). A study of 84 subjects included four separate groups: MPA alone, MPA and psychotherapy, placebo plus psychotherapy, and placebo alone. MPA was significantly more effective after the 3-month treatment period than psychotherapy or placebo. Patients reported a 50% reduction in pain in the MPA group and 33% reduction in pain score after receiving placebo. However, pain returned in the MPA group after stopping treatment but did not return in the placebo group. Psychotherapy did not reduce pain in the short term, but there was a positive interaction between MPA and psychotherapy 9 months after the treatment was concluded. However, 9 months post-treatment, improvement was reported irrespective of the treatment group. This response coupled with a strong placebo response reaffirms central factors in this condition. It also suggests that hormonal suppression with MPA or GnRH agonists with or without low-dose estrogen and progestin hormone add-back may be therapeutic. A prospective randomized trial looking at efficiency of goserelin acetate versus MPA using pelvic venogram scores and subjective symptomatic resolution (including anxiety, depressive states, and sexual functioning) found that 1 year after 6

months of treatments goserelin was superior to MPA (Soysal et al., 2001).

A few small noncontrolled studies have assessed the more invasive technique of transcatheter embolotherapy of the ovarian and internal iliac veins to treat pelvic congestion, with results revealing good short-term success (Capasso et al., 1997; Chung & Huh, 2003; Pieri et al., 2003; Sichlau et al., 1994; Tarazov et al., 1997). Longterm efficacy remains to be evaluated (Venbruz & Lambert, 1999).

SALPINGO-OOPHORITIS

Salpingo-oophoritis can cause chronic pelvic pain, although patients usually present with symptoms and signs of acute or subacute infection before the pain becomes chronic. More commonly, a patient will present with frequent recurrent infections. Sweet and Gibbs (1985) proposed criteria for making the diagnosis of salpingitis on clinical grounds. Patients should have a history of lower abdominal pain as well as lower abdominal tenderness (with or without rebound), cervical motion tenderness, and adnexal tenderness. In addition, they must have one of the following: temperature greater than 38°C, leukocytosis (greater than 10,500 white blood cells per cubic millimeter), culdocentesis fluid containing white cells and bacteria on Gram stain, presence of an inflammatory mass, elevated ESR, a Gram stain from the endocervix revealing Gram-negative intracellular diplococci, or a monoclonal smear from the endocervical secretions revealing chlamydia (Sweet & Gibbs, 1985).

Patients may complain of having had numerous episodes of pain associated with fever and may have been given the diagnosis of pelvic inflammatory disease. When these episodes become recurrent, the patient is often considered to have chronic salpingo-oophoritis, although it is not clear that a chronic inflammatory condition exists. Instead, subacute or subclinical disease with recurrent acute infections may be present. An additional possibility is that the patient may not have salpingitis at all. In all these situations, laparoscopy with peritoneal fluid cultures is diagnostic, although an experienced clinician can often make the diagnosis on the basis of clinical criteria. Broad-spectrum antibiotics and anaerobic coverage represent the standard treatment of acute or recurrent salpingo-oophoritis. Only rarely is hysterectomy and salpingo-oophorectomy required.

OVARIAN REMNANT SYNDROME

The ovarian remnant syndrome may cause chronic pelvic pain in a patient who has had a hysterectomy and bilateral salpingo-oophorectomy for severe endometriosis or pelvic inflammatory disease. Ovarian remnant syndrome results from residual ovarian cortical tissue that is left *in situ* after

a difficult dissection in an attempt to perform an oophorectomy (Steege, 1987). Often the patient has had multiple pelvic operations with the uterus and adnexa removed sequentially.

The diagnosis is suspected on the basis of history and physical examination (Price et al., 1990). The patient usually complains of pelvic pain that is often cyclic and may be accompanied by peritoneal signs. The patient may have a history of flank pain and frequent urinary tract infections, and there is on occasion intermittent, partial bowel obstruction. The painful symptoms usually arise 2 to 5 years after surgery. Pelvic exam may reveal a tender mass in the lateral region of the pelvis, and ultrasound following ovarian stimulation with 50 mg of clomiphene daily for 5 days usually confirms a mass with the sonographic characteristics of ovarian tissue. In a patient who has had bilateral salpingo-oophorectomy and is not on hormonal replacement, estradiol and follicle-stimulating hormone (FSH) assays reveal a characteristic premenopausal picture, although on occasion the remaining ovarian tissue may not be active enough to suppress FSH levels. Laparotomy and removal of residual ovarian tissue is necessary for treatment (Pettit & Lee, 1988). Importantly, it has been shown that those who have achieved pain relief with GnRH-agonist hormonal therapy prior to surgery are usually those who also receive relief with surgical removal of the remnant (Carey & Slack, 1996).

CYCLIC PELVIC PAIN

Cyclic pelvic pain consists of primary and secondary dysmenorrhea but also includes atypical cyclic pain, such as pain beginning 1 week prior to menses and lasting for up to 1 week following the cessation of menstrual flow with occasional mid-cycle pain as well. Atypical cyclic pain is a variant of secondary dysmenorrhea. The diagnosis of cyclic pain often depends on the review of a daily pain diary that patients should be asked to maintain. With the availability of NSAIDs and compounds that alter the female sex steroids, cyclic pelvic pain has become significantly more manageable.

Dysmenorrhea or "difficult monthly flow" is a common gynecologic disorder affecting up to 50% of menstruating women (American College of Obstetricians and Gynecologists [ACOG], 1983). Primary dysmenorrhea refers to pain with menses when there is no pelvic pathology, whereas secondary dysmenorrhea is painful menses with underlying pelvic pathology. Primary dysmenorrhea usually appears within 1 to 2 years after menarche, with the establishment of ovulatory cycles. The disorder primarily affects younger women with ovulatory cycles, especially teens, but may persist into the 40s. The pain of primary dysmenorrhea begins a few hours prior to or just after the onset of menstrual flow and usually lasts for 48 to 72 hours. The pain is labor-like with suprapubic cramp-

ing that may be accompanied by lumbosacral backache, pain radiating down the anterior thighs, nausea, vomiting, and diarrhea.

Secondary dysmenorrhea, on the other hand, usually, although not always, occurs years after menarche and may occur with anovulatory cycles (ACOG, 1983). The most common cause of secondary dysmenorrhea is endometriosis. Other common causes, listed in Table 30.2, include vaginal, cervical, uterine, fallopian tube, adnexal, and peritoneal pathology. The differential diagnosis of secondary dysmenorrhea includes primary dysmenorrhea and noncyclic pelvic pain and entails ruling out primary dysmenorrhea and confirming the cyclic nature of the pain. The etiology of primary dysmenorrhea has been established due to increased uterine prostaglandin production (Anon., 1979). Prostaglandin synthetase inhibitors are effective for the treatment of primary dysmenorrhea in 70 to 80% of the cases (Anon., 1979). For the patient with primary dysmenorrhea who has no contraindications to oral contraceptive agents and desires contraception, the birth control pill, cyclically or continuously without a menstrual period (newer alternatives include the patch and the vaginal ring or even the levonorgestrel-releasing intrauterine device), is the agent of choice (Chan & Dawood, 1980). More than 90% of women with primary dysmenorrhea have relief with birth control pills.

If the patient does not respond to prostaglandin synthetase inhibitors and does not desire oral contraceptive pills or other forms of contraception, or if either is contraindicated, narcotic analgesics should be administered for 2 to 3 days per month. Prior to the addition of narcotic medication, psychological factors and other organic pathology should be ruled out. Other modes of hormonal menstrual suppression include high-dose progestins (oral or depo intramuscular injection), continuous oral contraceptive pill administration, or GnRH agonists with or without continuous low-dose hormone (menopausal dosage) add-back. Breakthrough bleeding and associated pain are potential problems with these regimens.

A patient with dysmenorrhea who does not respond to prostaglandin synthetase inhibitors and/or estrogen progestin contraceptive formulations and in whom organic disease has been ruled out may also respond to the pain management approach and, in particular, acupuncture or transcutaneous electrical nerve stimulation (Kaplan et al., 1994; Mannheimer & Whaler, 1985). In one study, Kaplan et al. (1994) reported a 30% marked pain relief, 60% moderate pain relief, and 10% no pain relief in women with primary dysmenorrhea undergoing transcutaneous electrical nerve stimulations (TENS). To more fully evaluate the evidence for treating primary dysmenorrhea with TENS or acupuncture, a forthcoming study by the Cochrane Library aims to analyze all prospective randomized controlled trials comparing those modalities with medical treatment or placebo (Wilson et al., 2000).

The distinction between primary and secondary dysmenorrhea requires a thorough history as to the nature and onset of the pain, the duration of pain or symptoms, and a pain diary (if on first query the pain does not appear to be cyclic). A complete physical and pelvic examination is important, with focus on the evaluation of the size, shape, and mobility of the uterus and adnexal structures and for nodularity and fibrosis of the uterosacral ligaments and rectovaginal septum. Genital cultures for gonorrhea and chlamydia and a complete blood count (CBC) with ESR are usually warranted. If no abnormalities are found, a tentative diagnosis of primary dysmenorrhea may be made and the patient started on oral contraceptive pills and/or prostaglandin synthetase inhibitors. Having made a diagnosis of primary dysmenorrhea, a 4- to 6-month trial of combined estrogen/progesterone contraceptives and/or prostaglandin synthetase inhibitors is warranted before laparoscopy is performed to rule out secondary dysmenorrhea and, in particular, endometriosis. A strong family history of endometriosis and any clinical signs of endometriosis on exam may suggest that laparoscopy be performed sooner.

Surgical approaches to dysmenorrhea include laparoscopic uterine nerve ablation, presacral neurectomy, and in selected cases of secondary dysmenorrhea, hysterectomy (Malinak, 1980). The uterosacral ligaments carry the main afferent supply from the uterus, and if complete, the uterosacral ablation should be as effective as the presacral neurectomy, although Doyle (1995) described a 70% success rate. Long-term and controlled studies of the neurectomy procedures are described elsewhere in this chapter. The management of secondary dysmenorrhea involves treatment of the underlying pathology.

GASTROENTEROLOGIC CAUSES OF CHRONIC PELVIC PAIN

Many of the patients referred to gynecologists with chronic pelvic pain actually have GI pathology (Rapkin & Mayer, 1993; Reiter, 1990a). Because the cervix, uterus, adnexa, lower ileum, sigmoid colon, and rectum share the same visceral innervation, with pain signals traveling via the sympathetic nerves to spinal cord segments T10 to L1, it is often difficult to determine whether lower abdominal pain is of gynecologic or enterocoelic origin (Hightower & Roberts, 1981). In addition, as is true with other types of visceral pain, pain sensation from the GI tract is often diffuse and poorly localized. Skillful medical history and examination are usually necessary to make the diagnosis.

Irritable bowel syndrome (IBS) is one of the more common causes of lower abdominal pain and may account for as many as 7 to 60% of referrals to a gynecologist for chronic pelvic pain (Reiter, 1990a). About 70% of patients

with IBS are women; 48 to 79% of patients with chronic pelvic pain, dyspareunia, dysmenorrhea, or a history of numerous abdominal surgeries also have IBS (Smith, 2001). Women who have had a hysterectomy for chronic pelvic pain are twice as likely to have IBS (Longstreth, 1997). The predominant symptom of irritable bowel syndrome is abdominal pain (Ritchie, 1979). Other symptoms include excessive flatulence and alternating diarrhea and constipation. The pain is usually intermittent cramp-like and predominantly left lower quadrant in location, but occasionally the pain is constant. Pain is often improved after a bowel movement. The pain may last for only a few minutes, but 50% of patients may have pain for hours to days, and 20% of patients may complain of pain for weeks or longer. Symptoms are usually worse during periods of stress, tension, anxiety, and depression, and with the pre-menstrual and menstrual phases of the cycle (Ritchie, 1979). Depending on the main symptomatology, a patient with IBS can usually be placed into one of three subgroups including constipation-predominant IBS, diarrhea-predominant IBS, and IBS with alternating bowel habits (or "pain-predominant") (Whitehead, 1999).

Many attempts have been made to determine definite criteria for IBS that do not exclude patients who truly have the disease but are not too sweeping and may mistakenly include individuals with other disorders that may be treated differently. Manning attempted to define criteria in 1978 but these six criteria, although occasionally still used, have been mostly disregarded as not being sensitive enough to differentiate between IBS and other diagnoses such as non-ulcer dyspepsia and other organic GI disease (Talley et al., 1990). The Manning criteria were modified and took the form of Rome I and now Rome II criteria. The Rome II criteria state that the patient must have had at least 12 weeks, which need not be consecutive, in the preceding 12 months of abdominal discomfort or pain that included two of three features: (1) relief with defecation; (2) onset associated with a change in frequency of stool; and/or (3) onset associated with a change in form (appearance) of stool (Thompson et al., 1989, 1999). Using the Rome II criteria, IBS has been found to have around a 3 to 5% prevalence rate in the United States (Boyce et al., 2000; Mearin et al., 2003).

Before a final diagnosis of the IBS is made, other more serious conditions must be excluded especially if the patient complains of any "alarm symptoms" such as weight loss, GI bleeding, anemia, fever, or frequent nocturnal symptoms (Holten et al., 2000). These patients need a CBC, stool occult blood test, thyroid-stimulating hormone level, erythrocyte sedimentation rate, and electrolyte levels along with a gastroenterology referral (Holten et al., 2000). Patients 50 years or older should also be fully evaluated. Sigmoidoscopy, colonoscopy, and barium enema are often necessary and are routinely negative although there may be mucosal hyperemia on sigmoido-

scopy and increased haustral contractions or loss of haustration on barium enema (Hightower & Roberts, 1981). IBS is a waxing and waning disorder and treatment consists of reassurance, education, stress reduction, and symptomatic treatment. Diet changes should include eliminating foods containing lactose, sorbitol, alcohol, fat, and fructose. Products that contain caffeine can also cause abdominal bloating, cramping, and more frequent bowel movements. After a trial of diet change and fiber supplementation, if the patient still continues to be symptomatic, a short-term trial of an antispasmodic such as dicyclomine or hyoscyamine should be initiated (Howard, 2003b; Viera et al., 2002). Tegaserod, a 5-HT$_4$ agonist is a newer agent approved by the FDA for women with IBS. It has visceral antinociceptive effects and is beneficial as a short-term treatment (Viera et al., 2002). Please see the chapter on irritable bowel syndrome for further details.

Irritable bowel syndrome, as with chronic pelvic pain, has been associated with underlying psychological factors (either predisposing the patient to disordered sensory perception or as a result of a chronic illness). Patients who have IBS by Rome II criteria are likely to have pan-enteric dysmotility with frequent dyspepsia, associated with psychological morbidity and greatly impaired quality of life (Portincasa et al., 2003); therefore, psychological therapy may improve these patients' outcomes and include cognitive-behavior therapy, dynamic psychotherapy, and hypnosis (Guthrie et al., 1993; Viera et al., 2002). Patients with chronic diarrhea must be evaluated carefully, often with a gastroenterologist in consultation. Although symptoms may have become chronic, it is possible that the patient may have contracted infectious diarrhea due to any one of a number of bacteria or parasites including *Shigella, Escherichia coli, Salmonella, Camphylobacter,* or *Amoeba* (Hightower & Roberts, 1981).

Although appendicitis is a common cause of abdominal pain, the abdominal pain of appendicitis is severe enough that the patient presents to the physician within 12 to 48 hours after the onset of the symptoms. The practitioner treating a patient for chronic pelvic pain should be cautious when the patient suddenly has an increase in abdominal pain, especially if it is accompanied by localized right lower quadrant pain, as well as anorexia, nausea, vomiting, and peritoneal signs on exam. It is not uncommon that a patient under treatment for chronic pelvic pain develops acute appendicitis or other acute pelvic condition while in the process of evaluation for the chronic pain problem. Chronic appendicitis is a controversial entity (Lee et al., 1985).

Another cause of chronic enterocoelic pain is diverticulitis of the colon (Young et al., 1976). Of the adult population over age 40, 5% have been noted to have diverticulae (Painter, 1975). This percentage increases to 40% in individuals over the age of 70 although most patients never develop diverticulitis. Although diverticulosis is

usually asymptomatic, diverticulitis results in severe pain. Diverticulitis results from perforation of one or more of the diverticula and usually leads to the formation of a pericolonic abscess. The principal symptom of diverticulitis is left lower quadrant abdominal pain. A tender mass may be palpable on exam. Fever and leukocytosis are usually present. Sigmoidoscopy is diagnostic. These symptoms and signs, however, are usually those of an acute pathological pain process bringing the patient to a physician early in the course of pain.

Inflammatory bowel disease such as ulcerative colitis or granulomatous disease (Crohn's disease) similarly do not usually present as chronic pelvic pain because their presentation is usually more acute with diarrhea, fever, vomiting, and anorexia (Hightower & Roberts, 1981). A sigmoidoscopy or barium enema is diagnostic.

Tumors of the GI tract can cause chronic lower abdominal pain in women (McSherry et al., 1969). The most frequent and early symptoms of bowel carcinomas are change in bowel habits (74% of patients) and abdominal pain (65% of patients). Rectal bleeding and weight loss may be signs of advanced disease (McSherry et al., 1969). Most rectal tumors can be palpated on rectal examination. Sigmoidoscopy and biopsy as well as barium enema are diagnostic.

Included in the differential diagnosis of lower abdominal pain is hernia although there is a relatively low incidence of hernia in females (Hightower and Roberts, 1981). Anterior and posterior perineal hernias, usually limited to cystocele, rectocele, or enterocele, may cause lower abdominal/perineal pain in women although the pain is usually not severe. This type of pain usually responds to a pessary though the management is surgical.

UROLOGIC CAUSES OF CHRONIC PELVIC PAIN

Chronic pelvic pain of urologic origin may be related to recurrent cystoureteritis, urethral syndrome, interstitial cystitis (IC), infiltrating bladder tumors, ectopic pelvic kidney, or various ureteral causes such as ureteral obstructions or endometriosis (Summit, 1993; Vereecken, 1981).

The patient with acute infective cystitis presents with complaints of suprapubic pain, dysuria, frequency, and urgency; has pyuria on urinalysis; and has a positive urine culture (Vereecken, 1981). The symptoms usually respond to adequate antibiotic therapy. Relapses and reinfection can be diagnosed with the aid of history, urinalysis, and culture. The antibiotic and duration of therapy may have to be adjusted and on occasion, if the patient has recurrent cystoureteritis, antibiotics may have to be administered postcoitally for a prolonged period of time (Vereecken, 1981).

The urethral syndrome, more commonly known as urgency frequency syndrome, is a common condition in women and may present as chronic pelvic pain (Bodner, 1988). Symptoms of dysuria, urinary frequency, suprapubic pain, and dyspareunia are prominent and the diagnosis is one of exclusion. Negative urine analysis, urine culture, cervical culture (for gonorrhea and chlamydia), and urethral cultures, as well as negative evaluation for vulvovaginitis, increase the suspicion for the diagnosis of urethral syndrome; however, IC is the usual culprit. Treatment consists of a trial of antibiotics, preferably tetracycline for 2 to 3 weeks, and if without success (although this is controversial), urethral dilatation in reproductive-age women and vaginal estrogen for peri- and postmenopausal women (Bergman et al., 1989). Attention should be paid to psychological factors as well.

When a patient complains of symptoms of urinary frequency, urgency, nocturia, and suprapubic pain but laboratory studies are negative, the patient may actually have IC, an idiopathic chronic inflammatory condition (Karram, 1993; Messing & Stamey, 1978; Wesselmann, 2002). The prevalence of IC in the United States ranges from 10 to 67/100,000 (Held et al., 1990; Speizer et al., 1999).

The evaluation of patients with the preceding symptoms should include urinalysis and culture; urethral culture for chlamydia, mycoplasma, and gonorrhea; and cystoscopy with hydrodistension and possible biopsy. There are no true consensus criteria for the diagnosis of IC, and it is usually a diagnosis of exclusion. Signs and symptoms can consist of pain or bladder filling relieved by emptying, urinary urgency and frequency; nocturia, pressure and pain in suprapubic, pelvic, urethral, vaginal, or perineal region; glomerulations; Hunner's ulcers or patches (these are the only defining pathology); fibrosis on endoscopy, or decreased compliance on cystometrogram (Karram, 1993; Wesselmann, 2002). A validated questionnaire developed by O'Leary et al. called the Interstitial Cystitis Symptom Index and Problem Index measures lower urinary tract symptoms (Clemons et al., 2002; O'Leary et al., 1997). A positive score ($\geq$6) on either the symptom or problem index had 90% sensitivity and 95% specificity for diagnosing ICs. Clemons et al. (2002) evaluated the questionnaire as a screening tool and found that a score of 5 or more had 94% sensitivity and 93% negative predictive value in diagnosing IC and, therefore, concluded that it was a useful screening test. The use of a pelvic pain and urgency frequency symptom scale and a provocative bladder potassium intravesical test suggests that many women with pelvic pain or urgency/frequency alone may have early IC (Parsons et al., 2002). Some authors have advocated that during the initial evaluation of chronic pelvic pain, cystoscopy and exploratory laparoscopy should be performed concurrently. Chung found that of 58 patients with cystoscopy-confirmed IC, 54 had a concurrent diagnosis of active or inactive endometriosis (Chung et al., 2002). Of the 54 patients, 47 had biopsy-confirmed active endometriosis.

This very common association is important because of its impact on effective treatment.

Therapy for IC ranges depending on the severity of the patients' symptoms. Change in diet, stress reduction, and behavioral changes such as recording a voiding diary and pelvic floor muscle training can be attempted initially (Wesselmann, 2002). In addition, therapy consisting of intravesical distension with dimethylsulfoxide or lidocaine, intravesical instillation of analogues of glycosaminoglycan, TENS and biofeedback including pelvic floor muscle biofeedback training have all reduced pain in uncontrolled studies of patients with IC. Hydrodistension of the bladder performed under anesthesia at the time of diagnostic cystoscopy has been the most commonly used urological therapy for more than 50 years (Messing, 1989). Because treatment of the condition remains empiric and less than optimal, oral drugs such as anticholinergics, antihistamines, membrane-stabilizing agents, antispasmodics, NSAIDs, tricyclic antidepressants, narcotics, and pentosan polysulfate sodium, which is Food and Drug Administration approved for IC treatment, have all been used with some success (Sant, 1998). Sacral nerve modulation using a permanent InterStim implant or neurolytic surgery using laser destruction of the vesicoureteric plexus has been found to be successful at treating refractory IC (Gillespie, 1994; Peters et al., 2003).

Very severe chronic suprapubic pain may be caused by infiltrating carcinomas of the bladder, cervix, uterus, or rectum (Vereecken, 1981). These conditions should be apparent after performing the history, pelvic examination, urine analysis, and cystoscopy, although intravenous pyelogram or CT urogram may be necessary.

NERVE ENTRAPMENT OR INJURY

Abdominal cutaneous nerve entrapment or injury should always be considered in the differential diagnosis of chronic lower abdominal pain, especially if no visceral etiology is apparent. The syndrome most commonly occurs months to years after Pfannenstiel skin or other lower abdominal and even laparoscopic incisions but can also follow trauma or exercise (Sippo et al., 1987). Commonly involved nerves include ilioinguinal (T12 and L1), iliohypogastric (T12 and L1), and genitofemoral (L1 and L2). In addition to incisional injury, three common ways neurologic injury may occur at the time of gynecological surgery are (1) improper placement or positioning of retractors, especially retractors with deep lateral retractor blades; (2) improper positioning of patients in lithotomy position preoperatively; and (3) radical surgical dissection and subsequent autonomic nerve disruption (Irvin et al., 2004). Abdominal hysterectomy is the number one most common surgical procedure at fault for causing iatrogenic femoral nerve injury (Fardin et al., 1980).

Symptoms of nerve entrapment include pain that is typically elicited by movement and exercise (Sippo et al., 1987). The pain is described as stabbing, colicky, and sudden, and is usually judged as coming from the abdomen and not from the skin. The pain is located along the line of the lateral edge of the rectus margin and may be associated with a burning pain radiating horizontally or diagonally toward the linea alba and back to the flank or sacroiliac region if there is ilioinguinal or iliohypogastric nerve damage. Ilioinguinal and iliohypogastric nerve injury is more likely to occur if a Pfannenstiel incision is extended beyond the lateral border of the rectus abdominus muscle into the muscle of the internal oblique muscle (Irvin et al., 2004). The pathognomonic symptoms include (1) sharp, burning pain arising from the incision site and radiating to the suprapubic, labial, or thigh areas; (2) paresthesia over the corresponding nerve distribution; and (3) pain relief after infiltration with local anesthetic (Stulz & Pfieffer, 1982). Femoral nerve injury results usually after deep lateral retractor blades compress the nerve between the blade and the lateral pelvic sidewall and results in weakness or an inability to flex at the hip joint or to extend at the knee. Paresthesia can occur over the anterior and medial thigh (Irvin et al., 2004; Vosburg & Finn, 1961). Pudendal neuropathy can cause chronic pelvic, vulvar, and perineal pain. Pain due to nerve injury may be exacerbated by constipation, bloating, menstruation, and full bladder (Sippo et al., 1987).

On exam, the pain can usually be localized with the fingertip (McDonald, 1993). The maximal point of tenderness is the neuromuscular foramen at the rectus margin medial and inferior to the anterior iliac spine or, in the case of spontaneous nerve entrapment, at the site of exit from the aponeurosis of the other thoracic/abdominal cutaneous nerves. A maneuver that helps to make the diagnosis is Carnett's test and involves asking the patient to tense the abdominal wall by raising shoulders or raising and extending the lower limbs in a straight leg raising maneuver. The pain is exacerbated if abdominal wall pain is present. With the abdominal wall relaxed, the pain is relieved and becomes more diffuse. The tentative diagnosis is confirmed with a diagnostic nerve block consisting of injection of 2 to 4 ml of 1% lidocaine or 0.25% bupivacaine. Patients usually report immediate relief with symptoms after injection and many patients require no further intervention, although some patients require 3 to 5 weekly injections (McDonald, 1993; Srinivasan & Greenbaum, 2002). Only as a last resort should patients be considered for surgical removal of the involved nerves if no other psychological factors predominate and if visceral pathology can be ruled out. Complete relief of pain after nerve resection occurs in more than 70% of patients (Hahn, 1989; Lee & Dellon, 2000; Nahabedian & Dellon, 1997). On the other hand, deafferentation pain is a probable sequel to surgery. Medications such as low-dose tri-

cyclic antidepressants and anticonvulsants are also useful for pain control. Physical therapy may be necessary to educate the patient concerning strengthening other muscles to prevent reinjury.

MUSCULOSKELETAL CAUSES OF CHRONIC PELVIC PAIN

Women complaining of lower back pain without complaints of pelvic pain rarely have gynecologic pathology as the cause of their pain; however, low back pain may accompany pelvic pathology. Back pain may be caused by gynecologic, vascular, neurological, psychogenic, or spondylogenic (related to the axial skeleton and its structures) pathology (Morscher, 1981). Musculoskeletal abnormalities commonly contribute to the symptoms of chronic pelvic pain (Baker, 1993).

MYOFASCIAL PAIN

"Myofascial pain syndromes constitute a large group of muscle disorders characterized by the presence of hypersensitive points, called trigger points (TPs), within one or more muscles, the investing connective tissue, or both, together with a syndrome of pain, muscle spasm, tenderness, stiffness, limitation of motion, weakness, and occasionally autonomic dysfunction. The symptoms are usually referred to any area distant from the TPs, although local pain may also be present" (Sola & Bonica, 2001, p. 530). Reports of the prevalence of the syndrome vary, but only two papers assessing chronic pelvic pain patients for trigger points have been published. Reiter and Gambone found myofascial syndrome in 15% of their patients with somatic pathology. Patients with somatic pathology represented 47% of all patients referred to their pelvic pain clinic (Reiter, 1990a). Slocumb noted trigger points in most women presenting to the pain clinic with chronic pelvic pain irrespective of underlying pelvic pathology (Slocumb, 1984). Clinically, myofascial pain is exacerbated by activity within the muscle or muscle group and, in the case of abdominal wall trigger points and pelvic floor muscle, is exacerbated by activity in deeper visceral structures (bladder or rectal fullness, menses, and cervical motion and intercourse), which share the same dermatomal innervation (Slocumb, 1984, 1990; Travell, 1976). On digital exam of dermatomas of abdomen, back, or vagina, pressure on the trigger point evokes local and referred pain. Pain is exacerbated by the straight-leg raising maneuver (Carnett's test) described earlier. Treatment of myofascial trigger points includes injecting the trigger points with local anesthetic, as well as treating any physical and psychological factors such as depression, anxiety, learned behavior patterns, and postural elements that may accompany and exacerbate the condition (Slocumb, 1984;

Travell, 1976). Medications such as tricyclic antidepressants and anticonvulsants (medication intended for neuropathic pain) and physical therapy are also be useful.

CENTRAL (BRAIN) FACTORS IN CHRONIC PELVIC PAIN

Descending pain-modulating mechanisms, including those originating in the brain or spinal cord, probably involve various chemicals such as classical neurotransmitter, endogenous endorphin and nonendorphin analgesic systems, and excitatory amino acids. Anxiety, depression, and other psychological states may serve as facilitators or inhibitors of neurological transmission. Wall (1988) has suggested that it is important to consider the lability of central transmission pathways as well as seeking peripheral pathology in all painful conditions. From a psychological perspective, there are various factors that may promote the chronicity of pain. Described as a "diathesis-stress" model of pain, a woman is more susceptible in certain social contexts to develop chronic pain based on her preexisting vulnerabilities including those related to cognitive, affective, biological, and behavioral functioning (Jacob, 1997).

Studies on women with chronic pelvic pain have documented a high level of psychological disturbance. The Minnesota Multiphasic Personality Inventory (MMPI) conversion "V" profile (elevated scores on the hypochondriasis, hysteria, and depression scales) was described by Castelnuova-Tedesco and Krout (1970). In a survey of 40 women with pelvic pain. Gross et al. (1980) reported high levels of psychopathology in women with pelvic pain, as well as a past exposure to childhood sexual abuse in 90% of their sample. Studies using the MMPI have failed to find a correspondence between psychological and physiological findings. Renaer (1979) compared MMPI profiles of women having chronic pain without obvious pathology with those of women having pain arising from endometriosis and a control group. He found the two pain groups differed from controls but not from each other. Interestingly, treatment resulting in subjective improvement in pain severity and increased activity level produces a significant improvement in personality profile (Duleba et al., 1998).

Other studies have focused on the specific diagnosis of depression and pelvic pain. Magni (Richter et al., 1998) examined the role of depression and found higher depression scores for women with chronic pelvic pain without pathology compared with women found to have chronic pelvic pain and pathology as established by laparoscopy. Theses studies have also found a higher likelihood of depressive disorders in the family histories of women whose pain could not be attributed to organic pathology. A comparison of women with pelvic pain of unknown

etiology and a pain-free control group revealed the pain group to have a significantly higher prevalence of episodes of major depression (Richter et al., 1998). Most studies find no difference in the psychological profile in women with or without pathology on laparoscopic surgery (Walker et al., 1988). It has been suggested that pain may be augmented by depression, in view of the common neurotransmitter pathways mediating both pain and mood.

Studies have also examined the role of sexual abuse as a specific risk factor for chronic pelvic pain. Gross and associates (1980) reported a high prevalence (90%) of sexual abuse in their sample. A sample of 25 women with chronic pelvic pain of mixed etiology showed no differences in psychological functioning when divided according to presence or absence of organic findings (Harrop-Griffiths et al., 1988). However, when compared with a control group of gynecologic patients without pain, there was a higher prevalence of prior substance abuse, functional dyspareunia, inhibited sexual desire, higher scores on the SCL-90, and greater prevalence of sexual abuse—both as youths prior to age 14 and as adults. The authors identified a history of sexual abuse as a child, along with a past history of depression, as strongly related to the subsequent persistence of pelvic pain.

Rapkin et al. (1990) designed a study to assess whether prior abuse is more likely in patients with pelvic pain than in women with chronic pain in other sites or a painful control group, and whether the abuse was specifically sexual or extended to physical abuse as well. The prevalence of childhood sexual abuse did not differ significantly among the three groups: 19% of pelvic pain, 16% of other pain patients, and 12% of controls. There was a significant difference in the prevalence of physical abuse: highest for the pelvic pain patients (39%), compared with 18 and 9% in the other two groups. This study suggested abuse of any kind is linked to chronic pain (Rapkin et al., 1990). Walling and colleagues (1994) compared women having chronic pelvic pain with women having nonpelvic chronic pain (headache) and pain-free women, finding that women suffering pelvic pain reported a higher lifetime prevalence of major sexual abuse (56%) and physical abuse (50%). A more recent study by Lampe et al. (2003) looked at chronic pain syndromes in general. Of the patients, 40 had chronic low back pain, 43 had chronic pelvic pain, and 22 women made up the control group. The outcomes were assessed by interviews determining childhood sexual and physical abuse and using the Beck Depression Inventory. They found that childhood physical abuse, stressful life events, and depression had a significant affect on the occurrence of chronic pain in general and childhood sexual abuse was correlated with chronic pelvic pain exclusively. In yet another study, the same author determined that there was a significant association between sexual abuse before age 15 and the subsequent development of chronic pelvic pain (Lampe et al., 2000).

Abuse and post-traumatic stress disorders may predispose to chronicity of pain because they increase the vulnerability to depression, and the chronicity is likely fostered by alterations in neural circuitry as a result of early trauma (Grossman et al., 2002). Individuals who have suffered childhood abuse, physical and sexual, may possibly have impaired coping abilities and, as a result, may perceive life events as more stressful (Lampe et al., 2003). There is also evidence for the logical conclusion that chronic pain itself over time reduces physical and mental health, vitality, and social function, so that it leaves the researcher with a "chicken and egg, which came first?" phenomenon (Haggerty et al., 2003). For the above reasons the examining physician should not forget the importance of obtaining sexual and physical abuse histories and including at least a resource for psychological therapy in patients with chronic pelvic pain (Toomey et al., 1993).

Renaer (1980) has suggested that the diagnosis chronic pelvic pain without obvious pathology refers to patients who lack somatic pathology. Often, these patients have been considered to have psychogenic pain. As noted in the previous discussion, the majority of patients with chronic pain have abnormal psychogenic profiles, but those patients without pathology do not appear to be psychologically different from those with visible organic disease (Harrop-Griffiths et al., 1988; Renaer et al., 1979; Richter et al., 1998). Furthermore, the potential role of neurophysiological mechanisms in the brain and spinal cord in the maintenance of chronic pain (neuroplasticity) is well established. Abdominal wall, lower back, and pelvic floor muscle trigger points; nerve entrapment in surgical scars; IBS; and IC represent the most common sources of nonreproductive system chronic pelvic pain (Reiter, 1990b), all of which probably entail alterations of central processing. Interestingly, these patients also have a high incidence of comorbidity with panic disorder, somatization, or depression (Reiter, 1990b; Wood et al., 1990). It is reasonable, therefore, to suggest that chronic pelvic pain regardless of "pathology" is likely to involve all levels of the neuro-axis, and it is necessary to direct management approaches accordingly.

DIAGNOSIS AND MANAGEMENT OF CHRONIC PELVIC PAIN

Successful diagnosis and management of patients with chronic pelvic pain require a meticulous yet compassionate, multidisciplinary approach. As with the investigation of any other physical symptom, a thorough history should be obtained, and often must be acquired in stages. An intake questionnaire form ensures a thorough and in-depth research as to the nature of the patient's pain. In addition, it assists in accurate charting and recollection of the patient's complaints. A commonly used form is the ques-

tionnaire compiled by the International Pelvic Pain Society available on line (www.pelvicpain.org). Important on intake is a description of the nature of the pain, severity, location and radiation, aggravating and alleviating factors, timing, relationship to menses, and worsening or improving with exercise, work, stress, intercourse, and orgasm. A pain map can be used that reconstructs the general outline of the female body and is coded for the patient to mark types of pain to their locations (Howard, 2003b). These maps demonstrate that women frequently have multiple pain areas other than pelvic. Up to 60% of women with chronic pelvic pain also have headaches and up to 90% also have backaches (Howard, 2003b). If a patient marks both ventral and dorsal sources of pain, this is more suggestive of intrapelvic source rather than dorsally, which may be due to a musculoskeletal origin. It is important to determine how long the pain lasts and how much it affects the patient's daily life and activities. A visual analogue scale listing numbers 0 through 10 and stating "no pain and worst possible pain" can assess severity.

The context in which the pain arose should be ascertained. Did the pain begin postpartum, postabortal, or after physical or sexual trauma? Pregnancy risk factors include severe lumbar lordosis, delivery of a large infant, muscle weakness and poor physical conditioning, a difficult delivery, vacuum or forceps delivery, and use of gynecological stirrups for delivery (Howard, 2003b). There are additional questions: Have there been previous episodes of pain or inability to perform one's occupation? Is there pending litigation or workers' compensation? Are there other somatic symptoms that should be noted: genital tract (abnormal vaginal bleeding, discharge, Mittelschmerz, dysmenorrhea, dyspareunia, infertility); enterocoelic tract (constipation, diarrhea, flatulence, tenesmus, blood, changes in color or caliber of stool); musculoskeletal system (predominant low back distribution, radiation down posterior thigh, association with injury, fatigue, postural changes); and urologic tract (dysuria, urgency, frequency, suprapelvic pain)? Historical questions specific to all the peripheral pathologies noted in Table 30.2 should be asked.

Past history including medical, surgical, gynecologic, obstetric, medication intake, and prior evaluations for the pain should be documented. Operative and pathology reports are important if the patient has had surgery. It is important to note whether the pain is postoperative and involves the incision site or appears to be from nerve damage due to retractor misplacement.

Current and past psychological history — including psychosocial factors; history of past (or current) physical, sexual, and/or emotional abuse; history of hospitalization; suicide attempts; and chemical dependency — should be asked. The attitude of the patient and her family toward the pain, resultant behavior of the patient's family with respect to the pain, and current upheavals in the patient's life should be discussed. The part of the history addressing sensitive issues may have to be re-obtained after establishing rapport with the patient. Depression is an important predictor of pain severity and responsiveness to treatment in women with chronic pelvic pain, and it is important to use a screening tool such as the Zung or Beck depression inventories. In the multidisciplinary approach the team of clinicians would include a psychologist or social worker who would assist in completing this part of the history.

Symptoms of an acute process such as fever, anorexia, nausea, emesis, significant diarrhea or constipation, hematochezia, abdominal distension, abnormal uterine bleeding, pregnancy, or recent abortion should alert one to the possibility of an acute condition requiring immediate medical or surgical intervention. This is especially called for if accompanied by orthostasis, peritoneal signs, pelvic or abdominal mass, abnormal CBC, positive genital or urinary tract cultures, or positive pregnancy test.

One should perform a complete physical examination, with particular attention to the abdominal, back, vulva, perineum, vaginal, bimanual, and rectovaginal examinations. The goal of the exam is to reproduce the pain by palpation or positioning (Howard, 2003b). The supine part of the exam should include evaluation of the abdomen, looking for distention, abdominal ascites or masses, organomegaly, guarding, rebound, or rigidity suggesting an acute abdomen or peritonitis exists. The Carnett test is done with the abdominal muscles tensed (head raised off the table or with straight leg raising) to differentiate abdominal wall from visceral sources of pain. Abdominal wall pain is augmented and visceral pain is diminished with the preceding maneuvers. The patient should point to the area of pain and the amount of pressure needed to replicate pain, and the point of maximal pain (trigger point or area of nerve injury/entrapment) should be found. Abdominal wall pain or myofascial pain can be due to fibromyalgia, trauma, muscular strain, nerve entrapment, viral myositis, or an abdominal wall hernia. Active leg flexion, knee to chest, can ascertain if there is lower back dysfunction and abdominal weakness (Howard, 2003b). It is important to rule out hernias as a cause of abdominal/pelvic pain. Spigelian hernias are lateral to the lateral margin of the rectus sheath and protrude through the transversus abdominis aponeurosis resulting in severe pain. Surgical scar hernias should also be sought out. Palpation of the pubic symphysis is necessary for a thorough exam to rule out pelvic girdle relaxation, osteomyelitis, osteitis pubis, rectus muscle inflammation, or injury at its fascial insertion (Howard, 2003b).

Very important to the delineation of pelvic pain is the pelvic exam. External genitalia should be inspected for any abnormal findings such as discharge, redness, excoriation, fissures, ulcerations, condylomata, atrophy, abscesses, or trauma. The vulva and introitus should then be examined for hyperalgesia and allodynia. This should

be done with cotton tip localization of tender areas. After examination of the external genitalia, a speculum exam should be performed with close attention to not only the cervix but also the vaginal walls. The character of the discharge, lesions, erythema, whitened areas, or areas with atypical vascular patterns should be noted and cultured or biopsied accordingly. At this time cystocele, rectocele, and enterocele can be identified.

A bimanual examination should be performed beginning with a single digit exam noting introital spasm or vaginismus suggestive symptoms. Then the examiner can gently enter the vagina, palpating the levator ani muscles (including the puborectalis, pubococcygeus, and iliococcygeus), and inspecting the pelvic girdle for spasms and tenderness in addition to ruling out abnormal findings such as nodules or masses. The examiner should assess the course of the pudendal nerve for evidence of pudendal neuropathy. It is helpful to have a physical therapist who specializes in chronic pelvic pain to evaluate the patient as part of the multidisciplinary approach. If a muscular etiology is found, these individuals are trained in rehabilitation and are excellent at teaching patients relaxation techniques. The caudal anterior vaginal surface should be examined for tenderness representing a bladder or urethral origin of pain. In addition, any discharge or thickening should be noted and may mean that chronic urethritis, urethral syndrome, urethral diverticulum, a vaginal wall cyst, trigonitis, or interstitial pathology may exist (Howard, 2003b). Deeper vaginal palpation and examination of the uterus is then necessary. Pressing the uterus against the sacrum or between the examiner's abdominal and vaginal hand may illicit tenderness. Posterior uterine pressure that causes tenderness is suggestive of pelvic congestion, adenomyosis, pelvic congestion syndrome, or pelvic infection (Howard, 2003b). Rectovaginal exam should always be performed, not only to adequately evaluate ovaries, but also to check for posterior cul-de-sac pathology (severe endometriosis can result in dense adhesions, a retroflexed uterus, and nodules on the uterosacral ligaments and rectovaginal septum) and stool for occult blood. On rectovaginal exam coccydynia may be diagnosed if an attempt to move the coccyx about 30° results in pain.

Laboratory studies to be obtained the first visit include CBC, ESR, urine analysis and culture, cervical and urethral cultures (gonorrhea and chlamydia), wet mount of vaginal secretions, pap smear, stool guaiac, and—if diarrhea is present—stool culture including *Clostridium difficile* and ova and parasites. If the pelvic or abdominal exam is inadequate due to pain, guarding, or increased abdominal wall thickness or suggestive of a mass, ultrasound evaluation is indicated. If symptoms and signs are suggestive of other system involvement, fiberoptic or other appropriate imaging studies of other organ systems should be considered (e.g., upper and lower gastrointestinal stud-

ies, colonoscopy or computerized axial tomography [CAT] scan, CT urogram, and MRI of the spine).

The patient should be given a pain diary in which to note the onset and intensity of pain on a daily basis. Medication intake, menses, and aggravating and alleviating factors should be noted daily in the diary. A simple diary utilizes a visual analogue scale from 1 (no pain) to 10 (most severe pain ever). The diary should be maintained for at least 2 months. Previous medical records, surgical and pathological reports or scans, should be requested at the time of, or prior to, this first visit.

During the second visit, one should again pursue the psychosocial and sexual history. The pain diary, laboratory results, and previous records should be reviewed with the patient. Subacute conditions should be treated (e.g., cervicitis, salpingo-oophoritis, urethritis, cystitis), and the abdominal, back, and pelvic exam should be repeated with thorough evaluation for abdominal, lumbosacral, and vaginal trigger points if not performed on the first exam. A description of the evaluation and treatment of trigger points is provided by Slocumb (1984).

At the time of the second visit a psychologist familiar with the evaluation and management of chronic pain should evaluate the patient. The psychologist should preferably be located within the same office or clinic suite.

Psychological referral accomplishes evaluation, as well as opens the possibility for introducing cognitive behavioral pain management. The assessment should be designed to evaluate the pain complaint, its impact on life circumstances, and the controlling factors and coping mechanisms. Assessment in a chronic context involves a broader range of measures, reflecting social and psychological influences and sequelae, than may apply in the acute setting.

Assessment must evaluate the impact of the pain on the woman's lifestyle. Pelvic pain is likely to affect sexual functioning, which may have additional repercussions in terms of the quality of the patient's relationship and self-esteem. As with mood, a careful history is needed to establish whether the sexual problems existed before the pain or developed subsequently. Previous sexual abuse or trauma should be evaluated, as well as the impact of the pain on day-to-day functioning. Standardized psychological testing is helpful to determine if affective disturbance is present, as well as to establish a baseline against which to measure treatment response and guide treatment approaches.

If peripheral pathology is suspected or confirmed, workup and management should proceed as per treatment of the specific condition. Consultation with a urologist, gastroenterologist, orthopedist, or neurologist should be requested if indicated.

The third visit should include another review of the pain diary. Patients with cyclic or atypical cyclic pain should be evaluated for primary or secondary dysmenor-

rhea. Evaluation of pelvic pain, especially cyclic pain, may require elimination of the menstrual cycle using continuous estrogen/progesterone combinations, high-dose progesterone alone, or a GnRH analogue with or without add-back hormonal therapy. Pelvic ultrasound or transuterine venography may be helpful if pelvic congestion is suspected, but treatment can proceed on the basis of clinical suspicion. If trigger points or entrapped nerve sites were injected and the pain has persisted, but the initial reduction in pain outlasts the duration of the local anesthetic, injection should be repeated weekly or biweekly up to five injections. In addition, consideration should be given to a physical therapy consultation, especially if activity increases the pain or if low back pain is prominent.

A follow-up appointment (fourth visit) should be scheduled. Before the third and fourth visits, the "pain manager," the gynecologist (if not the pain manager), and the psychologist should consult. If pain persists, the patient should initiate cognitive behavioral pain management and various centrally acting pharmaceutical agents should be tried. Tricyclic antidepressants and membrane-stabilizing agents/anticonvulsants have been used successfully in patients with pelvic pain. To date, only one randomized controlled trial assessed the effect of selective serotonin reuptake inhibitors on pelvic pain, and the short 14-week trial of 23 women failed to show significant difference in measures of pain and functional disability (Engel et al., 1998; for review, see Stones & Mountfield, 2003). The patient should continue to have scheduled visits with the gynecologist on a regular basis.

SURGICAL MANAGEMENT OF CHRONIC PELVIC PAIN

DIAGNOSTIC LAPAROSCOPY

Diagnostic laparoscopy has become a standard procedure in the evaluation of patients with chronic pelvic pain. It has been reported that 40% of gynecologic diagnostic laparoscopies are done for chronic pelvic pain (Howard, 2003a). Between 14 and 77% of patients have no obvious pathology and two thirds of patients have findings of adhesions (85% of all laparoscopic diagnoses) that may or may not play a role in their pain. Furthermore, nonsurgical management of chronic pelvic pain (multidisciplinary pain clinics or trigger point injections) is successful in 65 to 90% of patients regardless of the presence of minimal pathology (Hornstein et al., 1997b; Reiter et al., 1991; Slocumb, 1990). Laparoscopy should probably be reserved for patients in whom other pathology has been ruled out, and for those with signs and/or symptoms of endometriosis, cyclic pelvic pain not responsive to hormonal therapy, or infertility. Some retrospective and prospective evidence suggests that laparoscopy provides patients with pelvic pain a positive psychological impact

(Elcome et al., 1997); however, it is costly and not without surgical and anesthetic risks.

A newer approach to diagnostic laparoscopy, called "conscious laparoscopic pain mapping," is performed under local anesthesia, with or without conscious sedation, and is intended to be used as a tool in which the patient can directly report sources of pain upon stimulation (Palter & Olive, 1996). A recently published study on the benefit of conscious pain mapping in 50 patients as compared with 65 others who did not undergo conscious pain mapping showed no improvement in outcome after laparoscopic treatment (Howard et al., 2000).

LYSIS OF ADHESIONS

The role of pelvic adhesions in the genesis of pain is unclear. Lysis of adhesions at laparotomy is frequently undermined by a high incidence of adhesion reformation. Laparoscopic lysis of adhesions may be less likely to result in significant reformation of adhesions; however, adhesions reform or form *de nouveau* after an adhesiolysis procedure. It is not unreasonable, therefore, to lyse adhesions at the time of diagnostic laparoscopy, but controlled studies have yet to be definitive. (See previous section on adhesions for further details.)

HYSTERECTOMY

Hysterectomy has long been performed to cure pelvic pain. In fact, up to 19% of hysterectomies are performed for the sole indication of chronic pelvic pain (Reiter, 1990b). However, 30% of patients presenting to pelvic pain clinics have already undergone hysterectomy without experiencing relief of pain (Chamberlain & La Ferla, 1987). Reiter and associates (1991) note a decline in the incidence of hysterectomy for the indication of chronic pelvic pain from 16.3 to 5.8% after the initiation of a multidisciplinary approach to the diagnosis and treatment of chronic pelvic pain. A prospective cohort study, the Maine Women's Health Study, evaluated the results of hysterectomy on symptom relief, quality of life, and the onset of new medical problems. Of the 418 women, the diagnoses leading to hysterectomy included uterine leiomyomas (35%), chronic pelvic pain (18%), abnormal bleeding (22%), and other (25%). One year later at postsurgical follow-up, pain was reported to have improved in 95% of the women who had pelvic pain before surgery. There were also improvements in scores indicating mental health, general health, and quality of life. New problems that developed after having had a hysterectomy included hot flashes, weight gain, depression, and decreased libido. Finally, before hysterectomy, 63% of the women reported pelvic pain and at the 2 year follow-up visit only 10% of the women reported pelvic pain (Carlson et al., 1994). Hillis et al. (1995) studied a prospective cohort of 308

women who underwent hysterectomy for chronic pelvic pain, thought to be of uterine origin. The outcome revealed a 74% response rate, with observed persistent pain associated with multiparity, prior history of pelvic inflammatory disease, lack of pathology, and Medicaid payer status (Hillis et al., 1995). Hysterectomy remains an option for appropriately selected patients with pain of uterine origin. In recognition of the fact that hysterectomy treats, at best, only some women, the American College of Obstetricians and Gynecologists (1998) established criteria to be met prior to performing such invasive surgery for pelvic pain. The criteria include that no remediable pathology is found on laparoscopic examination and that a 6-month presence of pain occurs with negative effect on the patient's quality of life.

Presacral Neurectomy and Uterine Nerve Ablation

Presacral neurectomy or sympathectomy (PSN) was first described by Cotte (1937) for the indication of dysmenorrhea. As is apparent from the discussion of the neuroanatomy of the pelvic organs, the presacral nerve, which is actually the superior hypogastric plexus, receives the major afferent supply from the cervix, uterus, and proximal fallopian tubes. Afferents traveling with the sympathetic nerve supply from the bladder and rectum also pass through the superior hypogastric plexus. Normal micturition and defecation are dependent on an intact sacral autonomic nerve supply and are relatively unaffected by resection of the superior hypogastric plexus. The nerve supply to the adnexal structures bypasses the hypogastric plexus, as the afferents from the ovary travel with sympathetic fibers accompanying the ovarian artery to the superior mesenteric plexus to enter the spinal cord at T9 and T10. These autonomic relationships constitute the rationale for Cotte's (1937) emphasis on differentiating dysmenorrhea with the maximum intensity of the pain localized to the uterus with radiation to the sacrum from lateralizing pain radiating to the lumbar region.

PSN has been studied in the management of central pelvic pain in the setting of both cyclic and noncyclic pain (Ingersoll & Meigs, 1948; Lee et al., 1986; Polan & DeCherney, 1980). Although most studies of PSN are uncontrolled, Polan and DeCherney's (1980) study did include a control group of patients who had had infertility surgery without PSN. In the latter group, only 26% experienced relief of pain as compared with 75% of patients who also underwent PSN. In another randomized controlled study by Tjaden et al. (1992), the study was prematurely terminated due to the overwhelming response to PSN compared with resection of moderate to severe endometriosis (Tjaden et al., 1992). However, when Candiani et al. (1992) studied PSN versus resection of moderate or severe endometriosis, initial central pain was reduced although 6-month follow-up revealed no signifi-

cant difference in pain. More recently, a randomized controlled study compared laparoscopic surgery with presacral neurectomy versus conservative laparoscopic surgery alone in 140 patients with severe dysmenorrhea (Zullo et al., 2003). The authors found that 87.3% of the patients who had sacral neurectomy performed versus 60.3% of the patients who had conservative laparoscopy alone were pain free at 6 months and 85.7% versus 57.1%, respectively, were pain free in 12 months (Zullo et al., 2003). The value of PSN remains controversial.

An alternative nerve ablation technique, initially tried in order to prevent pelvic pain, yet has fewer complications such as constipation, uterine prolapse, painless labor in subsequent pregnancies, and bladder dysfunction, which has been reported in some studies, is laprascopic uterosacral nerve ablation (LUNA). A randomized trial of women with endometriosis who received therapeutic laparoscopic surgery with LUNA as compared with no treatment showed that 62% of the women in the former group had improved or had complete resolution of their pain at 6 months postoperatively (Dwarakanath et al., 2002; Sutton et al., 1994). This same author found that at 1 year follow-up of the 62% of responsive patients, 90% were still pain free (Sutton et al., 1994). The weakness that exists in studies of this form is the inability to determine whether the therapeutic laparoscopic surgery alone resulted in diminishing the pain or if it was an effect of the LUNA itself. A large multicenter, prospective, randomized trial is being performed using questionnaires at baseline and postoperatively at 3, 6, 12, 24, and 36 months (Birmingham Clinical Trials Unit, 2000).

A Cochrane Database meta-analysis concluded that after review of the literature there was evidence that uterine nerve ablation was more effective for primary dysmenorrhea as compared with no treatment (Proctor et al., 2003). When comparing LUNA with PSN, there was no pain relief difference in the short term; however, PSN was better at relieving pain greater than 6 months or more postoperatively. (Chen et al., 1996; Proctor et al., 2003 They also found that LUNA combined with surgical treatment of endometrial implants as compared with surgical treatment without LUNA did not result in further pain relief (Proctor et al., 2003). The same results were true for PSN but there was a significant difference in relief of midline abdominal pain (Proctor et al., 2003).

Implantable Stimulator/Neuromodulation

An alternative to actual ablation of nerve fibers is neuromodulation. Neuromodulation techniques include sacral nerve stimulation, retrograde nerve root stimulation, and selective stimulation of the S2, S3, and S4 nerve roots. Retrograde stimulation involves implanting four quadripolar leads by a trained specialist with adequate experience because complications can include wet taps and

intrathecal electrode implantations (Feler et al., 2003). Another option that has been considered is superior hypogastric nerve block using neurolytic agents such as 10% phenol or 50% ethanol under fluoroscopic guidance. A small uncontrolled study of 10 patients using Transforaminal sacral nerve stimulation with an implantable neuroprosthetic device showed that 9 of 10 patients with the implant had a decrease in the pain severity of the worst pain compared with baseline at a median follow-up of 19 months (Siegel et al., 2001). There was an average decrease in the rate of pain from 9.7 at baseline to 4.4 on a scale of 10 = always to 0 = never having pain (Siegel et al., 2001).

MULTIDISCIPLINARY PAIN MANAGEMENT

MULTIDISCIPLINARY MEDICINE

Multidisciplinary pain management is important in the approach to chronic pelvic pain. Peripheral pathology is managed by the pain manager (gynecologist, anesthesiologist, internist, family practitioner). Spinal cord and central factors related to possible abnormalities of modulation of pain impulses are addressed with trigger point injections, nerve blocks, neuropathic pain medications, acupuncture, or TENS (Helms, 1987; Mannheimer & Whaler, 1985; Rapkin & Kames, 1987; Slocumb, 1984). Cognitive behavioral and other psychological psychosexual factors are addressed by the psychologist.

One program was successful in reducing pain by at least 50% in 85% of the subjects (Rapkin & Kames, 1987). Other studies have suggested that similar results may be obtained with a multidisciplinary team (Milburn et al., 1993; Pearce et al., 1982; Peters et al., 1991; Reiter et al., 1991; Wood et al., 1990;). In a prospective randomized study, the multidisciplinary approach was found to be more effective than traditional gynecologic (medical and surgical) management (Peters et al., 1991).

ALTERNATIVE MANAGEMENT OF CHRONIC PELVIC PAIN

With advances in media and the Internet, the practitioner will find that in general, patients are now more informed than ever before. Many patients not only desire more information about the disease process, but also very often value a practitioner's ability (especially in retractile chronic pelvic pain patients) to present alternative medical management options. Acupuncture is one of the most commonly used alternative forms of therapy. It is a crucial part of the traditional Chinese system of medicine and the oldest form of standardized neuromodulatory therapies. A recent study of men with chronic prostatitis/chronic pelvic pain syndrome assessed 12 men who had undergone at least 6 weeks of acupuncture treatment using a National Institutes of Health (NIH) Chronic Prostatitis Symptom

Index. The investigators showed that at the initial follow-up visit, 10 patients had significant improvement (greater than 50% positive symptomatology decrease) and at an average of 33 weeks post-treatment 8 patients had sustained improvement (Chen & Nickel, 2003). Although this study was in males, it is highly likely that this benefit would translate to women with chronic pelvic pain syndromes. A review by White (2003) of controlled trials of acupuncture and acupressure as self-treatment for infertility and dysmenorrhea concluded that there were only a small number of trials and these varied in quality. However, the techniques of acupuncture and acupressure as determined using these studies seem promising as a treatment for dysmenorrhea and infertility (White, 2003). As of yet, there are no studies using a sham or placebo arm to evaluate these techniques.
